However, Chapman et al.<sup>294</sup> reported that, although the 5-year survival rate for patients with an elevated CEA was 39% as compared with 57% for patients with a normal CEA level ( $P = .001$ ), the proportion of patients with an elevated CEA level increased with more advanced tumor stage and a poorly differentiated tumor grade. Once controls were in place for the variable of stage, CEA was not a predictor of survival. This study confirmed the work by other authors that failed to demonstrate a significant independent prognostic value for preoperative CEA level.<sup>295</sup> An elevated CEA level may be a reflection of a more advanced colorectal carcinoma.

**IMMUNE RESPONSE TO THE PRIMARY TUMOR.** Careful pathologic evaluation of the primary tumor site has demonstrated that a significant number of tumors exhibit evidence of local inflammation and that this reaction is a positive prognostic factor. Jass et al.<sup>207</sup> demonstrated that the presence of lymphocytic infiltration was a very important independent prognostic factor in colorectal cancer. This finding led to the development of the Jass staging system.<sup>207</sup> By univariate analysis, the presence of lymphocytic infiltration has been demonstrated to have prognostic importance for survival in colon cancer,<sup>208</sup> and lymphatic stroma reaction has been demonstrated to be of prognostic value for local failure in rectal cancer.<sup>296</sup> NSABP protocol R-01 showed that survival was significantly decreased with increasing numbers of eosinophils and mast cells present at the tumor border.<sup>297</sup> Recent work by Diederichsen et al.<sup>298</sup> using flow cytometry to study the phenotype of tumor-infiltrating lymphocytes in 41 cases of colorectal cancer showed that expression of class II human leukocyte antigens (HLA) did not correlate with any lymphocyte surface markers. Because tumor-infiltrating lymphocytes are "turned off" rather than stimulated when tumor cells express HLA class II but not CD80, the lack of correlations

could be due to anergy.

**DELETIONS IN COLORECTAL CANCER.** Allelic deletions involving chromosome 18q occur in more than 70% of colorectal cancers. In colorectal cancer, the *DCC* gene was cloned from a region of chromosome 18q, and whereas the *DCC* gene was expressed in most normal tissues, including colonic mucosa, its expression was greatly reduced or absent in most colorectal carcinomas tested.<sup>299</sup> The mechanism of action of *DCC* is unknown. It may function as a tumor suppressor gene by inducing apoptosis.<sup>300</sup> Experimentally, *DCC* induces apoptosis in the absence of ligand binding and blocks apoptosis when engaged by netrin-1. It is a caspase substrate, and mutation of the site at which caspase 3 cleaves *DCC* suppresses the proapoptotic effect of *DCC* completely.<sup>300</sup>

In a series of 118 patients who had undergone curative surgery for stage II or III colon cancer, those patients whose tumor exhibited no evidence of chromosome 18q allelic loss showed a better disease-free and overall survival than did those whose tumor demonstrated 18q allelic loss. When patients were stratified by tumor stage, a significant survival advantage for patients whose tumor had no allelic loss on chromosome 18q was observed in stage II and in stage III disease. In particular, patients with stage II disease whose tumor had no chromosome 18q allelic loss demonstrated an excellent clinical outcome, with a 5-year disease-free survival rate of 96%. In contrast, the 5-year disease-free survival rate of patients with stage II disease and chromosome 18q allelic loss was only 54%. In a multivariate analysis, the status of chromosome 18q was a significant independent prognostic factor for both disease-free and overall survival.<sup>213</sup> Several investigators have shown that not only deletion of and lowered messenger RNA expression of the *DCC* gene but also marked reduction of *DCC* protein occurred in colon cancer tissues.<sup>301</sup> In addition, colon cancer patients with liver metastases expressed significantly lower levels of *DCC* as compared to patients without such metastases.

### **Additional Tumor Biologic Features**

**ONCOGENES AND MOLECULAR MARKERS.** Oncogenes and molecular markers are discussed extensively in [Chapter 33.1](#). However, the study of molecular markers has enormously advanced our understanding of the development and treatment of colorectal cancer. Molecular markers have the potential to revolutionize the way such cancers are treated. Some of the areas of intensive research currently are thymidylate synthase,<sup>302</sup> dihydropyrimidine dehydrogenase (DPD),<sup>303</sup> and the presence of microsatellite instability.<sup>304</sup>

**p53 GENE** The *p53* gene located on chromosome 17p is a well-known tumor suppressor gene. Attallah et al.<sup>305</sup> reported no significant difference in *p53* overexpression between patients with stage II and III colorectal cancer; however, flow cytometric analysis revealed a slightly higher incidence of DNA aneuploidy in 75% of *p53*-positive cases as compared with 64.3% *p53* positivity in diploid tumors.

The abnormal *p53* appears to be a late phenomenon in colorectal carcinogenesis. This mutation may allow the growing tumor with multiple genetic alterations to evade cell-cycle arrest and apoptosis.<sup>306</sup> In a retrospective review of 141 patients with resected stage II and stage III colon carcinoma, the presence of a *p53* mutation was the single most important risk factor associated with poorer survival in patients with either stage of disease (stage II,  $P = .02$ ; stage III,  $P = .006$ ).<sup>307</sup> A *p53* mutation increased the risk of death by 2.82 times in patients with stage II disease and by 2.39 times in patients with stage III colon carcinoma.<sup>307</sup>

The Southwest Oncology Group (SWOG) assessed the prognostic value of *p53* in 66 stage II and 163 stage III colon cancer patients in adjuvant intergroup trial 0035.<sup>308</sup> *p53* expression was found in 63% of cancers and was associated with favorable survival in stage III but not stage II disease. Seven-year survival with stage III disease was 56% with *p53* expression versus 43% with no *p53* expression ( $F = .012$ ).<sup>308</sup> The true independent prognostic value of *p53* remains to be defined.

**IMMUNOLOGY AND MARKERS.** The most frequently used tumor marker in colorectal cancer continues to be CEA, though several other markers have been evaluated in this disease. For example, many investigators have demonstrated that the blood group antigens ABH and Lewis, which are normally expressed only in the proximal colon, can be reexpressed in distal colon cancers. Also, an antigen that is incompatible with the individual's blood type can be expressed.<sup>309</sup> Similar alterations occur in adenomatous polyps, but with reduced frequency. ABH antigens are not commonly expressed in hyperplastic polyps but are seen in neoplastic polyps.<sup>309</sup>

CA 19-9 is a carbohydrate cell surface antigen, a sialylated lacto-N-fucopentose related to the Lewis blood group substance. CA 19-9 does not appear to be as sensitive as CEA but does have some value as a prognostic factor, especially if combined with CEA.<sup>310</sup> However, currently available data do not justify the routine use of CA 19-9 in colorectal cancer outside of an investigational trial. Several other antigens have been defined with the use of monoclonal antibodies, but their use remains restricted and has not been adopted in clinical practice because these antibodies seem to add little to the currently available markers.

**ADDITIONAL FACTORS.** A comprehensive review of every prognostic factor studied in colorectal cancer is beyond the scope of this chapter. Extensive review of such factors as the amount of collagen type IV present in the tumor matrix,<sup>311</sup> the presence of reactive lymph nodes, and the morphometric measurements of the tumor cell (nuclear morphology) have yielded conflicting results.<sup>181</sup> Such other factors as proliferating cell nuclear antigen expression,<sup>312</sup> sucrase isomaltase,<sup>313</sup> helix pomatia agglutinin,<sup>314</sup> microacinar growth pattern,<sup>210</sup> autocrine motility factor,<sup>315</sup> ornithine decarboxylase,<sup>316</sup> fibronectin, and tumor-associated glycoprotein DF3<sup>317</sup> have shown some prognostic value, but the true value of many of these factors continues to be explored in colorectal cancer.<sup>318</sup>

## **TREATMENT OF PRECANCEROUS CONDITIONS**

### **NEOPLASTIC POLYPS (ADENOMAS)**

Adenomas are the most common neoplasms in the large bowel. They are classified into three types—tubular, tubulovillous, and villous—according to their histologic appearance. Tubular adenomas account for 75% of polyps found, tubulovillous adenomas account for 15% of all neoplastic polyps, and villous adenomas account for 10%. The malignancy rate of tubular adenomas is 5%, but it rises to 40% in villous adenomas. The malignancy rate for tubulovillous adenomas is 22%, suggesting that these tumors behave more like villous than like tubular adenomas. The entire colon must be examined if a histologically proven adenoma has been removed from the colon or is found on endoscopic biopsy.<sup>164</sup> Endoscopic removal of polyps should be performed to confirm the diagnosis of a benign or malignant polyp. Polyps with a stalk can be removed by endoscopic snare polypectomy. Sessile lesions can be removed in a piecemeal fashion; however, there is an increased risk of complications, and judgment must be used to assess this risk and the practicality of attempting piecemeal removal of tumors, especially in the relatively thin-walled abdominal colon.

The National Polyp Study demonstrated a synchronous polyp detection rate of 29% to 35% at colonoscopic follow-up for patients in whom an adenomatous polyp has been demonstrated.<sup>164</sup> This detection rate depends on the number of interventions and the time intervals from the last colonoscopy. Approximately 15% of patients will have evidence of small adenomas after the colon is considered cleared of polyps at colonoscopy.

Further management and timing of surveillance depends on the characteristics of the adenomas removed initially, as well as on their number and the clinical status of the patient. Follow-up of adenomas containing *in situ* carcinoma or severe dysplasia that have been completely removed is the same as that for benign adenomas: routine follow-up colonoscopy at 3-year intervals once the colon is cleared.<sup>164</sup> Individuals in whom the colon is not cleared of all polyps will require an earlier examination. In addition, patients having multiple adenomas are at a higher risk for oversight of synchronous adenomas and, therefore, these patients should be examined at 1 year. A large sessile adenoma that cannot be removed endoscopically will often require surgery.

Large villous adenomas (i.e., >2 cm in diameter) have a malignant potential that is significantly greater than that for other adenomatous polyps. Even small villous adenomas have a greater malignant potential than do adenomatous polyps of the same size. They are sessile, in most cases, and grossly appear velvety owing to frond-like glands. Villous adenomas require complete excision for histologic examination. Random biopsies of villous adenomas are unreliable and only contribute to difficulties in management. If such adenomas can be palpated in the rectum, they are more likely to be benign if they are soft. However, excision is still required.

Surgical resection should be performed. This is due to the high risk of recurrence, complications from endoscopic polypectomy, and presence of invasive cancer. When located in the rectum, such lesions can often be treated by local excision. Submucosal techniques of transanal excision or the Kraske approach, which are used for large lesions that otherwise cannot be approached by transanal excision, are appropriate in the complete excision of rectal villous adenomas.<sup>319</sup> Circumferential villous adenomas of the lower rectum can be removed in three to four longitudinal strips and have subsequent mucosal advancement. Alternatively, low anterior resection or proctectomy with coloanal anastomosis can be used to manage large circumferential villous adenomas of the lower rectum. Laser ablation of the lesion has the disadvantage of destroying tissue before pathologic examination is carried out. Nonetheless, this may be reasonable when an operative approach is prohibited.

## MANAGEMENT OF FAMILIAL ADENOMATOUS POLYPOSIS

Because the risk of development of colorectal carcinoma in patients with FAP is virtually 100% when the colon and rectum are left intact, resection is the only therapeutic intervention known to alter the natural history of this disease.<sup>98</sup> Owing to the high rate of development of carcinomas before the age of 40, this surgical intervention usually is performed relatively early in life (15 to 20 years of age). Surgery should not be delayed once the diagnosis is established.<sup>320</sup> Surgical procedures in these patients range from total abdominal colectomy and ileorectal anastomosis to total proctocolectomy with ileoanal anastomosis.<sup>321</sup> Total proctocolectomy and end ileostomy are rarely used for these patients except in the presence of a failed ileoanal reservoir, in patients older than 50 years, in the face of poor medical condition, or in patients with poor sphincter tone. An alternative to end ileostomy in these patients may be the use of a Kock pouch to act as a continent ileostomy.

Removal of the entire abdominal colon with a small bowel anastomosis performed to the upper rectum is the procedure selected for many patients with polyposis. It carries a relatively low mortality rate and low morbidity rate.<sup>322</sup> Advantages to this procedure include the avoidance of a stoma, relatively normal bowel habits, and avoidance of bladder and sexual dysfunction.<sup>323</sup> Selection of this procedure requires that the surgeon be able to remove or fulgurate any rectal polyps and necessitates continued endoscopic surveillance of the rectum. Risk of subsequent carcinoma in the rectal stump increases with age, the presence of malignancy in the original colectomy specimen, the length of the rectal stump, and the number of rectal polyps present preoperatively (Fig. 33.7-4).<sup>324</sup> Patients with a rectal stump greater than 10–15 cm long appear to be at greater risk of rectal cancer.<sup>325</sup> In a review of 11 member registries from the Leeds Castle Polyposis Group, the cumulative incidence of rectal carcinoma was found to be 13% at 25 years.

**FIGURE 33.7-4.** Cumulative risk of rectal cancer after ileorectal anastomosis over 25 years of follow-up.

Total proctocolectomy with ileoanal anastomosis is commonly used in patients who are unable to accept the risk of subsequent rectal carcinoma, those with extensive rectal polyps, or those who develop large numbers of rectal polyps after ileorectal anastomosis. The advantages of this procedure are virtual elimination of rectal cancer risk and avoidance of a permanent stoma. Total proctocolectomy with ileoanal anastomosis does carry a higher complication rate than does abdominal colectomy. Morbidity rates vary from 10% to 24%.<sup>326</sup> Stool frequency varies from three to six bowel movements per day, with occasional nocturnal stooling; however, quality of life is similar to that of patients with ileorectal anastomosis.<sup>327</sup> Continence and bowel habits improve with time, and most patients are free of antidiarrheal agents by 1 year after surgery. Satisfaction for patients undergoing total proctocolectomy and ileoanal anastomosis can be quite high. This operation can be performed in selected patients with FAP and coexistent cancer without compromising oncologic or functional outcomes.<sup>328</sup> It also can be performed after a previous ileorectal anastomosis.

Vasen et al. (1996) and Wu et al.<sup>329</sup> have described a correlation between specific sites of mutations within the *APC* gene and the subsequent development of rectal carcinoma after ileorectal anastomosis. Vasen's group noted that the risk of secondary surgery for cancer or polyps is higher in patients with a mutation after codon 1250 (RR, 2.7;  $P < .05$ ). Wu's group<sup>329</sup> reported that *APC* gene mutations at codons 1309 and 1328 were associated with severe polyposis and should be treated with total proctocolectomy. The utility of this technique in selecting patients for the appropriate surgical procedure requires further investigation.<sup>330</sup> A thorough discussion between patient and physician, taking into account the patient's medical characteristics, history, and wishes, will help in the decision making about management techniques for FAP.<sup>331,332</sup> Referral to an established registry will lower the stage of disease at which cancer is diagnosed in relatives of the proband and thereby will improve survival.

Colorectal carcinoma is but one component of the overall syndrome of FAP. Additional tumors of the GI tract (e.g., periampullary cancer) as well as thyroid, brain, or hepatic tumors can complicate this disease.<sup>333</sup> A difficult problem that occurs in approximately 3.5% to 38.0% of patients with FAP is desmoid tumor. Specific mutations can be associated with severe desmoid disease.<sup>330</sup> These tumors frequently occur in the mesentery of the small bowel and extend into the retroperitoneum. Mesenteric desmoid tumors often are unresectable because of involvement of the superior mesenteric vessels. Even if resected, there is a very high recurrence rate and a very high surgical morbidity rate.<sup>334</sup> Because of the poor results of surgical resection of mesenteric desmoid tumors, a variety of medical treatments, as well as radiation therapy, have been described. In an FAP patient who has been protected from colorectal cancer by surgery, upper GI tract tumors and desmoids become more frequent causes of mortality.<sup>98</sup>

## ULCERATIVE COLITIS

The process of screening and selection of patients for surgery based on biopsy-proven, high-grade dysplasia of the colon in patients with ulcerative colitis was presented earlier, in [Screening](#). As described, patients can be observed, with surgery performed only for those with high cancer risk or invasive carcinoma. This discussion of the indications for surgery related to the risk of colorectal cancer is not relevant to the indications for surgery related to complications of inflammatory bowel disease itself.

Commonly, the timing of colectomy is related to findings of dysplasia on random biopsy of the colon. Some studies have emphasized the development of cancer in patients with ulcerative colitis in whom dysplastic changes were seen in the colon on biopsy. Such findings have generated screening strategies based on the presence of dysplasia.<sup>335</sup> The disadvantages to this approach are the need for life-long screening even in the presence of quiescent disease and the requirement that experienced pathologists perform the evaluation for dysplasia.<sup>329</sup> The appeal of this technique is that it can provide indications for resection of the large bowel before the presence of a colorectal carcinoma becomes obvious by symptoms or gross appearance.

Duration of disease is another factor in timing surgery. Identifying neoplastic lesions at colonoscopy can be difficult because of the marked distortion of the mucosa and the flat appearance of many cancers associated with ulcerative colitis. The presence of a mass is an indication for surgery even in the absence of a biopsy specimen that exhibits dysplasia or cancer.

The options for a patient who has indications for surgery due to cancer risk in ulcerative colitis include total proctocolectomy with end ileostomy, total proctocolectomy with Kock pouch, total abdominal colectomy with ileorectal anastomosis, and total proctocolectomy with ileoanal anastomosis.<sup>336</sup> Each of these procedures has advantages and disadvantages that should be considered in light of each patient's individual circumstances. Total proctocolectomy with end ileostomy is most suitable for elderly patients, those with impaired sphincter function, and those in whom an ileoanal pouch is technically impossible or has failed. It is a single-stage procedure with a lower rate of complications than the alternative procedures. Total abdominal colectomy with ileorectal anastomosis is a relatively simple procedure that avoids any of the risks of proctectomy and the need for ileostomy. However, it does appear to carry the risks of recurrence of symptoms in the retained rectum as well as a small risk of carcinoma in the retained rectal segment. It should not be used in patients with preexisting large bowel cancer or rectal dysplasia, because of an approximately 70% risk of subsequent development of rectal carcinoma or dysplasia. Close endoscopic follow-up is required for any patient with a retained rectum who undergoes ileorectal anastomosis for chronic ulcerative colitis. Rectal cancer risk has been estimated to be 0% to 22%.<sup>336</sup>

In selected cases, restorative proctocolectomy can be performed for patients with cancer in the setting of ulcerative colitis.<sup>328</sup> Multicentricity is seen in 25% of such

patients.<sup>328</sup> A complication with this procedure can be pouchitis, which occurs in 7% to 42% of patients. Pouch failure occurs in a small number of patients because of either technical difficulties at the time of surgery or pelvic sepsis. Problems of early age at onset of colorectal cancer, multiple neoplasms, and need for surveillance are similar to those encountered by patients with Crohn's disease.<sup>337</sup>

## HEREDITARY NONPOLYPOSIS COLON CANCER

The development of molecular genetic techniques to establish a presymptomatic diagnosis of HNPCC and the increasing clinical recognition of families with this syndrome have made the consideration of prophylactic colectomy realistic. Total abdominal colectomy appears to be appropriate, even though there is still a small but cumulative risk of rectal carcinoma development in patients with HNPCC who have undergone abdominal colectomy.<sup>334</sup> Because the majority of such patients will be adequately treated by an abdominal colectomy, it could be considered as prophylactic management of their colorectal cancer risk.<sup>338</sup> It is appropriate to perform total abdominal colectomy at the time of operation for colorectal cancer or endoscopically untreatable colorectal polyps in patients with HNPCC, because of the high risk of synchronous and metachronous colorectal cancer.

Experience with this operation for FAP demonstrates that abdominal colectomy has low complication rates and good functional outcomes that are acceptable for such a prophylactic procedure. Some have recommended that patients with proven germline mutations be given the option of prophylactic abdominal colectomy. The Cancer Genetics Consortium, however, has not found adequate evidence to make a recommendation for prophylactic abdominal colectomy in patients with HNPCC.<sup>329</sup>

## MANAGEMENT OF POTENTIALLY CURABLE COLON CANCER

### PRETREATMENT EVALUATION

After colorectal carcinoma has been diagnosed, the pretreatment assessment is conducted to determine the most appropriate form of treatment. Whereas surgical management is required for most patients with a diagnosis of colon carcinoma, the appropriateness of a surgical resection will be determined by the extent of disease and comorbidities. Even in cases of metastatic colorectal carcinoma, surgery may be required for palliation. Some authors have recently documented an ability to manage colon cancer patients nonoperatively in the presence of metastatic disease without significant complications from bleeding, perforation, or obstruction.<sup>339</sup>

A well-conducted history and physical examination will provide a great deal of information about the patient's extent of disease and suitability for treatment. Specific aspects of the history taking should focus on a personal history of cancer or polyps and family history of colorectal cancer or polyps. Physical examination will reveal the patient's general suitability for anesthesia and extent of disease. Supraclavicular adenopathy can indicate advanced disease. The abdominal examination can reveal distention due to ascites or obstruction. An abdominal mass may be palpated to reveal the location of the tumor. Extensive hepatomegaly will produce a mass or tenderness in the right upper quadrant. Rectal examination can reveal presence of a mass outside the rectum, caused by peritoneal metastases, and may detect synchronous lesions in patients with colon cancer.

Laboratory examinations should evaluate for the presence of anemia or hepatic dysfunction. Both of which can be consequences of the patient's underlying carcinoma or comorbid conditions. The CEA level will be most useful in terms of subsequent assessment for disease recurrence if the initial CEA is elevated.

Complete colonic examination will not only allow a biopsy of the index lesion but will also provide information about the exact location of the lesion. Additionally, it will provide information on the presence or absence of synchronous colon cancers, which are present in 1.5% to 7.6% of cases. In addition, significant synchronous polyps can occur in 25% to 40% of patients.<sup>129</sup> The colon should be endoscopically cleared of these lesions. If polyps cannot be removed endoscopically, they should be included in the planned resection.

Chest radiography may reveal the presence of metastases or preexisting severe pulmonary disease that might contraindicate laparotomy. CT scanning is used to reveal clinically inapparent liver metastases or the extent of local spread of a colon carcinoma. Intraoperative ultrasonography is another useful technique that will be more sensitive in the detection of liver metastases.

### SURGICAL MANAGEMENT OF CARCINOMA OF THE COLON

Radical resection with curative intent is appropriate for 80% to 90% of patients with colon carcinoma. The surgical principles of elective colonic resection include the appropriate use of outpatient bowel preparation to reduce the fecal and bacterial load of the colon. This, along with the use of parenteral antibiotics and appropriate anastomotic techniques, will reduce the risk of postoperative sepsis and morbidity. In patients with partially obstructing lesions, modification of the bowel preparation or the use of hydration along with the bowel preparation may be required preoperatively. It is important to use prophylaxis for deep venous thrombosis to reduce the subsequent risks of deep venous thrombosis and pulmonary embolism. Measures such as early ambulation and the use of intermittent compression devices and consideration of the use of low-dose heparin or low-molecular-weight heparin in the perioperative period reduce the incidence of venous thrombosis.

Surgical management must include the assessment of liver metastases. Although this is commonly accomplished by palpation and inspection, intraoperative ultrasonography of the liver has increased the rate of detection of small metastases.<sup>340,341</sup> and <sup>342</sup> The Doppler perfusion index has also been found to predict liver failure, because occult disease alters liver blood flow.<sup>343</sup> However, liver metastases still occur in 13% to 21% of patients who have negative results on intraoperative ultrasonography.<sup>344</sup>

#### Extent of Resection

The extent of colonic resection is determined by the blood vessels that must be divided to remove the lymphatic drainage of the tumor-bearing portion of the colon with tumor-free margins (Fig. 33.7-5). This is the primary treatment approach in patients with colon carcinoma.<sup>345</sup> Segmental resections without extensive mesenteric resection sometimes are performed in palliative situations. Resection of intermediate and principal nodes requires ligation and division of the main vascular trunks to the affected colon segment. Tumor-free margins usually are accomplished by resection of at least 5 cm of normal bowel proximal and distal to the tumor. However, in very aggressive tumors with lymphatic submucosal spread, this may be inadequate. In general, spread beyond the gross limits of the tumor of more than 1.2 cm occurs only in rare cases.

**FIGURE 33.7-5.** A: Surgical resection for a cecal or ascending colon cancer. B: Surgical resection for a cancer at the hepatic flexure. C: Surgical resection for a descending colon cancer. D: Preferred surgical procedure for cancer of the middle and proximal sigmoid colon. In poor-risk patients, the inferior mesenteric artery and the left colic artery may be preserved. E: Surgical resection for cancer of the retrosigmoid. F: A more radical surgical resection for cancer of the retrosigmoid. (Modified from Enker WE, Surgical treatment of large bowel cancer. In: Enker WE, *Cancer of the colon and rectum*. Chicago: Year Book, 1978:73)

Tumors of the right colon include those of the cecum, ascending colon, hepatic flexure, and proximal half of the transverse colon. The ileocolic artery, right colic

artery, and right branches of the middle colic artery usually are divided, and resection of the distal 10 cm of ileum is carried out along with resection of the cecum, ascending colon, and proximal transverse colon. If the main branch of the middle colic artery is taken near the origin from the superior mesenteric vessels, the bowel resection is extended to the distal third of the transverse colon to ensure that there is viable bowel for anastomosis. Uncontrolled data exist to demonstrate improvement in outcomes from extending this resection.

For tumors of the left colon, which includes the descending and upper sigmoid colon, the IMA is ligated near its origin at the aorta, and the splenic flexure of the colon is anastomosed to the upper rectum. In more limited resections for tumors in the left half of the transverse colon and splenic flexure, the resection may be limited to the ascending and descending left colic arteries and left branch of the middle colic artery. Anastomosis then is constructed between the proximal transverse colon and proximal sigmoid colon. Tumors of the distal sigmoid colon are usually resected along with the IMA near its origin at the aorta and the vessels that supply the sigmoid colon. The anastomosis is created between the area of the splenic flexure and the upper rectum. Growths between the hepatic flexure and splenic flexure may require a transverse colectomy or an extended right colectomy. The aim of transverse colectomy is removal of the transverse colon, the attached greater omentum, and the lymphatics lying in the drainage of the middle colic artery. For all these procedures, anastomosis may be created by either hand-sewn techniques or the use of stapling devices, with a low rate of anastomotic leak.

### **Extent of Lymph Node Resection**

Some patients with node-positive colon carcinoma may be cured by surgical resection alone. Therefore, adequate lymphadenectomy is critical. In addition to its therapeutic benefits of preventing local progression and subsequent development of symptoms due to mesenteric recurrence, lymphadenectomy is critical in the staging of patients with colon carcinoma.<sup>329</sup> In colon cancer, recovery of lymph nodes is the parameter used for adjuvant therapy recommendations in the United States.

Controversy exists over the curative efficacy of extensive lymphadenectomy in patients with colon carcinoma. Excellent results have been obtained with wide mesenteric resection, whereas other studies have found patients with principle node involvement to be incurable. In a recent update regarding this issue, Slanetz and Grimson<sup>346</sup> reviewed 2409 cases of curative resections. They found that specific groups of patients benefited from high ligation of the vascular pedicle. These were patients with transmural node-negative tumors and those with limited nodal spread. Those in whom the highest nodes were involved did not appear to benefit.

### **Contiguous Organ Involvement**

For tumors that are adherent to adjacent organs, adhesions should not be divided. In one-half of cases, the adherence may be caused by invasion of these adjacent organs by a transmural bulky colon carcinoma.<sup>347</sup> Separation of sites of adherence can disrupt the tumor, increase recurrence, and reduce survival rates. The organs commonly involved with transverse colon tumors are the stomach and omentum. Tumors of the splenic flexure may involve the spleen, tail of pancreas, left kidney, or diaphragm. Tumors of the right colon or cecum may involve the duodenum or right kidney. Tumors anywhere in the colon may involve the abdominal wall or may have adherent loops of small intestine. Occasionally, tumors of the cecum or sigmoid may involve the bladder at its dome or, in female patients, the uterus. Adjacent organ involvement should be resected in continuity with the colon and primary tumor. Radical resection may still be curative in 20% to 50% of patients, even if adjacent tissues are invaded by malignant infiltration.<sup>347</sup>

### **No-Touch Technique**

Manipulation of a tumor-bearing colon during mobilization has been shown to release tumor cells into the circulation. This fact provides a theoretic basis for using a no-touch technique consisting of early vascular ligation prior to mobilization, to prevent subsequent development of distant metastases due to seeding. Molecular techniques have enhanced the ability to detect cancer cells released into the circulation during operative manipulation.<sup>348</sup> A prospective, randomized trial by Wiggers et al.<sup>349</sup> showed that in patients who underwent preliminary ligation of vessels, liver metastases appeared later than in patients who did not undergo this procedure. However, no overall survival benefit was demonstrated. The small benefit seen in this study occurred only in the subset of patients with sigmoid colon cancer and histologic evidence of venous invasion.

### **Laparoscopic Colectomy**

Laparoscopic techniques have become widely used in the management of benign and malignant colorectal conditions.<sup>350</sup> These techniques are able to be carried out safely and successfully, especially in the hands of an experienced laparoscopic surgeon. Even assessment of the liver is carried out by laparoscopic intraoperative ultrasonography.<sup>351,352</sup> With laparoscopic colectomies, there is a theoretic advantages of a shortened hospital stay and a more rapid recovery.<sup>353</sup> The shortened stay associated with laparoscopic colectomy, attributable to early postoperative feeding, has also translated to a change in the management of colon resection patients who are treated by open techniques.<sup>354</sup>

The overall complications of laparoscopic colorectal surgery are comparable to those of open resection in a large randomized trial of laparoscopic and open colectomy in the United States.<sup>355</sup> However, the intraabdominal complications with laparoscopic surgery may be somewhat different from those seen with open surgery and include cauterization injury to the bowel, hypercapnia, ureteric injury, and development of hernia at the port site.<sup>356</sup> The risk of an anastomotic leak from a colonic anastomosis in a laparoscopically assisted procedure is similar to the leak rate seen after open resection and anastomosis. An unusual problem of laparoscopic resection can be an inability to localize a small lesion due to loss of ability to palpate the bowel. This may be avoided by tattooing small lesions or using endoscopically placed clips near the lesions.

Data that are available on the extent of lymphadenectomy and resection margins suggest that oncologic laparoscopic resection is comparable to open colectomy for cancer.<sup>357</sup> Hase<sup>358</sup> has demonstrated that among candidates for a curative resection, approximately 10% will have a positive cytologic workup. If positive cytologic findings persist on postoperative peritoneal lavage, the risk of locoregional failure is high.<sup>358</sup> Though there is experimental evidence of an increase in trocar site implantation of colorectal cancer cells by pneumoperitoneum, the clinical importance of this is not clear.<sup>359</sup> Studies have documented estimated recurrence rates in port sites of 1.08% to 3.8% after laparoscopic resection. These recurrence rates are similar to those associated with laparotomy wounds in patients treated by open resection.<sup>355</sup>

A prospective, randomized trial is currently under way to compare the efficacy of laparoscopic colectomy with open colectomy for carcinoma.<sup>355</sup> The study involves patients with right, left, or sigmoid colon adenocarcinoma, and patients are randomly assigned to laparoscopically assisted or open colectomy. The primary end points of the study are disease-free and overall survival. The secondary end points are examinations of morbidity, cost-effectiveness, and quality of life. This study is providing important information on the long-term outcomes of laparoscopic colectomy for colon resection.

### **Prophylactic Oophorectomy**

Ovarian metastases and colorectal cancer can occur at the time of presentation in 2% to 8% of patients and as a subsequent site of metastases in 1% to 7% of curatively resected patients. Survival from ovarian metastases is poor in both settings, being 9% with synchronous metastases and 20% with metachronous metastases.<sup>360</sup> Ovarian metastases are almost always accompanied by additional metastases, most of which are unresectable. Isolated ovarian metastases should be resected.

Prophylactic removal of the ovaries at the time of colorectal cancer resection has been considered in order to reduce the risks of poor survival from metachronous metastases. This will be pertinent for only the 1% to 7% of women who develop metachronous metastases, of whom only 6% to 20% will have disease confined to the ovaries. Ultimately, this applies to approximately 1% to 4% of women undergoing curative resection for colorectal cancer. Disadvantages to prophylactic resection of the ovaries can be an increase in operative morbidity, infertility, and induced menopause in premenopausal women. The effects of oophorectomy on cardiovascular risk and bone density are important considerations in the quality of life of long-term survivors. A policy of prophylactic oophorectomy in postmenopausal women has been proposed owing to the risk of ovarian metastases or subsequent development of an ovarian primary cancer.

In a study of prophylactic oophorectomy in postmenopausal women by Sielezneff et al.,<sup>361</sup> the incidence of occult ovarian metastases was 2.4%. The 5-year survival rates in this study were equal, whether or not a prophylactic oophorectomy was performed.<sup>362</sup> In a preliminary report of a randomized trial of prophylactic oophorectomy in patients with Dukes stage B and C colorectal cancer treated at the Mayo Clinic, no incidence of gross or microscopic ovarian metastases was found in 77 patients randomized to oophorectomy. No differences were seen in overall survival, whether or not patients were randomized to oophorectomy. A trend was

noted toward an improved recurrence-free survival with prophylactic oophorectomy. No selection criteria based on tumor size, grade, or other characteristics exist at this time.<sup>363</sup>

In clinical practice, isolated synchronous ovarian metastases should be resected by oophorectomy. In premenopausal women, there is no substantial proof of benefit of this procedure, though the potential for harm by prophylactic oophorectomy does exist. In postmenopausal women, prophylactic oophorectomy can be considered after careful explanation to the patient of the risks and potential benefits.

### **Oncologic Results of Surgical Management**

For patients undergoing curative resection for colon cancer, overall survival rates vary between 55% and 75%, with most recurrences seen in the first 2 years of follow-up. Survival after curative resection is markedly affected by the presence of nodal metastases. For node-negative patients, survival with surgery alone varies between 75% and 90%.<sup>364</sup> Even in these cancers, such factors as depth of penetration, contiguous organ involvement, lymphatic and vascular invasion, differentiation, and perineural invasion, as well as molecular and cellular characteristics, will affect survival.<sup>365</sup>

Important issues in surgically resected apparently node-negative colon cancer are the methods of lymph node evaluation and the detection of occult metastatic disease. Standardizing node evaluation and using immunohistochemical techniques can identify occult nodal metastases in up to 26% of those whose nodes test negatively by routine techniques.<sup>366</sup> In addition, radioimmunologically guided surgical evaluation of apparently node-negative patients after resection is highly predictive of occult metastatic disease causing recurrence.<sup>367</sup> However, convincing data on survival improvement based on these techniques are lacking. Some have even questioned the relevance of occult micrometastatic disease in patients who have undergone curative resection.<sup>368</sup> In a group of surgically resected patients with micrometastases in resected nodes and original Dukes' stage A or B colorectal cancer, survival time was 48 months, which mimicked the survival time for patients without micrometastases.

Among patients with node-positive cancers, survival can be affected by the number of positive nodes. Patients with one positive node may have survival rates in the 69% to 75% range, whereas 5-year survival for those with four or more positive nodes or metastases along a named vascular trunk will be in the 27% to 40% range.<sup>364</sup> Overall, survival rates for patients with node-positive cancers appear to be approximately 40% to 50%. The analysis by Cohen et al. (1991) of node-positive colon cancer patients treated with resection alone showed a significant difference in survival for patients having one to three positive nodes (66% 5 year survival) and those with four or more positive nodes (37% 5-year survival).

### **Patterns of Recurrence**

Locoregional failure in colon cancer occurs in adjacent soft tissues, regional and retroperitoneal nodes, and the peritoneum. The major pattern of recurrence in colon cancer is disseminated disease with liver metastasis in two-thirds of patients in whom treatment fails. Few patients will have isolated recurrence. There is a 6% rate of anastomosis recurrence.<sup>369</sup> As mentioned, the abdominal colon consists of portions that are intraperitoneal (e.g., the cecum, transverse colon, and sigmoid colon) and portions that are less mobile and lie against the retroperitoneum (e.g., the ascending and descending colon and hepatic and splenic flexures). The portions lying against the retroperitoneum are at higher risk for minimal radial margins at the time of surgical resection and therefore are at higher risk for local recurrence. Gunderson demonstrated that local failure increased in these areas of immobility and with extension of tumor through the bowel. In patients with transmural node-positive disease, areas of mobile bowel had a 13% local failure rate, whereas areas of immobile bowel had a 29% local failure rate. Local recurrence rates were even higher when there was gross extension into pericolic fat. Retroperitoneal nodal failures can be seen in up to two-thirds of patients in whom resection of transmural tumors fails. Patients with node-positive disease exhibit locoregional failure more commonly than do those with negative nodes.

In lesions that occur in areas of the bowel covered by serosa, extension through the bowel wall will increase the risk for peritoneal spread. In the autopsy series reported from the University of Washington, treatment failure manifested as peritoneal seeding in 36% of patients who died from colon cancer. This is chiefly a component of multiple sites of recurrence. In a series of 533 patients studied at the Massachusetts General Hospital, peritoneal failure rates varied from 0% to 4% for stage A and B lesions, whereas for stage C lesions, rates of peritoneal failure ranged from 14% to 16%.

## **SPECIFIC MANAGEMENT PROBLEMS**

### **Synchronous Cancer**

Synchronous cancers are relatively uncommon, having an incidence of 3.4%, as described by Finan et al.<sup>370</sup> In addition to the presence of another malignancy, there can be up to a 30% to 40% incidence of synchronous neoplastic polyps in the colon of a patient with a large bowel carcinoma.<sup>371</sup> These facts emphasize the need for complete colonic examination at the time of diagnosis of a colon carcinoma.

Most synchronous neoplastic polyps can be removed at the time of preoperative colonoscopy. If this cannot be accomplished owing to obstructing lesions or an emergency operation for perforation, the index lesion should be addressed at the time of surgery and subsequent complete colonoscopic examination should be carried out in the early postoperative period.<sup>372</sup> If the synchronous lesions are in the same colonic segment, they can be included in the resection, which should maintain the principles of wide anatomic resection and lymphadenectomy.

When lesions are in widely disparate parts of the colon and cannot otherwise be cleared by endoscopic polypectomy, then consideration should be given to either two segmental resections or subtotal colectomy. Partial colectomies will require subsequent intensive colonic surveillance. However, they may be the most appropriate alternative for an elderly patient. Subtotal colectomy may be the treatment of choice for a younger patient with synchronous lesions.<sup>373</sup> Passman et al.<sup>373</sup> conducted an 18-year, multiinstitutional database study of 4878 patients with colon cancer. They found a 3.3% incidence of synchronous tumors. They also found that patients with synchronous colon cancers have the same survival rate as patients with solitary colon tumors when the highest stage of the synchronous tumor is considered.<sup>373</sup>

### **Obstructing Cancers**

Intestinal obstruction is the most common emergency presentation of colorectal carcinoma.<sup>374</sup> Poor prognosis is associated with this presentation, even when analyzed stage for stage, with an overall survival of 31% at 5 years. Patients who present with this problem are frequently elderly or in poor condition because of dehydration, and operative mortality can approach 28%.<sup>374</sup> Operative approaches in such patients have included a three-stage operation with an initial diverting colostomy followed by resection and then colostomy closure. An alternative approach is the use of a two-stage Hartmann procedure in which the resection is performed and an end colostomy is created while the distal colon is closed. The second operation then reestablishes continuity.

Staged resection is most useful in elderly persons with multiple comorbidities.<sup>374</sup> As techniques of preoperative resuscitation and perioperative care have advanced, further alternatives for obstructing lesions distal to the splenic flexure have been studied. The first is subtotal colectomy, the second is an extended right colectomy to include the obstructing lesion without colonic decompression, and a third is the use of intraoperative colonic lavage and segmental resection. Nyam et al.<sup>362</sup> reported on a series of 103 patients with obstructing left-side colon carcinomas undergoing an extended right colectomy without colonic decompression or a segmental left colectomy with intraoperative lavage. They found that both procedures had an acceptably low anastomotic leak rate and mortality. Poon et al.<sup>375</sup> studied emergency primary resection and anastomosis with intraoperative colonic lavage for left-sided obstruction. Hospital mortality rate was 5% to 9%. The anastomotic leak rate with this approach was 4%.

The alternative approach of subtotal colectomy with ileorectal anastomosis has been compared with intraoperative lavage in primary colonic anastomosis in a randomized trial.<sup>376</sup> This trial showed no difference in mortality or morbidity rates. However, patients with subtotal colectomy had a higher postoperative frequency of bowel movements.<sup>376</sup>

Patients with right-sided obstructing lesions should undergo a radical right hemicolectomy with primary anastomosis.

### **Perforating Cancers**

Perforation of the colon due to carcinoma can occur either at the site of the colon tumor itself (in approximately 65% to 82% of patients with perforation) or in the

## Adjuvant Radiation Therapy for Colon Cancer

**PATTERNS OF FAILURE OF AND THE RATIONALE FOR RADIATION THERAPY.** The role of adjuvant radiation therapy in colon cancer is less well defined than in rectal cancer. This is due to differences in the natural history of colon cancer as compared with rectal cancer. As seen in [Table 33.7-8](#), the most common failure site after potentially curative surgery in colon cancer is abdominal rather than local. Furthermore, because most local failures in colon cancer are extrapelvic, local failure usually does not result in the same degree of debilitating pelvic pain as that seen in rectal cancer.

Series	Definition of Failure	Stage	No.	No. Experiencing Local Failure (%)		No. Experiencing Abdominal Failure (%)		No. Experiencing Distant Failure (%)	
				Only	Compares	Only	Compares	Only	Compares
Gunderson (1985)	Reoperation, combined failure	All stages	31	22 (71)	8 (26)	1 (3)	2 (6)	7 (23)	8 (26)
		T3-4 and N0-2	21	17 (81)	6 (29)	1 (5)	2 (10)	7 (33)	8 (38)
Willett <sup>383</sup>	Clinical, reoperation, combined failure	All stages	333	1 (0.3)	2 (0.6)	11 (3.3)	2 (0.6)	1 (0.3)	2 (0.6)
		T3-4 and N0-2	305	1 (0.3)	2 (0.7)	11 (3.6)	2 (0.7)	1 (0.3)	2 (0.7)
Winsky (1988)	Clinical, first failure	All stages	201	1 (0.5)	1 (0.5)	1 (0.5)	2 (1.0)	1 (0.5)	1 (0.5)
		T3-4 and N0-2	201	1 (0.5)	1 (0.5)	1 (0.5)	2 (1.0)	1 (0.5)	1 (0.5)

In the Gunderson series, first reoperation or combined distant failure, whereas in the series by Willett and by Winsky, first reoperation or second abdominal failure.

**TABLE 33.7-8.** Patterns of Failure after Potentially Curative Surgery for Colon Cancer (All Stages) <sup>a</sup>

Although the overall incidence of local failure is relatively low in colon cancer, data suggest that, on the basis of anatomic location and selected pathologic features, certain subsets of patients have a higher incidence of local failure. However, there is not uniform agreement as to how to define these subsets. For example, Gunderson et al. (1985) divided the colon into two regions. The “anatomically immobile” (or mainly retroperitoneal) region included the ascending colon, hepatic flexure, splenic flexure, and descending colon. The “anatomically mobile” (or mainly intraperitoneal) region included the cecum and transverse colon. The highest incidence of local failure occurred in the cecum (30%), whereas the other intraperitoneal site, the transverse colon, had one of the lowest rates of local failure (13%).

In contrast, Minsky et al. (1988) reported a general trend of increased local failure with more distal colon sites. Patients with cecal cancer had a significantly lower incidence of local failure (3%), as compared to those with cancer of the transverse colon (15%) or descending colon (25%). These data do not support the notion that bowel mobility is predictive of local failure.

In the series by Willett et al. (1984), the colon was divided into two groups. Group 1 included the cecum and ascending, midsigmoid, transverse, and descending colon. Group 2 included the high and low sigmoid colon, the splenic flexure, and the hepatic flexure. In stage T1–2N0M0 disease, there was a higher incidence of local failure in group 1 tumors (16% to 24%) as compared with group 2 tumors (0% to 11%).

Overall, there is no consistency as to which anatomic site or sites have the highest local failure rates. This inconsistency may reflect the differences in methods used to detect failure (reoperation versus clinical or radiographic methods) and to determine failure (cumulative vs. first failure) rather than the true natural history of the disease.

**LOCOREGIONAL RADIATION THERAPY.** Although all the series are retrospective, the most comprehensive series examining the role of locoregional radiation therapy in colon cancer is the study by Willett et al. <sup>383</sup> at the Massachusetts General Hospital ([Table 33.7-9](#)). After potentially curative surgery for stages T3–4N0–2M0 colon cancer, 203 patients received postoperative adjuvant radiation therapy. Eligibility included patients with the following stages of disease: T4N0–2M0 tumors regardless of anatomic site, T3N1–2M0 tumors excluding midsigmoid and transverse colon, and selected high-risk T3N0M0 tumors with close margins. Patients received 45 Gy to the primary tumor bed with a 5-cm margin and inclusive of the primary draining lymph nodes. This was followed by a shrinking-field technique to 50.4 to 55.0 Gy depending on the volume of small bowel that could be excluded from the high-dose field. Of the 203 patients, 173 were treated in the adjuvant setting and 30 after a subtotal resection. Sixty-three received bolus 5-fluorouracil (5-FU) with a variety of doses and schedules.

Group	Stage	No.	Local Failure		5-Y Disease-Free Survival	
			No.	Success + Radiation (%)	Success (%)	Success + Radiation (%)
Adjuvant therapy	T3N0	83	10	97	76	72
	T4N0	83	11	94	63	79
	T3N1-2	100	15	90	41	47
	T4N1-2	40	13	73	27	33
Residual disease	All stages	—	—	47	—	37
Perforation or fistula	T4N0	21	4	81	43	51

Statistical comparison of local failure: (From Willett, Massachusetts General Hospital.)

**TABLE 33.7-9.** Local Adjuvant Radiation Therapy in Colon Cancer

The results were compared with a historical control group of 395 patients who underwent surgery only. Three patient groups appeared to benefit from postoperative radiation therapy. There was a significant improvement in local control and disease-free survival for patients with stage T4N0M0 or T4N1–2M0 disease. Also, patients with stage T4N0 disease with a perforation or fistula had improved local control and disease-free survival. Finally, radiation therapy salvaged some patients with residual disease after subtotal resection, resulting in a 37% 5-year disease-free survival. There was no benefit in local control or disease-free survival in patients with stage T3N0M0 or T3N1–2M0 disease.

For the total patient group, the incidence of grade 3+ acute bowel toxicity was 8%. The incidence was lower in the patients who received radiation therapy plus chemotherapy (4% vs. 16%, respectively). Grade 3+ long-term bowel toxicity was 4.5%. Therefore, with careful treatment techniques, the acute and long-term bowel toxicities of postoperative locoregional radiation therapy (with or without chemotherapy) for colon cancer are comparable with those reported for rectal cancer.

Other reports of adjuvant locoregional radiation therapy are limited by small numbers of patients and short follow-up. <sup>384</sup> Most have been limited to cecal cancers.

Based on the retrospective data from the Massachusetts General Hospital, a randomized phase III intergroup trial coordinated by the Mayo Clinic and NCCTG (INT 0130) was developed. Patients with T4 or selected T3N1–2 colon tumors were randomized to 12 cycles of bolus 5-FU plus levamisole with or without locoregional radiation therapy (45.0 to 50.4 Gy in 25 to 28 fractions) beginning with cycle two of chemotherapy. The trial was closed early due to poor accrual, with only 222 of the anticipated 400 patients randomized, leaving 189 eligible patients. <sup>385</sup> Grade 3+ toxicity was modestly higher in the combined-modality therapy arm (43% vs. 35%). With a median follow-up of 35 months, there was no significant difference in survival between the two arms. The patterns of failure data have not been reported.

In a phase I trial of 21 patients (4 with colon cancers) who received upper abdominal radiation plus continuous-infusion 5-FU at 150 mg/m<sup>2</sup>, Martenson et al. <sup>386</sup> reported a 40% grade 3+ toxicity rate. In contrast, the recommended dose of continuous-infusion 5-FU plus concurrent radiation for patients with rectal cancer who receive adjuvant therapy is 225 mg/m<sup>2</sup>. <sup>387</sup> These data suggest that the dose of continuous-infusion 5-FU needs to be attenuated in patients receiving

combined-modality therapy for upper abdominal malignancies. This is most likely related to the larger radiation field.

In summary, the retrospective data from the Massachusetts General Hospital suggest that there are subsets of colon cancer patients with high local failure rates in whom the addition of postoperative locoregional radiation therapy may improve local control and disease-free survival. The randomized INT 0130 trial did not show a survival advantage with combined-modality therapy versus chemotherapy alone. It must be emphasized, however, that the INT 0130 trial was closed prior to meeting its accrual goals and has not yet reported local control results. Although postoperative locoregional radiation therapy in colon cancer remains investigational, two clinical situations exist in which its use is reasonable: in a patient with close or positive resection margins and in a patient who has undergone a resection of a T4 colon cancer adherent to pelvic structures. These cancers (most commonly sigmoid or cecal primary lesions) have local failure rates similar to rectal cancers, and it is reasonable to treat them as such with adjuvant combined-modality therapy, including six cycles of 5-FU–based chemotherapy plus concurrent pelvic radiation. <sup>388</sup>

**WHOLE ABDOMEN RADIATION THERAPY.** The use of whole abdomen radiation therapy is limited by dose considerations. To treat the volume at risk with a potentially curative dose of radiation required for microscopic disease, the whole abdomen would need to receive 45 Gy. Although limited portions of the abdomen can tolerate this dose, the tolerance of the whole abdomen with conventional fractionation is 30 Gy. Based on the high incidence of abdominal failure in some colon cancers, a number of phase II adjuvant trials were designed to examine the efficacy of whole abdomen radiation therapy ( [Table 33.7-10](#)).<sup>389,390</sup>

Series	No.	Stage	Adjuvant Chemotherapy	In-Field RT Dose <sup>a</sup>	Follow-Up (%)	Survival	Toxicity
Benson (1985)	22	T1-4N0	5-FU	20	11	45% at 5 y (n=6)	35% SBO
Wick (1985)	8	T3-4N0	None	30 Gy + 10 to 16 Gy boost	31	35% SD at 36-50 mo	35% unable to complete treatment
Wang (1984)	39	T1-4N0-1	7 to 15 FU	14-21 Gy + 10 to 16 Gy boost	27	35% at 5 y	25-30% GI events
Edmon (1986)	41	T3-4N0	5-FU + maintenance	30 Gy + 16 Gy boost	13-22	47% at 5 y	17% grade 1-4 GI
Langford (1985)	38	T1-4N0-1	14 to 15 FU	30 Gy + 10 to 16 Gy boost	30-22 (n=)	76% at 5 y	17% grade 1-4 GI

GI, continuous infusion; SBO, small bowel obstruction; SD, no evidence of disease; RT, radiation therapy; SBO, small bowel obstruction.  
<sup>a</sup>In-field failure includes the tumor bed and the peritoneal cavity.  
<sup>b</sup>GI events include patients who had an unplanned treatment break, diarrhea, or the incidence is higher.

**TABLE 33.7-10.** Whole Abdomen Adjuvant Radiation Therapy for Colon Cancer

In general, patients received 20 to 30 Gy to the whole abdomen with or without a boost to the primary tumor bed. In three of the series, 5-FU was delivered with a variety of doses and schedules. The combined results revealed an in-field (abdominal) failure rate of 12% to 50%. Significant toxicity varied from 5% to 38%. Although the initial phase II results appeared promising, three of the series have never been updated.

The most encouraging data have been reported by Fabian et al.<sup>389</sup> from the SWOG 8572 study. In this phase II adjuvant pilot trial, 41 patients with T3N1–2M0 disease received whole abdomen radiation therapy plus continuous-infusion 5-FU (200 mg/m<sup>2</sup>/24 h) followed by 9 monthly cycles of maintenance continuous-infusion 5-FU (1000 mg/m<sup>2</sup>/24 h × 4 days). Due to unacceptable toxicity in the first six patients, the protocol was modified such that the 5-FU was started on day 1 and radiation began concurrently on day 8 and a 1-week treatment break from both the 5-FU and radiation was required at day 42. The tumor bed boost (1.6 Gy × 10 days) was delivered first, followed by whole abdomen radiation therapy (1 Gy/d × 30 days) for a total dose of 30 Gy to the whole abdomen and 46 Gy to the tumor bed.

With a median follow-up of 5 years, the 5-year disease-free and overall survival rates were 58% and 67%, respectively.<sup>389</sup> Limiting the analysis to the 20 patients with more than four positive nodes, the 5-year disease-free and overall survival rates were 55% and 74%, respectively. For the total patient group, the patterns of failure included local failure (12%), liver failure (22%), and peritoneal and other abdominal failure (15%). In contrast with other whole abdomen radiation therapy trials, toxicity during the combined-modality segment was tolerable (17%, grade 3; 7%, grade 4). The toxicity during the maintenance chemotherapy was also acceptable (25%, grade 3; 3%, grade 4). These results are encouraging, but further follow-up is needed. Currently, whole abdomen radiation therapy remains investigational.

### Adjuvant Systemic Therapy for Colon Cancer

**SINGLE-AGENT STUDIES.** The fact that a substantial number of patients treated surgically with curative intent eventually die of metastatic disease was understood early. Once the natural history of the disease became better defined, subsets of patients with a higher risk of recurrence could be identified. The next logical step was the development of adjuvant treatments attempting to improve the long-term disease-free and overall survival rates. The first trials were conducted in the 1950s,<sup>391,392</sup> and a partial summary of these first-generation studies is provided in [Table 33.7-11](#). The chemotherapeutic agents available were restricted to thiotepea, floxuridine (FUDR), and 5-FU, and they were commonly used with suboptimal intensity.

Study	Study Period	Treatment Regimen	Duration	Total Accrual
Dixon et al. <sup>391</sup>	1957-1960	Thiotepea	2 d	405
Deight et al. <sup>392</sup>	1957-1961	Thiotepea	2 d	1004
Deight et al. <sup>392</sup>	1961-1964	FUDR	7 wk	548
Higgins et al. <sup>393</sup>	1965-1969	5-FU	6 wk	308
	1969-1973	5-FU	18 mo	316
Grigg and Moss (1981)	1971-1976	5-FU	12 mo	253

5-FU, 5-fluorouracil; FUDR, floxuridine.  
 Note: All studies had a surgery-only control group.

**TABLE 33.7-11.** First-Generation Randomized Trials of Adjuvant Therapy for Large Bowel Cancer

Even though these early trials are generally considered negative because no dramatic benefit could be elicited, some studies with the fluoropyrimidines did demonstrate a 5% to 10% benefit in 5-year survival. The results were intriguing enough to justify continuous efforts with novel agents and combinations of the available agents in the same setting.

**INITIAL COMBINATION CHEMOTHERAPY STUDIES.** The combinations explored in the 1970s included chemotherapy and, occasionally, nonspecific immunotherapy with bacille Calmette-Guérin (BCG), BCG variations, and levamisole. These drugs are well represented in six large studies published in peer-reviewed journals and are summarized in [Table 33.7-12](#). Methyl-CCNU plus 5-FU (MF) and MF plus vincristine (Oncovin; MOF) were commonly used, because at that time, they were believed to be more active in advanced disease than 5-FU alone. With more than 3700 patients entered in these six trials, a trend favoring the chemotherapy-treated groups was noted. However, the only trials to achieve statistical significance were NSABP C-01 and NCCTG 78-48-52.

Study	Year	Design	Chemotherapy	Immunotherapy	Chemotherapy/Immunotherapy	Results
NSABP C-01	2004	Randomized	5-FU, leucovorin, and oxaliplatin	None	5-FU, leucovorin, and oxaliplatin	Significant improvement in disease-free survival (P = .02) and overall survival (P = .05) compared with control group.
NSABP C-02	2004	Randomized	5-FU, leucovorin, and oxaliplatin	None	5-FU, leucovorin, and oxaliplatin	Significant improvement in disease-free survival (P = .003) and overall survival (P = .003) compared with control group.
NSABP C-03	2004	Randomized	5-FU, leucovorin, and oxaliplatin	None	5-FU, leucovorin, and oxaliplatin	Significant improvement in disease-free survival (P = .0004) and overall survival (P = .003) compared with control group.
NSABP C-04	2004	Randomized	5-FU, leucovorin, and oxaliplatin	None	5-FU, leucovorin, and oxaliplatin	Significant improvement in disease-free survival (P = .0004) and overall survival (P = .003) compared with control group.
NSABP C-05	2004	Randomized	5-FU, leucovorin, and oxaliplatin	None	5-FU, leucovorin, and oxaliplatin	Significant improvement in disease-free survival (P = .0004) and overall survival (P = .003) compared with control group.
NSABP C-06	2004	Randomized	5-FU, leucovorin, and oxaliplatin	None	5-FU, leucovorin, and oxaliplatin	Significant improvement in disease-free survival (P = .0004) and overall survival (P = .003) compared with control group.
NSABP C-07	2004	Randomized	5-FU, leucovorin, and oxaliplatin	None	5-FU, leucovorin, and oxaliplatin	Significant improvement in disease-free survival (P = .0004) and overall survival (P = .003) compared with control group.
NSABP C-08	2004	Randomized	5-FU, leucovorin, and oxaliplatin	None	5-FU, leucovorin, and oxaliplatin	Significant improvement in disease-free survival (P = .0004) and overall survival (P = .003) compared with control group.
NSABP C-09	2004	Randomized	5-FU, leucovorin, and oxaliplatin	None	5-FU, leucovorin, and oxaliplatin	Significant improvement in disease-free survival (P = .0004) and overall survival (P = .003) compared with control group.
NSABP C-10	2004	Randomized	5-FU, leucovorin, and oxaliplatin	None	5-FU, leucovorin, and oxaliplatin	Significant improvement in disease-free survival (P = .0004) and overall survival (P = .003) compared with control group.

**TABLE 33.7-12.** Second-Generation Colon Cancer Adjuvant Trials

The NSABP C-01 study randomly assigned 1166 patients with Dukes stage B and C colon carcinoma to receive chemotherapy or immunotherapy or to be observed only. When compared with the control group, the patients treated with MOF had statistically superior disease-free survival ( $P = .02$ ) and overall survival ( $P = .05$ ). At 5-year follow-up, the group treated with MOF had an 8% survival improvement over the control group. There was no significant difference between the BCG and control groups ( $P = .40$ ).<sup>394</sup> This was the first randomized trial to demonstrate a benefit in disease-free and overall survival for patients treated with chemotherapy. The toxicity of the MOF regimen is significant, and five patients in the NSABP C-01 trial developed acute leukemia or myelodysplasia. This particular toxicity was evaluated by Boice et al., who found 19 cases of leukemia or myelodysplasia among 2067 patients treated with regimens containing MF, with an estimated risk of 2.3 cases per 1000 patients per year.

**Levamisole.** Levamisole is a synthetic, orally active agent with antihelmintic and immunomodulatory properties. The observation that levamisole enhances the immune response of mice vaccinated against *Brucella* bacteria led to its investigation in cancer. The drug is well absorbed from the GI tract after oral administration and is extensively metabolized by the liver.<sup>395</sup>

Levamisole was initially evaluated in the treatment of advanced colorectal cancer in combination with 5-FU. More than 400 patients were enrolled in three randomized trials evaluating the addition of levamisole to 5-FU chemotherapy. The results were disappointing, with no improvement in response rate, time to progression, or survival in favor of the levamisole-treated groups.<sup>396</sup>

Since 1974, levamisole has been investigated as a single agent in the adjuvant treatment of colorectal cancer.<sup>397</sup> Despite the good results seen initially, two large, prospective, randomized, placebo-controlled trials reported subsequently have failed to demonstrate a significant benefit for levamisole administered as a single agent.<sup>398</sup> Eventually, levamisole was combined with 5-FU in the adjuvant setting. Small trials comparing 5-FU-based chemotherapy with or without levamisole did not demonstrate a benefit for the levamisole-treated group. In a larger trial, after curative surgery for colorectal cancer, 141 patients were randomized to receive a 6-month course of 5-FU with or without levamisole or supportive treatment only.<sup>399</sup> After 5 years of follow-up, a significant survival advantage was detected in the patients receiving levamisole as compared with patients treated with 5-FU alone.

The true turning point in the adjuvant treatment of colorectal cancer came with the results of two well-known randomized trials (Table 33.7-13). In one, conducted by the NCCTG and the Mayo Clinic, 401 eligible patients with Dukes stage B and C colorectal cancer after curative surgery were randomized to receive no further treatment, levamisole alone, or 5-FU plus levamisole.<sup>400</sup> Levamisole plus 5-FU ( $P = .003$ ) and, to a lesser extent, levamisole alone ( $P = .05$ ) reduced cancer recurrence in comparison with no adjuvant therapy. Whereas both treatment regimens were associated with overall improvements in survival, these improvements reached borderline significance only for patients with stage C disease treated with levamisole plus 5-FU ( $P = .03$ ).<sup>400</sup> These promising results led to a large national intergroup confirmatory trial involving the NCCTG, the Eastern Cooperative Oncology Group, and SWOG, which changed dramatically the way oncologists approached and treated colon cancer.<sup>400</sup> Twelve hundred and ninety-six patients with Dukes stage B2 or C resected colon cancer were randomly assigned to observation or to treatment for 1 year with levamisole combined with 5-FU or with levamisole alone. Therapy with levamisole plus 5-FU reduced the risk of cancer recurrence among patients with stage C disease by 41% ( $P < .0001$ ) after a median follow-up of 3 years. The overall death rate was reduced by 33% ( $P = .006$ ). Treatment with levamisole alone had no detectable effect. The results in patients with stage B2 disease were equivocal, and no treatment recommendation could be made.<sup>400</sup> In 1995, Moertel et al.<sup>401</sup> updated the results of this trial. With the 929 patients with stage C disease followed for a median of 6.5 years, 5-FU plus levamisole reduced the recurrence rate by 40% ( $P < .0001$ ) and the death rate by 33% ( $P = .0007$ ). Levamisole alone reduced the recurrence rate by only 2% and the death rate by only 6%.<sup>401</sup>

**TABLE 33.7-13.** Adjuvant Studies of Levamisole plus 5-Fluorouracil

Toxic effects of levamisole alone were infrequent, usually consisting of mild nausea with occasional metallic taste, fatigue, dermatitis, or leukopenia, and those of levamisole plus 5-FU were essentially the same as those of 5-FU alone, including nausea, vomiting, stomatitis, diarrhea, dermatitis, and leukopenia. The cost-effectiveness of this treatment for a typical patient has been calculated as a very reasonable \$2094 per year of life saved. Even after using a variety of less favorable assumptions, cost-effectiveness remains less than \$5000 per year of life saved.<sup>402</sup> The NCCTG and the National Cancer Institute of Canada attempted to compare 5-FU plus conventional-dose levamisole with a 5-FU plus high-dose levamisole regimen. Accrual was stopped owing to the significant toxicity seen in the high-dose levamisole group.

**Combinations of 5-Fluorouracil and Leucovorin.** The relative success of combinations of 5-FU with leucovorin in the treatment of advanced colorectal cancer<sup>403</sup> led several investigators to explore this combination in the adjuvant setting. Combinations of 5-FU and leucovorin were tested against different control groups (Table 33.7-14). The NSABP C-03 randomized 1081 patients with Dukes stage B and C colon cancer to receive either MOF or 5-FU plus leucovorin.<sup>404</sup> A comparison of these two groups indicated a disease-free survival advantage for patients treated with 5-FU plus leucovorin ( $P = .0004$ ). The 3-year disease-free survival rate for patients in this group was 73%, as compared with 64% for patients receiving MOF. The overall survival at 3 years was 84% for those randomized to receive 5-FU plus leucovorin and 77% for the MOF-treated cohort ( $P = .003$ ). Patients treated with postoperative 5-FU plus leucovorin had a 30% reduction in the risk of developing a treatment failure and a 32% reduction in mortality risk as compared with similar patients treated with MOF.<sup>404</sup>

**TABLE 33.7-14.** Adjuvant Trials with 5-FU plus Leucovorin for Colon Cancer

In the International Multicentre Pooled Analyses of Colon Cancer Trials (IMPACT), three randomized trials conducted to investigate the efficacy of 5-FU and high-dose leucovorin after surgery for stage II and III colon cancer were pooled for combined analysis. All included trials using the same treatment regimen: 5-FU, 370 to 400 mg/m<sup>2</sup>/d, plus leucovorin, 200 mg/m<sup>2</sup>/d, 5 days every 28 days for six cycles. A pooled analysis of the results was performed, including 1493 eligible patients with resected stage II and III carcinoma of the colon. 5-FU plus leucovorin significantly reduced mortality by 22% and adverse events by 35%, increasing 3-year event-free survival from 62% to 71% and overall survival from 78% to 83%.<sup>405</sup>

In an Italian study reported by Francini et al.,<sup>517</sup> 239 patients with surgically resected Dukes stage B2 or C colon cancer were randomly assigned to chemotherapy with 5-FU and leucovorin or to observation alone. In stage B2, no significant difference between the adjuvant arm and the observation arm was noted. In stage C, adjuvant chemotherapy produced an advantage over observation in terms of a reduction in cancer recurrence rate, with a 3-year disease-free survival of 81% versus 64% and an improvement in overall survival ( $P = .0025$ ).

An intergroup study was planned to compare 5-FU plus leucovorin to control only, but the study was closed prematurely in September 1989 after 309 patients had been enrolled, when reports of the positive results of 5-FU plus levamisole adjuvant therapy precluded randomization to an untreated control group. Patients were randomized to observation or 5-FU plus low-dose leucovorin daily for 5 days every 28 days for six cycles. Preliminary results released after a median follow-up of 3.5 years showed a significant advantage in recurrences in favor of the 5-FU plus leucovorin group ( $P = .001$ ).<sup>406</sup>

**5-Fluorouracil plus Levamisole versus 5-Fluorouracil plus Leucovorin.** Both 5-FU plus levamisole and 5-FU plus leucovorin regimens have been found to be successful in prolonging disease-free and overall survival. The similar results obtained with the use of either levamisole or leucovorin as 5-FU modulators made necessary a direct comparison between the two modalities (Table 33.7-15). When these two regimens were directly compared in randomized clinical trials, it appeared that a small disease-free survival and overall survival advantage had emerged in favor of 5-FU plus leucovorin.<sup>407</sup>

**TABLE 33.7-15.** Summary of Randomized Trials of 5-FU plus LV as Compared with 5-FU for the Treatment of Advanced Colorectal Cancer

The intergroup study INT 0089 was the largest trial to address this question. Starting in 1989, 3759 patients with stage II (20%) and stage III (80%) colon cancer were randomly assigned to receive 5-FU plus low-dose leucovorin, 5-FU plus high-dose leucovorin, or 5-FU plus both levamisole and leucovorin for 6 to 7 months, or 5-FU plus levamisole for 12 months. The results are summarized in Table 33.7-16. The leucovorin-containing arms demonstrated a trend toward better results than the 5-FU plus levamisole only arm. Additionally, the toxicity profile was different among the regimens. Patients in the 5-FU plus low-dose leucovorin or the 5-FU plus levamisole arms experienced a greater incidence of stomatitis and neutropenia, whereas patients in the 5-FU plus high-dose leucovorin arm had a greater incidence of diarrhea.<sup>408</sup> The addition of levamisole to 5-FU plus leucovorin did increase toxicity, with no significant increase in disease-free or overall survival.<sup>408</sup>

The NSABP C-04 study, also summarized in Table 33.7-16, compared 5-FU plus levamisole to 5-FU plus high-dose leucovorin and to a combination of the three agents.<sup>409</sup> A total of 2152 patients with Dukes B (41%) or Dukes C (59%) colon cancer were randomized into one of the three treatment arms. At 5 years, there was an advantage for the leucovorin-containing arms, with 69% of the patients treated with 5-FU plus levamisole alive as compared to 74% of the patients receiving 5-FU plus leucovorin and 72% of those receiving 5-FU, leucovorin, and levamisole.<sup>409</sup>

**TABLE 33.7-16.** Recently Reported Adjuvant Colon Cancer Trials

The NCCTG joined with the National Cancer Institute of Canada to examine the effectiveness of a regimen of 5-FU plus levamisole plus leucovorin as adjuvant therapy for patients with high-risk colon cancer and evaluated 6 months versus 12 months of chemotherapy in the same setting.<sup>410</sup> A total of 891 eligible patients with stage II or III colon cancer were randomly assigned to receive adjuvant chemotherapy with 5-FU and leucovorin combined with levamisole or a standard regimen of 5-FU plus levamisole. Patients also were randomly assigned to receive either 12 months or 6 months of chemotherapy. After a median follow-up of 5.1 years, there was no significant improvement in patient survival when chemotherapy was given for 12 months as compared with 6 months. When chemotherapy was given for 6 months, standard 5-FU plus levamisole was associated with inferior patient survival ( $P < .01$ ). These data suggest that a 6-month regimen of 5-FU plus levamisole

analyzed, there were no significant differences in time to relapse or overall survival among the two groups.

A more recent study involving 254 patients presented by a group of Dutch investigators showed that in patients with stage II colon cancer, there was a 32% relative reduction in mortality when a tumor vaccine was compared with observation only.<sup>423</sup>

The use of vaccines for the treatment of colorectal cancer remains an interesting and active field of research. However, no conclusive evidence of benefit has emerged to this date, and it continues to be an experimental treatment reserved for clinical trials.

The use of passive-specific immunotherapy has met with more success. The monoclonal antibody 17-1A is specific for an antigen expressed on cells of human GI malignancies. It was originally developed in mice and later produced in a chimeric version.<sup>424</sup> The chimeric version of the monoclonal antibody 17-1A exhibits molecular characteristics of normal human immunoglobulin G (IgG) but retains the specificity and binding affinity of the native 17-1A murine monoclonal antibody.<sup>424</sup> Reithmuller et al.<sup>425</sup> recently published a 7-year analysis of their randomized trial comparing the use of the monoclonal antibody 17-1A to controls in 189 patients with resected stage III colorectal cancer. The monoclonal antibody was administered as a 500-mg infusion postoperatively followed by 4 monthly doses of 100 mg each.<sup>386</sup> After 7 years of follow-up, treatment had reduced overall mortality by 32% ( $P < .01$ ) and had decreased the recurrence rate by 23% ( $P < .04$ ). The reduction in recurrence and mortality is similar to that seen with the use of 5-FU plus levamisole or leucovorin.

In the United States, two large trials are evaluating the use of the monoclonal antibody 17-1A in the adjuvant setting. The first study randomized patients with stage III colon cancer to receive either modulated 5-FU or a combination of modulated 5-FU plus the antibody. The second study randomized stage II colon cancer patients to receive the antibody or no further treatment. In the next few years, the results of these trials will help to determine the role of the monoclonal antibody in the adjuvant treatment of colorectal cancer.

## TREATMENT OF INITIALLY ADVANCED COLON CANCER

### SYNCHRONOUS METASTATIC DISEASE

From 10% to 15% of patients with primary colorectal cancer will present with synchronous metastatic cancer disease. Scroggins et al.<sup>339</sup> have presented data on a series of patients presenting with stage IV disease. They found that only 8.7% of a selected asymptomatic group of patients managed nonoperatively required surgical intervention. None of the nonoperatively managed group required surgery for hemorrhage or perforation. These data challenge the traditional teaching that in patients with colon cancer who have metastatic disease at presentation the primary tumor should always be resected. Survivals were on the order of 14 to 16 months in this group of patients with asymptomatic intact primary tumors.

Patients with symptomatic primary colon tumors should have appropriate resections unless their medical condition does not allow it. Whereas palliative surgery in colorectal cancer patients with synchronous metastases is a reasonable method to control perforation, obstruction, hemorrhage, and bleeding, it can carry substantial morbidity and mortality. In a series presented by Liu et al., patients with colon cancer underwent resection as palliation. As compared with standard operative mortality for elective colon resection, 3% of patients in this group had an operative mortality of 10%, whereas in those in whom more than 50% of the liver was replaced, mortality was significantly higher.

Patients with synchronous metastases that are potentially resectable should undergo definitive surgical resection of the primary tumor.

### LOCALLY UNRESECTABLE COLON CANCER

Unresectable primary tumor in the absence of peritoneal metastases or unresectable visceral metastases is uncommon. The areas commonly involved with advanced colon tumors are the abdominal wall, retroperitoneum, kidney, duodenum, pancreas, and bladder. Fixation to major nerves or great vessels may confer unresectability based on local spread. Consideration should be given to preoperative irradiation. In such cases, conversion to resectability has been seen in up to 75% of cases. Extensive nodal disease is common with locally advanced primary tumors and can extend into the retroperitoneum and along the SMA. Perforated tumors can produce a profound inflammatory reaction around the site of perforation. After resolution of sepsis, such tumors can be reassessed for resectability, preoperative therapy, or both. Palliative ostomies and bypass procedures may improve quality of life for some patients.

## FOLLOW-UP AFTER POTENTIALLY CURATIVE TREATMENT

Follow-up is carried out to find potentially curable recurrences, to palliate symptomatic recurrences, and to identify and resolve treatment-related problems. The biology of colorectal cancer works both for and against the effectiveness of follow-up after the curative resection of colorectal cancer. Solitary liver and lung metastases can be resected and result in long-term survivals in a significant number of patients. Local recurrences of rectal cancer can also be resected with curative intent. Detection of these recurrences can be worthwhile in terms of survival. However, the reality is that most recurrences will represent the outgrowth of multiple occult metastatic sites that were unresponsive to initial surgery and adjuvant therapy. These are unlikely to respond to subsequent therapy, and so they prevent any survival advantage that might have resulted from earlier therapies. Most colorectal cancers that recur or metastasize are biologically determined to be incurable.

### FOLLOW-UP STRATEGIES

Critical factors in carrying out and designing follow-up protocols for colorectal cancer patients are the cost-effectiveness of such follow-up and the effects of follow-up on survival. An important study was carried out by Schoemaker et al. in a university hospital setting in South Australia. These researchers conducted a randomized controlled trial with 5-year follow-up in patients who had undergone curative resections for colorectal cancer. Patients were followed by either an intensive follow-up regimen or a standard follow-up regimen. The study group encompassed Dukes stage A, B, and C cancer patients. Standard follow-up consisted of history and physical examination, blood counts, and liver function tests that were carried out every 3 months for 2 years and every 6 months thereafter. The intensive follow-up consisted of the standard follow-up plus annual chest radiography, CT of the liver, and colonoscopy. The results of this study demonstrated no difference in the survival rate at 5 years between patients who received intensive follow-up and those who received standard follow-up.

In a prospective, randomized study of follow-up after radical surgery for colorectal cancer, Kjeldsen et al.<sup>426</sup> made similar findings. The differences between the randomized groups in this study were based on the frequency of follow-up. The intensively followed group had examinations at 6 and 12 months after treatment, whereas the other group had examinations at 5 and 10 years. It was found that recurrences were detected with the same frequency in both groups, but the diagnosis of recurrence was made earlier in the intensively followed group. There was no overall improvement in survival by the intensive follow-up regimen.

The pattern of recurrence of rectal cancer as opposed to colon cancer is an important factor in evaluating the role of follow-up strategies. The role of follow-up in detection and management of local recurrences of colorectal cancer was studied by Pietra et al.<sup>427</sup> Patients were randomly assigned to either a conventional follow-up or to intensive follow-up after resection of primary colorectal carcinoma. In the intensively followed group, local recurrence of rectal carcinoma was more frequently detected. More than 90% of these recurrences in the intensively followed group were detected at scheduled visits. Again, local recurrences were detected earlier in the intensively followed group, and curative re-resection was more frequently carried out in this group. In this study, patients in the intensive follow-up group had an improved 5-year survival, mainly due to the re-resection of local recurrences of rectal carcinoma. The usefulness of CEA determination in detecting luminal recurrences of colorectal cancer was also supported, because it initiated workup for recurrence in asymptomatic patients who were most likely to undergo a curative reoperation.<sup>428</sup>

Other studies have disputed the value of CEA in the follow-up of patients with colorectal carcinoma, on the basis of a lack of detectable increase in survival. In a study of second-look operations for recurrent colorectal cancer initiated by an elevation of CEA level, it was found that nearly half of the colorectal cancer patients who developed recurrence underwent second-look operations and that approximately half of these patients underwent resection.<sup>429</sup> As determined by modern imaging techniques, 1 patient in 72 who underwent exploration for recurrence had no detectable disease at the second-look operation. The group who underwent resection at a second-look operation had a 5-year survival rate of 41%. It appears that when modern imaging techniques are used to evaluate an elevated CEA level, patients can be more appropriately selected for surgery.

The issue of cost in the postsurgical surveillance of patients with colon cancer is addressed by Graham et al.<sup>430</sup> In a cooperative group study of 421 patients who underwent surgical resection for Dukes stage B2 and C colon carcinoma, patients were treated with surgery and adjuvant therapy. Patients underwent physical

examination every 3 months, along with CEA determination, chest radiography, and colonoscopy every 6 months in year 1, physical examination and CEA level determination every 6 months in years 2 through 5, and colonoscopy every 1 to 2 years during this period. Costs were estimated on the basis of Medicare reimbursement guidelines. It was found that of the 421 patients in whom recurrent disease was found, 96 underwent surgical resection with curative intent. CEA level determination was the most cost-effective way to identify patients with recurrence that could be surgically treated. CEA monitoring is controversial but has been adopted for routine surveillance by national groups in the United States. <sup>431</sup>

Rosen<sup>432</sup> conducted a metaanalysis evaluating two randomized and three comparative cohort studies examining more than 2000 patients. The analysis looked at the outcomes of curative resection rates, survival after re-resection, length of survival after recurrence, and cumulative 5-year survival in these patients. Fourteen single-cohort studies were also included in the analysis, and a study of these additional patients supported the findings of the metaanalysis. The metaanalysis indicated that the cumulative 5-year survival rate was 1.16 times higher in the intensively followed group ( $P = .003$ ). Furthermore, 2.5 times more curative re-resections were performed for patients undergoing intensive follow-up, and those in the intensive follow-up group had a higher survival rate than did those followed less intensively.

## EXTENT OF DISEASE WORKUP AFTER RECURRENCE

Certain groups of patients with proven or suspected recurrence may benefit from a more extensive workup to identify occult metastatic disease. Examples of this situation are patients with potentially resectable hepatic metastases or patients with locally recurrent rectal cancer. Another group that may benefit are those patients with a rising CEA level in whom the source has not been identified on conventional evaluation with physical examination, endoscopy, chest radiography, and CT scan.<sup>433</sup> Two such tests are 18-fluorodeoxyglucose PET and scanning after the injection of radiolabeled antibodies that bind to CEA.

Studies of patients with recurrent or metastatic colorectal cancer have demonstrated high sensitivity (91% to 93%) and specificity (98% to 100%) of these tests in identifying sites of recurrence.<sup>434</sup> In patients with solitary hepatic metastases on conventional imagery, PET found additional inoperable disease in 11%. PET was able to identify additional unsuspected sites of tumor in 21% of patients. Overall, approximately 20% to 30% of patients with a potentially resectable recurrence have been found by PET to have additional disease.<sup>434</sup> The positive predictive value of elevated CEA determinations in patients with an equivocal or negative conventional workup was 89%.<sup>435</sup> This group of patients appeared to benefit most from the additional information provided by PET.<sup>436</sup> It appears, however, that PET will be limited in detecting certain variances due to small size or the presence of necrotic low metabolically acting tumors.

The use of injectable radiolabeled antibodies demonstrated the presence of occult metastatic sites in many patients believed to have a localized primary lesion or recurrent disease.<sup>437</sup> This technique appears to be especially adept at identifying microscopic disease in celiac or extraperitoneal nodes that usually are not evaluated by traditional surgical exploration.<sup>438</sup> When imaging techniques were used to identify antibody uptake, there was a significant increase over the use of CT alone in the ability to detect unresectability.<sup>439</sup>

## CHEMOTHERAPY FOR METASTATIC COLORECTAL CANCER

Metastatic colorectal cancer is a resistant disease, and the dismal 5-year survival reflects this difficulty extremely well. Both *MDR1* and GSH S-transferase gene expression are thought to be increased in colon cancer cells.<sup>440</sup> However, this belief has not been confirmed universally.<sup>441</sup> The human *mdr1* P glycoprotein is overexpressed in multidrug resistant tumor cells and is believed to play a role in the elimination of certain cytotoxic drugs used in the chemotherapy of colorectal cancer.<sup>442</sup> GSH S-transferases are thought to impart resistance to different chemotherapeutic agents, especially alkylating agents.<sup>443</sup> The mean GSH S-transferase level is significantly increased in colon cancer as compared with the level in adjacent normal tissue.<sup>444</sup> The paucity of chemotherapeutic agents with activity in colorectal cancer reflects the intrinsic resistance demonstrated in those cells.

### 5-FLUOROURACIL

Since its introduction by Heidelberger et al. (1957) in 1957, 5-FU has become firmly established as the most important antineoplastic drug in the treatment of colorectal cancer. Early trials demonstrated that 5-FU's bioavailability when administered orally is erratic, with less than 75% of a dose reaching the systemic circulation and marked variability in plasma levels observed among patients. This pharmacologic observation led to the development of 5-FU as an intravenous agent. The variability in oral absorption might be associated with varying levels of DPD, the first catabolic enzyme in 5-FU metabolism in the GI tract. 5-FU has been used in a variety of schedules, and determining the best dose, method, and duration of its administration has been the object of intense investigation.<sup>403,445</sup>

The overall response rate for single-agent 5-FU has been reported to be as high as 30% but, realistically, it is closer to 20%. Median survival for patients responding to 5-FU treatment is believed to be in the 12- to 18-month range. Accumulated clinical evidence suggests that the use of protracted intravenous infusion of 5-FU may be superior and better tolerated than intravenous bolus dosing<sup>446</sup> and that modulation of 5-FU may yield higher response rates.<sup>403,447</sup>

#### *Continuous Infusion*

Lokich et al.<sup>448</sup> demonstrated clearly the feasibility of a continuous infusion of 5-FU as a treatment for colorectal cancer. When administered for protracted periods, the major toxicity of 5-FU is mucositis. Additionally, hand-foot syndrome is seen in approximately 5% to 25% of patients.<sup>446</sup> The lack of significant hematologic toxicity makes continuous-infusion regimens very attractive. The results from larger randomized trials are encouraging. Despite a response rate and overall survival that are statistically equivalent to those of bolus regimens, as shown in the SWOG experience, the single-agent infusion regimens demonstrated a favorable toxicity profile and a trend toward longer survival.<sup>449</sup> A metaanalysis involving 1219 patients treated in six randomized trials confirmed the superiority of continuous infusion 5-FU over bolus regimens regarding response rates and toxicity. Even though the overall survival was superior for the continuous-infusion group, the medians were very similar.<sup>450</sup> The need for a central venous catheter, with its inherent problems (e.g., infection, thrombus, and slippage) and for a portable pump and the cost and inconvenience for the patients are the major problems associated with continuous-infusion regimens. However, they are acceptable alternatives in the treatment of colorectal cancer patients.

#### *Biochemical Modulation of 5-Fluorouracil*

The relatively disappointing results of single-agent 5-FU led many investigators to explore the use of agents that could modulate its activity. One approach to improve the activity of 5-FU has been the addition of biochemical modulators to 5-FU regimens. Several modulators have been studied, among them leucovorin, methotrexate, trimetrexate, and IFN- $\alpha$ .<sup>451</sup> Of these biochemical modulators, leucovorin is without doubt the most successful.<sup>452</sup> This agent, also known as folinic acid, is a tetrahydrofolic acid derivative that can enhance the therapeutic and toxic effects of fluoropyrimidines such as 5-FU.<sup>403</sup> The reduction in DNA synthesis by 5-FU involves the formation of a complex of FdUMP, thymidylate synthetase (TS), and a cofactor designated 5'-methylene tetrahydrofolate (Me-THP). The enzyme TS is essential to DNA synthesis because it is the only source of thymidylate in the cell, converting dUMP to dTMP. If the enzyme becomes trapped in a complex with FdUMP and Me-THP, it is no longer available to convert dUMP to dTMP, and DNA synthesis is reduced. DNA synthesis is not completely inhibited because there is turnover of the FdUMP/TS/Me-THP complex, freeing up the TS to convert dUMP to dTMP, although in reduced quantities. Leucovorin enhances the inhibition of DNA synthesis by stabilizing the FdUMP/TS/Me-THP complex.<sup>453</sup>

In a metaanalysis of nine randomized clinical trials of advanced colorectal cancer comparing 5-FU alone with 5-FU plus leucovorin, significant improvement in response rate was seen in patients receiving 5-FU and leucovorin as compared with those receiving 5-FU alone.<sup>454</sup> This improvement in response did not result in a significant survival advantage in most studies.<sup>454,455</sup> However, Poon et al.<sup>403,447</sup> were able to demonstrate a statistically significant survival advantage for the combination of 5-FU with leucovorin over 5-FU alone or in combination with methotrexate. The leucovorin dose and schedule required for optimal modulation of 5-FU has not been clearly defined. Doses ranging from 20 to 500 mg/m<sup>2</sup>/d of leucovorin have been administered on daily or weekly schedules.

In an attempt to determine the best regimen of 5-FU, the SWOG randomly allocated 626 patients to receive one of seven regimens: (1) 5-FU alone, (2) 5-FU with low-dose leucovorin, (3) 5-FU with high-dose leucovorin, (4) 5-FU by continuous infusion, (5) 5-FU by continuous infusion plus weekly leucovorin, (6) 5-FU by 24-hour infusion, and (7) 5-FU by 24-hour infusion plus PALA.<sup>449</sup> There was no statistical difference in the response rates, which ranged between 15% and 29%, with a median survival for the entire group of 14 months. Despite the statistically equivalent efficacy, the single-agent infusion regimens demonstrated encouraging results, with a favorable toxicity profile trend toward longer survival.<sup>449</sup>

A metaanalysis involving 1219 patients treated in six randomized trials confirmed the superiority of continuous-infusion 5-FU over bolus regimens in terms of response rates and toxicity. Even though the overall survival was superior for the continuous-infusion group, the medians were very similar. <sup>450</sup>

A bimonthly regimen combining bolus with 24-hour infusion of 5-FU plus high-dose leucovorin has been extensively examined in France. A study comparing bimonthly with monthly 5-FU plus leucovorin noted a higher response and more favorable toxicity profile for the bimonthly schedule but no statistically significant improvement in overall survival. <sup>456</sup>

**INTERFERON.** The combination of IFN- $\alpha$  and 5-FU has demonstrated synergistic cytotoxicity against human colon cancer cell lines in preclinical studies. <sup>457,458</sup> The exact mechanism of action of IFN when combined with 5-FU is unknown. IFN has been shown to enhance conversion of 5-FU to FdUMP, <sup>459</sup> to reduce TS, <sup>460</sup> to inhibit thymidine salvage pathways, <sup>459</sup> and to potentiate 5-FU-induced DNA strand breaks. The addition of IFN also seemed to increase the 5-FU exposure by decreasing its clearance. <sup>461</sup>

Wadler et al. <sup>457</sup> initially reported a response rate of 63% for the combination of 5-FU and IFN. Based on this promising result, multiple trials were conducted using IFN as a 5-FU modulator, showing response rates in the range of 25% to 40%. <sup>418</sup> The toxic effects were significant and included leukopenia, mucositis, diarrhea, fever, chills, myalgia, and neurotoxicity. A group of researchers at the Royal Marsden Hospital randomized patients to receive 5-FU, 750 mg/m<sup>2</sup>/d by continuous infusion for 5 consecutive days, followed by weekly bolus 5-FU, 750 mg/m<sup>2</sup> either with or without IFN (10 MU subcutaneously three times weekly). Objective response was observed in 19% of the patients who received 5-FU plus IFN and in 30% of those who received 5-FU only. Patients who received IFN did experience significantly more toxicity. <sup>462</sup> The NSABP C-05 protocol compared 5-FU plus leucovorin with the same combination plus IFN. With 2176 patients evaluated, there was no statistically significant difference in either disease-free survival or overall survival. Toxic effects were observed in 61.8% of patients in the 5-FU plus leucovorin group and in 72.1% of patients in the IFN group. <sup>419</sup> These results indicate that the use of IFN as a 5-FU modulator added to the toxicity of the regimen without affecting efficacy. This regimen has been largely abandoned and should not be used outside an investigational trial.

**TRIMETREXATE.** Trimetrexate, a dihydrofolate reductase inhibitor, potentiates the cytotoxicity of 5-FU. <sup>463</sup> Phase II studies demonstrated objective responses with trimetrexate plus 5-FU and leucovorin in patients previously treated with and without 5-FU. <sup>402</sup> However, severe diarrhea and hypersensitivity were observed with this combination regimen. Blanke et al. <sup>464</sup> reported the results of a phase II study combining trimetrexate, 5-FU, and leucovorin in patients with advanced colorectal cancer. Thirty-six patients received trimetrexate, 110 mg/m<sup>2</sup> on day 1, leucovorin, 200 mg/m<sup>2</sup> on day 2, and 5-FU, 500 mg/m<sup>2</sup> on day 2 immediately after leucovorin. Oral leucovorin, 15 mg, was given every 6 hours for seven doses. This regimen was repeated weekly for six courses every 8 weeks. Two patients achieved a complete response, and the overall response rate was 50%. Diarrhea was the most common toxicity. A phase II trial involving patients with previously treated colorectal cancer disclosed a disappointing 4% overall response rate. <sup>465</sup> A randomized phase III trial comparing 5-FU plus leucovorin against a combination of 5-FU, leucovorin, and trimetrexate has completed accrual. Final results have not been reported.

## ORAL FLUOROPYRIMIDINES

Oral fluoropyrimidines are thought to provide prolonged exposure to 5-FU with lower peak concentrations than those observed with bolus schedules of intravenous 5-FU. This may reduce the occurrence of toxic effects associated with a high plasma concentration of 5-FU, such as neutropenia and stomatitis. 5-FU has been studied in several different dosing schedules, and clinical trials suggest the importance of constant exposure to 5-FU. <sup>450</sup> The toxicity profile of 5-FU is schedule-dependent and, whereas bolus schedules produce mainly neutropenia, protracted infusions produce mainly stomatitis and hand-foot syndrome. <sup>446</sup> Additionally, cancer patients seem to prefer the convenience of oral instead of intravenous medications, as long as the efficacy remains at least equal for both modalities. <sup>466</sup>

In the last decade, several oral agents have been introduced for the treatment of colorectal cancer in the Western world ( [Table 33.7-18](#)). The erratic bioavailability of oral 5-FU caused by the varying GI levels of DPD, the primary catabolic enzyme of 5-FU, <sup>467,468</sup> was overcome by the development of 5-FU prodrugs that are well absorbed enterally and then are enzymatically converted to 5-FU or by the coadministration of DPD inactivators. <sup>303</sup>

**TABLE 33.7-18.** Summary of Recent Randomized Trials Comparing Intravenous 5-FU/LV versus Oral Fluorinated Pyrimidines for the Treatment of Advanced Colorectal Cancer

### Uracil, 5-Fluorouracil, and Tegafur

Tegafur is a prodrug of 5-FU originally studied in the United States as an intravenous medication. The agent was believed to be too toxic, and so its development as an intravenous medication was discontinued. In the early 1980s, tegafur was tested as an oral medication at the M. D. Anderson Cancer Center, and it was shown to have antitumor activity when administered this way. At the same time, Japanese investigators began to study and use tegafur as an oral medication. <sup>469</sup> Uracil, a competitive inhibitor of DPD, was later combined with tegafur to provide sustained levels of 5-FU. <sup>470</sup> The combination of uracil, 5-FU, and tegafur is known as *UFT*. The previously demonstrated activity and favorable toxicity profile of UFT led to its development as an oral alternative to intravenous 5-FU for the treatment of solid tumors, especially colorectal cancer. <sup>471</sup>

Two large, multinational phase III trials comparing the oral regimen of UFT plus leucovorin to intravenous 5-FU and leucovorin as the initial treatment for patients with metastatic colorectal cancer have been reported. <sup>472,473</sup> In the first trial, 816 patients were randomly allocated to intravenous 5-FU plus leucovorin or to oral UFT and leucovorin. <sup>472</sup> UFT was taken at a dose of 300 mg/m<sup>2</sup>/d in three divided doses for 28 days followed by 1 week of rest. Oral leucovorin was administered at 90 mg/d, with the UFT administered at the same frequency daily. The intravenous 5-FU and leucovorin were administered for 5 consecutive days, with cycles repeated every 28 days. The study demonstrated statistical equivalence between the treatment arms, with a median survival of 12.4 months for the UFT plus leucovorin arm and 13.4 months for the intravenous arm. No statistical difference was seen for the two treatment arms regarding response (12% for UFT plus leucovorin and 15% for intravenous 5-FU plus leucovorin). Severe neutropenia and stomatitis were less common in the oral regimen. <sup>472</sup>

The second trial compared time to progression between patients receiving an intravenous 5-FU plus leucovorin regimen or UFT plus leucovorin. <sup>473</sup> Three hundred and eighty patients were randomized to two treatment groups that were identical to those described in the first study except that the intravenous 5-FU plus leucovorin was repeated every 35 days. The treatment arms were equivalent in terms of time to progression, with a median of 3.4 months in the UFT plus leucovorin group and 3.3 months in the intravenous 5-FU plus leucovorin group. The median survival times were 12.2 and 11.9 months, respectively. <sup>473</sup>

### Capecitabine

Capecitabine, a fluoropyrimidine carbamate, was developed as an oral alternative to intravenous 5-FU. <sup>474</sup> Capecitabine is absorbed through the intestinal mucosa as an intact molecule, not being affected by the thymidine phosphorylase present in the intestines. It then is metabolized in the liver by carboxylesterase to

5'-deoxy-5-fluorocytidine (5'DFCR), which is converted by cytidine deaminase to 5'DFUR mainly in the liver and tumor tissues. Finally, 5'DFUR is metabolized by thymidine phosphorylase to 5-FU at the tumor site.<sup>475</sup> Preclinical studies demonstrated capecitabine's activity in 5-FU-sensitive and -resistant cell lines.<sup>476</sup> Colorectal cancers, like many other solid tumors, tend to have high levels of thymidine phosphorylase, which is known for its angiogenic properties.<sup>477</sup>

In phase I trials, diarrhea, vomiting, and hand-foot syndrome (palmar-plantar erythrodysesthesia) were dose-limiting toxic effects.<sup>478</sup> A large multinational, randomized, open-label phase II trial evaluated three schedules of capecitabine (i.e., continuous, intermittent, and intermittent with leucovorin) in metastatic colorectal cancer. The response rates for the three groups ranged from 21% to 24%. The median time to disease progression ranged from 127 to 230 days, with the best time to disease progression seen in patients treated in the intermittent capecitabine arm, without leucovorin.<sup>479</sup> The addition of leucovorin seemed to increase the incidence of toxic effects, without improving therapeutic activity.

Results of two phase III trials comparing capecitabine, 2500 mg/m<sup>2</sup>/d for 2 weeks every 3 weeks, to bolus 5-FU, 425 mg/m<sup>2</sup>/d, plus leucovorin, 20 mg/m<sup>2</sup>/d, daily for 5 days every 4 weeks, as first-line treatment for metastatic colorectal cancer, were recently reported at the 1999 American Society of Clinical Oncologists' meeting. The first trial enrolled 602 patients, and the second trial enrolled 605 patients. Both trials demonstrated a higher response rate with capecitabine as compared with bolus 5-FU plus leucovorin. Taking into account all randomized patients using intention-to-treat analysis, investigator response rates were 26.6% versus 17.9% (95% CI, 1.9% to 15.1%) in the first trial and 24.8% versus 15.5% (95% CI, 2.8% to 15.5%) in the second trial. The median survival duration was 54 versus 57.1 weeks ( $P = .2363$ ), respectively. The toxicity profile of capecitabine was favorable, with fewer treatment-related serious adverse events and hospitalizations in the capecitabine arm as compared with the 5-FU plus leucovorin arm. The most common adverse events with capecitabine were palmar-plantar erythrodysesthesia (hand-foot syndrome) and diarrhea.

### Eniluracil

Eniluracil, also known as 776C85 and *ethynyluracil*, is a potent irreversible inactivator of DPD, the first enzyme in the degradative pathway of 5-FU.<sup>480</sup> When it is used in combination with an oral formulation of 5-FU, eniluracil makes the absorption and bioavailability of 5-FU more reliable,<sup>481</sup> and the 5-FU bioavailability and half-life are increased.

Phase I trials have demonstrated that a dose ranging from 10 to 40 mg/d of eniluracil inactivates DPD maximally. The concentration of 5-FU obtained with a 28-day oral dosing regimen of this agent plus eniluracil is similar to steady-state concentrations from protracted intravenous infusions of 5-FU.<sup>481</sup> Main toxic effects included fatigue and diarrhea. Nausea, vomiting, mucositis, pain, dehydration, and constipation were relatively uncommon.

Based on these results, a phase II trial of 5-FU, 1.0 mg/m<sup>2</sup>, plus eniluracil, 10 mg/m<sup>2</sup>, orally twice daily for 28 days followed by a 7-day rest period was conducted in patients with previously untreated colorectal cancer.<sup>482</sup> However, after approximately one-third of the patients had been treated, the doses of both agents were increased because of the unexpectedly low toxicity observed. The doses were increased to 5-FU, 1.15 mg/m<sup>2</sup>, and eniluracil, 11.5 mg/m<sup>2</sup>, twice daily for 28 days. The objective response rate was 29%.<sup>482</sup> This dose and schedule is currently being used in two pivotal trials comparing this oral combination with intravenous 5-FU plus leucovorin and with a protracted intravenous schedule of 5-FU in metastatic colorectal cancer patients.

### IRINOTECAN

Camptothecin is an agent derived from the Chinese ornamental tree *Camptotheca acuminata*. Its clinical development began in the United States in the late 1960s but was eventually halted due to excessive toxicity. In the late 1980s, irinotecan, also known as *CPT-11*, an analogue of camptothecin, was developed in Japan.<sup>483</sup> Pivotal phase II studies of irinotecan in advanced colorectal carcinoma were conducted in the United States, including patients who had received prior chemotherapy with 5-FU and had progressed while on treatment within the last 6 months. The dose of irinotecan ranged from 100 to 150 mg/m<sup>2</sup> given weekly for 4 weeks, followed by 2 weeks of rest. The overall response rate ranged from 12.5% to 23%. Grade 3 and 4 toxicities were noted in 30% of patients, with a 20% hospitalization rate for management of toxicity-related events. The principle toxicities included diarrhea, nausea, vomiting, and neutropenia. Severe diarrhea was seen in up to 23% of patients and was not well controlled by standard therapy but was limited by use of an intensive loperamide regimen and appropriate dose modification.<sup>484</sup>

The real value of irinotecan in the treatment of metastatic colorectal cancer refractory to 5-FU was determined by two randomized clinical trials conducted in Europe. In the first one, Cunningham et al.<sup>479</sup> randomly assigned patients in whom 5-FU therapy had failed to receive either 300 to 350 mg/m<sup>2</sup> of irinotecan every 3 weeks or supportive care alone (Fig. 33.7-7). A total of 189 patients were randomized to the irinotecan arm and 90 to the supportive-care alone arm. The mean age of the participants was 58.8 years; performance status was 0 in 79 patients (42%), 1 in 77 patients (41%), and 2 in 32 patients (17%). After a median follow-up of 13 months, the overall survival was significantly better in the irinotecan group ( $P = .0001$ ), with a 36.2% 1-year survival rate in the irinotecan group versus 13.8% in the supportive-care group. In a quality-of-life analysis, all significant differences except diarrhea favored the irinotecan group.<sup>479</sup>

**FIGURE 33.7-7.** Probability of survival of the 279 patients enrolled in a trial of irinotecan versus supportive care for metastatic colorectal cancer refractory to 5-fluorouracil. (From ref. 479, with permission.)

Rougier et al.<sup>485</sup> reported the results of the second trial, in which 267 patients with advanced colorectal cancer in whom 5-FU therapy had failed received either second-line fluorouracil by continuous infusion or irinotecan, 300 to 350 mg/m<sup>2</sup> infused once every 3 weeks. Patients treated with irinotecan lived longer than patients receiving second-line infusional 5-FU ( $P = .035$ ). Median survival duration was 10.8 months in the irinotecan group and 8.5 months in the 5-FU group (Fig. 33.7-8).<sup>485</sup>

**FIGURE 33.7-8.** Survival curve in patients on irinotecan or infused 5-fluorouracil for advanced colorectal cancer refractory to first-line 5-fluorouracil. (From ref. 485, with permission.)

A randomized phase III trial compared the combinations of irinotecan plus 5-FU and leucovorin with 5-FU plus leucovorin and single-agent irinotecan as first-line treatment of patients with advanced colorectal cancer (Table 33.7-19).<sup>412</sup> Approximately 220 patients were enrolled in each of the three treatment groups. Objective responses were noted in 51% of patients receiving the three-drug combination, 29% of patients receiving 5-FU with leucovorin, and 30% of patients receiving single-agent irinotecan ( $P < .001$ ). The median time to treatment failure for each of the three treatment groups was 5.4, 3.9, and 3.2 months, respectively. The median survival duration, however, did not achieve a statistical difference, with a median survival of 14.4 months for the triple combination, 12.6 months for 5-FU plus leucovorin, and 12.0 months for the group receiving irinotecan ( $P = .173$ ). A new analysis is planned when the data mature further.

Study	No. of Patients	Regimen	Response Rate (%)	Median TTF (mo)	Median OS (mo)
Iorio et al. <sup>412</sup>	220	5-FU, 400 mg/m <sup>2</sup> /d (1200 mg/m <sup>2</sup> /d) + irinotecan 120 mg/m <sup>2</sup> + leucovorin 40 mg/m <sup>2</sup>	51%	5.4	14.4
		5-FU, 400 mg/m <sup>2</sup> /d (1200 mg/m <sup>2</sup> /d) + leucovorin 40 mg/m <sup>2</sup>	29%	3.9	12.6

TABLE 33.7-19. Summary of Recent Randomized Trials Comparing 5-FU/LV versus Irinotecan or Oxaliplatin for the Treatment of Advanced Colorectal Cancer

A second phase III trial, conducted primarily in Europe, examined the role of irinotecan plus 5-FU and leucovorin in the first-line setting. This trial randomized 387 patients to receive either of two commonly used 5-FU plus leucovorin regimens with or without irinotecan. Response rates were significantly improved with the use of irinotecan (49% vs. 23%). Additionally, the median survival was statistically superior for the group receiving irinotecan with the 5-FU plus leucovorin (16.8 vs. 14 months). The combination of irinotecan with 5-FU and leucovorin is being investigated against other promising combinations and against standard 5-FU plus leucovorin in a large intergroup trial in the United States.

### OXALIPLATIN

Oxaliplatin is a novel diaminocyclohexane platinum agent that acts mainly by causing interstrand and intrastrand cross-links in DNA.<sup>481</sup> It has been investigated as a single agent in colorectal cancer both in previously treated and untreated patients. In chemotherapy-naïve patients with advanced colorectal cancer, two phase II trials assessed the activity of oxaliplatin, 130 mg/m<sup>2</sup> given over 2 hours every 3 weeks.<sup>486</sup> Response rates ranged from 20% to 24%, with a median response duration of 6 to 7 months and a median progression-free survival of approximately 4 months. Peripheral neuropathy and laryngopharyngeal dysesthesia were the main toxicities reported. In previously treated patients, the overall response rate was considerably lower ( $>10\%$ ), and the median survival duration was 8.5 months.<sup>481</sup>

Preclinical models demonstrated synergy between oxaliplatin and 5-FU, and this was subsequently confirmed in clinical trials.<sup>487</sup> A phase II trial involving 90 patients with advanced colorectal cancer evaluated the combination of chronomodulated 5-FU, 700 mg/m<sup>2</sup>/d, leucovorin, 300 mg/m<sup>2</sup>/d, and oxaliplatin, 25 mg/m<sup>2</sup>/d, given for 4 days every 2 weeks. The response rate was 58%, and the median survival duration was 15 months.<sup>488</sup>

The potential benefits of oxaliplatin when added to 5-FU and leucovorin as first-line therapy for patients with advanced colorectal cancer were subsequently evaluated in phase III randomized trials (see Table 33.7-19). A study with 200 patients compared chronomodulated 5-FU plus leucovorin administered every 3 weeks with or without oxaliplatin at 125 mg/m<sup>2</sup> given over 6 hours on day 1. The overall response rates were 53% versus 16% ( $P < .001$ ) for the combinations with and without oxaliplatin, respectively. However, the overall survival duration was equivalent in both arms (19.4 vs. 17.6 months, respectively). This survival equivalence was attributed to crossover and surgery after chemotherapy.

A second study reported by De Gramont et al. randomized 420 patients to receive 5-FU plus leucovorin on days 1 and 14 of a 28-day schedule with or without oxaliplatin, 85 mg/m<sup>2</sup>. The response rates in the first 200 patients were 57% versus 26% in patients treated with and without oxaliplatin, respectively. The corresponding median progression-free survival duration for the treatment groups were 39.6 versus 27.8 weeks. Once more, however, no significant impact on overall survival has been demonstrated ( $P = .12$ ).

As second-line therapy, oxaliplatin in combination with 5-FU and leucovorin has also shown promising results. In one trial, 46 patients with 5-FU-refractory colorectal cancer were treated with oxaliplatin administered as a 2-hour infusion on day 1, followed by leucovorin on days 1 and 2, and 5-FU as a 24-hour infusion for 2 consecutive days. Treatment was repeated every 2 weeks. The overall response rate was 46%, and median survival duration was 17 months. Limiting toxicities were neutropenia and peripheral neuropathy. A second trial involving the addition of oxaliplatin, 85 mg/m<sup>2</sup> every 2 weeks, to the same 5-FU plus leucovorin regimen under which patients had progressed produced an overall response rate of 20%, a median response duration of 37 weeks, and a median survival duration of 57 weeks.<sup>489</sup>

The combination of oxaliplatin and irinotecan in patients with 5-FU-refractory colorectal cancer was recently reported. The overall response rate among the 34 treated patients was 44%, with stable disease in another 35% and a median time to progression of 7.5 months.

### RALTITREXED

Raltitrexed is transported into cells by the reduced folate carrier, metabolized to a polyglutamate species, and retained intracellularly, resulting in prolonged TS inhibition.<sup>490</sup> It is the first of the specific TS inhibitors to have undergone extensive clinical evaluation,<sup>490</sup> and it is currently approved for treatment of colorectal cancer by regulatory agencies in Europe, Canada, Australia, and South America.

The efficacy of raltitrexed as monotherapy for patients with advanced colorectal cancer was evaluated in three phase III clinical trials.<sup>491</sup> Two international trials, one with 439 patients<sup>492</sup> and the other with 495 patients,<sup>493</sup> compared intravenous bolus raltitrexed, 3 mg/m<sup>2</sup> repeated every 3 weeks, to daily intravenous bolus 5-FU, 425 mg/m<sup>2</sup>/d, plus leucovorin, 20 mg/m<sup>2</sup>/d for 5 days (Mayo regimen), or to 5-FU, 400 mg/m<sup>2</sup>/d, plus leucovorin, 200 mg/m<sup>2</sup>/d (Machover regimen) repeated every 4 weeks. The third trial was conducted in the United States<sup>494</sup> and compared two raltitrexed dosages (3 mg/m<sup>2</sup> and 4 mg/m<sup>2</sup> every 3 weeks) with the Mayo regimen. However, because of the unacceptable toxicities seen with the 4 mg/m<sup>2</sup> dose, subsequent analyses were based on a two-treatment comparison with 427 patients. All three trials produced similar response rates ranging from 14% to 19% for the raltitrexed group and from 15% to 18% for the 5-FU plus leucovorin group. In all three trials, survival duration ranged from 10 to 12 months. The study conducted in the United States showed a significant difference in survival duration (9.7 vs. 12.7 months;  $P = .01$ ) between the two treatment groups, favoring the 5-FU with leucovorin group. The main advantage of raltitrexed is its easy schedule, allowing a single intravenous treatment every 3 weeks.

Several studies have been conducted using hepatic arterial infusion in patients with advanced colorectal cancer with liver metastasis. Response rates have been consistently superior for the arms using hepatic arterial infusion; however, a convincing survival advantage has never been shown (Table 33.7-20). The use of hepatic arterial infusion for treatment of advanced colorectal cancer still must be considered investigational.

Study	Treatment	Drug	Arm	No. of Patients	Design	Objective Response Rate (%)	Median Survival Rate (mo)

**TABLE 33.7-20.** Hepatic Intraarterial Fluoropyrimidine Therapy for Liver Metastases in Colorectal Cancer

## SUMMARY

After four decades, 5-FU remains the mainstay of treatment for colorectal cancer. However, the advent of newer agents has introduced new options for the treatment of this disease. Ongoing trials are determining which agent, or combination of agents, should be considered the gold standard in treatment of advanced colorectal cancer. The increased response rates and prolonged progression-free survival seen with the combinations of 5-FU, leucovorin, and either irinotecan or oxaliplatin are very exciting and warrant their consideration as front-line therapy. The use of agents that are able to maintain the same efficacy as older regimens with improved convenience and less toxicity may have a positive impact in the quality of life of patients as well. However, an improvement in survival will be needed for the establishment of a clear new standard. For now, whenever possible, patients should be encouraged to participate in well-designed clinical trials involving new regimens, because despite the impressive advances seen in the last few years, advanced colorectal cancer remains a highly lethal disease.

## MISCELLANEOUS COLORECTAL TUMORS

### CARCINOIDS

Carcinoid tumors of the GI tract, although characteristically indolent, are also quite heterogeneous with respect both to histologic and endocrine features and to clinical presentation and behavior. Because they are relatively uncommon, most reports do not have a significant number of patients for a detailed analysis. For decades, a series including 2837 cases published in 1975 remained the largest available reference. Modlin and Sandor recently evaluated an impressive 8305 cases. The most frequent sites for carcinoids were the GI tract (74% of cases) and the bronchopulmonary system (25% of cases). Within the GI tract, 29% of cases occurred in the small bowel, 19% in the appendix, and 13% in the rectum. The highest incidence rates were seen among African American men (2.12 per 100,000 per year). This large analysis indicates that metastases are already evident at the time of diagnosis in 45% of the patients and that the overall 5-year survival rate of all carcinoid tumors, regardless of site, is 50%. The 5-year survival rate for carcinoid tumors of the GI tract varied markedly. It was considerably lower for pancreatic (34%), colonic (41%), and small intestinal tumors (55%) and better for appendiceal (86%), bronchopulmonary (76.6%), and rectal carcinoids (72.2%).<sup>495</sup> These improved 5-year survival rates were associated with a lower incidence of invasive growth or metastatic spread. A search for additional tumors is generally advised, because multiple carcinoids and second neoplasms are not uncommon.<sup>496</sup>

Most carcinoid tumors are clinically silent, and the diagnosis is not made before surgery. Surgical treatment depends on the localization and size of the tumor. Small bowel carcinoid tumors metastasize in 20% to 30% of the cases if the tumor is smaller than 1 cm. Therefore, the primary tumor should always be resected widely, including the regional lymph nodes. Carcinoid tumors of the appendix measuring less than 1 cm usually do not metastasize. For such patients, an appendectomy is the treatment of choice. For tumors larger than 2 cm, a right hemicolectomy should be performed. If the tumor is between 1 and 2 cm, surgical treatment depends on the presence of positive lymph nodes, extension of the tumor into the mesoappendix or subserosal lymphatic invasion, and age of the patient.<sup>497</sup> Carcinoid tumors of the colon and rectum measuring less than 2 cm rarely metastasize. Surgical treatment for patients with such small tumors is local excision, whereas for patients with tumors larger than 2 cm, wide resection is advocated.<sup>497</sup>

### SARCOMAS

Rarely, tumors may arise directly from the stromal and smooth muscle elements in the colon or rectum. These tumors are known as *smooth muscle tumors* or *stromal tumors* of the colon and rectum. These mesodermal tumors are essentially leiomyosarcomas. The true incidence of leiomyosarcomas in the colon and rectum is unknown. Only small numbers of patients have been reported to date, all in small series.<sup>498</sup>

The most common anatomic location of leiomyosarcoma is the stomach (47%), followed by small intestine (24%), rectum (11%), colon (7%), duodenum (5%), and esophagus (5%). Symptoms and physical findings are nonspecific, with pain, palpable masses, and melena being the most common. Patients frequently present with GI bleeding and significant anemia. The only therapy with accepted value is surgery with wide margins. Chemotherapy is of unproven value as an adjuvant and as treatment for this type of tumor. The tumor grade is an important prognostic factor. In patients resected with curative intent who have low-grade lesions, disease-free survival at 8 years exceeds 80%, as compared with a mean disease-free interval of only 18 months for patients with high-grade lesions.<sup>499</sup>

Other authors have confirmed that the stage of the tumors and the presence of high-grade features are the main independent factors that affect survival. DNA ploidy is not an independent prognostic factor for survival in patients with leiomyosarcomas.<sup>500</sup> Recurrences are noted at regional and distant sites.<sup>501</sup> The prognosis for patients with leiomyosarcoma is guarded, and almost two-thirds of the patients die within 1 year. The use of adjuvant radiation therapy in patients with resected leiomyosarcomas of the rectum may improve local control and allow for sphincter preservation.<sup>501</sup> It is unlikely that large randomized trials for the treatment of colorectal leiomyosarcomas will ever be conducted owing to the rarity of this disease. Patients with advanced cases should be encouraged to participate in trials designed for GI leiomyosarcomas in general.

### LYMPHOMA

Colorectal lymphomas account for fewer than 1% of all colorectal cancers but account for 15% of all GI lymphomas.<sup>502</sup> Most cases involve the cecum and the rectum.<sup>503</sup> Virtually all colorectal lymphomas are non-Hodgkin's type, including both B- and T-cell types of low-, intermediate-, and high-grade histologies. Immunohistochemical studies usually show a preponderance of B-cell phenotype. Colorectal non-Hodgkin's lymphoma is a disease that affects both the pediatric and adult population and, although pediatric patients have an excellent prognosis, long-term survival can be expected in only approximately 50% of adult patients.

The diagnosis of colorectal lymphoma must be confirmed histologically and by the absence of evidence of primary lymphoma elsewhere by imaging studies or clinical examination (i.e., evidence of splenomegaly, or palpable lymphadenopathy). In addition, both the peripheral smear and the bone marrow must be determined to be normal. Colorectal lymphomas usually present with a mass, symptoms of obstruction, or signs of bleeding.<sup>502</sup> The clinical presentation is usually indistinguishable from that of colorectal adenocarcinoma, and most patients are symptomatic at the time of diagnosis.<sup>503</sup>

Patients with colon lymphoma often are treated initially with surgery. The lack of well-designed trials makes any recommendation extremely difficult. The use of combined-modality treatment, including surgery and chemotherapy, seems to yield superior results.<sup>504</sup> Several authors have recommended the use of radiation therapy, especially in cases involving low-grade lymphomas, bulky disease, positive lymph nodes, or incomplete resection. The true role of radiation therapy in colon lymphomas is still uncertain.

Radiation therapy is more attractive in cases involving the rectum. However, patients treated with radiation therapy alone have a very poor long-term survival.<sup>502</sup> Whenever possible, combined-modality surgery and radiation therapy should be considered. The use of chemotherapy in earlier disease stages is controversial but should be considered for patients with advanced-stage disease or more aggressive histologic types. Because of the rarity of this cancer, patients should be encouraged to be treated in larger centers where there is experience in the management of lymphomas.

## SMALL CELL CARCINOMA

Extrapulmonary small cell cancers are very uncommon, accounting for fewer than 1000 cases annually.<sup>505</sup> Histologically, small cell cancers arising from different organs are indistinguishable, and a lung primary should always be ruled out.<sup>506</sup> Fewer than 100 cases have been reported since 1961, the most frequent site being the rectum, followed by the cecum and sigmoid.<sup>506</sup>

The presentation is similar to that of adenocarcinomas and includes weight loss, bleeding, abdominal pain, and change in bowel habits.<sup>507</sup> Metastasis is common, affecting 85% of the patients at the time of diagnosis.<sup>506</sup> The liver is the organ most frequently involved by metastasis, but almost any organ may be affected. Patients with localized disease should be treated aggressively with a multimodality approach, including local therapy with surgery or radiation therapy (or both) and chemotherapy. Patients with advanced disease should receive chemotherapy.<sup>508</sup> The chemotherapy should be based on accepted treatment regimens used in the treatment of small cell lung carcinomas.<sup>506</sup>

## INTRODUCTION

Many overlapping issues in the management, biology, pathology, and staging of colon and rectal cancer are discussed in [Chapter 33.7](#). Issues of sphincter preservation, locoregional recurrence, and the application of multidisciplinary management in rectal cancer are the focus of this chapter.

## ANATOMY

The rectum is usually divided into three portions ( [Fig. 33.8-1](#)). The lower rectum is the area 3 to 6 cm from the anal verge. The midrectum is 6 to 10 cm, and the upper rectum extends approximately 10 to 15 cm, from the anal verge. The rectum usually reaches its upper limit at approximately 12 cm from the anal verge. Externally, its upper extent can be identified where the tenia spread to form a longitudinal coat of muscle. The upper third of the rectum is surrounded by peritoneum on its anterior and lateral surfaces. At the rectovesical or rectouterine pouch, the rectum becomes completely extraperitoneal. The rectum follows the curve of the sacrum in its lower two-thirds. It enters the anal canal at the level of the levator ani. The anorectal ring is at the level of the puborectalis sling portion of the levator muscles. The location of a rectal tumor is usually indicated by the distance between the anal verge, dentate line, or anorectal ring and the lower edge of the tumor. These points of reference are all different. Also, these measurements differ depending on the use of a rigid or flexible endoscope.

**FIGURE 33.8-1.** Division of the rectum into upper, middle, and lower thirds.

## LYMPHATIC DRAINAGE

The majority of the lymphatic drainage of the rectum passes upward along the superior hemorrhoidal artery toward the inferior mesenteric artery. Perirectal nodes above the midrectum drain along the superior hemorrhoidal artery. Below 7 to 8 centimeters from the anal verge, they drain laterally along the middle hemorrhoidal artery and the iliac nodes and the obturator fossa. Hypogastric and iliac node drainage is along the aorta. Lymphatics are common in the rectovaginal septum in women, which is analogous to the Denonvilliers' fascia in men.

## BOWEL FUNCTION

Mechanisms of fecal continence include both sphincter control and creation of the neorectal angle where the rectum sweeps anteriorly and then enters the anal canal. The floor of the pelvis is formed by the levator ani muscles, which separate the pelvis from the perineum and ischioanal fossa. The urethra, vagina, and anus pass through the levators.

Surgical procedures for rectal carcinoma can have marked impact on rectal function. The degree of this alteration depends on the extent of rectal resection. Other factors affecting bowel function include postoperative radiation therapy or pelvic sepsis. These may reduce the compliance of the newly constructed rectal reservoir. <sup>1</sup> Although overall sphincter function usually is maintained after sphincter-preserving surgery and adjuvant therapy, subtle changes in function can be observed that reduce discrimination between gas, liquid, or formed stool.

## AUTONOMIC NERVES

An understanding of the autonomic nerve supply to pelvic organs is critical in preservation of sexual and bladder function after rectal cancer surgery. <sup>2</sup> The sympathetic trunks converge over the sacral promontory to form the hypogastric plexus. These trunks run underneath the pelvic peritoneum laterally to the sidewall of the pelvis. These trunks are lateral to the mesorectum. The fibers from these nerves follow arteries supplying the pelvic viscera. Parasympathetic fibers to the pelvic viscera emerge from the second, third, and fourth sacral nerve roots overlying the piriformis muscle. The parasympathetic fibers proceed laterally as the nervi erigentes to join the sympathetic fibers at the site of the pelvic plexus that is just lateral and somewhat anterior to the tips of the seminal vesicle in men. <sup>3</sup> Sharp section of the mesorectum preserves these structures. <sup>4</sup>

## DIAGNOSIS

Compared to more proximal colon cancers, tumors arising in the rectosigmoid area are much more prone to present with symptoms. Although all colorectal cancers have a high rate of occult blood in the stools, and the right-sided colon cancers are associated with a higher incidence of anemia, left colon and rectal cancers have a higher incidence of gross bleeding. <sup>5</sup> Cheung and colleagues <sup>6</sup> evaluated prospectively 337 patients presenting with frank rectal bleeding. After making a clinical diagnosis, flexible sigmoidoscopy followed by barium enema was performed. Excluding seven digitally palpable rectal cancers, 30 cancers (9.5%), 34 polyps (10%), 7 cases of proctocolitis (2%), and 25 cases of bleeding diverticula (7%) were detected. The authors concluded that patients with frank rectal bleeding should be screened routinely for left colon cancer irrespective of the clinical diagnosis. <sup>6</sup> This recommendation highlights the fact that hemorrhoids should be considered a diagnosis of exclusion. Patients should have a total colon examination by either a combination of flexible sigmoidoscopy and barium enema, or by a colonoscopy. Barium enema may miss a distal cancer and should not be used alone.

Changes in the bowel habits are a common presenting feature for rectal cancers. Although the incidence of bowel obstruction appears to be lower for the rectal lesions, <sup>5</sup> compromise of the rectal reservoir by tumor makes symptoms common. Unexplained constipation, frequently alternating with diarrhea, and changes in the caliber of stools are classic presenting symptoms for rectal cancer and should be promptly investigated. The entire colon should be carefully evaluated, with particular attention to the rectosigmoid area.

Another common symptom from rectal cancer is tenesmus. This sensation results from the circumferential growth and transmural penetration by the primary tumor. It is characterized by a sensation of urgency and inadequate emptying of the rectum. Even though some degree of tenesmus may be seen with less extensive tumors located distally in the rectum, it is usually a sign of advanced disease. Additional symptoms of local invasion are seen with tumors that have invaded the prostate or bladder or that have destroyed the high sacral nerve roots, causing urinary symptoms. Tumors invading posteriorly may cause buttock or perineal pain. These symptoms imply a locally advanced tumor and poor overall prognosis.

Besides the obvious benefits from early diagnosis of colorectal cancer, appropriate staging in rectal cancer is of particular importance. Increased emphasis has been placed on conservative surgical techniques as an alternative to radical surgery for selected patients. The goals of conservative management are to select patients with low risk for nodal metastases and achieve local tumor control while preserving anal sphincter function. Patient selection is critical to obtain results comparable to patients treated with radical surgery. <sup>7</sup> Alternatively, interest has been increasing in the use of neoadjuvant combinations of chemotherapy and radiotherapy in the treatment of more advanced rectal cancers. <sup>8</sup>

## RADIOLOGIC EVALUATION

### Computed Tomography

The intravenous pyelography that was obtained preoperatively in the past has fallen out of favor <sup>9</sup> and has been replaced by the use of other imaging techniques, such as the computed tomographic (CT) scan. Although conventional CT scanners and experienced radiologists are now widely available, this test remains of limited value in the staging of rectal cancer. It is very useful to evaluate the presence of distant metastasis, <sup>10</sup> to evaluate gross invasion of adjacent organs, and as a follow-up tool.

However, it still lacks sufficient accuracy to be used for preoperative staging as a single test.

Netri and colleagues (1985) preoperatively evaluated 78 patients with rectal adenocarcinoma with digital rectal examination, proctoscopy, double-contrast barium enema, pelvic CT scan, liver ultrasound, and chest x-ray. Data obtained by each diagnostic procedure were compared with the pathologic data. CT scan had an accuracy of 100% for detecting infiltration of the muscularis of the rectum. However, it was less accurate in identifying extrarectal tumor invasion, with an accuracy of 72%. In the evaluation of lymph node involvement, accuracy was 77%, specificity was 74%, and sensitivity was 80%. Liver metastases were detected with 94% accuracy, 97% specificity, and 50% sensitivity. Similarly, Zheng and colleagues (1984) assessed the extent of local spread in 85 patients with rectal carcinoma. In 37 patients with carcinoma of the rectum who were scanned before surgery, good correlation was found between the extent of local invasion assessed by scanning and by postoperative histologic assessment. Scanning was not a reliable method for assessing regional lymph node involvement.

Hundt and colleagues<sup>11</sup> evaluated the use of a subsecond spiral-CT scanner using two contrast medium phases in staging of 37 patients with proven colorectal cancer (14 patients with rectal primaries). The results were compared with the findings of pathologic examination after surgery. The spiral CT had a sensitivity of 97% in the arterial phase and 89% in the venous phase in detecting the carcinoma. The staging results were in accordance with the pathology in 30 of 37 cases (81%) during the arterial phase and in 24 of 37 cases (65%) in the venous phase. Lymph nodes were detected in 27 of 32 patients (84%) during the venous phase. The correct classification of the N stage was possible in 23 of 34 cases (68%). The authors concluded that the arterial phase is superior compared with the venous phase for local tumor staging, and the venous phase is used for lymph node assessment.<sup>11</sup> These results are not dramatically better than the ones previously reported with conventional CT.<sup>12</sup> The role of conventional CT in assessing patients with colorectal tumors is well established. However, the low accuracy of CT for identifying early stages of primary colorectal cancers prevents its routine use for preoperative clinical staging.<sup>13</sup>

### **Magnetic Resonance Imaging**

Magnetic resonance imaging (MRI) remains a relatively expensive imaging method and is not as widely used as CT scanning. However, it has been extensively studied in the diagnosis and staging of rectal cancer.<sup>14,15</sup> Kusunoki and colleagues (1994) used MRI to evaluate preoperatively the local extension of rectal cancer in 33 patients. The sensitivity rate was 84.2% and the specificity rate was 92.9%. In a series including 61 patients, MRI was reported to have an accuracy of 79% for extent of local involvement, but only 58% for extent of lymph node involvement. These results were inferior to the ones obtained with the use of ultrasound in the same population.<sup>16</sup>

MRI using an endorectal coil allows for an excellent anatomic detail of the three rectal wall layers and a very high spatial resolution. Regular MRI has been compared with endorectal MRI and with endorectal ultrasound (EUS) for preoperative staging of rectal carcinoma.<sup>17</sup> In a small series, the results of the preoperative staging were correlated with the histopathologic findings in 15 patients. MRI correctly staged 10 of 15 patients. Without the endorectal surface coil, only three of six were correct, and with the endorectal surface coil, seven of nine were correct. The authors of this study suggested that endorectal surface coil MRI use may lead to better staging results than with other MRI techniques and that the results with endorectal MRI could equal those of EUS for staging small tumors in the rectal wall. Another study<sup>17</sup> evaluated 23 patients with rectal carcinoma using endorectal MRI. The diagnostic accuracy in the evaluation of tumor extent and nodal involvement as compared to surgical pathology was 78.2% and 78.9%, respectively. The major problem was a tendency to overstage parietal infiltration and lymph node involvement.<sup>17</sup>

Although not widely used in the initial staging of rectal cancer, MRI has gained respect for its results in the evaluation of local recurrences. In a small study<sup>18</sup> comparing the relative values of MRI versus CT in diagnosing local recurrence for rectosigmoid cancer, MRI showed superior sensitivity, specificity, and accuracy to CT and better definition of the extent of tumor. At the time of the initial imaging, ten patients had recurrent tumor and four of the remaining eight patients later demonstrated local recurrence. MRI demonstrated 91% sensitivity and 100% specificity, with an accuracy of 95%. CT demonstrated a sensitivity of 82% and a specificity of 50%, with an accuracy of 68%. In four cases, MRI revealed tumor involving the sacrum and sacral nerves not apparent on CT.<sup>18</sup> MRI is also useful to distinguish recurrent rectosigmoid carcinoma from benign postoperative fibrosis.<sup>19</sup>

### **ENDORECTAL ULTRASOUND**

The interest in developing endoscopic ultrasound as an accurate imaging technique for rectal cancer is not recent. In rectal cancer, the depth of tumor infiltration and metastatic involvement of lymph nodes are important prognostic factors, and EUS of the rectum combines the advantages of both endoscopy and sonography, providing information not available from other imaging diagnostic techniques ( Fig. 33.8-2). Early animal models using dogs demonstrated its superiority against conventional CT scans, and its potential in predicting pathologic stage.<sup>20</sup> The superiority of EUS against CT scan has been confirmed in studies involving human patients,<sup>21</sup> and it has become the preferred method of preoperative local tumor staging.<sup>7</sup> Hildebrandt and Feifel (1985) even proposed an ultrasonic staging system, which corresponded to the standard pathologic staging systems (e.g., uT for ultrasound T stage, uN for ultrasound N stage).

**FIGURE 33.8-2.** Layers of the rectal wall on endorectal ultrasound.

Detry and colleagues<sup>22</sup> suggested that a low percentage of affected lymph nodes were detected by EUS and that lymph node size was the most reliable parameter to determine tumor involvement. The group at the University Hospital of Würzburg examined the value of EUS in the preoperative staging of 160 potentially locally resectable tumors. The sensitivity for adenomas and T1 tumors was 81% and the specificity was 98%. For T2 tumors, the sensitivity was only 41% and the specificity, 92%. The majority of T2 tumors were overstaged. The overall staging accuracy for all tumors was 77.5%. The accuracy for lymph node staging was 83%. The authors concluded that adenomas and T1 tumors could be assessed with a high degree of accuracy using EUS. However, T2 carcinomas tended to be overstaged.<sup>23</sup> Similarly, Bernini and colleagues (1996) found that EUS after adjuvant therapy for rectal cancer is of a lesser predictive value, chiefly because of overstaging. However, a more recent report by Massari and colleagues<sup>24</sup> that included 85 patients affected by rectal carcinoma showed an overall accuracy in staging depth of infiltration of 91%. Overstaging occurred in only 4% of patients, whereas understaging occurred in 5%. The overall accuracy in staging lymph node involvement was 76%, sensitivity was 69.8%, specificity was 84.4%, positive predictive value was 85.7%, and negative predictive value was 67.5%. The authors concluded that EUS is a safe and accurate diagnostic method for staging both tumor invasion and lymph node metastatic involvement, and for selecting an appropriate surgical strategy in patients affected by rectal cancer.<sup>24</sup>

It is interesting to note that the accuracy of EUS is improving in more recent series, indicating that experience and new knowledge may have an impact on the staging inaccuracies resulting from over- or underestimation of tumor depth and misinterpretation of lymph node involvement. Technical pitfalls in EUS of the rectal wall include difficulty locating the lesion, improper balloon inflation, improper imaging plane, shadowing artifacts due to air or stool, reverberation artifacts, refraction artifacts, and inappropriate transducer setting. Sources of error in tumor staging with EUS include interpretation differences, operator bias, tumor stenosis, peritumoral inflammation, postbiopsy and postsurgical changes, postirradiation changes, hemorrhage, and pedunculated or villous tumors.<sup>25</sup> Sailer and colleagues<sup>26</sup> suggested that the rectal anatomy affects staging accuracy of EUS in the lower rectum because the structure of the ampulla recti renders the examination more difficult and that the endosonographic layers are less well defined at this level. The same study did not show a predictive value for the tumor position with respect to rectal circumference.<sup>26</sup> The presence of peritumoral tissue reaction (PTR) is a common cause of overstaging. Maier and colleagues<sup>27</sup> evaluated the preoperative EUS results in 40 consecutive patients with biopsy-proven rectal cancer and compared them with histopathologic reports on the specimens. Twenty-eight (70%) of 40 rectal

cancers were staged correctly with EUS. PTR was responsible for the misinterpretation in six of seven overstaged cases. In a second part of the study, another 40 patients were prospectively evaluated with EUS. The thickest part of the PTR was measured, and results were compared with the histopathologic findings. Thirty-eight (95%) of 40 cancers were staged correctly, and the presence or absence of PTR was described in 39 cases (98%). A statistically significant positive correlation was noted between histopathologic classification of PTR and its thickness measured with EUS ( $P = .0001$ ).<sup>27</sup>

Despite the increased use of preoperative radiotherapy alone or in combination with chemotherapy for the treatment of stages II and III rectal cancers, our ability to assess local eradication of rectal cancer after radiation therapy remains poor. Conventional imaging and clinical examination techniques are unable to safely predict which patients do not require surgical excision after curative radiation therapy for rectal cancer.<sup>28</sup> The postradiation preoperative staging results of 25 patients with rectal cancer who were found to have stage T0N0 lesions after surgery were examined. All 25 patients were staged by digital rectal examination. In addition, 13 patients were assessed using CT, six by EUS, and one by MRI. Radiologic assessment and physical examination overstaged most irradiated lesions. No technique could reliably distinguish between postradiation fibrosis and residual cancer.<sup>28</sup>

## CLINICAL STAGING SYSTEM

The same pathologic staging systems extensively described in [Chapter 33.7](#) are used for rectal tumors. However, the pathologic staging systems cannot be used for making preoperative treatment decisions. Furthermore, patients treated with local modalities, such as transanal resection, do not have a lymph node pathologic evaluation. A reliable and reproducible clinical staging system would be very useful.

Several authors have proposed innovative ways of clinically staging rectal cancer patients. Abrams (1980), for example, evaluated the gross and microscopic pathologic features of 167 rectal cancers. He demonstrated that 63% of nonulcerated tumors were limited to the bowel wall versus only 28% of the ulcerated ones. Zorzitto and colleagues (1982) retrospectively evaluated six clinical variables: the presence or absence of metastatic disease; whether the rectal tumor was fixed; an annular rectal tumor; and the systemic symptoms of weight loss or anorexia, weakness, and anemia. They were able to classify patients in four clinical stages, with substantial gradients in survival among them. However, the correlation between the clinical stage and Dukes' stage was not reliable. Several authors have devised clinical staging systems centered in the degree of mobility of the primary tumor. However, correlation with the pathologic stage was at best 67% to 83%, being lower for less-experienced physicians.

At the University of Texas M. D. Anderson Cancer Center, preoperative treatment of rectal cancers with chemotherapy and radiotherapy has become common. Patients are routinely staged by physical examination, proctoscopy, and conventional imaging studies (i.e., chest x-ray, CT scans of abdomen and pelvis). The degree of rectal wall involvement and the presence of involved lymph nodes are determined by EUS. Based on the results of these studies, patients are clinically classified according to a "clinical" TNM stage. The main problem with this approach is the risk of overstaging,<sup>29,30</sup> especially if the EUS is done by inexperienced physicians, because this imaging modality is highly operator-dependent. Prospective studies are still required to determine the best clinical staging for rectal cancer. The new molecular markers and positron emission tomography (PET) should be added and explored in future clinical staging systems.

## TREATMENT OF RESECTABLE RECTAL CANCER

Goals in the treatment of rectal carcinoma are local control of disease and cure, with maintenance of an acceptable quality of life. The biology of a particular patient's tumor is the most important factor in overall outcome. Adequate surgical removal of the tumor is the major treatment factor affecting local control and cure. The principles of the surgical management of rectal cancer are (1) removal of the primary tumor with adequate margins of normal tissue, (2) treatment of the draining lymphatics, and (3) restoration of function. Appropriate adjuvant therapies can enhance local control, reduce systemic recurrence, and increase organ preservation. Clinical staging by history, physical examination, proctoscopy, and imaging is appropriate for establishing resectability and proper sequencing of adjunctive therapies. The management of rectal cancer is best planned by clinical staging that takes into account the extent and location of the primary tumor, its locoregional spread, and presence or absence of metastatic sites.

In patients with low rectal cancer, abdominoperineal resection (APR) has been the standard of management. However, APR requires a permanent colostomy, which adversely affects the patient's quality of life. The majority of patients with rectal cancer do not require a permanent colostomy for curative therapy. Curative excisions can extend from endoscopic removal of malignant polyps to local excision, radical resection, or multivisceral resections.

## SITE-SPECIFIC TREATMENT OPTIONS

For purposes of surgical management, the rectum is usually divided into thirds. The middle and lower thirds are extraperitoneal, whereas the upper third may be covered on its anterior or lateral surfaces by peritoneum. The selection of an appropriate surgical technique takes into account not only the extent and location of the tumor, but also the biologic characteristics of the tumor and the patient's overall condition ([Table 33.8-1](#)).

---

Abdominoperineal resection
Low anterior resection
Proctectomy and coloanal anastomosis
Local excision
Transanal excision
Posterior proctotomy
Transanal endoscopic microsurgery
Ablative procedures
Endoscopic laser
Fulguration

---

**TABLE 33.8-1.** Surgical Procedures for Rectal Cancer

### Upper Third

Recurrence patterns and cure rates for tumors in the upper third of the rectum are similar to those for the colon. Advanced tumors in this location may involve the retroperitoneal structures (i.e., ureters, bladder, muscle) or major vessels. The lowermost edge of these tumors is usually 10 to 12 cm from the anal verge. Extirpation of these tumors should include resection of the bowel segment containing the tumor along with the mesorectum to approximately 5 cm below the lower edge of the tumor (Lopez-Kostner, [1998]). It is usually inappropriate to attempt local excision techniques in this area because of the relationship between the upper rectum and peritoneal cavity and because of the poor exposure due to the distance from the anal verge.

### Middle Third

The appropriate procedure for radical resection of most rectal carcinomas is a low anterior resection (LAR). This procedure encompasses the sigmoid colon, a segment of the rectum containing the tumor with a margin of tissue below the tumor, and the mesorectum. Reconstruction is performed between the left colon and the rectal stump. Most tumors in the middle rectum are not amenable to local excision because of the proximal extension of the tumor. APR does not reduce local recurrence rates compared to appropriate sphincter-preservation surgery for patients with midrectal tumors.

### Lower Third

Cancers in the distal rectum can require APR for adequate radial and distal margins. The entire mesorectum is included in this resection. Management of these tumors has been most clearly affected by multidisciplinary treatment strategies that allow for adequate oncologic resection and preservation of the anal canal. Important techniques have been proctectomy and coloanal anastomosis (CAA), as well as local excision.<sup>31</sup> Both of these treatments are commonly combined with

either preoperative or postoperative radiation therapy.<sup>32</sup>

The use of staplers has evolved to make an anastomosis easier when there is a short rectal stump deep within the pelvis. The double-staple technique of Knight and Griffin is most commonly used to restore intestinal continuity after resections in which a short rectal stump remains (Griffin, 1990). Alternative forms of local therapy for low rectal cancers include transanal endoscopic microsurgery (TEM), endocavitary radiation, fulguration, and laser ablation.

## SURGICAL ISSUES IN RESECTABLE RECTAL CANCER

This section discusses the major issues that are common to surgical procedures for rectal cancer.

### Mucosal Margins

Attaining tumor-free margins at the edges of a rectal cancer resection specimen is the hallmark of curative surgical therapy. The purpose of obtaining such a margin is to prevent local failure and effect cure.

Spread beyond the lower edge of a rectal cancer may occur by submucosal spread in intramural lymphatics. Fewer than 5% of rectal cancers show distal mucosal spread beyond the edge of the tumor, and only 2.5% have histologic evidence of spread beyond 2 cm. These tumors commonly show aggressive biologic characteristics. Margins may need to be increased in locally aggressive tumors, such as those showing poor differentiation or vascular and lymphatic invasion. In these cases, the spread may be discontinuous. It does not appear that a mural mucosal margin of 5 cm is necessary to prevent local recurrence. Even margins of 1 cm have been demonstrated to provide adequate protection from local recurrence in the absence of aggressive histologic features.<sup>33</sup> Distal margins of more than 2 cm do not reduce the risk of anastomotic recurrence.<sup>34</sup>

The impact of neoadjuvant therapies on the suitability of margins is unclear at this time. However, some have proposed that distal margins may be reduced in the face of preoperative chemoradiation. These concepts have allowed for an increase in sphincter-preserving procedures without detracting from local control and survival. However, clinical response at the primary site can be misleading. Many patients have residual microscopic disease within the bowel wall, despite a complete response at the mucosal surface.<sup>35</sup> Complete excision of the primary site with margins of normal tissue is recommended.

The difference between margins reported in the literature and margins *in situ* at surgery can be significant. This fact is due to contraction of the specimen after its excision and the stretching of the rectal wall. Therefore, generous gross margins can be required to assure adequate resection. A microscopically involved margin is unacceptable for a curative resection and will not be salvaged by radiation and chemotherapy. The need for negative mural margins also applies to local excision specimens for which a 1-cm margin of grossly normal bowel wall around the tumor is recommended for satisfactory resection.<sup>36</sup>

### Proximal Lymph Node Dissection

The lymphatic spread of rectal cancer is upward as well as lateral and distal. The proximal extent of the mesorectum and the rectosigmoid mesentery should be included in the resection. Lymph node excision at the base of the inferior mesenteric artery does not enhance survival compared with lymph node excision just distal to the origin of the left colon. This is particularly true for low rectal cancers in which positive nodes between the left colic origin and the inferior mesenteric artery origin are found in fewer than 6% of resectable cases.<sup>37</sup> For low rectal resections or CAA, however, ligation of the inferior mesenteric artery just above its origin at the aorta is required to eliminate tension on the anastomosis. Retroperitoneal adenopathy above the level of the inferior mesenteric artery is frequently a harbinger of occult systemic spread that is not amenable to cure by surgery alone.

### Total Mesorectal Excision

The mesentery of the rectum contains its blood supply and lymphatics in a bilobed fat packet situated immediately posterior and lateral to the thick-walled rectum. Both are contained in the visceral layer of the endopelvic fascia. The majority of resectable primary rectal tumors and involved lymph nodes in rectal cancer specimens are found within this structure. Nodes are involved in T1 cancers in 5.7% of cases; T2 tumors have positive nodes in 19.6%, and T3 and T4 cancers have positive nodes in 65% and 78% of cases, respectively.<sup>38</sup> Involvement of the radial or circumferential margin correlates with subsequent local recurrence and poor survival.<sup>39</sup> Resection of the mesorectum should extend farther distally than the acceptable margin for rectal wall transection ( Fig. 33.8-3). Because the mesorectum tapers as it proceeds distally, it is totally excised for most middle and lower rectal cancers. More proximal rectal tumors can be treated by a mesorectal excision extending 5 cm beyond the lower tumor edge. Total mesorectal excision has been associated with a high rate of anastomotic leak when used for upper rectal tumors.<sup>40</sup>

FIGURE 33.8-3. Total mesorectal excision.

The work of Quirke and others (1986) has dramatically demonstrated the importance of lateral tumor spread in the local recurrence of resected rectal cancers ( Table 33.8-2). Among patients with local recurrence, tumor involvement at the circumferential margin of resection has been found in 85% of cases. Because of difficulty in obtaining adequate exposure in the low pelvis and the surrounding structures, circumferential margins around rectal cancer can be highly variable and minimal. Surgical experience and surgical technique have demonstrated their key role in the prevention of local recurrence by controlled sharp dissection done with attention to these margins.<sup>41</sup> The mechanism for involvement of the circumferential margins can be direct spread, mesenteric implants, vascular or lymphatic invasion, or cancer-bearing lymph nodes. Up to 23% of patients can have mesorectal tumor implants aside from discrete nodes.<sup>42</sup> Tumor involvement of the circumferential margins of resection is frequently due to spread in the mesorectum distal to the tumor that can be violated by blunt dissection.<sup>43</sup> It has been implied that a positive circumferential margin after mesorectal excision is a prognostic factor for distant metastases also.<sup>44</sup>

Curative Resection Specimens (N = 20)	Distal Mesorectal Spread	Involvement of Radial Margin
16	Negative	2 (13%)
4	Positive	2 (50%)

[From Adam JJ, Mohamdee MO, Martin JG, et al. Role of circumferential involvement in the local recurrence of rectal cancer. *Lancet* 1994;344(8924):707, with permission.]

**TABLE 33.8-2.** Distal Mesorectal Spread in Producing an Involved Radial Margin

Circumferential clearance of rectal tumors by total mesorectal excision has become the accepted surgical procedure for the management of most rectal cancer. Total mesorectal excision by full mobilization of the rectum along anatomic planes has been demonstrated to be effective in the surgical management of rectal cancer.<sup>45,46</sup> Dissection is carried out along areolar planes that allow for hemostasis, identification of important nerves, and prevention of violation of the visceral fascia investing the mesorectum.<sup>47</sup> This type of surgical resection for rectal cancer produces a negative surgical margin in more than 90% of resectable rectal cancers and reduces the possibility of local recurrence.

#### **Lateral Pelvic Lymph Node Dissection**

Lymphatic drainage of the rectum not only flows proximally along the inferior mesenteric vessels, but also follows the middle rectal vessels to the lateral pelvic sidewall and into internal iliac nodes. These nodes may be a source of recurrence. The incidence varies from 1% to 7% in resectable cases. Wide pelvic lymphadenectomy including lateral pelvic lymph nodes has been proposed for the treatment of rectal cancer. Although there is little doubt that the presence of metastases in such lymph nodes is a significant negative prognostic factor, no evidence supports a therapeutic benefit of the routine addition of extensive lymphadenectomy to standard locoregional procedures.<sup>48</sup> Gross disease can be resected when this procedure would provide a negative margin of resection.<sup>47</sup> The morbidity of this procedure is significant, with the majority of patients developing urinary dysfunction and impotence.

#### **RADICAL SURGICAL TREATMENT OPTIONS**

Patients with stage II and III rectal cancer (60% to 80% of patients with rectal cancer) have tumors that are large and biologically aggressive. They are at higher risk of local and systemic recurrence after treatment. Accordingly, strategies have been developed to address these issues through locoregional resection and multimodality therapy. However, adequate surgical resection and technique are the most critical treatment factors determining patient outcome.

The surgical management of stage II and III tumors is based on several issues: (1) the importance of the lateral spread of rectal cancer in local tumor recurrence; (2) the need for total mesorectal excision to minimize pelvic recurrence; (3) restoration of function by CAA after resection of low rectal cancers; and (4) optimization of bowel function and quality of life after low rectal anastomosis. Oncologic results of radical resection and patterns of failure are discussed later in this chapter.

#### **Selection of Radical Excision Procedures**

The surgical procedure chosen for radical excision is determined largely by tumor location. Three different operative procedures can be performed, all with adherence to the principles of total mesorectal excision: LAR, APR, and total proctectomy with CAA. For rectal cancer patients, a major component of quality of life is sphincter preservation. This is simple to accomplish in middle and upper rectal cancers where LAR achieves adequate removal of the tumor and surrounding lymphatics and end-to-end anastomosis. In patients with low rectal cancers that do not involve the levators or sphincters, the anus may still be spared by proctectomy and CAA.<sup>49</sup> Preoperative chemoradiation may facilitate this. However, patients with levator or sphincter involvement are best managed by APR and permanent colostomy.

#### **Abdominoperineal Resection**

Preoperative planning of the stoma site and counseling about the consequences of a colostomy are critical to a successful outcome. Proper selection of a site must be planned preoperatively with attention to belt lines, scars, and body habitus. APR involves a combined transabdominal and perineal approach to complete resection of the rectum, mesorectum, levator muscles, and anus, with formation of a permanent colostomy. The rectum and mesorectum are mobilized via an abdominal approach down to the levator muscles. A perineal approach is used to widely resect the levator complex and anus along with an appropriate margin of perianal skin. A permanent end colostomy is done. As sphincter preservation (LAR and proctectomy plus CAA) has advanced, the overall proportion of rectal cancer patients undergoing APR has decreased.<sup>50</sup> However, APR remains the only surgical option for some patients with rectal cancer, specifically in those patients with sphincter complex involvement or levator muscle involvement.

#### **Low Anterior Resection**

LAR involves the transabdominal resection of a portion of the rectum as well as the mesorectum. After complete mobilization of the rectum *en bloc* with the mesorectum, the rectum is divided at least 2 cm below the distal edge of the tumor (see Fig. 33.8-3). Although the length of mesorectal excision will exceed this, evidence indicates that total mesorectal excision is not required for upper rectal cancers. Reconstruction of the rectum is then carried out between the completely mobilized left colon and the remaining rectal stump. The use of LAR in midrectal and selected low rectal cancer has increased for two main reasons. First, the double-stapled technique has permitted a simpler and lower anastomosis, with leak rates (clinical or radiographic) similar or better than with handsewn techniques. Second, although 5 cm was previously felt to be the minimum acceptable distal margin, the acceptance of a 2-cm distal margin has enabled lower tumors to be resected by LAR.<sup>51</sup> The timing of sphincter-preserving surgery after preoperative radiation has been demonstrated to influence sphincter preservation. A 6- to 8-week interval increases the sphincter preservation rate from 68% for a 2-week interval to 76%.<sup>52</sup>

#### **Proctectomy and Coloanal Anastomosis**

Although LAR and APR are the traditional methods of locoregional resection in rectal cancer, proctectomy with CAA has emerged as a well-accepted surgical option in carefully selected patients. This procedure spares patients a permanent colostomy while obtaining good functional and cancer-related outcomes.<sup>48</sup> A review of 117 patients from the Mayo and Cleveland Clinics provides a perspective on the current utility of proctectomy and CAA in patients with low rectal cancer.<sup>53</sup> The patients were treated over a 10-year period (1981 to 1991). The median distance of the tumor from the anal verge was 6 to 7 cm. The technique used required complete mobilization of the rectum to the levators, transanal transection of the rectum, complete mobilization of the left colon, and endoanal anastomosis ( Fig. 33.8-4). The authors recommend loop ileostomy. The effectiveness of the procedure in preventing local recurrence was demonstrated by the low local recurrence rate of 7%. Fecal continence was satisfactory in 78%, and overall bowel function appeared to be improved in patients who had a colonic J pouch reservoir created for the CAA. No surgery-related deaths were reported. Early and late complications were related mainly to the anastomosis leaking and healing with a stricture.

**FIGURE 33.8-4.** Coloanal anastomosis.

The mobilization of the rectum is extended down to the level of the upper anal canal and levators. Lateral ligaments are divided with attention to obtaining an adequate radial margin and to preserving the pelvic autonomic nerves. This dissection results in the complete exposure of the pelvic floor and complete excision of

the mesorectum. The fully mobilized rectum can be amputated by a transanal technique or by transection at the upper end of the anal canal with a stapler. The reconstruction consists of delivering the mobilized left colon to the anal canal and performing an anastomosis. A hand-sewn anastomosis can be performed with full-thickness sutures through the colon and internal sphincter. Alternatively, a stapled anastomosis may be done. A diverting stoma is then usually created.

Several groups have reported on patients who have a 6- to 10-cm colonic J pouch reservoir constructed with no additional risk or compromise of the anastomosis.<sup>54</sup> The formation of the colonic pouch has been compared to the straight CAA in a randomized clinical trial. Hallbook and colleagues (1996) demonstrated a reduction in the frequency and urgency of bowel movements in the first year after pouch formation. Physiologic measures and short-term outcomes appear to be improved with the pouch. However, these differences may disappear with time.<sup>55</sup> It has been suggested that lower leak rates with a colonic J pouch may be obtained because of improved vascular supply to the apex of the pouch and the side-to-end anastomosis.<sup>56</sup> Postoperative problems after CAA are related to rectal capacitance and compliance. These manifest as the problems of urgency and frequency in bowel movements. This gradually improves over the 9 to 10 months after temporary stoma closure. Complete fecal continence usually is achieved in 85% to 100% of patients. In a series from the Mayo Clinic by Drake et al.,<sup>57</sup> patients who had a CAA for malignancies had a stool frequency of 2.6 per 24 hours, and only 1 of 19 patients had any incontinence. The Mayo and Cleveland Clinics study is similar to the reports of others in describing proctectomy and CAA for rectal cancer.<sup>58</sup>

### **Multivisceral Resection for Locally Advanced Rectal Cancer**

Approximately 6% to 10% of rectal cancers are locally advanced in, and require extensive surgery for, complete tumor extirpation. Pelvic exenteration involving *en bloc* removal of the rectum, bladder, distal ureters, and other pelvic organs can be required to obtain negative margins of resection.<sup>59</sup> A number of studies have demonstrated 5-year survival rates ranging from 33% to 50% for these selected patients with locally advanced rectal cancer. Despite the ability to achieve long-range survival rates in selected patients, the operation remains a formidable one, with significant morbidity and a mortality up to 6%.<sup>60</sup> Patients who undergo such resections for primary tumors have better survival rates than those with recurrence.

Meterissian et al.<sup>35</sup> reported a series of 40 patients undergoing pelvic exenteration for rectal carcinoma in which tumor-free margins were obtained. The 5-year overall survival rate was 49%, with a median survival of 56 months. Adjuvant chemoradiation appeared to provide a reduction in risk of recurrence. In the series, five patients experienced local failure. Comparable results have been recorded by Lopez and associates (1987). Long-term local control is obtained in approximately 70% of the patients who undergo resection with tumor-free margins. The results of such surgery cannot be separated from the benefits of adjuvant chemoradiation in this high-risk population.

Results from surgical procedures for rectal cancer requiring multivisceral resection have improved.<sup>61</sup> This finding may be related to improvements in perioperative care, patient selection, and surgical techniques. Of major importance in the management of such patients, who are often heavily radiated, is the use of vascularized tissue flaps to accomplish healing of pelvic and perineal wounds.<sup>62</sup>

### **Morbidity and Mortality from Radical Resection**

The major cause of infection in procedures in which reconstruction has been done is anastomotic leak. Anastomotic leaks can occur in 2% to 5% of cases, and they may result in subsequent stricture.<sup>63</sup> The consequences of pelvic sepsis can be a major cause of mortality from resection of rectal cancer. Use of a diverting stoma for a low rectal anastomosis will not prevent anastomotic leak, but it will reduce the clinical manifestations of sepsis, the need for reoperation, and mortality.

Bladder dysfunction can be a complication of extensive pelvic dissection, especially if disruption of autonomic nerve trunks occurs. Sacral parasympathetic nerve injuries result in loss of the awareness of the need to void. Management by intermittent catheterization, medications, or transurethral resection may be required.

Resection of the rectum for carcinoma has been associated with a high rate of erectile dysfunction or retrograde ejaculation in men. This sexual dysfunction is caused by injury to pelvic autonomic nerves and is especially frequent in cases in which extensive lateral dissection has been done. Pelvic dissection to preserve the hypogastric sympathetic nerve trunks arising from the preaortic plexus and the parasympathetic trunks arising from the sacral nerve roots can reduce this morbidity.<sup>64</sup> It is also important to realize that erectile dysfunction is not uncommon in the age group of individuals who develop sporadic rectal cancer and that factors other than an intact autonomic nervous system can impact on a patient's sexual function after the diagnosis and management of rectal carcinoma.

With sharp nerve-sparing dissection, impotence has been reduced to a rate of 10% to 28%, or lower, in many series with resection of rectal carcinoma.<sup>2</sup>

Creation of a stoma can produce complications requiring reoperation in 15% to 20% of patients.<sup>65</sup> Reconstruction of the rectum avoids a permanent colostomy. However, bowel movements and urgency may be frequent because of the smaller neorectum.<sup>66</sup> The reconstructed rectum usually is composed of a more proximal segment of left colon, which is brought down to a rectal stump of varying lengths. Improving the rectal reservoir function by construction of a colonic J pouch improves short-term functional results.<sup>67</sup> Function does improve with time. The use of fiber supplements may enhance this improvement. Episodic clustering of bowel movements is also a prominent symptom in patients with a small rectal pouch after reconstruction. Anal sphincter tone and local reflexes regulating sphincter function are generally preserved after resection. Actual sphincter function usually is maintained in the majority of patients. Function is diminished by the presence of postoperative pelvic sepsis or the use of postoperative radiotherapy. Operative mortality for radical resections ranges from 0.6% to 3.0%.<sup>46,63</sup>

## **TREATMENT OF INVASIVE CANCER BY NONRADICAL APPROACHES**

### **SELECTION OF PATIENTS**

The criteria used to select patients for local excision are intended to make a negative-margin, full-thickness local excision technically feasible and to ensure a low risk of lymph node metastases (Table 33.8-3). Physical assessment, CT, and EUS are helpful in the preoperative evaluation of these rectal cancer patients. Imaging findings can be used to select patients for local excision procedures by determining the depth of tumor penetration into the rectal wall and the presence of enlarged lymph nodes in the mesorectum. Ninety percent of rectal cancers do not meet the criteria for treatment by local excision alone because of the size or extent of the tumor.<sup>68</sup> Factors that can help identify patients who are at low risk for lymphatic metastases include small tumor size, absence of lymphatic and vascular invasion, well or moderate tumor differentiation ploidy, and absence of clinical or radiologic evidence of enlarged lymph nodes.<sup>69</sup>

**TABLE 33.8-3.** Indications for the Local Excision of Rectal Cancer

The major factor predicting patient survival and perirectal lymph node metastases is the depth of penetration of the primary tumor. Morson (1966) has reported that lymphatic metastases occur with 10% of tumors confined to the submucosa, 12% of tumors invading the muscularis propria, and 58% of tumors extending beyond the bowel wall. A study of T1 and T2 tumors treated by radical resection showed an incidence of lymphatic metastasis of 12% for T1 tumors and 22% for T2 tumors. The incidence of lymphatic metastasis was increased by lymphatic or blood vessel invasion (BVI) and in poorly differentiated tumors.<sup>70</sup> Nelson et al.<sup>71</sup> reported that 29% of

patients with lesions smaller than 2 cm in diameter had evidence of lymph node metastasis. Thus, selection for local excision based on the classic indications fails to adequately treat a significant number of patients with lymphatic involvement. This makes the addition of adjuvant therapy to local excision a logical choice.

## LOCAL EXCISION TECHNIQUES

Full-thickness local excision is effective in the treatment of selected early, low rectal cancers. Local excision is used as curative therapy for patients who have superficial tumors, and it is used as alternative therapy in medically compromised patients and in those who refuse standard therapy. Patient selection is paramount to using these techniques successfully, which requires an understanding of the limitations of the techniques and an appreciation of the biology of T1–2 rectal cancer. The oncologic results of local treatment with and without adjuvant treatment are described in [Adjuvant Radiation Therapy for Resectable Rectal Cancer](#), later in this chapter.

The choice of technique for local excision is dictated by tumor characteristics and the surgeon's ability to have adequate exposure and control of the margins of excision. In general, the transanal approach has less morbidity. Posterior approaches can offer the advantage of better exposure for larger lesions. However, posterior approaches entail a higher rate of fistula formation and the potential for tumor seeding of the posterior wound. Whichever method is selected, the surgeon must perform a full-thickness excision with at least 1-cm margins of normal tissue surrounding the tumor. An inadequate margin is a predictor of failure.<sup>72</sup> Piecemeal or submucosal excision is not considered adequate surgical treatment of invasive rectal cancer. Fragmentation of the tumor is associated with an increased incidence of local recurrence. If the lesion cannot be adequately resected by local excision, then a more standard locoregional operative approach should be used. In a curative case, the patients should be counseled to consider local excision as a form of definitive biopsy. This is especially true when transmural penetration or adverse histologic characteristics are found in the local excision specimen. In most instances, these patients should undergo more extensive surgical therapy.

### Transanal Excision

Transanal excision is the most common method used for local excision. Size and degree of circumferential involvement predict the potential for a technically successful transanal excision. Both adequate dilatation of the anus and a good light source are essential, and exposure is aided by the use of specialized retractors.<sup>73</sup> The excision is begun by marking a margin of normal tissue around the lesion, which must be greater than 1 cm.<sup>74</sup> The local excision is performed in a full-thickness manner, meaning that the deep plane of dissection includes the perirectal fat. The defect usually is closed to avoid subsequent scarring. Proper orientation of the specimen is required for pathologic assessment of the margins. Lymph nodes are usually not recovered by this technique.

### Posterior Proctotomy

A posterior proctotomy is useful for large posterior lesions and provides better access to more proximal lesions. Otherwise known as a *Kraske's procedure*, a posterior longitudinal incision is made just above the anus to the inferior border of the gluteus maximus. The coccyx is removed and the underlying levator muscles are divided in a longitudinal fashion in the midline. This permits excellent exposure for mobilization of the rectum and allows for a full-thickness local excision or, alternatively, a sleeve resection. A transsphincteric excision (Bevan's or York-Mason) involves a similar approach as the posterior proctotomy, except the entire anal sphincter is divided posteriorly in the midline. It is critical to identify, mark, and reconstruct each portion of the sphincter complex, but if this is done, minimal functional problems are observed.<sup>75</sup>

### Transanal Endoscopic Microsurgery

TEM, in which either submucosal (for adenomas) or full-thickness (for invasive carcinomas) excision is performed through an operating rectoscope, has emerged as an option for the local treatment of rectal cancer.<sup>76</sup> It allows improved exposure compared to the transanal approach and does not carry the risk of fecal fistula or sphincter dysfunction associated with posterior or transsphincteric proctotomy. In one series, local recurrence occurred in 2 of 16 (13%) patients with T1 lesions undergoing TEM.<sup>76</sup> The authors of this series believe that TEM alone is not an appropriate treatment for T2 lesions. Further follow-up and experience is required to establish the role for TEM.

### Fulguration

Fulguration can be used in highly selected patients to treat lower rectal carcinomas.<sup>77</sup> Chin and Eiserstat<sup>78</sup> have reported good results with rectal coagulation for rectal cancers less than 4 cm in diameter that are well or moderately differentiated and less than 7.5 cm from the anal verge. Eighty-one of 114 patients with low rectal cancers were treated primarily by electrocoagulation with curative intent, and a 65% 5-year survival rate is achieved in highly selected individuals. Stahl et al.<sup>79</sup> reported similar results in 33 patients treated with electrocoagulation. This is carried out through an operating proctoscope. Bipolar coagulating current is used to coagulate the lesion along with a 1-cm margin of normal mucosa. This procedure is followed by débridement of the coagulated tissue, and the process is repeated until no residual tumor is noted. This technique can be carried out through the entire bowel wall for posterior and lateral lesions. Although it is used for anterior lesions, it should be carried out with caution because of the proximity of the rectovaginal septum or prostate. Complications of this procedure can include bleeding, stricture, abscess, or perforation. The overall complication rate is 21%, and a mortality rate of 2.7% was reported.

### Endoscopic Laser

Endoscopic laser may be used for palliative purposes in patients with extensive metastases for rectal obstruction or hemorrhage. It may be used as definitive therapy in those who refuse surgery or are a poor surgical risk, as a bridge to neoadjuvant therapy, or to allow bowel preparation. It is most useful for noncircumferential lesions that are less than 7 cm in diameter and have limited invasion. It may be combined with external-beam radiotherapy after successful recanalization.<sup>80</sup> Highly selected patients with small tumors who undergo complete local destruction of the tumor with subsequent negative biopsies can occasionally be treated definitively. A mean survival of 50 months has been achieved by Brunetaud et al.<sup>81</sup> in a series of patients treated by such techniques. Laser treatment can be combined with photosensitizing agents to achieve more efficient tumor ablation. This technique of photodynamic therapy is especially useful in patients being managed for obstruction who are otherwise unresectable.

### Endocavitary Irradiation

Radiation has been used as a single modality with curative intent for selected early rectal cancers. Most investigators have used intracavitary irradiation alone for early, noninvasive tumors. For more advanced tumors, it is combined with a temporary iridium 192 implant or external-beam radiation, or both.<sup>82</sup> Before delivery, the anus is dilated and a 4-cm proctoscope is introduced. A low-energy x-ray unit is placed through the scope almost against the tumor. Generally, 50-kV x-rays, in doses of 30 Gy per treatment, are given using this "contact" approach. Three or four such treatments over 1 month are required. Bulky tumors may require additional irradiation with an <sup>192</sup>Ir implant or external beam to reach the deeper pararectal tissues.

## RESULTS OF TREATMENT OF RECTAL CANCER

This section presents the results after potentially curative surgery alone for clinically resectable rectal cancer. Overall, cure rates for cancers in the lower third of the rectum are lower than those for cancers in the upper two-thirds.

### ONCOLOGIC RESULTS OF RADICAL SURGICAL RESECTION ALONE

Numerous studies have compared the oncologic results of APR with those of sphincter-preserving procedures (LAR or proctectomy plus CAA). In a randomized clinical trial intended to examine the benefit of adjuvant therapy in rectal cancer, patients who underwent APR had a higher recurrence rate than patients undergoing LAR ( $P < .05$ ).<sup>83</sup> However, this finding was likely reflective of the larger, more advanced tumors seen in the patients undergoing APR. Several other studies involving large numbers of rectal cancer patients have shown no significant differences in local recurrence or survival between patients undergoing APR and those undergoing sphincter preservation.<sup>83</sup> Survival does not appear to be compromised.

Outstanding surgical results have indicated that total mesorectal excision is the optimal technique for the radical resection of rectal cancer ( [Table 33.8-4](#)). McAnena et al.<sup>84</sup> have described the long-term outcome of 57 patients treated by this approach. The mean follow-up was 4.8 years. Local recurrences were seen in only 3.5% of

the patients, and the overall 5-year survival rate was 81%. In a report by MacFarlane and coworkers <sup>85</sup> on patients undergoing operation exclusively, 135 patients with Dukes' B and C rectal cancers were treated over a 13-year period with a mean follow-up of 7.5 years. None of these patients received adjuvant radiation or chemotherapy. Despite this fact, only a 5% local recurrence rate was reported.

Series	n	Stage	Local Recurrence Rate (%)
Enker et al. <sup>86</sup> 1999	156	I, II, III	7
Arbman et al. <sup>84</sup> 1996	128	I, II, III	7
Pocard et al. <sup>85</sup> 1998	118	I, II, III	15
Zaheer et al. <sup>83</sup> 1998	514	I, II, III	7

**TABLE 33.8-4.** Local Recurrence Rates after Surgery Alone

Further long-term follow-up of a larger group of patients confirmed these findings, specifically with a 10-year local recurrence rate of 4% and a 10-year disease-free survival rate of 78%.<sup>73</sup> Heald (1986) reported his group's experience between 1978 and 1997 with 380 patients who underwent curative resection with a 10-year local recurrence rate of 8%. This reduction in local recurrence rate has been reported as the reason for a high survival rate for these patients.<sup>45</sup> This compares favorably with the results from the North Central Cancer Treatment Group (NCCTG) study that forms the basis for current recommendations for adjuvant therapy in the United States in which chemotherapy and radiation were used for high-risk rectal cancers in addition to surgical resection.

In North America, similar results have been obtained with high rates of local recurrence-free survival when a total mesorectal excision is done by meticulous sharp dissection along the pelvic sidewalls. Enker's report on this subject called for full rectal mobilization along anatomic planes to obtain complete mesorectal excision. In a series of 42 men who underwent sphincter-preserving surgery for low rectal cancer using this technique, only one local recurrence was noted (median follow-up, 20 months).<sup>2</sup> This result was accomplished with preservation of potency in 86.7% of patients. In 156 stage I and II rectal cancer patients treated without adjuvant therapy between 1987 and 1995 at Memorial Sloan-Kettering Cancer Center, local recurrences rates were reduced to 8.3% by using mesorectal excision without radiotherapy.<sup>86</sup> Zaheer (1998) reported the Mayo Clinic experience in 514 patients with surgical resection of stage I, II, and III rectal cancer. Two hundred seventy-two of these patients had stage I disease, and 173 had stage II or III rectal cancer. The local recurrence rate for all stages was 7%, whereas the local recurrence rate for node-positive cancers was 13%.<sup>63</sup>

#### SURGEON-RELATED OUTCOMES

The frequency of local recurrence varies greatly for individual surgeons, from less than 10% to more than 50%. Norwegian surgeons have removed rectal cancer surgery from routine surgical teaching and concentrate training in total mesorectal excision among specialized surgeons. They propose that the surgical specimens obtained by such surgeons be audited. Where regionalization of all rectal cancer surgery has occurred, survival appears to have improved and local recurrence rates have dropped to 7% after the addition of total mesorectal excision from historical controls, with a local recurrence rate of 23%.<sup>50</sup>

Several studies have suggested that the surgeon is an important prognostic factor in rectal cancer. In a population-based study of 683 patients, Porter et al. (1998) found a significant local recurrence and survival advantage in patients of both surgeons with colorectal surgery fellowship training and surgeons with a higher caseload. In addition, a greater rate of sphincter preservation for low rectal cancer also was found to be associated with higher case loads. Other studies suggest that hospital volume, hospital type (university vs. community), and surgeon experience improve survival and recurrence outcomes.<sup>87</sup>

#### ONCOLOGIC RESULTS OF NONRADICAL APPROACHES

The incidence of lymph node metastases in patients with T1 tumors approximate the recurrence rate for T1 cancer treated by local excision alone. Studies describe a 3% to 10% rate of local recurrence after excision alone.<sup>88</sup> Survival rates in patients with T1 rectal carcinomas treated with local excision alone or radical resection are 90% to 100%.

In patients with T2 rectal carcinomas, the risk of lymph node metastasis is 10% to 30%. Recurrence rates may be 17% to 24% in patients with T2 tumors after local excision alone. Survival rates are 78% to 82% with excision alone.

Many studies, mostly retrospective and single institutional studies, examine the results of local excision alone in the management of T1–2 rectal cancer ( [Table 33.8-5](#)). In a review of all published series with reasonable follow-up describing this approach, Graham et al. <sup>88</sup> found the combined local recurrence rate for T1 lesions was 5% (range, 0% to 12%) and for T2 lesions was 18% (range, 8% to 27%). Lower local recurrence rates in similar patients treated by APR (0% to 10%) <sup>89</sup> have brought into question the use of local excision alone for early rectal cancer. <sup>90</sup>

Series	n	Local Recurrence
Chakravarti et al. <sup>117</sup>	52	10 (19%)
Bailey et al. <sup>106</sup>	28	2 (7%)
Willett et al. <sup>118</sup>	40	6 (15%)
Biggers et al. <sup>91</sup>	141	36 (25%)

**TABLE 33.8-5.** Patterns of Local Recurrence after Local Excision Alone

Papillon and colleagues (1992) in Lyon, France, pioneered the treatment of selected patients with rectal cancers using endocavitary irradiation. Exophytic, superficial, well to moderately differentiated tumors without colloid histology with a maximum diameter less than 4.5 cm were treated. If the tumor was felt to invade muscle, an interstitial <sup>192</sup>Ir implant was added. In 245 patients, the 5-year disease-free survival rate was 76%, and the local failure rate was only 5%. Sischy and associates (1984) have reported similar results. The local failure rate in 94 patients treated with endocavitary irradiation alone was 5%. Hull et al. (1994) reported a 71% disease-free survival rate in 126 patients. With a median follow-up of 55 months, Schild and associates <sup>91</sup> reported 10% local failure and 76% 5-year survival. In 102 patients treated by Maingon et al.,<sup>82</sup> the local failure rate was 15% and the 5-year survival was 81%. In 22 patients who were stage T1,N0 by rectal ultrasound, none developed local failure.<sup>92</sup>

Five-year survival rates with local treatment options vary from 50% to 90%, with many deaths secondary to intercurrent disease and not related to cancer. In selected patients, a 10% cancer-related 5-year mortality can be expected with local excision, fulguration, or primary irradiation. For clinically staged T1 and early T2 cancers, our treatment preference is to perform a full-thickness local excision when possible. This allows an assessment of margins and other pathologic features, thereby

providing the best determination of whether any additional therapy is needed.

In an attempt to help select the ideal combination of radiotherapeutic and surgical approaches for sphincter preservation, the Dijon clinical staging system has been proposed. The staging system takes into account the tumor size and depth of penetration of the rectal wall. Briefly, T1A tumors are defined as superficial, exophytic, and smaller than 3 cm; CS T1B tumors have a limited infiltrative component and are smaller than 3 cm; CS T2A tumors are superficial, exophytic, and are 3 to 5 cm in size; CS T2B tumors have a limited infiltrative component and are 3 to 5 cm; and CS T3 tumors are deeply infiltrative or fixed, regardless of size. High-grade and colloid tumors are excluded. The rationale for the different T stages is based on the technical parameters of endocavitary radiation. Tumors smaller than 3 cm are easily covered with the intracavitary cone, whereas tumors 3 cm or larger require overlapping of fields and therefore a higher level of technical expertise. The radiotherapeutic doses and techniques of Papillon (1992) were used.

According to the Dijon guidelines, patients with CS T1A tumors can be adequately treated with endocavitary radiation alone. Stages CS T1B and T2A require the combination of endocavitary radiation and interstitial <sup>192</sup>Ir brachytherapy, and CS T2B tumors should receive preoperative external-beam therapy followed by, depending on the tumor response, either surgery or endocavitary radiation.

In an update from Maingon et al.<sup>82</sup> of 151 patients treated with this approach, the incidence of initial local control and ultimate local control by stage was 78% and 87% for T1, 58% and 79% for T2, and 54% and 69% for T3, respectively. For the Dijon stage T1 tumors (treated by endocavitary radiation alone), local failure increased with tumor size (13% for 3 cm or smaller vs. 28% for larger than 3 cm).

**Nonradical Approaches: Advanced Rectal Cancers**

Patients with extensive T2 or transmural (T3) disease are not adequately treated with conservative measures such as local excision, fulguration, cryosurgery, or endocavitary radiation alone. Those selected for radiation therapy alone are usually medically inoperable or have such advanced local disease that resection would compromise a vital structure. In the nonradical setting, a variety of techniques have been used, including various combinations of external-beam, <sup>192</sup>Ir interstitial brachytherapy, and endocavitary radiation. Papillon and Berard (1992) have treated 67 patients with T2–3 rectal cancers with pelvic radiation (3 Gy × 10) followed by endocavitary radiation. The 5-year disease free survival rate was 60%. A similar approach was reported by Kodner et al. (1993). Twenty-eight patients with invasive but favorable tumors received 45 Gy followed 6 weeks later by 60 Gy with endocavitary radiation. Favorable tumors were defined as smaller than 3 cm, mobile, well to moderately differentiated, and clinically confined to the rectal wall. No local failures were reported, and the cure rate was 82%. As already discussed, Maingon et al.<sup>82</sup> have recommended the addition of preoperative external-beam radiation or <sup>192</sup>Ir brachytherapy for these more advanced tumors.<sup>82</sup>

Although the best results are seen in patients who are able to have radical surgery as a component of their therapy, some patients do not undergo surgery because they are medically inoperable, present with extensive unresectable disease grossly invading bone, have received prior pelvic radiation, or refuse surgery. In general, they have been treated with external-beam radiation with or without chemotherapy. The largest series is from the Princess Margaret Hospital, which reports a 14-month median survival rate and 5% 5-year survival rate in 519 patients.<sup>93</sup> In the subset of patients in whom high doses of radiation are delivered (50 Gy or more), the median survival is 24 months and is 13% at 5 years. Other series report similar results (14% at 3 years<sup>94</sup> and 31% at 2 years<sup>95</sup>); however, they have shorter follow-up and a smaller number of patients. Selected series are seen in Table 33.8-6. In a subset of patients without metastatic disease who received more than 46 Gy, Overgaard and colleagues (1984) reported a 30% 2-year survival rate. A 30% 3-year survival rate was reported by Minsky and associates (1991).

Series	Definition of Failure	Number of Patients	Stage	Local Failure (%)	Local Failure (%) <sup>a</sup>
Quaranta et al. <sup>93</sup>	Chemotherapy by reoperation	74	AC/BE/C	66 (89%) <sup>b</sup>	
Wick et al. <sup>94</sup>	Chemotherapy by external irradiation and surgery	80	MAAC A/BB	8 (10%)	
		10	MAAC BB	3 (30%)	
		30	MAAC C	20 (67%)	
		15	MAAC D	10 (67%)	
		7	MAAC E	5 (71%)	
Minsky et al. <sup>95</sup>	Pilot failure by external irradiation and surgery	107	MAAC C/D	52 (48%)	
		11	MAAC E	11 (100%)	
		30	MAAC BB	3 (10%)	
		10	MAAC BB	1 (10%)	
		11	MAAC C	1 (9%)	

**TABLE 33.8-6. Palliative Radiotherapeutic Options (Nonsurgical)**

Pelvic radiation also provides very effective palliation. In the subset of 84 patients who received more than 45 Gy in the series from the Princess Margaret Hospital, the following presenting symptoms were palliated by 6 to 8 weeks after the completion of radiation: pain (89%), bleeding (79%), neurologic (52%), mass effect (71%), discharge (50%), urologic (22%), and other (42%).<sup>93</sup> In the Thomas Jefferson University series, symptomatic relief was achieved in the following categories: pain (65% complete, 28% partial), bleeding (100% complete), and mass effect (24% complete, 64% partial).<sup>94</sup> The duration of palliation was 8 to 10 months.

Even in elderly patients, pelvic radiation offers effective palliation. Valentini et al.<sup>96</sup> delivered combined modality therapy [38 to 45 Gy plus mitomycin C and continuous infusion 5-fluorouracil (5-FU)] to a group of 17 patients with a median age of 79 (range, 75 to 90). Symptomatic relief was obtained in four of four patients with pelvic pain and five of six patients with rectal bleeding. The 18% incidence of grade 3+ toxicity was similar to that reported for the general population who receive preoperative combined modality therapy.

These data suggest that patients with advanced rectal cancers who are medically inoperable should be treated aggressively with pelvic radiation therapy as a component of their therapy. It offers not only a defined cure rate but a high degree of palliation of symptoms.

**PATTERNS OF RECURRENCE AFTER RADICAL SURGERY**

Despite radical surgery, local-regional failure occurs frequently in patients with transmural or node-positive rectal cancers. The incidence of treatment failure in the pelvis is directly related to the extent of transmural penetration (microscopic vs. gross) and the additive risks of lymph node metastases. Local failure rates as a function of stage are listed in Table 33.8-7. Wound recurrence is rare (0.6%); however, it is a harbinger of metastatic disease.<sup>97</sup>

Series	Definition of Failure	Number of Patients	Stage	Local Failure (%) <sup>a</sup>
Quaranta et al. <sup>93</sup>	Chemotherapy by reoperation	74	AC/BE/C	66 (89%) <sup>b</sup>

		30	MAAC BB	3 (10%)
		10	MAAC BB	1 (10%)
		11	MAAC C	1 (9%)
		11	MAAC C/D	1 (9%)
		10	MAAC C/D	1 (10%)

**TABLE 33.8-7. Local Failure after Surgery Alone for Resectable Rectal Cancer: Selected Single Institution Series**

A major limitation in assessing the true incidence and patterns of failure is the heterogeneity of the series. This is due to variables such as the diagnosis by clinical, surgical, or autopsy criteria; reporting failure as the first site or as total (cumulative) failure; whether local failure includes extrapelvic disease; whether crude or actuarial calculations are used; the technical expertise of the surgeon<sup>98</sup>; and whether patients have received adjuvant therapy. For example, in a series from the Netherlands,<sup>95</sup> 36% of patients received radiation therapy.

Based on a compilation of selected series, the incidence of local failure (as a component of failure) is less than 10% in stage T1–2N0M0; this rate increases to 15% to 35% in stages T3N0M0 and T1N1M0 and is as high as 45% to 65% in stage T3–4N1–2M0.<sup>100,101,102</sup> and<sup>103</sup> When local failure does occur, it is severely debilitating and salvage has been of limited success. Therefore, decreasing local failure is, by itself, an important end point in the treatment of rectal cancer.

## RADIATION THERAPY ALONE FOR RESECTABLE RECTAL CANCER

In most cases, radiation therapy without surgery is limited to patients who are medically inoperable. This section excludes patients amenable to a local excision and adjuvant radiation therapy.

A variety of techniques have been used, including various combinations of external-beam irradiation, <sup>192</sup>Ir interstitial brachytherapy, and intracavitary irradiation. In a report from Papillon,<sup>104</sup> 71 patients with clinical T2 or T3 rectal cancers received 3 Gy × 10 to the pelvis. Eight weeks later, an additional 25 Gy was delivered by intracavitary irradiation and 20 to 30 Gy by <sup>192</sup>Ir interstitial brachytherapy. The 5-year disease-free survival rate was 65%, and 62% of patients retained normal sphincter function. Although 7% developed anal necrosis, they all healed.

In a report from the Princess Margaret Hospital,<sup>93</sup> 42 patients with early-stage, potentially resectable (T2–3) disease who were either medically inoperable or refused surgery received 50 Gy or more with or without 5-FU and achieved a 5-year survival rate of 21% (see [Table 33.8-6](#)). At the Centre Hospitalier Lyon Sud, 29 patients received endocavitary radiation plus 39 Gy of accelerated pelvic radiation with or without brachytherapy.<sup>105</sup> With a median follow-up of 46 months, the local failure rate was 38% and the 5-year survival rate was 68%.

A similar approach was reported by Myerson and coworkers (1989). Thirty patients received 45 Gy followed 6 weeks later by 30 to 90 Gy with intracavitary irradiation. Their tumors were defined as larger than 3 cm, nonmobile, well- or moderately well-differentiated, and clinical stage T2 or pathologic stage T3. Deeply ulcerated or infiltrating tumors were excluded. With a median follow-up of 2 years, the local failure rate was 30%, and the 2-year disease-free survival rate was 42% (55% with salvage). Minor proctitis occurred in 17%.

As recommended for patients with advanced disease, patients with clinically resectable but medically inoperable disease should be treated aggressively with radiation therapy as a component of their therapy.

## ADJUVANT THERAPY AND SPHINCTER-SAVING OPERATIONS AS AN ALTERNATIVE TO ABDOMINOPERINEAL RESECTION

Conservative management (sphincter preservation) has been used in two broad groups of patients with distal rectal cancer as an alternative to APR. The first are early localized tumors. In general, these include small, exophytic, mobile tumors without adverse pathologic factors [i.e., high grade, BVI, lymphatic vessel invasion (LVI), colloid histology, or the penetration of tumor into or through the bowel wall].<sup>106</sup> These selected tumors comprise 3% to 5% of all rectal cancers and are adequately treated with a variety of local therapies alone.

The second group of patients includes those tumors that otherwise would be suitable for one of the above local therapies except for (1) invasion of tumor into or through the muscularis propria, (2) positive lymph nodes, or (3) the presence of one or more adverse clinical or pathologic factors. In the context of conservative management, these tumors are considered unfavorable, because local therapy alone is not adequate treatment.

## LOCAL EXCISION AND POSTOPERATIVE RADIATION THERAPY

The standard surgical treatment for resectable, transmural, or node-positive rectal cancer is an LAR or APR. If the pathology confirms that the tumor penetrates through the bowel wall or involves the mesorectal or pelvic lymph nodes, adjuvant combined modality therapy consisting of six cycles of 5-FU–based chemotherapy plus concurrent pelvic radiation therapy is recommended.<sup>107</sup>

Given the morbidity of standard surgery as well as the frequent need for adjuvant therapy, the use of a more conservative approach, such as local excision plus adjuvant therapy (radiation therapy with or without chemotherapy), as primary therapy for selected cases of rectal cancer is appealing. This approach has been successful in other anatomic sites, such as in breast cancer and sarcomas of the extremities. In the rectum, it offers an opportunity for sphincter preservation.

The results of local excision and postoperative therapy depend on a number of factors, such as the type of surgery (full-thickness vs. piecemeal excision), and clinicopathologic factors, such as tumor size, T stage, grade, margins, and LVI. Most series include some patients who have undergone suboptimal surgery, such as a piecemeal excision, or have positive or unassessable margins.<sup>108</sup> Because few of the published series have adequate numbers to perform a meaningful multivariate analysis, it is difficult to determine the influence of these selected clinicopathologic features on one another. Until more complete data are available, a patient should not be excluded from treatment with local excision and radiation therapy based solely on these clinicopathologic features.

Local excision has been performed both before and after radiation therapy. The advantage of performing a local excision before radiation is that pathologic details, such as margins, depth of bowel wall penetration, and histologic features, can be well characterized.<sup>108,109</sup> Knowledge of these details are useful in the development of selection criteria.

## SELECTION CRITERIA

To determine which tumors have a high enough incidence of local failure or positive mesorectal or pelvic lymph nodes to require adjuvant pelvic radiation, it first must be determined which tumors are adequately treated with local therapy alone. The selection of tumors for local therapy is based on both clinical and pathologic factors. Clinical information such as tumor size, mobility, location, and circumference can be obtained at the time of physical examination. Accurate pathologic information is more difficult to obtain from a biopsy. Of the available local therapies, only a full-thickness local excision provides accurate pathologic information.

### *Clinical*

A major limitation of the series that examine local excision alone is that the analyses are univariate rather than multivariate. Therefore, clinical and pathologic factors are not examined as independent variables. Furthermore, variation is seen in patient selection, the definition of clinical and pathologic features, and the length of follow-up among the series. Because of these differences, it is difficult to make firm recommendations for the selection of patients for conservative management based solely on clinical criteria. The most reasonable approach is to determine whether a local excision can be performed adequately (i.e., full thickness, nonfragmented, and with negative margins). If so, then the clinical criteria for a local excision have been met.

### *Pathologic*

Pathologic criteria are more objective. Patients with T1 tumors without adverse pathologic factors have a low enough incidence of local failure (5% to 10%) and positive nodes (less than 10%) that they do not require adjuvant therapy. However, once adverse pathologic factors are present (high grade, BVI, LVI, colloid histology, signet-ring cell).<sup>110,111</sup> or the tumor invades into or through the muscularis propria,<sup>31,110</sup> the local failure rate is at least 17% and the incidence of positive mesorectal or pelvic nodes is at least 10% to 15%. Biggers et al.<sup>31</sup> reported the results of 141 patients with T2 rectal cancers who underwent local excision alone at the Mayo Clinic. Blumberg and associates<sup>112</sup> found positive nodes in 10% of T1 and 17% of T2 cancers. In the combined group of 159 patients, the incidence increased with the presence of LVI (14% for LVI vs. 33% for LVI-positive). Even in the 42 patients with the most favorable characteristics (well or moderately differentiated, LVI-negative, T1 cancers), 7% had positive nodes. The 5-year survival rate was 65% and the local failure rate was 27%. Hager and colleagues (1983) performed a local excision on 20 patients with T2 rectal cancers that were otherwise “low risk” (nonmucinous, well to moderately differentiated, no LVI, with negative

margins). The incidence of local failure was still 17%. Other series have reported local failure rates as high as 43% in patients with T2 cancers after either local excision or transanal excision.<sup>113</sup>

Willett et al.<sup>110</sup> reported a group of 40 patients who underwent local excision alone at the Massachusetts General Hospital (MGH). In this series, a separate analysis was performed on those patients whose tumors had unfavorable clinical and pathologic factors. Factors including tumor size larger than 3 cm, high grade, T2 stage or higher, vascular invasion (BVI and/or LVI), moderate or marked stromal fibrosis, a fragmented resection, and positive margins were associated with a local failure rate of at least 20% as well as an increase in distant metastasis. Therefore, local therapy alone is inadequate for tumors with these adverse pathologic factors.

An alternative approach to pathologically determine the incidence of positive pararectal lymph nodes is ultrasound-guided biopsy. Milsom and colleagues<sup>114</sup> from the Cleveland Clinic performed biopsies on 26 patients and reported an accuracy rate of 77%, with a sensitivity of 71%, a specificity of 89%, a positive predictive value of 92%, and a negative predictive value of 62%.

## RESULTS

### Results Compared with Radical Surgery

Because the pelvic lymph nodes are not pathologically examined at the time of a local excision, it is not possible to accurately compare, stage for stage, the results of this approach with radical surgery.

Although data exist to help predict the incidence of positive pelvic nodes based on the clinical and pathologic features of the primary tumor,<sup>69,115</sup> an accurate comparison of this approach with standard surgery requires a randomized trial. Most series select patients for adjuvant therapy based on the presence of unfavorable clinical or pathologic features, or both. In the series from the University of Florida,<sup>116</sup> for example, patients had at least one or more of the following adverse features: equivocal, close, or positive margins; T2–3 disease; perineural invasion; and had undergone a fragmented excision. Likewise in the MGH series,<sup>117</sup> 38 of the 47 patients had T2 or high-risk T1 cancers (poorly differentiated and/or LVI).

### Survival

As seen in Table 33.8-8, the 5-year actuarial survival in these selected series is approximately 80% (range, 70% to 94%).<sup>32,116,117,118,119,120,121,122,123</sup> and 124 In most series, patients had T1–3 tumors and underwent a local excision followed 4 to 6 weeks later by 45 to 50 Gy to the pelvis. Some patients received an external-beam or brachytherapy boost. In most series, a limited number of patients received 5-FU. Although not randomized, these survival data appear comparable with the results of radical surgery alone for stage T1–2N0 disease.

Site	Number of Patients	% T1	% T2	% T3	Survival	Resection	Local Failure Salvaged with RT
University of Florida <sup>116</sup>	42	2	4	94	85% (range 70-94)	—	One of two salvaged

RT, radiotherapy; T1, T1 disease; T2, T2 disease; T3, T3 disease.

116, 117, 118, 119, 120, 121, 122, 123, 124, 125: Abbreviations: RT, radiotherapy; T1, T1 disease; T2, T2 disease; T3, T3 disease.

116, 117, 118, 119, 120, 121, 122, 123, 124, 125: Number in parentheses in the % T1, % T2, % T3, and Survival columns is the number of patients who underwent a local excision and received postoperative radiation therapy plus chemotherapy.

TABLE 33.8-8. Local Excision plus Postoperative Therapy: Survival, Salvage, and Functional Results: Selected Series

The Intergroup Cancer and Leukemia Group B 8984 trial is the only prospective, multiinstitutional phase II trial. Patients underwent a local excision with careful assessment of negative margins and, depending on T stage, received postoperative combined modality therapy.<sup>125</sup> A total of 110 eligible patients (all with negative margins) were entered. The 51 patients with T2 disease received postoperative combined modality therapy. With a median follow-up of 48 months, the crude local failure rate was 14%, the 6-year failure-free survival rate was 71%, and overall survival was 85%. This approach is feasible in a multiinstitutional, cooperative group setting.

### Local Failure

When the series are combined, the average crude local failure rate increases with T stage: 5% for T1, 14% for T2, and 22% for T3 (Table 33.8-9). When the series are combined, the crude incidence is 12% and increases with the percentage of T3 cancers included in each series.

Site	Follow-up (mo)	Local Failure (%)			Total
		T1	T2	T3	
University of Florida <sup>116</sup>	36 months	—	—	—	11% (14/124)

116, 117, 118, 119, 120, 121, 122, 123, 124, 125: Data were not reported by T stage.

116, 117, 118, 119, 120, 121, 122, 123, 124, 125: Number in parentheses in the % T1, % T2, % T3, and Total columns is the number of patients who underwent a local excision and received postoperative radiation therapy plus chemotherapy.

TABLE 33.8-9. Local Excision plus Postoperative Therapy: Local Recurrence by T Stage: Selected Series

Actuarial analysis is an alternative method of determining the risk of local failure. The actuarial method, which accounts for the different length of follow-up for each patient, offers the most accurate method of risk analysis. As with crude failure, the incidence of actuarial failure increases with increasing T stage. It was 10% in the series of T1–2 cancers from the MGH,<sup>117</sup> 14% from the University of Florida series in which only 2% of patients had T3 cancers,<sup>116</sup> and 27% in the Memorial Sloan-Kettering Cancer Center series in which 21% of patients had T3 cancers.<sup>120</sup>

The impact of positive margins on local failure is unclear. In the Memorial Sloan-Kettering series, for the total patient group, 5-year actuarial local failure was higher in patients with positive versus negative margins (35% vs. 23%).<sup>120</sup> A similar increase in crude local failure rates was reported in the Vancouver series (40% vs. 6%).<sup>122</sup> In contrast, no significant differences were reported in the series from Fox Chase Cancer Center<sup>124</sup> or the MGH.<sup>117</sup> In the MGH series, this lack of difference may have been related to a higher radiation dose delivered to that subset. Of the six patients with positive margins (none of whom developed local failure), five of the six received doses of more than 60 Gy.

A full-thickness local excision is recommended because patients who undergo a piecemeal excision usually have higher local failure rates. <sup>126</sup>

In those patients who do undergo a full-thickness excision, the impact of positive margins is unclear. Most investigators would recommend that negative margins be obtained if technically feasible and a reexcision performed if needed, providing that it does not compromise sphincter function. If this is not possible, doses of more than 50.4 Gy, if the small bowel is excluded from the high-dose field, are probably necessary.

In patients who undergo radical surgery for rectal cancer, 80% of local recurrences occur within the first 2 years. In contrast, the Memorial Sloan-Kettering series <sup>120</sup> has reported local failures at 48 months, and the MGH series <sup>117</sup> has reported local failures as late as 64, 72, 86, and 91 months. Furthermore, in the MGH series the median time to local recurrence was 55 months compared with 14 months in a group of 52 patients with more favorable prognostic factors who underwent local excision alone. Therefore, patients who are treated with local excision and postoperative adjuvant therapy require close follow-up beyond 5 years.

On a positive note, most local failures occur at the anastomotic site and not in pelvic lymph nodes. Of the 18 local failures reported in the MGH series, only one involved the pelvic nodes. None were seen in the series from the University of Pennsylvania <sup>32</sup> and Catholic University. <sup>123</sup> Furthermore, salvage of local failures is possible. With the exception of the University of Florida experience, in which only one of five local failures could be salvaged with an APR, most series report that at least one-half of the patients who undergo a salvage APR can be cured: Beth Israel Deaconess Medical Center reported three cures out of four <sup>118</sup>; University of Pennsylvania, two of two <sup>32</sup>; Memorial Sloan-Kettering Cancer Center, five of eight <sup>120</sup>; Vancouver, three of seven <sup>122</sup>; Catholic University, one of two <sup>123</sup>; Fox Chase, three of four <sup>124</sup>; Intergroup trial, four of seven <sup>125</sup>; and MGH, five of nine. <sup>117</sup>

### **Sphincter Function**

However, a few series prospectively assess functional results. As seen in [Table 33.8-8](#), the five series that do measure sphincter function report favorable outcomes. Both the Memorial Sloan-Kettering <sup>120</sup> and Catholic University <sup>123</sup> series use the previously published Memorial Sloan-Kettering Sphincter Function Scale. <sup>127</sup> They report 94% and 100% good to excellent function, respectively. Using a different scale, investigators from Fox Chase Cancer Center <sup>124</sup> reported 82% good to excellent function, the University of Pennsylvania <sup>32</sup> reported 92% satisfactory function, <sup>32</sup> and the M. D. Anderson Cancer Center <sup>119</sup> reported that all patients were continent.

### **Chemotherapy**

Limited data are available on the use of chemotherapy in patients who undergo local excision and postoperative radiation therapy. In most series, 5-FU was delivered as a radiosensitizer rather than in the adjuvant setting. In a subgroup analysis, the MGH reported a lower 5-year actuarial local failure rate (4% vs. 19%,  $P = NS$ ) but at the same time a lower relapse-free survival rate (67% vs. 81%,  $P = NS$ ) in patients receiving 5-FU-based combined modality therapy versus radiation alone. <sup>117</sup> Because the numbers are limited and the data are not stratified by T stage, the impact of chemotherapy is unclear. However, given the positive impact of chemotherapy on local control and survival in patients with resectable rectal cancer reported in the randomized postoperative rectal adjuvant trials, <sup>128</sup> all patients should receive two cycles of 5-FU-based therapy concurrently with radiation. For patients with T2–3 disease in whom the incidence of pelvic lymph nodes is at least 20%, an additional four cycles of adjuvant chemotherapy for a total of six cycles is recommended.

### **Summary**

The data suggest that the approach of local excision and postoperative radiation is a reasonable alternative to radical surgery in selected patients. It should be limited to patients with either T2 tumors, or T1 tumors with adverse pathologic factors (poorly differentiated and/or LVI). Although the local failure rates are approximately double those reported with radical surgery, one-half of the failures can be salvaged with an APR without an apparent detriment to overall survival. Functional results are generally good to excellent. Transmural (T3) tumors have a 25% local failure rate and are treated more effectively with radical surgery and pre- or postoperative therapy. The results of local excision and postoperative radiation therapy are encouraging; however, randomized trials are needed to determine if this approach ultimately has similar local control and survival rates as radical surgery.

## **PREOPERATIVE RADIATION THERAPY FOLLOWED BY SURGERY**

Sphincter preservation is a major goal of preoperative therapy. A number of preoperative treatment approaches have been used, and their selection depends on factors such as tumor histology, size, location, mobility, and anatomic constraints, and the technical expertise of the surgical, radiation, and medical oncologists.

An analysis of 1316 patients treated in two previously published Scandinavian trials of intensive short course radiation reveals that down-staging is most pronounced when the interval between the completion of radiation and surgery is at least 10 days. <sup>129</sup> However, none of the randomized trials of intensive short course preoperative radiation address whether the degree of down-staging is adequate to enhance sphincter preservation.

From the viewpoint of sphincter preservation, the advantage of preoperative therapy is to decrease the volume of the primary tumor. When the tumor is located in close proximity to the dentate line, this decrease in tumor volume may allow the surgeon to perform a sphincter-preserving procedure that would not otherwise be possible. However, patients whose tumors directly invade the anal sphincter are unlikely to undergo sphincter preservation, even after a complete response to radiation therapy.

In general, when sphincter preservation is the goal of therapy, the use of preoperative therapy should be limited to patients who are not technically able to undergo a local excision because of tumor size or anatomic constraints. For example, if the tumor is close to the anal sphincter, a full-thickness local excision with negative margins may require partial removal of the sphincter, resulting in compromised sphincter function.

Two surgical approaches have been used after preoperative pelvic radiation: local excision and LAR plus CAA. To assist in the choice of the surgical procedure, some investigators have used transrectal ultrasound for restaging after the completion of preoperative therapy. However, most series reveal that posttreatment staging is only of modest accuracy. Williamson and colleagues <sup>130</sup> reported that, in 15 patients who completed preoperative combined modality therapy, 38% were down-staged by transrectal ultrasound. At pathology, T stage was down-staged in 47% and N stage in 88%. Another series found that, in 25 patients who received preoperative radiation, digital rectal examination, CT, and transrectal ultrasound accurately staged only 24%, 23%, and 17%, respectively, of the primary tumors that were stage T0 at pathology. <sup>28</sup> Bernini and associates <sup>30</sup> found transrectal ultrasound correctly predicted the T and N stage in 62% and 76%, respectively. In another series, the accuracy of transrectal ultrasound was 93% for T stage, but only 61% for N stage. <sup>131</sup> Newer techniques, such as color Doppler flow <sup>132</sup> and intracavitary MRI coils <sup>133</sup> and PET, <sup>134,135</sup> and <sup>136</sup> are being investigated. In a comparative study of 89 patients, the accuracy of predicting T stage and N stage preoperatively was 81% and 84% with transrectal ultrasound, 65% and 57% with CT, and 81% and 63% with an MRI endorectal coil, respectively. <sup>137</sup>

### **LOCAL EXCISION**

The results of 25 patients who received 34.95 Gy at 2.33 Gy per fraction to a partial pelvic field followed in 6 to 8 weeks by a transanal or transsphincteric local excision and a 20- to 25-Gy boost with afterloading <sup>192</sup>Ir was reported by Otmezguine et al. <sup>138</sup> The median tumor size was 4 cm, 80% were exophytic, 72% were well to moderately differentiated, and all were mobile. With a mean follow-up of 41 months, the local failure rate was 20%, and three of the five failures were salvaged with an APR. Of the six patients with positive margins, two developed local failure. The 20 patients with local control had “normal” sphincter function.

In a report by Mohiuddin et al., <sup>139</sup> 48 selected patients who met specific criteria [group I, T3 and medically unsuitable for a LAR ( $n = 15$ ); group II,  $<T2$  and  $<3$  cm suitable for a local excision ( $n = 18$ ); or group III, T3 or  $>3$  cm down-staged with preoperative radiation to  $<T2$  and  $<3$  cm] underwent a local excision after 45 to 55 Gy. With a median follow-up of 40 months, the 5-year actuarial survival rate was 84% and the local failure rate was 10%. Local failure by group was 20% for group I, 11% for group II, and 0% for group III. Postoperative wound complications were seen in 10%, and four patients required a subsequent colostomy (three for local failure). Sphincter function was good to excellent in 88% of patients with an intact rectum. In an update of 44 patients with tumors of 3 cm or smaller from the dentate line selected to undergo a local excision after preoperative radiation therapy, the local failure rate was 14% and the 5-year survival rate was 90%. <sup>140</sup>

## **LOW ANTERIOR RESECTION AND COLOANAL ANASTOMOSIS**

In summary, five of the seven trials suggest that preoperative therapy allows sphincter preservation in approximately 75% of patients judged clinically to require an APR. The majority have good to excellent functional results. Given the suggestion of decreased acute toxicity and enhanced sphincter preservation with preoperative radiation therapy, three randomized trials of conventional dose preoperative versus postoperative combined modality therapy for clinically resectable, T3 rectal cancer have been developed. Two are from the United States (INT 0147, NSABP R-03) and one from Germany (CAO/ARO/AIO 94). All three use conventional doses and techniques of radiation therapy and concurrent 5-FU–based chemotherapy, and they require a preoperative clinical assessment declaring the type of operation required. However, low accrual resulted in the early closure of the INT 0147 trial and may jeopardize the NSABP R-03 trial as well. The German trial continues to accrue patients and should help provide an answer to the relative effectiveness of preoperative versus postoperative therapy and its ability to enhance sphincter preservation.

## TREATMENT RECOMMENDATIONS

For patients with clinically resectable disease, the preoperative approach should be used in situations in which sphincter-preserving surgery is not technically possible at initial presentation. The decision of whether to use preoperative radiation therapy or preoperative combined modality therapy is based on the results of transrectal ultrasound. If a transrectal ultrasound reveals T2 disease, the patient may have pathologic T2N0M0 disease; therefore, the sole reason for the preoperative therapy is to convert the operation from an APR to an LAR plus CAA. In this setting, preoperative radiation therapy alone is recommended. If positive mesorectal or pelvic lymph nodes are identified at the time of surgery, the patient should receive 6 months of adjuvant postoperative 5-FU–based chemotherapy. Two potential disadvantages are associated with this approach. First, the ultrasound may under-stage approximately 10% of patients who have pathologic stage T3 disease. Second, because preoperative radiation down-stages pelvic lymph nodes by approximately 50%, the true incidence of node-positive disease is unknown, and some node-positive patients may not receive chemotherapy. Obviously, these disadvantages need to be weighed against the risk of overtreating these patients with combined modality therapy.

For patients with transrectal ultrasound stage T3 disease, preoperative combined modality therapy followed by surgery and postoperative 5-FU–based chemotherapy is recommended. This approach is based on extrapolation of the significant improvement in local control and survival in patients with T3 or N1–3 disease who receive adjuvant postoperative combined modality therapy. Whether preoperative combined modality therapy is more effective than preoperative radiation therapy is unknown. An ongoing randomized trial from the European Organization for Research and Treatment of Cancer (EORTC) will address this question.

At the present time, the most common preoperative combined modality therapy regimens include 45.0 to 50.4 Gy of pelvic radiation at 1.8 Gy per fraction plus concurrent bolus 5-FU plus leucovorin<sup>146,157</sup> or continuous infusion 5-FU.<sup>158,159</sup> Some have advocated 5-FU plus mitomycin C, which is more commonly used in the treatment of anal cancer.<sup>149</sup> One trial using neoadjuvant 5-FU plus methotrexate followed by continuous infusion 5-FU plus concurrent radiation did not report a benefit compared with conventional 5-FU plus leucovorin.<sup>160</sup> Phase I/II trials are in progress combining new systemic chemotherapeutic agents, such as raltitrexed (Tomudex),<sup>161,162</sup> Orzel (oral tegafur, uracil, and 5-fluorouracil plus leucovorin),<sup>163</sup> CPT-11,<sup>164,165</sup> and oxaliplatin, with preoperative radiation therapy. Whether any of these combinations will be more effective than 5-FU–based therapy remains to be determined.

## ADJUVANT RADIATION THERAPY FOR RESECTABLE RECTAL CANCER

The rationale of radiation therapy is based on the patterns of failure after potentially curative surgery (see [Table 33.8-7](#)). The incidence of local failure as a component of failure is less than 10% in stages T1–2N0M0; the incidence increases to 15% to 35% in stage T3N0M0 and is as high as 45% to 65% in stages T3–4N1–2M0.<sup>100,101</sup> and <sup>102</sup> When local failure does occur, it is severely debilitating and salvage has been of limited success. In 1936, Daland et al. (1936) stated that the morbidity associated with local failure is often devastating, and as many as 68% of patients have one or more pelvic symptoms, including infection, ulceration, obstruction, and intractable pain for 9 to 12 months before death. The same holds true today. Therefore, even though it does not increase survival, the ability of radiation therapy to decrease local failure is, by itself, an important end point.

For unsubstantiated reasons, some consider colorectal adenocarcinomas to be radioresistant. This assumption has been based on the observation that these tumors do not respond as rapidly to radiation as other histologies. The radioresistant theory was disproved in 1965 by Suit et al. (1965), who showed that the rapidity of tumor response to radiation is not an accurate reflection of their curability. Brierley et al. (1995) reported the results of 66 patients with rectal cancer treated with radiation therapy alone. As seen in [Figure 33.8-5](#), of the patients who achieved a complete response to radiation therapy, only 60% had achieved the complete response by 4 months.

**FIGURE 33.8-5.** Time to a complete response from the start of treatment for 66 patients with inoperable rectal cancer who received radiation therapy alone and achieved a clinical complete response. (From Brierley JD, Cummings BJ, Wong CS, et al. Adenocarcinoma of the rectum treated by radical external radiation therapy. *Int J Radiat Oncol Biol Phys* 1995;31:255, with permission.)

Some physicians contend that adjuvant therapy is not necessary if patients undergo resection with a total mesorectal excision. In one series, total mesorectal excision, which involves sharp dissection around the integral mesentery of the hindgut, decreased the local recurrence rate to 5%.<sup>85</sup> These data must be interpreted with caution for a number of reasons. First is selection bias. This operation allows the identification and exclusion of patients with more advanced disease as compared with patients treated in the adjuvant trials in which more conventional surgery is performed. Second, some patients with T3 or N1–2 disease received radiation therapy with or without chemotherapy (i.e., 18% in the series by Haas-Kock et al.,<sup>166</sup> 28% in the series from Enker and associates,<sup>86</sup> and 58% in the series from Arenas et al.<sup>167</sup>). In a combined analysis of 1411 patients from five international centers, an undisclosed number received adjuvant radiation or combined modality therapy.<sup>47</sup> Third, some series (i.e., Aitken et al.<sup>168</sup>) exclude operative deaths. Lastly, total mesorectal excision may also be associated with higher complication rates. In the Basingstoke Hospital experience reported by Carlsen and colleagues,<sup>169</sup> the anastomotic leak rate was 16% in patients who underwent total mesorectal excision (all of whom required hospitalization) compared with a leak rate of 8% in a similar group of patients who underwent conventional surgery (with only 25% requiring hospitalization). Poon and colleagues<sup>170</sup> recommend the creation of a diverting stoma to decrease the high leak rate with total mesorectal excision.

The Dutch CKVO 95-04 trial examines the role of intensive short course preoperative radiation therapy in patients who undergo a total mesorectal excision. Patients are randomized to an intensive short course of radiation (5 Gy x 5) versus surgery alone. Postoperative radiation, which is performed with conventional doses, is reserved for patients in the surgery-only arm who do not undergo a curative resection. Investigator participation is limited to surgeons who have demonstrated proficiency in performing a total mesorectal excision. The trial is open to accrual.

Dahlberg and colleagues<sup>50</sup> report a 3% local failure rate in patients with resectable rectal cancer with the combination of total mesorectal excision and intensive short course preoperative radiation. Because patients with clinical stage T1–3 disease were included, it is difficult to compare these results with series that are limited to T3 disease.

The use of total mesorectal excision has increased awareness of the importance of surgical technique. Careful surgical techniques are central to the successful management of rectal cancer. However, they should be considered a valuable component of therapy, not competitive with adjuvant therapy. Given the selection bias,

higher complication rates in some series, and the fact that adjuvant therapy is used in some series, the benefits and risks of total mesorectal excision must be more carefully documented. The total mesorectal excision series need to focus on all end points, such as local control, survival, sphincter preservation and function, surgical morbidity and mortality, and quality of life.

Radiation therapy has been used in three major approaches to the adjuvant treatment of resectable rectal cancer. These include postoperative, preoperative, and pre-plus postoperative radiation therapy.

### ADJUVANT POSTOPERATIVE RADIATION THERAPY

Most patients in the United States undergo surgery and, if needed, receive postoperative therapy. The primary advantage with this approach is pathologic staging. Despite advances in preoperative imaging techniques, which allow more accurate patient selection, postoperative therapy remains the most common approach. The primary disadvantages include an increased amount of small bowel in the radiation field <sup>171</sup> and a potentially hypoxic postsurgical bed, and if the patient has undergone an APR, the radiation field must be extended to include the perineal scar.

#### Nonrandomized Trials

Nonrandomized data from the MGH<sup>172,173</sup> and the M. D. Anderson Cancer Center<sup>174,175</sup> reveal crude local failure rates of 4% to 31% in patients with stage T3–4N0M0 disease and 8% to 53% in patients with stage T3–4N1–2M0 disease who received 4500 to 5500 cGy ( Table 33.8-11 ). The MGH series is the largest reported experience from a single institution in which careful radiation techniques were used and long follow-up is available. The MGH results were compared with a historical control group of 142 patients who underwent surgery only. Stage for stage, an improvement was seen in both local control and survival in those patients who received postoperative radiation therapy. The MGH results of 261 patients who received postoperative radiation therapy have been updated, providing 5-year actuarial local control data.<sup>173</sup> Actuarial local control by stage include 87% for T3N0M0, 83% for T4N0M0, 76% for T1–2N1–2M0, 77% for T3N1–2M0, and 23% for T4N1–2M0.

Site	Stage	Local Failure %				5-Year Survival %	
		Number of Patients	Surgery	Surgery + Radiation	Surgery	Surgery + Radiation	
Massachusetts General Hospital <sup>173</sup> (1900-2000 Gy + boost) (31 patients had SRT)	T3N0	41	25	11	5	47	74 (95)
	T4N0	25	33	7	0	27	49
	T1-2N1-2	4	25	25	25	25	40

SRT, Short-course SRT; data not available in the manuscript; SRT, no evidence of disease.  
\*Cumulative local failure as a component of failure.

TABLE 33.8-11. Adjuvant Postoperative Radiation Therapy for Resectable Rectal Cancer: Selected Nonrandomized Trials

Wiggenraad and associates<sup>176</sup> treated 123 patients with postoperative radiation and correlated results with p53 status as determined by immunohistochemistry. With a median follow-up of 40 months, no significant difference was noted in local failure or survival by p53 status.

#### Randomized Trials

Five randomized trials have examined the use of adjuvant postoperative radiation therapy alone in stages T3 or N1–2 rectal cancer. <sup>83,177,178</sup> and <sup>179</sup> None have shown an improvement in overall survival. The series from Odense University is a two-arm trial comparing postoperative radiation therapy with surgery alone. In two of the series, one of the arms included radiation plus chemotherapy [Gastrointestinal Tumor Study Group (GITSG)] <sup>83,177</sup> or chemotherapy alone (NSABP R-01).<sup>178</sup> In the Mayo Clinic/NCCTG trial 79-47-51, there was no surgery-only control arm.

Two trials reveal a decrease in local failure: NSABP R-01 (16% vs. 25%,  $P = .06$ ) and the Medical Research Council (21% vs. 34%,  $P = .001$ ).<sup>179</sup> These trials are discussed at length in the section on combined modality therapy of resectable rectal cancer (see [Radical Surgery and Adjuvant Postoperative Combined Modality Therapy for Resectable Rectal Cancer](#), earlier in this chapter). In this section, the discussion is limited to the comparison of the radiation therapy arm compared with the surgical control arm.

As discussed in the section on patterns of failure (see [Patterns of Recurrence after Radical Surgery](#), earlier in this chapter), local failure rates depend on whether they are reported as first or cumulative failure. The randomized trials usually express failure as first site of failure as opposed to the nonrandomized trials, which express failure as cumulative failure. For example, in the Mayo Clinic/NCCTG trial, the incidence of local failure in node-positive patients was 25% when expressed as first failure compared with 63% when expressed as cumulative failure. More favorable local failure results (local failure as the first site of failure) were reported from the GITSG (18%)<sup>83,177</sup> and the NSABP (15%).<sup>178</sup>

In the GITSG series, 58 patients underwent surgery alone and 50 received postoperative radiation therapy (40 to 48 Gy). No significant differences were noted in either local failure or survival between these two arms. <sup>83,177</sup> Many criticisms have been leveled at the radiation therapy techniques used in the GITSG series. First, 39% of the patients treated with radiation therapy varied from the protocol specifications. Second, the radiation dose was chosen by the individual investigator (patients could receive 40 or 48 Gy). The issue of radiation dose is important, because dose response in radiation therapy follows a sigmoidal distribution. Therefore, a small decrease in dose can result in a large difference in local control. For example, in the Mayo Clinic/NCCTG trial 79-47-51, patients in the postoperative radiation-alone arm who received 50.4 Gy had a slightly lower local failure rate compared with those who received 45 Gy (18% vs. 24%). Although no difference in overall survival was reported, patients who received adjuvant radiation therapy in the NSABP trial had a borderline significant decrease in local failure compared with surgery alone (16% vs. 25%,  $P = .06$ ).<sup>178</sup>

In the series from Odense University, 494 patients were randomized to postoperative radiation therapy (45 to 50 Gy) versus surgery alone. In patients with stage T2–3N0 disease, no difference was noted in the incidence (6%) or mean time to local failure between the arms. In patients with stage T1–3N1–2 disease, no difference was reported in local failure (6% vs. 9%); however, the mean time to local failure was significantly longer in patients who received radiation therapy compared with the surgical control arm (19 months vs. 6 months,  $P = .01$ ). This series also has raised many criticisms. These include a short median follow-up (3 years) and that 43% of the patients were not randomized, the radiation therapy was split course, 20 patients in the radiation arm received less than 45 Gy, and the incidence of local failure in the surgery control arm was unusually low for node-positive cancers (9%).

The EORTC randomized 172 patients with T3 or N1–2 disease to 46 Gy versus observation. <sup>180</sup> No significant difference was seen in local failure or survival. An increase was noted in chronic diarrhea and cystitis in the radiation arm; however, it must be emphasized that patients were treated with only two fields per day. As discussed in the section on toxicity of pelvic radiation (see [Complications of Pelvic Radiation Therapy](#), later in this chapter), this two-field technique is associated with an increase in radiation associated toxicity.

In summary, the retrospective data suggest that postoperative radiation therapy decreases local failure. The only randomized trial, which confirms this finding (with borderline significance), is from the NSABP. It should be noted that, of the randomized trials that compare radiation therapy to a surgical control arm, the NSABP is the only trial in which the radiation therapy was delivered with a continuous course, in full doses, and with “modern” techniques.

### ADJUVANT PREOPERATIVE THERAPY

Preoperative adjuvant therapy (most commonly radiation therapy combined with systemic chemotherapy) is an alternative to postoperative therapy. <sup>52,141,145,146,147,148</sup> and

<sup>149,181,182,183</sup> and <sup>184</sup> The primary advantages of preoperative therapy are sphincter preservation and a lower incidence of acute toxicity.

The disadvantage of preoperative radiation therapy is the potential of overtreating patients with either early (pathologic stage T1–2N0) or metastatic disease. With improved imaging techniques, such as EUS,<sup>185</sup> ultrasound-guided pararectal lymph node biopsy,<sup>114</sup> CT, MRI with a phased-array<sup>186</sup> or an endorectal coil,<sup>187</sup> and PET,<sup>188</sup> the number of patients who are overtreated is decreased. Experienced investigators report the accuracy of EUS in predicting T stage preoperatively as high as 90%.<sup>189</sup>

### **Results of Adjuvant Preoperative Therapy**

Nonrandomized trials of preoperative radiation therapy with or without chemotherapy have reported decreased local recurrence and, possibly, improved survival.<sup>151</sup> Some trials include patients with early-stage or metastatic disease. Because these patients are excluded from the postoperative adjuvant therapy trials, a randomized trial is necessary to accurately compare the results of preoperative and postoperative therapy. The phase I/II trials in which preoperative radiation or combined modality therapy is used to enhance sphincter preservation have been discussed in the section on sphincter preservation (see [Adjuvant Therapy and Sphincter-Saving Operations as an Alternative to Abdominoperineal Resection](#), earlier in this chapter) and are reviewed in [Table 33.8-10](#).

The only randomized trial comparing preoperative versus postoperative radiation therapy (without chemotherapy) is the Uppsala trial, in which 471 patients were randomized to receive either intensive short course preoperative radiation (25.5 Gy in five fractions) or, for patients with T3 or N1–2 disease, 60 Gy postoperatively.<sup>190</sup> A significant decrease was noted in local recurrence with preoperative radiation (13% vs. 22%,  $P = .02$ ); however, no difference was found in 5-year survival (42% vs. 38%). Although a significant increase of perineal wound sepsis was seen in the preoperative group (33% vs. 18%,  $P < .01$ ), other short- and long-term side effects were decreased. For example, the incidence of small bowel obstruction (5% vs. 11%) and total grade 3+ toxicity (20% vs. 41%) was lower in the preoperative group compared with the postoperative group. The increase in the incidence of perineal wound sepsis in the preoperative arm may have been related to the antiquated radiation techniques and high dose per fraction delivered. It should be emphasized that this increase has not been reported in the series that use conventional radiation doses and block the perineal skin in the lateral fields.

Given the advantage of the addition of concurrent chemotherapy to radiation therapy in the postoperative setting, a variety of preoperative combined modality treatment programs have been developed. Retrospective studies suggest that preoperative combined modality therapy increases pathologic down-staging compared with preoperative radiation therapy<sup>191</sup> and is associated with a lower incidence of acute toxicity compared with postoperative combined modality therapy. Most trials of preoperative combined modality therapy primarily include patients with unresectable disease. These are discussed in the section on locally advanced and unresectable rectal cancer (see [Treatment of Locally Advanced and Unresectable Rectal Cancer](#), later in this chapter). Most preoperative combined modality therapy trials for patients with clinically resectable disease have used either bolus<sup>146</sup> or continuous infusion 5-FU–based chemotherapy.<sup>192</sup>

Combining the results of the published series, grade 3+ toxicity during the combined modality segment is 15% to 25%, the pathologic complete response rates are 9% to 29%, and the incidence of local failure is 0% to 10%. The limited data do not allow a valid comparison of the results of bolus versus continuous infusion 5-FU.

Whether preoperative combined modality therapy is more effective than preoperative radiation therapy is being addressed in an ongoing randomized trial from the EORTC. This trial will determine if bolus 5-FU plus leucovorin, either preoperatively or postoperatively, or both, is superior to preoperative radiation therapy alone.

Eleven modern randomized trials of preoperative radiation therapy (without chemotherapy) for resectable rectal cancer are ongoing.<sup>107</sup> All use low to moderate doses of radiation. The Second Medical Research Trial, which revealed a significant improvement in local control, distant control, and disease-free survival is excluded from this discussion because patients had fixed or partially fixed disease.<sup>193</sup>

Some of the trials show a decrease in local recurrence, and in five of the trials, this difference reached statistical significance. An analysis of the trials reported before 1988 suggests that a dose-response effect may favor preoperative radiation compared with postoperative radiation.<sup>194</sup> Although in some trials a subset analysis has revealed a significant improvement in survival,<sup>195</sup> until the Swedish Rectal Cancer Trial<sup>142</sup> none had reported a survival advantage for the total treatment group.

### **Intensive Short Course Preoperative Radiation**

The first randomized trial of preoperative radiation therapy to reveal a significant improvement in survival by intent to treat was the Swedish Rectal Cancer Trial.<sup>142</sup> A total of 1168 patients with clinically resectable rectal cancer were randomized to 25 Gy in five fractions, followed by surgery 1 week later versus surgery alone. With a median follow-up of 75 months, patients randomized to the preoperative arm had a significant decrease in local failure (12% vs. 27%,  $P < .001$ ) and an improvement in 5-year survival (58% vs. 48%,  $P = .004$ ). A separate analysis of 798 patients from Sweden who underwent surgery alone during the same period but were not enrolled in the randomized trial revealed a 5-year survival rate (48%) and incidence of local failure (27%) identical to the surgical control arm, providing further validation of the surgical control arm.<sup>196</sup>

Although the results are intriguing, these data need to be confirmed by additional studies, because the other ten randomized trials of preoperative radiation therapy have been negative. Even if future trials confirm this survival advantage, other equally important end points in rectal cancer need to be addressed. These include acute toxicity, sphincter preservation and function, and quality of life. Radiation fraction sizes and techniques have a major impact on these end points.

Conventional radiation techniques include the use of multiple fields rather than simple anteroposterior fields, computerized treatment planning, and customized blocking. These techniques allow the delivery of high doses of radiation while sparing the surrounding normal tissues, such as the small bowel. The simple anteroposterior radiation techniques commonly used with the other intensive short course radiation therapy trials, such as the Uppsala trial,<sup>190</sup> are associated with an increase in toxicity.

Although prior trials of intensive short course radiation have revealed a significant increase in mortality,<sup>143</sup> these differences were not reported in the Swedish Rectal Cancer Trial. This may have been related to the use of multiple-field techniques. In the Swedish Trial, patients who received radiation with multiple-field techniques had a significant decrease in postoperative mortality compared with those who received treatment with anteroposterior techniques (3% vs. 15%,  $P < .001$ ). The postoperative mortality with surgery alone was 12%. However, the incidence of postoperative morbidity for the total group of patients receiving radiation (regardless of the technique) was still significantly higher when compared with the surgery control arm (44% vs. 34%,  $P = .001$ ). This increase is consistent with other trials of intensive short course preoperative radiation.<sup>144</sup>

The absence of an increase in mortality in the Swedish trial may have been related to the fact that 91% of patients received radiation using the more sophisticated multiple-field radiation techniques. In patients who receive conventional doses and techniques of preoperative combined modality therapy, the volume of small bowel in the radiation field may be the dose-limiting organ with radiation therapy.<sup>197</sup>

It should be noted that even when multiple-field techniques are used, data from the Stockholm I and II trials<sup>143</sup> report a significant increase in postoperative mortality when patients receive intensive short course radiation compared with surgery alone (4% vs. 1%). These high complication rates with intensive short course radiation have not been reported in patients who receive conventional doses and techniques of preoperative radiation. In the R90-01 trial,<sup>52</sup> patients were treated with multiple-field techniques but with 3-Gy fractions. The anastomotic complication rate was 17%.

Another criticism of the intensive short course preoperative radiation trials is the lack of preoperative staging. Myerson et al.<sup>198</sup> treated 83 patients with this approach, and only 20 had transrectal ultrasound staging.

In summary, even with suboptimal radiation techniques, the more recent randomized preoperative trials reveal a significant decrease in local failure. Although the intensive short course (25 Gy) of preoperative radiation therapy is used in some European countries, it is not favored in North America because (1) it is unlikely that it could be combined with adequate doses of systemic chemotherapy; (2) it is not designed to enhance sphincter preservation; and (3) regardless of the technique, it is still associated with a significant increase in postoperative morbidity.

## **PREOPERATIVE AND POSTOPERATIVE RADIATION THERAPY**

The approach of using both preoperative and postoperative therapy, also known as the *sandwich technique*, includes a short preoperative course of radiation (5 to 15 Gy), followed by surgery, and in patients with T3N1M0 disease, an additional 40 to 45 Gy postoperatively. This approach was designed to combine the theoretical advantages of low-dose preoperative radiation therapy (decreased tumor seeding) while reserving postoperative radiation therapy for those patients with T3 or N1–2M0 disease. The results of this approach have been reported by a number of investigators.<sup>199</sup>

The Radiation Therapy Oncology Group (RTOG) presented the results of a randomized trial of 350 patients (87% with rectal cancer) who were randomized to 5 Gy preoperative therapy versus surgery alone (RTOG 81-15). Patients with a pathologic stage T3 or N1–2 disease received a minimum of 45 Gy postoperatively. No chemotherapy was delivered. With a minimum follow-up of 5 years, no differences were found in local failure, distant failure, or overall survival between the arms. A retrospective analysis of 155 patients treated at the Institut Gustave Roussy also revealed no advantage of the sandwich technique compared with preoperative radiation.<sup>199</sup> Because the randomized trials of postoperative combined modality therapy reveal a significant improvement in survival, the benefits of preoperative therapy, including down-staging and sphincter preservation, require a standard dose rather than low to intermediate doses of radiation, and because the RTOG randomized trial was negative, the sandwich approach should be abandoned.

## SELECTED CONTROVERSIES IN THE ROLE OF PREOPERATIVE THERAPY

### PREDICTION OF RESPONSE WITH TUMOR MARKERS

A variety of tumor markers have been identified that may help predict those tumors that will respond favorably to preoperative therapy (Table 33.8-12). Based on the experience that rapidly dividing cells are more sensitive to radiation, Willett et al.<sup>200</sup> analyzed the proliferative index in patients with locally advanced or unresectable disease who received preoperative radiation therapy with or without 5-FU.<sup>200</sup> Tumors with a higher proliferation index had a higher response rate to preoperative therapy and, after radiation, a corresponding reduction was noted in the proliferative index.<sup>201</sup> In a follow-up study, the authors reported that the addition of 5-FU to preoperative radiation decreased three markers of proliferation [mitotic counts, Ki-67, and proliferating cell nuclear antigen (PCNA)] compared with radiation therapy alone.<sup>202</sup>

Site	Number of Patients	Clinical Stage	Preoperative Therapy	% CR	Findings
Scott <sup>199</sup>	30	T3-4	CRT	20	↑ response index with CR. No relationship to pT or pN.
Thompson et al. <sup>199</sup>	52	T3-4	CRT	—	↑ response index after preoperative CRT. ↑ proliferation (Ki-67, PCNA) after CRT but did not predict the CR rate.
Lapierre et al. <sup>199</sup>	30	T3-4	CRT	0	↑ CR with normal pT or pN.
Scott <sup>199</sup>	30	T3-4	RT	4	↓ downstaging with normal pT and pN.
Scott <sup>199</sup>	40	T3-3	RT	4	↓ downstaging. ↑ local failure and ↓ survival with normal pT and pN.
Makaris et al. <sup>199</sup>	30	T3-4	CRT + 5-FU	—	↓ downstaging with ↑ response index, higher correlation with pT and pN.
Willett et al. <sup>200</sup>	105	T3-4	RT + CRT	0	↓ downstaging with ↑ growth fraction (↑ mitotic count and Ki-67 and PCNA).
Scott et al. <sup>199</sup>	100	T3-3	RT	—	No change in pT response per T or pN.
Scott et al. <sup>199</sup>	140	T3-4	RT	—	↓ pT response index, ↑ preoperative RT decreased local failure, ↓ pT response index, but no benefit from preoperative RT.

CRT, combined modality therapy (radiation + chemotherapy); CR, pathologic complete response; PCNA, proliferating cell nuclear antigen; RT, radiation therapy; T, tumor; N, node; CR, complete response.

RT and/or CRT were performed in randomized fashion in parallel trials.

**TABLE 33.8-12.** Prognostic Predictors of Response to Preoperative Therapy in Rectal Cancer

Desai and colleagues<sup>203</sup> reported a higher incidence of recurrence but less down-staging in PCNA-positive rectal cancers. By multivariate analysis, Neoptolemos and associates<sup>204</sup> showed that this index did not add to the prognostic value of the Dukes' staging system. The proliferative index may be useful in predicting the response to preoperative therapy. However, given the conflicting data, additional experience is needed.

In the series reported by Rich<sup>192</sup> of 50 patients treated with preoperative combined modality therapy, tumors with a low spontaneous apoptosis index and positive BCL-2 staining had lower rates of down-staging. In 167 patients treated with preoperative radiation, a significant increase in down-staging in well-differentiated cancers was reported.<sup>205</sup> Using residual tumor cell density rather than stage as a measure, this difference did not reach statistical significance. By univariate analysis, patients with a pathologic complete response had a nonsignificant improvement in survival. Berger and associates<sup>206</sup> found that well-differentiated tumors had a greater degree of down-staging compared with moderately or poorly differentiated tumors.

In conclusion, although some tumor markers may be predictive of response, the decision to use preoperative therapy should not be made solely on their presence or absence. The development of tumor markers to predict response and prognosis remains an active area of investigation.<sup>207</sup>

### DOES THE RESPONSE OF THE PRIMARY TUMOR PREDICT OUTCOME?

Most studies suggest that sphincter preservation is increased with a corresponding increase in the response rate of the primary tumor. It is more controversial as to whether the response rate predicts outcome and if the subset of patients who achieve a complete response still require radical surgery.

In an analysis of 88 patients with clinical T3–4 rectal cancers who received preoperative radiation with or without 5-FU plus leucovorin, a decrease was noted in local failure (4% vs. 15%) and a significant increase was noted in 5-year cancer-specific survival (100% vs. 45%,  $P = .01$ ) in patients who achieved a complete or near-complete response (pathologic stage T0–2N0 disease) compared with those with less of a response (pathologic stage T3–4 or N1–2).<sup>181</sup> Ahmad and colleagues<sup>182</sup> reported a 5-year actuarial local control rate of 96% and a 91% survival rate in the subset of 49 of a total of 315 patients with clinical T3–4 disease who achieved a complete response after preoperative radiation.

Two studies have examined whether surgery is still necessary after a complete response, and the reported results have been conflicting. Habr-Gama and colleagues<sup>183</sup> treated 118 patients with clinical T1–3 rectal cancers with preoperative 50.4-Gy radiation plus 5-FU plus leucovorin. Of the 36 patients who achieved a biopsy-proven complete response, 30 did not undergo surgery. With a median follow-up of 36 months, 28 (93%) remained without evidence of disease. In a smaller series from Rossi et al.,<sup>184</sup> 16 patients (13 with tethered disease) received similar preoperative treatment. If they achieved a biopsy-proven complete response, they received an additional boost of 20 to 30 Gy with brachytherapy. Of the six patients (38%) who had a complete response, they remained without evidence of disease for a median of only 11 months.

Although the results from Habr-Gama and colleagues<sup>183</sup> are intriguing, radical surgery after preoperative adjuvant therapy remains the standard of care. In the subset of patients who are either medically inoperable or refuse radical surgery, local excision may be an alternative.<sup>140</sup>

## RADICAL SURGERY AND ADJUVANT POSTOPERATIVE COMBINED MODALITY THERAPY FOR RESECTABLE RECTAL CANCER

The anatomy and natural history of rectal adenocarcinoma require attention to issues of local and systemic tumor control. Despite many clinical trials, until 1990 there was considerable controversy about whether adjuvant therapy improved the survival rate of patients undergoing surgical resection of their primary tumors. Even a metaanalysis of the worldwide published experience, which demonstrated a statistically significant benefit for adjuvant chemotherapy in rectal cancer patients (38% decrease in the mortality rate), was not completely convincing for many physicians. However, a Consensus Development Conference sponsored by the National Institutes of Health in 1990 concluded that effective adjuvant therapy exists for stages II and III (Modified Astler Collier stages B2 and C or TNM stage T3 or N1–2) rectal cancers. This conclusion was based on the clinical data derived over the preceding 20 years. Especially important were the results of some of the randomized studies summarized in Table 33.8-13. Two of the studies included a surgery-only control group, and four studies used surgery plus postoperative pelvic irradiation as the means for achieving definitive local control.<sup>83,177,208</sup>

Trial	Year	Design	Results
INT 0114 <sup>216</sup>	1993	Randomized	RT + 5-FU vs. RT + 5-FU + CCNU vs. RT + 5-FU + CCNU + Leu. Significant improvement in local control (P = .001).
Mayo/NCCTG 79-47-51 <sup>209</sup>	1980	Randomized	RT + 5-FU vs. RT + 5-FU + CCNU vs. RT + 5-FU + CCNU + Leu. Significant improvement in local control (P = .001).
NSABP R-01 <sup>178</sup>	1988	Randomized	RT + 5-FU vs. RT + 5-FU + CCNU vs. RT + 5-FU + CCNU + Leu. Significant improvement in overall survival (P = .05).
INT 0114 <sup>216</sup>	1993	Randomized	RT + 5-FU vs. RT + 5-FU + CCNU vs. RT + 5-FU + CCNU + Leu. Significant improvement in local control (P = .001).
Mayo/NCCTG 86-47-51 <sup>128</sup>	1986	Randomized	RT + 5-FU vs. RT + 5-FU + CCNU vs. RT + 5-FU + CCNU + Leu. Significant improvement in local control (P = .001).
INT 0114 <sup>216</sup>	1993	Randomized	RT + 5-FU vs. RT + 5-FU + CCNU vs. RT + 5-FU + CCNU + Leu. Significant improvement in local control (P = .001).

**TABLE 33.8-13.** Stage T3N1–2M0 Rectal Cancer: Selected Completed Adjuvant Trials

The majority of U.S. patients undergo surgery and, if they have stage T3 or N1–2 disease, receive postoperative adjuvant combined modality therapy. The most compelling advantage to this approach is pathologic staging. Although advances in preoperative imaging techniques allow more accurate patient selection, it still remains the most common approach. The primary disadvantages of the postoperative approach include an increased amount of small bowel in the radiation field <sup>171</sup> and a potentially hypoxic postsurgical bed, and if the patient has undergone an APR, the radiation field must be extended to include the perineal scar.

### RESULTS OF POSTOPERATIVE THERAPY

After the publication of the randomized trials from the GITSG <sup>83,177</sup> and Mayo/NCCTG (79-47-51), which revealed a significant improvement in local control (Mayo/NCCTG) and survival (GITSG and Mayo/NCCTG) with postoperative radiation plus bolus 5-FU plus methyl chloroethylcyclohexylnitrosourea (CCNU; lomustine), the National Cancer Institute Consensus Conference concluded in 1990 that combined modality therapy was the standard postoperative adjuvant treatment for patients with T3 or N1–2 disease. Although radiation therapy decreases local recurrence in one-half of patients, it is the addition of 5-FU–based chemotherapy that further decreases local recurrence to approximately 10% to 12% and is the agent responsible for increasing overall 5-year survival rates by approximately 10% to 15% (from 50% up to 60% to 65%).

With this increase in local control and survival with the addition of chemotherapy comes an increase in acute toxicity. The incidence of grade 3+ toxicity in the combined modality arms of the GITSG and Mayo/NCCTG 79-47-51 trials was 25% to 50%. Furthermore, the percentage of patients finishing six cycles of chemotherapy in those trials was only 65% and 50%, respectively. Miller and colleagues <sup>209</sup> reported that patients who received combined modality therapy versus radiation therapy alone in the Mayo/NCCTG 79-47-51 trial had a higher rate of severe and life-threatening diarrhea, both during radiation (20% vs. 4%,  $P = .001$ ) and at any time during treatment (22% vs. 4%,  $P = .001$ ). As previously discussed, the acute toxicity with preoperative combined modality therapy may be less than in the postoperative setting.

The majority of combined modality therapy regimens include six cycles of 5-FU–based chemotherapy plus concurrent pelvic radiation. Six cycles of chemotherapy are thought to be necessary to treat systemic disease. However, in a randomized trial from Norway, 144 patients were randomized to postoperative radiation plus bolus 5-FU (500 to 750 mg/m<sup>2</sup> limited to days 1 and 2 of weeks 1, 2, and 3 of radiation) versus surgery alone. <sup>210</sup> Despite the fact that 5-FU was delivered with radiosensitizing doses rather than doses adequate to treat systemic disease, this combined modality therapy regimen significantly decreased local recurrence (12% vs. 30%,  $P = .01$ ) and improved 5-year survival (64% vs. 50%,  $P = .05$ ). Although these results with limited-dose 5-FU are encouraging, additional experience with this approach is needed before modifying the standard recommendation of six cycles of systemic chemotherapy.

Retrospective data suggest that there may be subsets of patients with T3N0 disease who may not require adjuvant therapy and that there may be patients with stage I disease who should be considered for adjuvant therapy. In a review of 117 patients with T3N0 disease, Willett et al. <sup>211</sup> identified a favorable subset of patients with well- or moderately differentiated cancers invading less than 2 mm into the perirectal fat who, after surgery alone, had a 10-year actuarial local failure rate of only 5% compared with 29% in T3N0 patients without those favorable features. In a separate analysis, they identified a subset of patients with stage I disease who have an increased incidence of local failure after an APR. <sup>212</sup> These results must be confirmed in a randomized trial before a change in the standard of care of combined modality therapy can be recommended.

Since the 1990 National Cancer Institute Consensus Conference, the focus of the intergroup postoperative trials has been the identification of the optimal chemotherapeutic agents and their method of administration. In the follow-up trial to the 79-47-51 trial, the Mayo/NCCTG designed a four-arm trial (86-47-51) to determine if methyl CCNU was necessary, as well as to compare the relative effectiveness of 5-FU when delivered as a bolus versus a continuous infusion. <sup>128</sup> Because methyl CCNU did not improve either local control or survival, it is no longer recommended for use in the adjuvant treatment of rectal cancer. <sup>213</sup>

When compared with bolus 5-FU (with or without methyl CCNU), patients who received continuous infusion 5-FU (also known as *prolonged venous infusion*) had a significant decrease in the overall rate of tumor relapse (37% vs. 47%,  $P = .01$ ), distant metastasis (31% vs. 40%,  $P = .03$ ), as well as an improvement in 4-year survival (70% vs. 60%,  $P = .005$ ). These data suggest that, when 5-FU is used as a single agent with radiation therapy, it is more effective as a continuous infusion compared with a bolus.

Differences were also found in the individual acute toxicities of continuous infusion and bolus 5-FU regimens. For example, during the combined modality segment, patients who received continuous infusion 5-FU had a significant increase in grade 3+ diarrhea (24% vs. 14%,  $P < .01$ ), whereas they had a significant decrease in grade 3+ leukopenia (2% vs. 11%,  $P < .01$ ) compared with bolus 5-FU.

Building on the positive results of continuous infusion 5-FU reported in the Mayo/NCCTG 86-47-51 trial, the replacement postoperative Intergroup trial INT 0114 was designed. The primary end point of this trial is to determine whether a benefit exists to continuous infusion 5-FU throughout the entire chemotherapy course (six cycles) as compared with continuous infusion only during the combined modality segment (two cycles) and bolus 5-FU during the remaining four cycles. The control arm is arm 4 (bolus 5-FU, leucovorin, and levamisole). The trial opened to accrual in 1993 and is actively accruing.

The NSABP R-01 three-arm trial of comparing the postoperative methyl-CCNU, vincristine (Oncovin), and 5-FU (MOF) regimen vs. radiation therapy vs. surgery alone revealed a significant improvement in 5-year disease-free survival (42% vs. 30%,  $P = .006$ ) and overall survival (53% vs. 43%,  $P = .05$ ) with postoperative MOF chemotherapy compared with surgery. <sup>178</sup> The advantage in overall survival of the chemotherapy arm was most evident in males (60% vs. 37%) and in males younger than 65 years of age (44% vs. 26%). In contrast, females who received chemotherapy experienced a lower survival (37% vs. 54%). It should be emphasized that the trial was not stratified by gender. Additional studies revealed that overexpression of thymidylate synthase in the primary tumor was associated with a worse prognosis <sup>214</sup> and that such patients derived the greatest benefit from adjuvant MOF chemotherapy.

As a follow-up to the R-01 trial, the NSABP designed a four-arm trial (R-02) in which patients were randomized, depending on gender, to either MOF with or without radiation or 5-FU plus leucovorin with or without radiation. <sup>215</sup> A preliminary analysis revealed a significant decrease in local failure in the two combined modality therapy arms compared with the two that included chemotherapy alone (7% vs. 11%,  $P = .045$ ). <sup>215</sup> However, this decrease in local failure did not result in an increase in median survival. Other results are pending.

The most recent Intergroup postoperative trial to report results was INT 0114 (see [Table 33.8-13](#)). <sup>216</sup> This was a four-arm trial in which all patients received six cycles of postoperative chemotherapy plus concurrent radiation therapy during cycles three and four. The goal of this trial was to determine if combinations of bolus 5-FU–based chemotherapy (5-FU plus low-dose leucovorin vs. 5-FU plus levamisole vs. 5-FU and leucovorin and levamisole) were superior to single-agent 5-FU.

With a median follow-up of 4 years, no significant differences were found between the four arms (5-FU alone, 5-FU plus leucovorin, 5-FU plus levamisole, or 5-FU and leucovorin and levamisole) in terms of local failure (12%, 9%, 13%, 9%, respectively) or 3-year survival (78%, 80%, 79%, 79%, respectively). <sup>216</sup> Although the total incidence of acute grade 3+ toxicity was similar for the four arms (76%, 72%, 70%, 75%, respectively), differences were noted between the regimens. For example, the 5-FU alone arm had a higher incidence of hematologic toxicity, whereas the 5-FU plus levamisole arm had a higher incidence of diarrhea. A subset analysis

revealed that, in all four arms, women had a significantly greater incidence of acute grade 3+ toxicity compared with men. The reason for this difference in toxicity by gender is unclear.

The choice of which postoperative adjuvant regimen to recommend in the nonprotocol setting remains controversial. Given that the Mayo/NCCTG 86-47-51 trial revealed that continuous infusion 5-FU is more effective than bolus 5-FU and because modulation with leucovorin, levamisole, or both did not improve the results of bolus 5-FU alone in the INT 0114 trial, one could argue that continuous infusion 5-FU is the regimen of choice. INT 0114 directly compares continuous infusion 5-FU with bolus 5-FU, leucovorin, and levamisole; however, the results are not yet available. Therefore, for patients not enrolled in a clinical trial, acceptable regimens at this time include either continuous infusion 5-FU (225 mg/m<sup>2</sup> days 1 to 7, or 300 mg/m<sup>2</sup> days 1 to 5) or bolus 5-FU plus modulation with leucovorin (5-FU, 325 mg/m<sup>2</sup>, plus leucovorin, 20 mg/m<sup>2</sup> bolus daily × 5), levamisole, or both. However, because the colon adjuvant trials reveal that six cycles of 5-FU plus leucovorin is as effective as 12 cycles of 5-FU plus levamisole,<sup>217,218</sup> most physicians no longer use levamisole in the adjuvant treatment of either colon or rectal cancer. When a 7-day continuous infusion of 5-FU is combined with oral leucovorin and pelvic radiation, the recommended 5-FU dose is decreased to 150 mg/m<sup>2</sup>.<sup>219</sup> In summary, bolus or continuous infusion 5-FU, when combined with radiation in the treatment of rectal cancer, probably have equal efficacy, and the choice of a regimen should be based on factors such as their acute toxicity profiles and patient compliance.

## FUTURE OF ADJUVANT THERAPY

Given the increased morbidity and marginal benefits seen in the randomized trials of low- or moderate-dose adjuvant preoperative radiation, interest in treating resectable rectal cancer with preoperative therapy was limited until the 1990s. The primary focus of clinical research in the adjuvant treatment of resectable rectal cancer had involved the use of postoperative combined modality therapy. However, there are three reasons why the postoperative approach may not be the most innovative one: increased toxicity, less chance of sphincter preservation, and lower chemotherapy doses.

Despite the survival advantage of postoperative combined modality therapy, it is associated with substantial toxicity. For example, the incidence of grade 3+ toxicity in patients who received combined modality therapy in the GITSG trial was 26% for hematologic toxicity and 35% nonhematologic toxicity.<sup>83,177</sup> In the Mayo Clinic/NCCTG 79-47-51 trial, the most significant grade 3+ toxicities included diarrhea (41%) and leukopenia (33%). The only grade 3+ toxicity in patients receiving radiation therapy alone was diarrhea (5%). In the GITSG and Mayo Clinic/NCCTG trials, 35% to 50% of the patients never finished all the planned cycles of chemotherapy. The total incidence of grade 3+ toxicity in the INT 0114 trial of postoperative radiation with 5-FU with or without leucovorin and/or levamisole modulation was 72% to 76%.<sup>216</sup>

Preoperative radiation therapy increases the chance of sphincter preservation. By down-staging the primary tumor, preoperative irradiation allows the surgeon to change the planned operation from an APR to a LAR and CAA.<sup>107</sup>

Higher initial doses of chemotherapy can be delivered with preoperative than with postoperative irradiation. This difference was observed in comparing two phase I trials of combined bolus 5-FU, high-dose leucovorin, and radiation therapy (50.4 Gy) reported from Memorial Sloan-Kettering Cancer Center.<sup>220</sup> Patients with unresectable disease received preoperative radiation therapy and two cycles of concurrent 5-FU plus leucovorin followed by surgery and postoperative 5-FU plus leucovorin. Patients with resectable disease received the same chemotherapy and radiation therapy in the postoperative setting. The dose of radiation and leucovorin remained constant while the 5-FU dose was escalated. The maximal tolerated dose of 5-FU was higher with preoperative versus postoperative therapy.

Based on its toxicity, increased chance of sphincter preservation, and higher chemotherapy doses, preoperative combined modality therapy, if delivered with appropriate doses and techniques, is an attractive approach and is a standard of care for clinical T3 disease. The NSABP R-03 and the German CAO/ARO/AIO 94 randomized trials will help determine the relative effectiveness of preoperative versus postoperative combined modality therapy.

## COMPLICATIONS OF PELVIC RADIATION THERAPY

### ETIOLOGY AND MANIFESTATIONS

As seen with other cancer therapies, pelvic radiation is associated with acute and long-term toxicity. Complications of pelvic radiation therapy are a function of the volume of the radiation field, overall treatment time, fraction size, radiation energy, total dose, and technique.<sup>221</sup> Large field sizes, a short overall treatment time, large fraction sizes (more than 2 Gy per fraction), orthovoltage or low-energy megavoltage radiation (cobalt 60), doses of more than 50.4 Gy when small bowel is in the high-dose field, the use of a two-field [anteroposterior (AP)/posteroposterior (PA)] technique, treatment of only one field per day, the use of a direct perineal boost field, and the lack of computerized dosimetry all contribute to an increased incidence of radiation complications.

Risk factors unrelated to radiation techniques include patients with pelvic inflammatory disease, hypertension, diabetes mellitus, inflammatory bowel disease, or obesity, and patients who have had prior pelvic surgery or receive concurrent chemotherapy.

Most studies describing the tolerance of patients with inflammatory bowel disease have been limited to case reports.<sup>222</sup> Furthermore, most do not indicate whether the disease is active, requiring antiinflammatory therapy, or if the patient had undergone a total proctocolectomy.<sup>223</sup> This factor is important because the issue of toxicity may not be relevant for patients with ulcerative colitis who have undergone a total proctocolectomy. The most comprehensive analysis of the tolerance of patients with inflammatory bowel disease was reported by Willett and colleagues.<sup>224</sup> They examined the records of 28 patients (17 colorectal patients and 11 who received concurrent 5-FU) who were treated with 40 Gy or more of pelvic or abdominal radiation therapy. Of the 28 patients, 18 had ulcerative colitis and 10 had Crohn's disease. Overall, 43% of patients had active disease requiring antiinflammatory therapy.

The total incidence of severe toxicity was 46%, which caused 22% of patients to stop radiation and 29% to undergo surgery for complications. Acute toxicity was similar in ulcerative colitis and Crohn's disease; however, late toxicity was limited to patients with ulcerative colitis. In the 16 patients treated with specialized radiation techniques to reduce total dose to or exclude the small and large bowel from the radiation field, the 5-year actuarial incidence of late toxicity was 23% compared with 73% in the 12 patients who were not treated with these specialized techniques ( $P = .02$ ). Unless the large bowel can be excluded from the radiation field in patients with ulcerative colitis and the large and small bowel is excluded from the radiation field in patients with Crohn's disease, the use of radiation in patients with inflammatory bowel disease is contraindicated.

Radiation complications also are increased in patients with collagen vascular disease. However, a report of six patients with systemic lupus erythematosus who received chest wall radiation for breast cancer or Hodgkin's disease suggests that it is not an absolute contraindication to radiation therapy.<sup>225</sup>

Acute (short-term) and long-term complications of pelvic radiation occur with distinct clinical courses and pathologic manifestations.<sup>226</sup> The most frequent serious complication of pelvic radiation is small bowel damage. In animals, transforming growth factor- $\beta$  and mast cell hyperplasia may be involved in the molecular pathogenesis of radiation enteritis.<sup>227</sup>

### ACUTE COMPLICATIONS

Acute complications occur in all patients during treatment and include thrombocytopenia, leukopenia, dysuria, and effects on the small bowel (diarrhea, abdominal cramping, and increased bowel frequency) and large bowel (acute proctitis, tenesmus, bloody or mucus discharge). Proctoscopic examination of the rectal mucosa normally reveals an inflamed, edematous, and friable rectal mucosa consistent with acute radiation proctitis and should be discouraged while patients are receiving radiation therapy. These symptoms usually are transient and resolve within a few weeks after the completion of radiation therapy. They appear to be a function of the dose rate and fraction size more than of the total dose of radiation. The mechanism is primarily the depletion of actively dividing cells in what is otherwise a stable cell renewal system. In the small bowel, loss of the mucosal cells results in malabsorption of various substances, including fat, carbohydrate, protein, and bile salts. The management of bowel-related complications usually involves the use of diphenoxylate, narcotics, or both. The bowel mucosa usually recovers in 1 to 3 months after the completion of radiation.

Dysuria occurs in 10% to 15% of patients and is usually controlled with phenazopyridine hydrochloride (Pyridium). Skin erythema most commonly occurs in skin folds and is treated prophylactically with nonmetallic skin creams. If grade 3+ toxicity develops, a 3-day to 1-week treatment break commonly is required.

Although concurrent chemotherapy significantly improves the local control rate of radiation therapy, it increases the acute toxicity. The incidence of grade 3+ toxicity with postoperative radiation therapy is approximately 5%, whereas in some reports it is increased to as high as 25% to 50% in patients receiving postoperative combined modality therapy.<sup>228</sup> In the INT 0114 trial of postoperative combined modality therapy using 50.4 Gy plus bolus 5-FU with or without leucovorin and/or levamisole, the total incidence of grade 3+ toxicity was 72% to 76%.<sup>216</sup> An analysis of 204 patients who received the postoperative combined modality therapy arm of the Mayo/NCCTG 79-47-51 trial showed the incidence of acute grade 3+ diarrhea was 22% compared with 4% who received radiation therapy alone ( $P = .001$ ).<sup>229</sup> The acute toxicity of preoperative combined modality therapy appears to be lower than postoperative combined modality therapy.<sup>107,171,230</sup>

## LONG-TERM COMPLICATIONS

Long-term complications occur less frequently but are substantially more serious. The initial symptoms commonly occur 6 to 18 months after completion of radiation. Complications may include persistent diarrhea, increased bowel frequency, proctitis, small bowel obstruction, perineal and scrotal tenderness, delayed perineal wound healing, urinary incontinence, and bladder atrophy and bleeding. Injury to the vascular and supporting stromal tissues of the bowel is the presumed pathophysiology. Schuster et al.<sup>231</sup> found that bile acid malabsorption due to ileal dysfunction was not an inevitable late complication of pelvic radiation, and it is not the major determinant in the pathophysiology of chronic radiation-induced diarrhea.

The most common long-term complications are due to small bowel damage and include enteritis, adhesions, and small bowel obstruction requiring surgical intervention.<sup>221,232</sup> At the MGH, 165 patients received 45 Gy postoperatively to the pelvis with a boost to the tumor bed to 50.4 Gy.<sup>172</sup> The incidence of long-term mild to moderate complications was 8% [2% proctitis, 2% perineal and scrotal tenderness (resolved), 1% delayed perineal wound healing, 1% small bowel obstruction (resolved), 1% urinary incontinence, and 1% bladder atrophy and bleeding (resolved)]. The incidence of small bowel obstruction requiring surgery was similar in the patients who received radiation (6%) compared to a historical group of patients who were treated with surgery alone (5%).

A retrospective review of 304 patients treated with a median of 50.84 Gy of postoperative pelvic radiation at the Mayo Clinic was presented by Miller et al.<sup>232</sup> The median follow-up was 5.3 years; 65% of patients received chemotherapy; and the small bowel was excluded after 50.4 Gy. The crude incidence of complications included 4% acute enteritis, 6% chronic enteritis, and 12% chronic proctitis. The actuarial incidence of complications at 5 years included 14% proctitis and 7% enteritis. The mean time from diagnosis to complications was 2.1 years. By multivariate analysis, the two independent factors associated with an increase in complications were increasing age (median age, 67 years vs. 62 years) and radiation dose (median, 54 Gy vs. 50.4 Gy).

Other long-term complications, such as pelvic fractures<sup>233,234</sup> and lumbosacral plexopathy,<sup>235,236</sup> are very rare occurrences and may be caused by factors unrelated to the radiation, such as osteoporosis or disease progression.

Overall, the incidence of small bowel obstruction requiring surgery after postoperative pelvic radiation for rectal cancer is 4% to 12% in most series and as high as 17.5% in earlier series.<sup>172,174,175</sup> In patients treated with surgery only, 2% to 15% may develop similar complications. Small bowel–related late complications are directly proportional to the volume of small bowel in the radiation field. Late radiation proctitis, similar to small bowel injury, is related to the treatment volume and dose of radiation.

## SPHINCTER FUNCTION

Radiation therapy can adversely effect sphincter function; however, most series are retrospective, nonrandomized, nonblinded, retrospective telephone surveys. Furthermore, sphincter function is affected by other factors, such as the type of operation, the functional scale used, and whether patients received conventional radiation techniques as opposed to intensive short course radiation.

Using a retrospective telephone survey, Kollmorgen et al.<sup>153</sup> from the Mayo Clinic assessed the impact of postoperative combined modality therapy delivered with conventional doses and techniques of pelvic radiation and 5-FU–based chemotherapy on bowel function and compared it with a matched group of patients who underwent surgery alone. The 41 patients who received combined modality therapy had a significant increase in the number of bowel movements, clustering of bowel movements, nighttime bowel movements, occasional incontinence, urgency, and wore pads more often compared with 59 patients who underwent surgery alone. Sphincter function after a CAA was retrospectively assessed by Paty and associates.<sup>154</sup> The 40 patients who received pre- or postoperative radiation therapy, or both (with or without chemotherapy) after a CAA had increased stool frequency and difficulty with evacuation compared with 41 patients who underwent surgery alone. Unconventional radiation doses and techniques were used in 43% of patients.

In contrast with the previous studies, Birnbaum and colleagues have prospectively examined the short-term<sup>155</sup> and long-term<sup>156</sup> impact of preoperative radiation therapy on sphincter function. Patients received conventional doses and techniques of radiation and were assessed objectively by anal manometry with or without transrectal ultrasound. In the 20 patients assessed for short-term and ten patients assessed for long-term results, radiation therapy had a minimal effect on sphincter function. As one would predict, patients who receive preoperative radiation with intensive short course radiation have inferior function results. Patients who received 5 Gy × 5 in the Swedish Rectal Cancer Trial had a significant increase in bowel frequency, incontinence, urgency, and emptying difficulty.<sup>237</sup> This impaired the patient's social life 30% of the time compared with 10% of the time with surgery alone. In another analysis of patients who received 5.1 Gy per fraction, a significant increase in bowel frequency was found.<sup>238</sup>

## SEXUAL FUNCTION

In addition to the previously discussed variables that can effect assessment of sphincter function, series examining sexual function using subjective methods have the additional shortcoming of bias due to the sensitive nature of the questions. Answers to such questions are subjective and may be influenced by the interaction between the patient and interviewer. Age and psychological factors, such as depression and anxiety about the diagnosis of cancer, can further influence the results. Furthermore, it should be emphasized that both the surgery required for an APR and the psychological impact of a permanent colostomy can have an adverse impact on sexual function.

A retrospective analysis of sexual function in men and women by Havenga and associates<sup>3</sup> found that radiation therapy with or without 5-FU had a negative impact after total mesorectal excision for rectal cancer. In a review of 18 males with a median age of 70 who received 52.5 Gy with an unconventional fraction size of 2.63 Gy per fraction for bladder cancer, 56% were able to attain an erection sufficient for intercourse compared with 72% of patients in the 6 months before the start of radiation therapy.<sup>239</sup> Because the patients did not undergo surgery, receive hormonal therapy, or have prostate cancer, this study is a better indication of the impact of radiation therapy alone.

In conclusion, although radiation can adversely affect sphincter and sexual function, the ultimate functional results are a result of a combination of therapies, including radiation, surgery, and chemotherapy. The risk of dysfunction must be evaluated in the context of the benefit of adjuvant therapy, which includes decreased local failure, improved survival, and, in selected patients, the ability to perform sphincter-preserving surgery as an alternative to an APR.

## MINIMIZING TOXICITY OF RADIATION THERAPY

### RADIATION TREATMENT TECHNIQUES

Small bowel–related complications are directly proportional to the volume of small bowel in the radiation field.<sup>197</sup> In patients receiving combined modality therapy, the volume of small bowel in the radiation field limits the ability to escalate the dose of 5-FU.<sup>171</sup> A number of simple radiotherapeutic techniques are available to decrease radiation-related small bowel toxicity (Table 33.8-14). First, small bowel contrast allows identification of the location of the small bowel. The use of multiple-field techniques (preferably a three-field technique) permits a larger volume of small bowel to be blocked from the pelvis compared with an AP/PA (two-field) technique. In one series, the small bowel obstruction rate in patients with rectal cancer who received pelvic radiation therapy was higher with a single-field (21%) as compared with a multiple-field technique (9%).<sup>240</sup> The small bowel obstruction rate increased to 30% when an extended-field radiation was used.

Surgical techniques
Pelvic reconstruction to exclude small bowel from the pelvis
Reperitonealize pelvic floor
Retract the uterus
Construct an omental sling
Absorbable mesh
Pelvic signs to delineate high-risk areas
Radiation therapy techniques
Treatment simulation and planning
Small bowel contrast
Prone position
Multiple-field techniques (three-field preferred)
Wire perineum and block if an abdominoperineal resection has not been performed
Use high-energy (20 MeV) linear accelerators
Shaped blocks
Computerized dosimetry
Do not exceed 50.4 Gy to the small bowel
Standard fraction sizes (1.8-2.0 Gy/fraction)
Bladder distention and belly board—providing it does not make the patient uncomfortable, thereby causing movement
During treatment
Treatment of all fields each day
Low-fiber, low-fat diet

**TABLE 33.8-14.** Techniques to Minimize the Acute Toxicity to the Small Bowel from Radiation Therapy

The treatment of all fields each day results in a lower integral dose and more homogeneous dose distribution. A study by Sigmon et al. <sup>241</sup> suggests that patients with endometrial or rectal cancer who receive pelvic radiation by a continuous course as compared with a planned split course have fewer chronic bowel complications. The use of lateral fields for the boost as well as positioning the patient in the prone position further decreases the volume of small bowel in the lateral radiation fields.

The treatment should be designed with the use of computerized radiation dosimetry and be delivered by high-energy linear accelerators, which, by nature of their depth dose characteristics, deliver a higher dose to the tumor volume while sparing the surrounding normal structures. When the perineal scar must be treated, it should be included in the pelvic radiation fields. The use of a separate perineal field is associated with an increased risk of overlap of the radiation fields and should be avoided.

Even in expert hands, daily variations occur in patient positioning for pelvic radiation ranging from 3.4 to 9.0 mm. <sup>242,243</sup> Using electronic portal imaging, Tinger et al. <sup>244</sup> found that errors exceeding 5 mm or 10 mm are significantly more frequent intertreatment (40% to 51%, and 3% to 23%, respectively) compared with intratreatment (1% to 7%, and 0%, respectively). In national clinical trials, pretreatment quality control review can decrease the error rate in radiation field design. <sup>245</sup>

The advantage to the combination of a multiple-field technique, high-energy photons, and computerized dosimetry is illustrated in [Figure 33.8-6](#). With this combination, a homogenous dose distribution is maintained throughout the target volume such that prescribing to the 98% isodose line covers the volume at risk and gives only 35% to 55% of the dose to the small bowel. In contrast, when the same patient receives <sup>60</sup>Co with an AP/PA arrangement, an inhomogeneous dose distribution is provided throughout the target volume such that the dose must be prescribed to the 90% isodose line to cover the volume at risk, thereby giving 110% to 130% of the dose to the small bowel. Furthermore, if computerized treatment planning was not performed and the dose was prescribed to the midplane, parts of the tumor volume would be underdosed by 10%.

**FIGURE 33.8-6.** Small bowel sparing using high-energy linear accelerator radiation combined with prone three-field treatment. AP/PA, anteroposterior/posteroanterior.

After pelvic surgery, the small bowel commonly fills the pelvis. Adhesions can form, resulting in fixed loops of small bowel in the radiation fields. In this situation, despite treatment of the patient in the prone position, the use of multiple-field techniques may be of limited value ([Fig. 33.8-7](#)). In contrast, when radiation therapy is delivered preoperatively to a patient who has not undergone prior pelvic surgery, the small bowel is usually mobile. As illustrated in [Figure 33.8-8](#), when no small bowel fixation is present, treatment in the prone position was successful in excluding most of the small bowel from the posteroanterior field and completely from the lateral fields.

**FIGURE 33.8-7.** Radiation treatment fields in a patient in the prone position receiving postoperative radiation therapy using a three-field technique. Despite the prone position, the small bowel (arrows) remains fixed in the pelvis, and it cannot be excluded from the lateral fields.

**FIGURE 33.8-8.** Radiation treatment fields in a patient in the prone position receiving preoperative radiation therapy using a three-field technique. The small bowel

(arrows) is excluded from the lateral fields.

[Figure 33.8-8](#) also illustrates the technique of placing a wire on the perineum to allow blocking in the lateral preoperative radiation fields. This technique not only decreases acute grade 3+ skin toxicity (reported as high as 94% by Rossi et al. [184](#) when this technique is not used) but decreases the high incidence of perineal wound sepsis in those patients who have an APR (reported as high as 33% in the Uppsala trial [190](#)). A more comprehensive review of techniques for the delivery of pelvic radiation has been published. [221](#)

Clinical series document the importance of field size and technique in minimizing the toxicity of pelvic radiation. In the series from the M. D. Anderson Cancer Center, 62 patients received postoperative pelvic radiation (40 to 50 Gy plus 6- to 10-Gy boost). [174,175](#) Some patients received the radiation by a combination of AP/PA and a boost with opposed laterals or a direct perineal field. In selected patients, the superior border of the field was at L2-3 and the incidence of small bowel obstruction requiring surgery was 17.5%. When the superior border of the field was decreased to L5, the incidence of small bowel obstruction decreased to 10% to 12%. The incidence of small bowel obstruction after surgery alone was 5%.

Various physical maneuvers to exclude the small bowel from the pelvis have been examined. Gallagher et al. [246](#) determined the volume, distribution, and mobility of small bowel in the pelvis after a variety of maneuvers. Regardless of the prior surgical history, a significant decrease was seen in the average small bowel volume when the patients were treated in the prone position with the combination of abdominal wall compression and bladder distention compared with the supine position. Use of a four-field technique further decreased the volume of small bowel. Treatment in the prone position without abdominal wall compression was not consistently effective in displacing small bowel and, in some patients (most commonly obese), the volume of small bowel increased.

Caspers and Hop (1983) performed a similar study in 50 patients who received pelvic radiation for bladder or prostate cancer. The use of the Trendelenburg or inclined procubitus positions were helpful in excluding small bowel from the pelvic radiation fields, especially for obese patients. Although the prone position was less effective than these inclined positions, it was superior to the supine position.

### **SMALL BOWEL CONTRAST**

Small bowel contrast is essential to determine the position of small bowel during radiation simulation. It should be used routinely in patients receiving curative pelvic radiation therapy. Herbert et al. [247](#) found that, in patients with endometrial and rectal cancer who had small bowel contrast used at the time of radiation simulation, there was a change in the treatment field as well as a lower incidence of overall and chronic complications. [247](#) A multivariate analysis revealed that both the use of small bowel contrast and a lower superior border of the treatment field were predictive for decreased radiation toxicity. Visualization of small bowel contributed to an adjustment in the radiation field, resulting in a decrease in the incidence of toxicity.

### **IMMOBILIZATION MOLDS AND TISSUE EXPANDERS**

The effectiveness of custom bowel immobilization molds (belly board) in 30 patients with pelvic malignancies has been analyzed by Shanahan et al. [248](#) Using a CT-based volumetric analysis, the combination of the prone position and immobilization molds decreased the mean small bowel volume in the radiation field by 66% compared with patients treated in the supine position without the immobilization mold. Fu and colleagues [249](#) reported that, when patients with pelvic malignancies were treated in the prone position, a belly board reduced the volume of small bowel by 28% to 50%, depending on the type of prior surgery. A similar benefit using dose volume histogram analysis in 12 patients was reported by Das and associates. [250](#)

Pelvic tissue expanders are also effective in decreasing the volume of small bowel in the radiation field. Herbert and colleagues [251](#) reported a significant decrease in small bowel volume in 14 patients who had a tissue expander compared with 63 who did not (25 cm<sup>3</sup> vs. 239 cm<sup>3</sup>,  $P < .0001$ ). The decrease of small bowel volume was associated with a decrease in acute toxicity. Hoffman and colleagues [252](#) recommended their use when native tissue is not available for small bowel exclusion. To examine the effectiveness of a silicone rubber-molded balloon during pelvis radiation, Sezeur et al. [253](#) measured stool weight, steatorrhea, and  $\alpha_1$ -antitrypsin clearance. The tests remained stable, suggesting that the tissue expander was effective throughout the course of radiation.

It must be emphasized that any physical maneuver beyond the use of the prone position may be associated with patient discomfort, thereby leading to increased movement and daily set-up errors. For example, Brierley and associates [254](#) analyzed the variation of small bowel volume in the pelvis before and during adjuvant pelvic radiation therapy for rectal cancer. They found that the displacement of small bowel from the posterior pelvis by bladder distention was not reliably maintained throughout the treatment course. Therefore, the previously described physical maneuvers and techniques, such as abdominal wall compression and belly boards, may not be beneficial. The use of such techniques should be tailored to the individual patient.

Likewise, uncertainties exist with the use of small bowel contrast. Gallagher et al. [246](#) reported a 20% average increase in small bowel volume after full doses of pelvic radiation when patients were reexamined after the completion of treatment.

### **THREE-DIMENSIONAL RADIATION TREATMENT PLANNING**

Innovative techniques using three-dimensional treatment planning are being investigated. In a report from the Photon Treatment Planning Collaborative Working Group, it was found that the most important contribution of three-dimensional treatment planning in rectal cancer was the ability to plan and localize the target and normal tissues at all levels of the treatment volume rather than using the traditional method of planning with only a single central transverse slice and simulation films. A slight improvement also was noted when no constraints were placed on the type of plans (i.e., when non-coplanar beams were used). A randomized trial of conformal versus conventional radiation therapy in 266 evaluable patients with pelvic malignancies has been reported by Tait et al. [255](#) Although a decrease in the volume of normal tissue volumes in the radiation field was seen with conformal versus conventional treatment (689 cm<sup>3</sup> vs. 792 cm<sup>3</sup>), no difference was noted in the level of symptoms or in medication prescribed.

Investigators in Uppsala examined six patients with rectal cancer who underwent both proton and conventional photon treatment planning. [256](#) By dose-volume histogram analysis, protons offered only a marginal benefit in sparing normal tissues.

### **RADIATION THERAPY AND SURGERY SEQUENCING**

The major disadvantage of delivering radiation therapy in the postoperative setting is the increased incidence of fixed loops of small bowel in the pelvis. The potential merits of the use of preoperative compared with postoperative radiation therapy have been previously discussed. From the issue of toxicity, the primary advantages of preoperative radiation are decreased volume of small bowel in the radiation field and the absence of a perineal scar to be treated.

Some of the randomized trials of preoperative radiation therapy report an increased incidence of complications compared with surgery alone. However, as previously discussed, the radiation therapy in these trials was commonly delivered with inferior techniques, such as AP/PA <sup>60</sup>Co using large fields and fraction sizes. These techniques all contribute to an increased incidence of radiation complications. For example, in the Stockholm Rectal Cancer Study Group, the radiation therapy was delivered in 5-Gy fractions, the superior border was at L2, the majority of patients received <sup>60</sup>Co with an AP/PA technique, and surgery was within 7 days of the completion of radiation. [257](#) In contrast, the nonrandomized trials of preoperative radiation therapy that use higher doses with smaller fraction and field sizes reveal that, when preoperative radiation therapy is delivered with careful radiation techniques, the toxicity is minimized.

### **SURGICAL TECHNIQUES**

Surgical techniques to minimize small bowel injury include reperitonealization of the pelvic floor [258](#); construction of an omental pedicle flap [259](#); retroversion of the uterus; placement of clips in the high-risk areas to better define the tumor volume; and the use of absorbable mesh, which temporarily removes the small bowel from the pelvis. [260](#) Rodier and colleagues [261](#) reported their experience with polyglycolic acid mesh in 60 patients. The mesh was effective in excluding the small bowel from the pelvis in 93% of patients with various pelvic malignancies. It was completely resorbed in 3 to 5 months, and the complication rate related to the mesh was 8%.

Thom and associates<sup>260</sup> used a similar approach in 52 patients. They noted a prolonged postoperative ileus (median, 8.5 days), but no other unusual postoperative complications. In 20 patients who underwent placement of mesh, Beitler et al.<sup>262</sup> reported postoperative complications possibly related to mesh in five patients and a mild postoperative ileus in 17. Because pelvic radiation therapy does not begin until approximately 4 months postoperatively, the mesh may be resorbed by that time.

## DIETARY SUPPLEMENTS AND RADIOPROTECTORS

The benefit of dietary supplements and radioprotectors is controversial. Five randomized trials have examined the efficacy of various compounds to decrease bowel toxicity. These trials have included such compounds as butyric acid to decrease chronic radiation proctitis,<sup>263</sup> sucralfate enemas to decrease acute radiation proctitis,<sup>264</sup> olsalazine to decrease acute enteritis, and mesalazine (5-aminosalicylic acid) to decrease acute radiation enteritis.<sup>265</sup> All of these randomized trials have been negative. In another randomized trial of 73 patients with pelvic malignancies, the addition of 5-aminosalicylic acid increased rather than decreased acute radiation toxicity. Diarrhea was more frequent in the radiation plus 5-aminosalicylic acid arm compared with radiation alone (91% vs. 74%,  $P = .07$ ).

In a phase II trial using an elemental diet, Craighead and Young<sup>266</sup> reported a decrease in acute enteritis in 17 patients with gynecologic cancer, but only 77% of the patients complied with the diet. McArdle et al. (1986) compared the results of an elemental diet in 24 patients with bladder cancer who received 4 Gy × 5 before cystectomy with a similar historical group of 32 patients who received a regular diet or total parenteral nutrition with the same therapy. A significant decrease was reported in the incidence and severity of diarrhea, nausea and vomiting, abdominal cramps, and the time to the recovery of small bowel function in the patients who received the elemental diet. The mechanism of protection of the mucosa by an elemental diet is unclear. Theories include a reduction of pancreaticobiliary secretion, the removal of abrasive bulk in the chyme, and a decrease in the rate of crypt cell turnover.

In a phase I/II study of 13 patients with chronic radiation proctitis, oral sodium pentosanpolysulfate resulted in a complete resolution of symptoms in 82% and a partial resolution in 9%. Although patients receiving pelvic radiation have reduced lactose absorption, the available data suggest that lactose-restricted diets do not prevent radiation-induced diarrhea. Stryker and Bartholomew<sup>267</sup> examined 64 patients undergoing pelvic radiation for various malignancies who were randomized to a regular diet, a regular diet including lactase enzyme, or a lactose-restricted diet. No significant differences were found in stool frequency or diphenoxylate usage among the three dietary groups.

Liu et al.<sup>268</sup> performed a randomized trial of pelvic radiation therapy (2.25 Gy per fraction to 45 Gy) with or without the radioprotector WR-2721 in patients with inoperable or unresectable rectal cancer. The incidence of RTOG long-term grade 3+ gastrointestinal, genitourinary, and skin toxicity was 3% in the radiation therapy alone arm compared with 0% in the radiation therapy plus WR-2721 arm. A separate trial by Montana and colleagues (1992) showed no benefit with a topical application of WR-2721 to the rectal mucosa. Based on these data, WR-2721 does not offer radioprotection in patients with rectal cancer who receive pelvic radiation therapy.

Patients with gynecologic malignancies who receive pelvic radiation therapy may have a lower long-term incidence of severe toxicity with increased caffeine consumption. One study suggested that sucralfate may decrease acute and long-term small bowel toxicity in patients receiving pelvic radiation therapy for prostate and bladder cancer.

In summary, all cancer therapies have associated toxicities. It must be emphasized that all patients receiving pelvic radiation therapy have acute treatment-related toxicity, and despite the use of careful treatment techniques, approximately 1% have severe long-term toxicity. These toxicities must be examined in perspective, because the benefits of radiation therapy include significantly decreasing local failure and, in the preoperative setting, sphincter preservation. This is all the more reason to pay careful attention to techniques, which help to decrease the acute and long-term toxicities of pelvic radiation.

The exclusion of small bowel from the treatment field is the most important factor in decreasing the toxicity. With the use of careful radiation techniques as well as physical and surgical methods, the toxicity can be reduced to an acceptable level. In patients who have not had prior pelvic surgery, preoperative radiation therapy (when delivered with conventional fractionation and multiple-field techniques) may have less toxicity compared with postoperative radiation therapy.<sup>220</sup> The results of the ongoing randomized trials of preoperative versus postoperative combined modality therapy for resectable rectal cancer (NSABP R-03 and CAO/ARO/AIO 94) will provide a more definitive answer. Unless a contraindication exists, the most simple techniques to decrease radiation toxicity, such as the use of small bowel contrast, multiple-field techniques, high-energy linear accelerators, custom blocks, avoiding a direct perineal boost, and treatment in the prone position, should be part of the standard treatment of patients receiving curative adjuvant radiation therapy.

## TREATMENT OF LOCALLY ADVANCED AND UNRESECTABLE RECTAL CANCER

A significant improvement in local control and survival can be achieved for patients with primary resectable (T3) rectal cancer with the use of combined modality therapy.<sup>83,177</sup> It is more difficult to obtain these results for locally advanced or unresectable cancers. For locally advanced or unresectable rectal cancers, collectively defined as T4 disease, no uniform determination of resectability has been established. Depending on the series, T4 disease can vary from a tethered or "marginally resectable" cancer to a fixed cancer with adherence or direct invasion of adjacent organs or vital structures. This definition has prognostic implications, because patients with gross invasion of tumor into vital pelvic structures may be approached in a palliative rather than a curative fashion. The definition of resectability also depends on whether the assessment is made by radiographic criteria, a clinical office examination, examination under anesthesia, or at the time of surgery. For example, tumors thought to be unresectable at the time of clinical or radiographic examination may be found to be more mobile when the patient is relaxed under anesthesia. Prognostic differences also exist between primary and recurrent tumors, and many series do not report the results separately. The heterogeneity of the disease and absence of a uniform definition of resectability may explain some of the variation in results seen among the series.

### TUMORS AMENABLE TO POTENTIALLY CURATIVE RADICAL SURGERY

Selected patients with primary unresectable disease may be cured with radical surgery, such as a pelvic exenteration. These include tumors invading the prostate, the base of the bladder, or the uterus, where the disease can be resected *en bloc* with negative margins.

### MULTIVISCERAL RESECTION FOR LOCALLY ADVANCED RECTAL CANCER

Approximately 6% to 10% of rectal cancers are locally advanced and require extensive surgery for complete tumor extirpation. Pelvic exenteration involving *en bloc* removal of the rectum, bladder, distal ureters, and reproductive organs can be required to obtain negative margins of resection.<sup>146</sup> A number of studies have demonstrated 5-year survival rates ranging from 33% to 50% for these selected patients with locally advanced rectal cancer. Despite the ability to achieve long-range survival rates in selected patients, the operation remains a formidable one, with significant morbidity and a mortality of up to 6%.<sup>60</sup> Patients who undergo such resections for primary tumors have better survival rates than those with recurrence.

In a report by Meterissian et al.,<sup>35</sup> a series of 40 patients undergoing pelvic exenteration for rectal carcinoma obtained tumor-free margins. The 5-year overall survival rate was 49% with a median survival of 56 months. Adjuvant chemoradiation appeared to provide a reduction in risk of recurrence. In the series, five patients developed local failure. Comparable results have been recorded by Lopez et al. (1987), Kraybill et al. (1988), and Boey et al. (1982). Long-term local control is obtained in approximately 70% of the patients who undergo resection with tumor-free margins. The results of such surgery cannot be separated from the benefits of adjuvant chemoradiation in this high-risk population.

Improved results from surgical procedures for rectal cancer requiring multivisceral resection have occurred in more recent years.<sup>61</sup> This finding may be related to improvements in perioperative care, patient selection, and surgical techniques. Of major importance in the management of such patients, who are often heavily radiated, is the use of vascularized tissue flaps to accomplish healing of pelvic and perineal wounds.<sup>62</sup>

Physical examination, CT scan, MRI, and cystoscopy all play a role in staging patients with locally advanced rectal cancer. Involvement of the sciatic notch indicated by symptoms or scans predicts a situation unlikely to be helped by surgery. With CT or MRI imaging, recurrent pelvic tumor, especially following an APR, is difficult to differentiate from scar. PET may offer a more accurate assessment.<sup>136</sup>

## RADIATION THERAPY

## Preoperative Pelvic Radiation Therapy

Because surgery commonly leaves residual disease in the pelvis in patients with locally advanced or unresectable disease, the standard approach has been to use preoperative pelvic radiation therapy. Given the increased complete response <sup>269</sup> and resection<sup>157</sup> rates when 5-FU-based chemotherapy is added to radiation in the preoperative setting, as well as the improvement in local control in the postoperative setting, most patients receive combined modality therapy. The goals of preoperative therapy are to convert an unresectable cancer to a resectable status and decrease the incidence of local failure.

The optimal use of preoperative radiation therapy requires full doses (45 Gy or more) and, to achieve optimal down-staging, a 4- to 6-week delay between the completion of radiation and surgery. This discussion is limited to those series that meet these criteria.

In a seminal report from the MGH of 25 patients with recurrent or primary unresectable cancer, a complete resection with negative margins was possible in 64% of patients after preoperative radiation therapy. Despite negative margins, the incidence of local failure was 38%. The nine patients who were unable to undergo a complete resection were dead of disease within 28 months.

The British Medical Research Council completed a randomized trial of preoperative radiation therapy (40 Gy in 20 fractions) versus surgery alone for 279 patients with clinical T4 primary rectal cancer.<sup>193</sup> Patients who received preoperative radiation had a significant decrease in local failure (36% vs. 46%,  $P = .04$ ) and distant failure (35% vs. 48%,  $P = .02$ ). An improvement was noted in median survival (31 months vs. 24 months,  $P = NS$ ), but no difference in survival was reported (32% vs. 28%). The 36% local failure rate after preoperative radiation is consistent with the MGH data and supports the need for additional treatment, such as intraoperative radiation therapy (IORT).

As one would predict, the results of the patients with primary disease are more favorable than those with recurrent disease. In the MGH series, the rate of complete resection with negative margins was 59% for patients with primary cancers<sup>270</sup> compared with 44% of those with recurrent cancers.<sup>271</sup> Limiting the analysis to the most favorable group of patients with primary cancers and negative margins, the 5-year actuarial local failure rate was 29%, and the disease-free survival rate was 60%. Therefore, even in the most favorable group of patients (primary cancer and negative margins), local failure is still almost 30%. At the University of Florida, in the 48% of patients who were able to undergo a complete resection with negative margins, the local failure rate was 55% and the 5-year determinate survival rate was 20%.<sup>272,273</sup> Tobin and colleagues<sup>274</sup> reported a local failure rate of 20% and a 5-year survival rate of 60% in 85 patients treated with preoperative radiation. At Memorial Sloan-Kettering Cancer Center, 58% of patients underwent a complete resection with negative margins after preoperative radiation, and the local failure rate was 25%.

Tethered cancers have the most favorable outcome of all T4 cancers. In a separate report from the MGH, the results of 28 patients with tethered rectal cancers treated with preoperative radiation were presented.<sup>275</sup> Tethered was defined as the sensation on the examining finger of partial tumor mobility consistent with extensive perirectal spread and adherence but not fixation to unresectable structures. Although a complete resection with negative margins was possible in 93%, the local failure rate was 24%. Tobin et al.<sup>274</sup> report a local failure rate of 14% and 5-year survival rate of 68% in 49 patients with tethered cancers treated with preoperative radiation.

In summary, after full-dose preoperative radiation, most series report that 48% to 64% of patients are converted to a resectable status. However, despite a complete resection and negative margins, the local failure rate varies, depending on the degree of tumor fixation, from 24% to 55%.

## IMPROVING THE RESULTS OF PREOPERATIVE RADIATION THERAPY

A major limitation of pelvic radiation therapy is that the dose required to achieve an adequate level of local control, in many cases, exceeds the tolerance of the surrounding normal tissues. In an attempt to improve the results of preoperative radiation, a number of approaches have been used. The most promising have included IORT and the addition of systemic chemotherapy.

### Intraoperative Radiation Therapy

The primary advantage of IORT is that radiation can be delivered at the time of surgery to the site with the highest risk of local failure (the tumor bed) while decreasing the dose to the surrounding normal tissues. IORT can be delivered by two techniques: electron beam and brachytherapy. With the electron-beam technique, the radiation is delivered by a linear accelerator and, with the use of a cone, is directed to the tumor bed. When the IORT is finished, the cone is removed and the surgery is completed.

Brachytherapy is delivered with both low-dose and high-dose techniques. The low-dose method involves implantation of radioactive sources, with either removable <sup>192</sup>Ir-afterloading catheters or iodine 125 or palladium 103 permanent seeds.<sup>276</sup> The permanent seeds can be sutured or implanted directly into the tumor. As an alternative, they can be placed in a Dexon mesh that is then sutured to the tumor bed.<sup>277</sup> Most of the low-dose brachytherapy experience has been in patients with gross residual disease. It also has been used as an alternative to electron-beam IORT in patients with negative margins.<sup>278</sup> High dose-rate brachytherapy uses a flexible multichannel applicator that conforms to the tumor bed. The applicator is positioned, and an <sup>192</sup>Ir source is programmed to deliver a uniform dose to the area at risk using a similar dose rate to electron-beam IORT.<sup>278,279</sup>

The results of IORT depend on whether the patient has primary unresectable or recurrent disease and whether the margins of resection are negative or whether microscopic or gross residual disease is present. This discussion is limited to patients who, in general, receive preoperative pelvic radiation with or without 5-FU-based chemotherapy. Most receive 45.0 to 50.4 Gy to the pelvis and 10 to 20 Gy IORT with either electrons or high dose-rate with a flexible applicator. The lower IORT dose is used for patients with negative margins, and the higher doses are used for patients with microscopic or gross residual disease.

### Primary Unresectable Disease

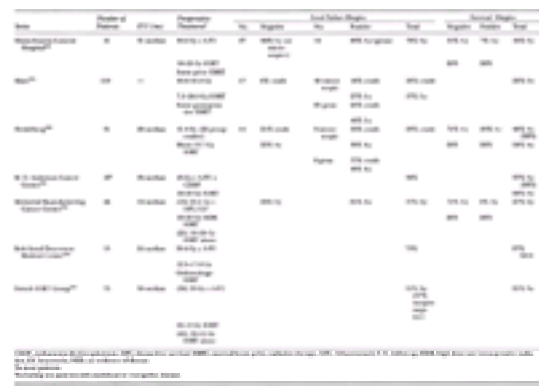

The largest experience and longest median follow-up in preoperative therapy followed by IORT has been reported from the MGH.<sup>280</sup> As seen in Table 33.8-15, for patients with negative margins, local failure is decreased from 18% without IORT to 11% with IORT. In patients with positive margins, local failure is decreased from 83% without IORT to 43% with IORT if gross residual disease is present and to 32% with IORT if microscopic residual disease is present. For the total patient group (with or without IORT), the 5-year disease-free survival rate was 63% for patients with negative margins and 32% for patients with positive margins. These results underscore the importance of delivering preoperative therapy to help achieve the most complete resection possible. If negative margins cannot be obtained, then microscopic residual is still preferable to gross residual. Series from the Mayo Clinic<sup>281</sup> and Memorial Sloan-Kettering Cancer Center<sup>278</sup> report similar local failure rates in patients with negative margins (7% and 8%, respectively). The results of other series from Munich,<sup>279</sup> Heidelberg,<sup>282</sup> and the Beth Israel Deaconess Medical Center<sup>283</sup> are seen in Table 33.8-15.

Author	Year	No. of Patients	Preoperative Radiation (Gy)	IORT (Gy)	Local Failure (%)	Distant Failure (%)	5-Year Survival (%)

TABLE 33.8-15. Primary Locally Advanced or Unresectable Rectal Cancer with and without Intraoperative Radiation (IORT): Selected Series

## Recurrent Disease

In the setting of recurrent disease, the largest experience with IORT is from the Mayo Clinic.<sup>284</sup> In contrast with the series of patients treated for primary unresectable disease, those with recurrent disease have less uniform treatment programs, including some who have received prior pelvic radiation<sup>284,285</sup> and some treated with IORT alone.<sup>278</sup> Selected series in which all patients received IORT are seen in [Table 33.8-16](#).

**TABLE 33.8-16.** Role of Intraoperative Radiation (IORT) in Recurrent Rectal Cancer: Selected Series

At the Mayo Clinic, 119 patients received, in general, 50.4 to 54.0 Gy preoperatively followed by 7.5 to 20.0 Gy electron-beam IORT.<sup>284</sup> The higher IORT doses were used for patients with residual disease. For patient with negative margins, the crude local failure rate was 6%, which increased to 18% for microscopic and 25% for gross residual disease. The 5-year actuarial local failure rates were 27% for microscopic disease and 45% for gross residual disease. For the total patient group, overall 5-year survival was 20%. The M. D. Anderson Cancer Center,<sup>286</sup> Memorial Sloan-Kettering Cancer Center,<sup>278</sup> and the French IORT group reported similar local failure rates for the total patient group (36%, 37%, and 31%, respectively). In one series of 25 patients selected to receive IORT, the 5-year survival rate was 21%.<sup>287</sup> In contrast, the results from the MGH were not as favorable.<sup>285</sup> They reported an 89% 5-year actuarial local failure rate for patients with gross residual disease and 70% for the total patient group. The 5-year disease-free survival rate was 21% for patients with negative margins and only 7% for those with positive margins. Memorial Sloan-Kettering reported no survivors at 2 years with positive margins,<sup>278</sup> whereas in the Heidelberg series, the 4-year disease-free survival rate was 29%.<sup>288</sup> In contrast to patients with recurrent disease who have negative or microscopic positive margins, it is unclear if those with positive margins benefit from aggressive therapy.

### Complications of Electron-Beam Intraoperative Radiation Therapy

Initial reports of neuropathy, vasculitis, bone necrosis, and ureteral injury in dogs who received IORT have been described.<sup>164,165</sup> In two series, hyperthermia increased the neurologic complication of IORT.<sup>289</sup> In canines, IORT-induced secondary malignancies are seen in 15%, with most occurring with doses of more than 25 Gy.<sup>290</sup>

As the IORT data have matured, similar morbidity has been reported in humans. The incidence of toxicity depends on whether the patient has primary or recurrent cancer. In the MGH IORT experience, the incidence of complications was higher in those with recurrent disease (10%, soft tissue or sacral injury; 10%, pelvic neuropathy) compared with primary disease (2%, sacral necrosis or ureteral obstruction).<sup>270,271</sup>

Higher complication rates have been reported from the Mayo Clinic.<sup>291</sup> In patients with primary or recurrent colorectal cancer, the incidence of peripheral neuropathy was 32%. The symptoms of pain, numbness, and tingling resolved in 40% of patients, but only 13% had resolution of weakness. Ureteral obstruction or hydronephrosis were seen in 63% of patients who did not have evidence of ureteral obstruction at presentation. Although no relationship was found between the incidence of complications and the external-beam dose, the incidence of complications increased with the IORT dose.

In contrast to patients who undergo adjuvant therapy for resectable rectal cancers, it is difficult to clearly separate treatment-related complications from disease-related complications in patients with recurrent rectal cancers. Complications such as delayed healing, infection, fistula, and neuropathy may be the result of recurrent tumor, aggressive surgery, radiation, or a combination of these. The 2-year actuarial risk of significant complications in the 42 patients with advanced or recurrent rectal cancer who received IORT as a component of their therapy in the RTOG 85-08 trial was 16%.<sup>292</sup> However, compared with a nonrandomized group who underwent surgery without IORT, no significant increase was found in acute surgical complications in the IORT patients.<sup>293</sup>

In summary, the phase I/II data suggest that the addition of IORT to preoperative radiation therapy improves local control compared with preoperative radiation therapy alone. The results in the subset of patients with recurrent cancer or residual disease are not optimal. No phase III trials of IORT are in progress.

### Preoperative Combined Modality Therapy

The encouraging results seen in patients with resectable rectal cancer who receive adjuvant postoperative combined modality therapy<sup>83,177</sup> have resulted in a shift to preoperative combined modality therapy. A number of potential advantages to such therapy exist. First, nonrandomized data from Minsky et al. (1992) suggest that the patients are able to tolerate higher chemotherapy doses and experience significantly lower acute toxicity compared with postoperative combined modality therapy.

Second, in patients with unresectable disease, the addition of chemotherapy to preoperative radiation therapy increases the down-staging and resectability rates.<sup>269</sup> Frykholm et al.<sup>294</sup> reported an enhanced resectability rate in patients with unresectable rectal cancer who received preoperative radiation therapy, 5-FU, methotrexate, and leucovorin rescue compared with 38 patients who received radiation alone (71% vs. 34%). Enhanced resectability is important, because patients with initially unresectable rectal cancer who have microscopic or gross residual disease have higher local failure rates and lower survival rates compared with those patients who undergo a complete resection.<sup>280,284,295</sup>

The third advantage is that the start of systemic therapy is not delayed, the metastatic burden is the smallest, and few drug-resistant cells are likely to be present.<sup>296</sup> The fourth advantage is sphincter preservation.

A number of phase I/II trials of preoperative combined modality therapy for patients with T4 disease have been conducted.<sup>279,280,282,283,284,285</sup> and <sup>286,288,295,297,298,299</sup> and <sup>300</sup> Some include patients with T3 disease, thereby making interpretation of the local control and survival results difficult.<sup>151,159,273</sup> The majority have used 45.0 to 50.4 Gy plus two cycles of concurrent 5-FU-based chemotherapy, with bolus 5-FU plus leucovorin or continuous infusion 5-FU, followed by surgery and an additional four cycles of postoperative chemotherapy. Some have used methotrexate<sup>160</sup> or interferon.<sup>301</sup> Marsh et al.<sup>273</sup> have combined chronobiologically shaped 5-FU infusion with preoperative radiation therapy. Trials examining the use of newer chemotherapeutic agents, such as raltitrexed (Tomudex),<sup>161,162,302</sup> Orzel (oral tegafur, uracil, and 5-fluorouracil plus leucovorin),<sup>163</sup> CPT-11,<sup>164,165</sup> and oxaliplatin, with preoperative radiation therapy are in progress.

## INTRAOPERATIVE OR POSTOPERATIVE RADIATION THERAPY FOR RESIDUAL DISEASE

For a variety of reasons, some patients with locally advanced or unresectable cancer do not receive preoperative radiation therapy or, despite a preoperative assessment of resectability, are not able to undergo a complete resection. In this setting, does IORT or postoperative pelvic radiation therapy have any benefit? As previously discussed, the interpretation of treatment results is complicated, because many studies combine patients with primary and recurrent cancers as well as

those with gross and microscopic residual disease. Patients are randomly selected to receive chemotherapy, and some series include patients with metastatic disease. This discussion is limited to those series in which patients have disease limited to the pelvis.

Likewise, for patients who have been unsuccessful with prior pelvic radiation, the options are limited. The standard therapy is usually palliative surgery or systemic chemotherapy. The response rate with chemotherapy may be reduced in a pelvis that has received full-dose radiation. Is there a role for more aggressive treatment? A variety of radiotherapeutic options for patients who have been unsuccessful with prior pelvic radiation are available and are listed in [Table 33.8-17](#). Although these are investigational approaches in selected patients, they may offer an improvement in local control.

Series	Number of Patients	Treatment	Median (IQR) (mo)	Stages	5-Year Actuarial Survival	Survival
Thomas Jefferson University <sup>303</sup>	25	Preoperative 50-Gy external beam + surgery	38	—	33%	245 to 476 mo
USC/Mem <sup>304</sup>	38	Surgery and brachytherapy	27	29 gross 9 microscopic	42%	295 to 323 mo
Mem <sup>304</sup>	38	Surgery and IORT	38	—	35%	405 to 411 mo
Ohio State <sup>304</sup>	39	Surgery and IORT	38	—	37%	365 to 475 mo
Memorial Sloan-Kettering Cancer Center <sup>304</sup>	38	Surgery and brachytherapy	31	Gross	41%	235 to 411 mo
Memorial Sloan-Kettering Cancer Center <sup>304</sup>	48	IORT + IORT + surgery	33	—	37%	479 to 481 mo

 \*Data are 5-year survival.  
 †Includes 14 patients who received preoperative radiation who did not receive postoperative radiation.

**TABLE 33.8-17.** Failure after External Beam Radiation: Aggressive Surgical and Radiotherapeutic Options

### SUBTOTAL RESECTION AND POSTOPERATIVE RADIATION THERAPY

At the Mayo Clinic, 17 patients with rectal cancer received postoperative radiation therapy (40 to 60 Gy).<sup>303</sup> Six received concurrent 5-FU–based systemic chemotherapy. For the total patient group, local failure was 76% and 5-year actuarial survival was 24%. The seven patients with gross residual disease had higher local failure (86% vs. 70%) and lower survival (14% vs. 30%) compared with the ten patients with microscopic residual disease. No clear dose-response curve emerged, but only one patient received 56 Gy or more.

In a separate report from the Mayo Clinic, the results of 106 patients who underwent a palliative (subtotal) resection for locally recurrent rectal cancer were presented.<sup>304</sup> 5-FU was delivered in 48%. In the subset of 34 patients with gross residual disease who received IORT and postoperative therapy, the 3-year survival rate was 44%. However, despite the encouraging survival rate, 40% developed local failure and 60% developed distant failure. Univariate analysis revealed a significant improvement in survival in those patients with microscopic compared with gross residual disease, the use of IORT, a limited number of sites of tumor fixation, and higher performance status. These data suggest that, even in patients with locally recurrent residual disease, an aggressive approach should be considered.

Other reports have included patients with both rectal and colon cancers as well as patients with both primary and recurrent disease. At the MGH, patients received somewhat higher doses of radiation (60 to 70 Gy) compared with the Mayo Clinic external-beam therapy alone series.<sup>305</sup> Seven patients received electron-beam IORT. For the total group, local failure was 42% and the 5-year disease-free survival rate was 18%. The 23 patients with gross residual disease had a higher local failure rate (57% vs. 30%) and a significant decrease in survival (4% vs. 42%) compared with the 30 patients with microscopic residual disease. The improvement in local control compared with the Mayo Clinic external-beam therapy alone series may have been related to the higher radiation doses. No clear dose-response curve was noted in patients with gross disease, but patients with microscopic residual disease who received less than 60 Gy did have a higher incidence of local failure compared with those who received 60 Gy or more (38% vs. 26%).

Another factor that may have an impact on the local failure rate is the volume of gross residual disease. As seen in [Table 33.8-15](#) and [Table 33.8-16](#), this is consistent with the experience from the MGH<sup>280,285</sup> and the Mayo Clinic<sup>284,295</sup> IORT series, in which patients with gross residual disease had lower survival and higher local failure rates compared with patients with microscopic residual disease.

The dose of radiation needed to treat potential microscopic disease (after a complete resection) is 45.0 to 50.4 Gy, which is within the tolerance of the surrounding normal tissues. However, when microscopic or gross biopsy-proven residual disease is present (after a subtotal resection), the dose of required radiation is higher. Even in situations in which the small bowel can be excluded from the external-beam radiation field, other surrounding normal tissues limit the dose to 60 to 65 Gy, which may be inadequate to control large volumes of gross residual tumor. Therefore, it is not surprising that the results for patients with residual disease who receive postoperative radiation therapy are disappointing. The obvious advantage of preoperative therapy is that it decreases the primary tumor volume, thereby allowing maximum surgery and IORT.

### REIRRADIATION FOLLOWED BY SURGERY

In patients with a local recurrence who have received prior pelvic radiation, Lingareddy et al.<sup>94</sup> reported the use of reirradiation in a selected group of 39 patients. They received a median dose of 36 Gy using limited lateral fields plus continuous infusion 5-FU. The whole pelvis was not treated, and the bladder and small bowel were excluded as much as possible from the radiation field. With a median follow-up of 3 years, the 5-year actuarial local failure rate was 55% and survival was 24%. In highly selected patients, retreatment with limited fields may be an option; however, this approach should be considered experimental.

### EXTERNAL-BEAM RADIATION THERAPY ALONE

Patients selected for radiation therapy alone are usually medically inoperable or have very advanced local disease such that resection would compromise a vital structure. This approach has been previously discussed in the section [Radiotherapy Alone for Rectal Cancer](#)<sup>93,94</sup> and <sup>95,105</sup> (see [Table 33.8-6](#)).

### POSTOPERATIVE RADIATION THERAPY AND CHEMOTHERAPY

Two randomized trials of postoperative combined modality therapy versus radiation alone have been conducted in patients with medically inoperable or advanced local disease. In the RTOG trial, 129 patients with residual, primary unresectable, or recurrent rectal cancer were randomized to radiation therapy plus concurrent 5-FU followed by maintenance 5-FU plus methyl CCNU versus radiation therapy alone. Some patients received IORT. No significant difference was reported in the estimated actuarial 2-year survival rate in patients who received combined modality therapy compared with radiation therapy alone (44% vs. 36%). Of the patients with gross residual disease (in either arm), 25% were without evidence of disease, 6% were locally controlled, and 50% died with a component of local failure.

The Eastern Cooperative Oncology Group randomized 30 patients with recurrent, residual, or primary inoperable rectal cancer to postoperative continuous course radiation therapy versus split course radiation therapy plus 5-FU followed by maintenance 5-FU plus methyl CCNU. The median survival in both arms was 17 months. The five patients with primary inoperable cancer (considered gross residual) had the shortest 2-year survival rate (0%), compared with the 16 patients with recurrent disease (25%) or the nine with residual disease (54%).

Therefore, postoperative combined modality therapy, as delivered in these two randomized trials, did not have a significant impact on survival compared with postoperative radiation therapy alone in this subset of patients. Other chemotherapeutic agents and schedules are being investigated.

### INTRAOPERATIVE RADIATION THERAPY ALONE FOR GROSS RESIDUAL DISEASE

A subset of patients with recurrent rectal cancer have clinically unresectable gross residual pelvic disease and, because of prior full-dose pelvic radiation therapy, would require an attempt at resection without the benefit of pre- or postoperative radiation therapy, or both. Furthermore, when IORT is not available, this group of

patients is commonly approached in a palliative fashion, because surgery alone cannot control gross residual disease.

The results of 36 patients with recurrent rectal cancer who had gross residual disease remaining in the pelvis after biopsy alone or subtotal resection were reported by Minsky et al.<sup>276</sup> from the Memorial Sloan-Kettering Cancer Center. With a median follow-up of 24 months, the local failure rate was 44% and the 4-year actuarial survival rate was 25%. The local control rate was dependent on the volume of residual disease. With brachytherapy, the tumor volume is proportional to the volume of the implant. The local failure rate was lower in those patients who underwent subtotal resection compared with a biopsy alone (33% vs. 66%), and in those with an <sup>125</sup>I implant volume of less than 40 cm<sup>3</sup> compared to 40 cm<sup>3</sup> or more (39% vs. 100%). Severe treatment-related complications were seen in 11% of locally controlled patients.

The experience with electron-beam IORT in this group of patients is more limited. Calvo et al.<sup>306</sup> reported a subgroup of five patients with gross residual or recurrent colorectal cancer who received 10- to 80-Gy electron-beam IORT. All tumors were larger than 4 cm. With a median follow-up of 11 months, the incidence of local failure was 40%. Complications included pelvic abscess (in one patient), pelvic pain (in two), and lower extremity neuropathy (in one). The more recent trial by Martinez-Monge and associates<sup>137</sup> included patients with extrapelvic disease; therefore, it is not discussed.

In summary, the limited data suggest that IORT with electrons or brachytherapy does not improve the ultimate survival rate in this group of patients. However, it does offer reasonable local control (56% to 60%) with acceptable morbidity. Because local control, in and of itself, is an important end point in the treatment of rectal cancer, it is appropriate to continue to evaluate IORT as part of an overall aggressive approach in patients with residual disease who are unable to receive pelvic radiation therapy.

## INVESTIGATIONAL RADIATION THERAPY APPROACHES

A number of investigational radiation therapy approaches have been used in an attempt to enhance the treatment results in patients with both resectable and unresectable rectal cancers and other pelvic malignancies. These include neutron beam radiation, hyperthermia, radiosensitizers, and altered radiation fractionation schemes. Radioprotectors<sup>263,264</sup> and<sup>265,268</sup> (discussed earlier in [Dietary Supplements and Radioprotectors](#)) and three-dimensional treatment planning<sup>255</sup> (discussed earlier in [Three-Dimensional Radiation Treatment Planning](#)) already have been described.

### NEUTRON BEAM RADIATION THERAPY

The theoretical advantages of neutrons compared with more conventional radiation include increased sensitivity of hypoxic cells and more advantageous radiation repair and sensitivity characteristics of normal tissues. The results of two randomized trials that have compared neutrons and photons in patients with unresectable and recurrent rectal cancers were reported by Duncan et al.<sup>307</sup> A total of 35 patients received neutrons using a variety of techniques and doses. Not only were no significant differences in local control or survival detected, but patients who received neutrons experienced higher acute and long-term grade 3+ skin toxicity. The preferential absorption in fat of neutrons may have contributed to the complications seen in the skin and subcutaneous tissues. Similar severe and fatal complications were reported in a series of 25 patients with advanced rectal cancer treated by Battermann et al. (1982). Despite the theoretical advantages, little interest has been shown in the treatment of rectal cancer with neutrons.

### HYPERTHERMIA

Hyperthermia, in conjunction with radiation, has been mostly used as a palliative modality in rectal cancer.<sup>308,309,310,311</sup> and<sup>312</sup> Its rationale is based on an *in vitro* synergistic interaction of radiation and hyperthermia. The results of this combination in patients with various pelvic and abdominal malignancies has been reported in a phase I/II trial by the RTOG.<sup>313</sup> The acute and long-term toxicities were acceptable; however, in 68% of the patients, the hyperthermia had to be discontinued because of discomfort. Final results are pending. Hyperthermia has been reported to increase the neurologic complications of patients receiving IORT.<sup>289</sup>

### RADIOSENSITIZERS

Randomized clinical trials in rectal cancer have clearly shown that 5-FU is a radiosensitizer. When combined with adjuvant postoperative radiation therapy, it significantly decreases local failure compared with radiation therapy alone.<sup>83,177</sup> Various mechanisms for 5-FU-mediated radiosensitization have been proposed, but none alone explain all the interactions.<sup>314</sup> Nonrandomized data from Rhomberg et al.<sup>315</sup> suggest that razoxane may improve local control and median survival in patients who receive radiation for inoperable recurrent rectal cancer. Other trials of radiosensitizers have not revealed a clear benefit.

### ALTERED RADIATION FRACTIONATION SCHEMAS

Various fractionation programs have evolved with the goal of enhancing tumor cell damage by radiation without increasing normal tissue injury. The repair of subcellular injury, regeneration, cell-cycle redistribution, and reoxygenation are all factors at the cellular level contributing to differences in how various normal tissues and tumors respond to fractionated radiation. The use of hyperfractionation and accelerated fractionation schemes take advantage of some of these factors. The late effects should be the same as or, more likely, less than conventional fractionation schemes. A phase I trial from Lausanne of postoperative accelerated hyperfractionation (1.6 Gy twice a day to 48 Gy) reported acceptable acute toxicity.<sup>316</sup> Updated data from this group suggests that twice daily radiation is better tolerated when delivered preoperatively rather than postoperatively.<sup>317</sup> Bozzetti et al.<sup>318</sup> reported a pathologic complete response rate of 9% in 59 patients with ultrasound stage T2–3 disease who preoperatively received 1.5 Gy twice a day to 45 Gy. This rate was lower than the 14% pathologic complete response rate in 36 patients with ultrasound stage T2–3 disease who received 50.4 Gy with conventional 1.8-Gy fractions at the Memorial Sloan-Kettering Cancer Center.

The major limitation of accelerated hyperfractionation is acute normal tissue toxicity. Because it is unlikely that these altered fractionation schemes can be combined with adequate doses of systemic chemotherapy, Movsas and colleagues<sup>298</sup> have limited the hyperfractionated portion to the boost. In their phase I trial of preoperative combined modality therapy, patients receive conventional pelvic radiation plus continuous infusion 5-FU followed by a boost with escalating doses of hyperfractionated radiation (1.2 Gy twice a day).<sup>298</sup> Providing that the small bowel was excluded after 52.3 Gy, the recommended dose level with this approach was 61.8 Gy.

In a randomized trial of patients receiving radiation therapy for pelvic malignancies, three-dimensional conformal radiation therapy decreased the volume of normal tissue in the field, but did not decrease acute toxicity.<sup>255</sup> Other techniques, such as neutron beam radiation, hyperthermia, radiosensitizers, radioprotectors, altered radiation fractionation schemes, and proton and three-dimensional treatment planning, are encouraging but remain experimental.<sup>107</sup>

## TREATMENT OF PATIENTS WITH SYNCHRONOUS METASTATIC DISEASE

A subset of patients present with unresectable pelvic disease and synchronous extrapelvic disease. Because the natural history of these patients is dependent on a variety of factors, such as the volume and site(s) of metastatic disease and, in those with recurrent disease, the disease-free interval, treatment recommendations are individualized and no standard of care has been established. The management of these patients is discussed in greater detail in [Chapter 52.3](#). At Memorial Sloan-Kettering, the general approach is to deliver preoperative combined modality therapy both as a therapeutic measure and to help identify those who may benefit from an aggressive surgical approach. If after the completion of therapy a response has been seen in both the primary and metastatic site(s), then the patient is evaluated, on a case by case basis, for surgery of the primary and metastasis.

## FOLLOW-UP AFTER POTENTIALLY CURATIVE TREATMENT

Patients should follow up with their primary treatment team after curative treatment for many reasons. An important aspect of this follow-up is management of treatment-related problems and assessment for local-regional recurrences. These may have an impact on quality of life that is not apparent from survival statistics. Dietary modifications, including the use of a fiber supplement, may be necessary for management of bowel function. Antidiarrheal agents frequently are required. This management can occur on an ongoing basis during follow-up, because these symptoms are most profound during the initial year after treatment and tend to abate during the latter part of the follow-up period. In addition, patients who undergo creation of ostomies for their colorectal cancer management benefit from consultation with an enterostomal therapist. Counseling and appropriate referral for the management of sexual or bowel dysfunction can occur during follow-up visits.

## TREATMENT OF RECURRENCE

Management of recurrent disease is individualized. The treatment is based on the extent of recurrence as well as the patient's overall potential for curative therapy and their medical condition. In most patients, recurrent disease is multifocal and treated with systemic chemotherapy. Highly selected patients can be considered for operative therapy. Others with an unresectable recurrence may need palliation. A chief symptom requiring palliation in patients with recurrent rectal carcinoma is obstruction. The use of salvage surgery for recurrence after local excision is presented in [Recurrent Disease](#), earlier in this chapter. The use of surgery for lung metastases or hepatic metastases is discussed in [Chapter 52.2](#) and [Chapter 52.3](#), respectively.

## PALLIATION OF OBSTRUCTION DUE TO LOCALLY RECURRENT RECTAL CANCER

In patients with synchronous metastatic disease, the management of rectal obstruction can make use of a number of techniques that can help avoid palliative colostomy. Frequently, patients in this circumstance are markedly debilitated and very poor surgical risks. These circumstances often make the risks of surgical intervention prohibitive, especially in light of the limited potential for survival. Palliative pelvic irradiation is a useful technique in patients who have not undergone previous radiotherapy. Palliative endoscopic placement of self-expanding metallic stents has also been used as an alternative to palliative colostomy. Success rates can be high with stenting. In a majority of patients, this technique results in the successful placement of the stent. Many have no further complications from their obstruction for a period of 1 to 7 months after stent placement.<sup>319</sup> For those in whom stent placement is unsuccessful, palliative colostomy can be performed. Neodymium:yttrium-aluminum garnet laser treatment also can be highly successful in relieving obstruction.<sup>320</sup>

## SURGERY FOR LOCALLY RECURRENT RECTAL CANCER

Among patients with failure after curative treatment of rectal carcinoma, between 10% and 30% of recurrences are confined to the pelvis. The absence of metastatic disease is one of the key factors in determining a patient's potential for curative surgical resection for locally recurrent disease. Local recurrences of rectal cancer tend to be highly symptomatic, with pelvic pain, rectal obstruction, bleeding, urinary tract dysfunction, and fistulas.

## LOCATION OF RECURRENCE

Localized pelvic recurrences may be classified based on the tumor location within the pelvis. Recurrences can be heterogeneous, and the pattern of extension of local recurrence is much more infiltrative within the previous operative bed than primary rectal cancers. They tend to be in perianastomotic tissues and more frequently involve adjacent organs.<sup>321</sup> Axial recurrences appear centrally in the pelvis. These may include anastomotic recurrences after local or radical surgery. Anteriorly based recurrences in the pelvis chiefly involve the seminal vesicles and prostate in men and the vagina and uterus or bladder in women. Posterior recurrences tend to predominantly involve the sacrum and may extend into the piriformis muscle, the sciatic notch, and sciatic nerve. Lateral recurrences can involve the soft tissues of the pelvic sidewall and the iliac blood vessels and lymph nodes, as well as the obturator internus muscles and the piriformis muscles. Recurrences may extend into the bony sidewalls of the pelvis.

## EVALUATION OF THE PATIENT WITH LOCALLY RECURRENT RECTAL CANCER

The preoperative workup of a patient with a suspected local rectal cancer recurrence involves assessment of both the presence of extrapelvic metastatic disease and a determination of the extent of the local recurrence. Under certain circumstances, intraoperative exploration may be required to reveal an unresectable recurrence; however, it is best to avoid this procedure because of morbidity without improvement in survival.

When patients present with locally recurrent rectal cancer, they usually are symptomatic. These symptoms may range from cramping or constipation from bowel obstruction to pelvic or sciatic pain to dysuria and urinary tract dysfunction. Important examinations are pelvic examination in females, digital rectal examination, proctoscopy, and cystoscopy. Examination of the inguinal lymph nodes in patients with a previous low rectal cancer can detect lymph node recurrence.

## IMAGING PATIENTS WITH LOCAL RECURRENCE

When presented with a patient having locally recurrent rectal carcinoma, staging of the abdomen and pelvis, either with CT or MRI, and imaging of the pulmonary fields with chest x-ray is required. These tests do an excellent job of identifying patients with visceral metastases; however, peritoneal implants may be missed until surgery is done.

The operative approach is determined by the extent and location of the recurrence. Specific questions can be asked from pelvic imaging studies, such as MRI or CT, that help to determine resectability and the procedure required. These questions pertain to (1) sacral nerve root involvement and the level at which this involvement occurs; (2) invasion of the sciatic nerve or lumbosacral plexus; (3) extension outside the pelvis through the sciatic notch or levators; and (4) involvement of seminal vesicles or prostate and bladder in men and involvement of vagina, cervix, and bladder in women. Although EUS can aid in the assessment of local recurrence, it is limited because of the postoperative changes seen around a rectal anastomosis. CT scan identifies distant metastases as well as the extent of pelvic involvement. However, postoperative or postradiation chemotherapy changes may lead to fibrosis, making it indistinguishable from recurrence. CT scanning sensitivity for detecting pelvic recurrences is between 70% and 82%.<sup>322 323 and 324</sup> CT scans can also identify potential sites for fine-needle aspiration biopsies of suspected areas of recurrence. MRI studies can be useful in evaluating the extent of local recurrence and in planning operative therapy. MRI appears to be especially useful in determining neurologic and sacral involvement and planning for the resections of these structures.

Nuclear imaging has been reported to be useful in the pretreatment evaluation of patients with recurrent colorectal cancer. It can identify sites of occult metastatic disease that would make pursuit of an extensive resection fruitless. Although nuclear imaging studies frequently lack the anatomic definition necessary to enhance the determination of the local extent of disease, their ability to exclude patients with clinically undetectable metastatic disease may be of value.<sup>325</sup> A further discussion of this topic is found in [Chapter 33.7](#).

PET is a technique that has been used in conjunction with the glucose analogue [<sup>18</sup>F]fluorodeoxyglucose to image colorectal cancers. Accuracy in detecting sites of recurrent colorectal cancer has been reported to approach 83% in patients with recurrent colorectal cancer.<sup>188</sup> PET whole body scanning has provided additional information beyond conventional imaging.<sup>326</sup>

## SURGERY FOR RECURRENCE

In patients taken to the operating room for locally recurrent rectal cancer, cystoscopy and bilateral ureteral stent placement should be performed to facilitate subsequent evaluation and to allow the operation to proceed with alacrity. Thorough exploration of the abdominal cavity should be carried out to assess for evidence of metastatic disease. Specific sites to be examined are the peritoneal surface, omentum, retroperitoneal lymph nodes, and liver. If metastatic sites are found, then consideration can be given to palliative management, such as colostomy or urologic diversion.<sup>327</sup> Patients with perianastomotic recurrence should undergo resection to achieve negative margins. In most cases, this involves an APR. In perineal recurrences after APR, patients should undergo wide excision. It should be noted, however, that the tumor presenting at the level of the perineal skin is often a small component of the overall pelvic recurrence. Most of these cases require extensive soft tissue reconstruction for adequate closure of the excision site. Recurrences that involve adjacent structures may require pelvic exenteration to achieve negative margins. Multiple organs may be adherent to the site of the recurrence, and these should be resected *en bloc* to avoid violation of the recurrent tumor. This requires development of planes outside the normal anatomic planes used for resectable lesions. Removal of nodal disease along the internal iliac artery and wide excision of the pelvic floor is required.

In patients with a posterior extension of pelvic recurrence, sacrectomy can be required in combination with the pelvic visceral resection. When there is limited distal sacral and coccyx involvement, this can be resected *en bloc* with the pelvic viscera resected through an abdominal and perineal approach. If more extensive sacral involvement is present, the patient can undergo a combined abdominal, perineal, and posterior approach for formal sacrectomy.<sup>328 329</sup> Vascular ligations of the internal iliac vessels and nodal resection below this level are carried out through the abdominal approach as well as the division of any remaining rectal segment and division of the ureters and construction of an ileal conduit.<sup>330</sup> The patient can then be turned into a prone position for subsequent resection of the perineal soft tissues, laminectomy, and ligation of the dural sac followed by *en bloc* removal of the pelvic tissues.<sup>331</sup> Patients with extensive pelvic sidewall involvement can undergo extended lateral resections to include obturator and internal iliac nodes as well as surrounding pelvic soft tissues. Areas of close margins can be treated with IORT or

brachytherapy techniques.<sup>300,332</sup> Patients who undergo such extensive soft tissue resections in the irradiated pelvis require soft tissue reconstruction with a rectus abdominus myocutaneous flap or gracilis flap to provide for an adequately healed or vaginal reconstruction wound and to minimize complications of pelvic sepsis and bowel obstruction.<sup>333</sup>

## INTRODUCTION

Anal cancers, while still uncommon tumors, have increased substantially in incidence since the 1980s.<sup>1</sup> As discussed in this chapter, it is possible that this increase in incidence is due to sexual transmission of human papilloma virus (HPV). Thus, in theory at least, anal squamous cell (epidermoid) tumors may represent a preventable disease. For almost two decades, combined modality treatment involving radiation and chemotherapy has resulted in 5-year survival rates of approximately 80% and in sphincter preservation for most patients with squamous cell carcinomas of the anal canal. Surgical resection involving an abdominal perineal resection (APR) is reserved for patients with local failure or progression. This approach has served as a model for other cancers of the successful use of curative nonoperative combined modality therapy.

## EPIDEMIOLOGY AND ETIOLOGY

### INCIDENCE, AGE, AND GENDER

In the United States, cancers of the anal region account for 1% to 2% of all large bowel cancers and 3.9% of all anorectal carcinomas. The majority of these patients (75% to 80%) have squamous cell carcinomas.<sup>2</sup> Approximately 15% have adenocarcinomas. In 1998, a total of 3300 cases of cancers of the anal region were reported in the United States, including 1400 men and 1900 women.<sup>1</sup> It is estimated that there will be 500 deaths per year.

The U.S. National Cancer Database provided data to examine the epidemiology of patients with anal canal cancer. In this analysis, a total of 2339 cases of anal carcinoma diagnosed in 1988 and 1993 were compared. There was little difference in mean age or in the male to female ratio during the 5-year period. Two-thirds of newly diagnosed patients were women, indicating that both in the United States and in Europe, women are substantially more likely to develop anal canal cancers than are men. Most patients were white. The proportion of patients with squamous cell carcinoma increased slightly, comprising between 75% and 80% of newly diagnosed patients. Seventy-five percent of patients have stage I or II tumors. In this analysis, no comment was made regarding the incidence of disease in homosexual or bisexual men.

### HUMAN PAPILLOMA VIRUS INFECTION AND ANAL CANCER

HPV infection is closely correlated with squamous cell carcinoma. Frisch et al. conducted a population-based case-control study in Denmark and Sweden for patients with anal canal cancers.<sup>3</sup> Two control groups (patients with adenocarcinoma of the rectum and healthy persons from the general population) were included. A variety of behavioral factors, such as sexual activity and venereal infection, tobacco consumption, and anal inflammatory lesions, were examined. In this large study involving 417 patients with anal cancer, 534 controls with adenocarcinoma of the rectum, and 554 general population controls, a strong positive correlation was found both in univariate and multivariate analysis for the amount of sexual activity and the risk of anal cancer. An additional association between venereal infection in both men and women was noted. The authors concluded that sexual activity was strongly associated with the development of anal canal cancer and that HPV infection was the presumed etiologic cause.

Anal intraepithelial neoplasia (AIN) is rare in heterosexual men, whereas the incidence is 5% to 30% in human immunodeficiency virus (HIV)–negative homosexual men. Similarly, such changes are rare among HIV-negative women. High-grade anal lesions that almost always contain HPV have been reported, primarily among HIV-positive individuals. It is suspected that, similar to cervical carcinoma in which HPV is strongly associated and may be a necessary factor for development of the disease, high-grade AIN lesions are the immediate precursors to anal cancer.<sup>4,5 and 6</sup>

### ANAL CANCER AND ACQUIRED IMMUNODEFICIENCY SYNDROME

An association between acquired immunodeficiency syndrome (AIDS) and an increased risk for anal canal cancer has been noted for some time. Treatment of the HIV-positive patient is discussed later in this chapter (see [Treatment of the Human Immunodeficiency Virus–Positive Patient](#)). Melbye et al. linked databases for AIDS and those for cancer in American patients.<sup>7</sup> The relative risk (RR) of anal cancer at the time of or after AIDS diagnosis was 84.1 among homosexual men. The relative risk of anal cancer for up to 5 years before AIDS diagnosis was 13.9. This marked increased risk of anal cancer in patients with AIDS is presumably because of immunodeficiency, perhaps increasing susceptibility to HPV infection. A similar increase in risk has been noted for renal transplant patients undergoing

immunosuppression.<sup>8</sup>

Although earlier studies suggested that anal-receptive intercourse was directly linked to an increased risk of anal cancer, this finding has not been confirmed in more recent larger scale trials. Particularly in women, most patients did not report sexual activity involving anal intercourse.

Goldie et al. reviewed the clinical outcome and cost effectiveness of screening for premalignant (squamous intraepithelial lesions) or malignant anal lesions in homosexual and bisexual HIV-positive men.<sup>9</sup> Their analysis indicated that screening of homosexual and bisexual men who were HIV-positive, no matter what the stage of their HIV status, prolongs quality-adjusted life expectancy.

Anal canal carcinoma has also been associated with condylomata in both the general population and in male homosexuals.<sup>10,11 and 12</sup> Pfister and Fuchs also noted that HPV-16 infection has a strong association with high-grade AIN and a risk of anogenital malignancy. HPV infection alone may be insufficient for malignant transformation, however, as many persons with HPV-positive cytology do not develop either AIN or anal carcinoma.<sup>13</sup>

In women without a history of genital warts, anal cancer was associated with seropositivity for herpes simplex virus type 1 (RR, 4.1) and *Chlamydia trachomatis* (RR, 2.3).<sup>14</sup> In men without a history of warts, there was an association with gonorrhea (RR, 17.2). Among individuals with AIDS, an increased risk of anal cancer has been found.<sup>7,15</sup>

## MOLECULAR AND CHROMOSOMAL ABNORMALITIES

The E6 oncoprotein of HPV inactivates the growth-controlling p53 suppressor gene product, which may play an important role in the pathogenesis of anal cancer.<sup>16,17</sup> Overexpression of p53 protein has been studied in patients receiving combined modality therapy. In an analysis involving approximately 20% of patients entered into Radiation Therapy Oncology Group (RTOG) protocol 87-04, in whom 5-fluorouracil (5-FU) plus radiation with or without mitomycin C was given, immunohistochemistry for p53 overexpression was performed. Although there was a trend toward worse outcome (decreased local control and survival) in patients overexpressing p53, this did not reach statistical significance.<sup>18</sup>

Other investigators have studied MIB-1 in patients with anal canal carcinomas receiving radiation therapy alone or combined modality therapy. In a group of 55 patients, MIB-1 murine monoclonal antibody measuring Ki-67, used as an index of cellular proliferation, failed to predict outcome for patients treated with radiation with or without chemotherapy.<sup>19</sup>

## OTHER ASSOCIATIONS

Anal canal carcinomas have been associated with anal fistulas and other benign conditions. In one study, 41% of anal canal carcinomas were preceded by benign anorectal disease for at least 5 years.<sup>20</sup> However, two studies have now shown only a temporal relationship but no evidence of causation.<sup>21,22</sup> There is a high risk of anal cancer in the first year after diagnosis of the benign lesion and a rapid decline in risk thereafter. In a study from California, however, homosexual men had an elevated risk of anorectal squamous cell carcinoma with a history of anal fissure or fistula (RR, 9.1).<sup>23</sup> Anal canal cancers have been reported in patients with Crohn's disease, but the incidence appears low.<sup>24</sup>

Frisch et al. studied the relationship between anal canal cancers and smoking in Danish and Swedish patients.<sup>25</sup> A positive correlation for an increased risk of anal canal cancer in premenopausal women who smoked versus lifelong nonsmokers was noted [odds ratio (OR), 5.6]. Smoking was not statistically significantly related to anal canal cancers in men or postmenopausal women. They suggested that suppression of estrogen may play a role for anal carcinogenesis in premenopausal women. In the case-control study reported by Daling and colleagues, current cigarette smoking was a major risk factor in both sexes (RR, 7.7 in women and 9.4 in men).<sup>14</sup> This is similar to the report by Daniell, who noted that 54% of 13 women with anal cancer were current smokers, compared with only 26% of 202 age-matched patients with colon cancer.<sup>26</sup> In a matched controlled study of 56 women with anal carcinoma, there were strong associations with herpes simplex virus titer, cigarette smoking, and increasing numbers of sexual partners. In a multivariate analysis, cigarette smoking was an independent variable.<sup>27</sup>

Prior radiation therapy may play a role in the development of anal carcinoma, as may immunosuppression.<sup>28,29 and 30</sup> Immunosuppressed renal transplant patients have a 100-fold increase in anogenital tumors compared with the general population.<sup>8</sup> As noted previously, increasing immunosuppression in HIV-positive patients is correlated with increased risk for anal canal cancer.

Several general conclusions with regard to etiology can be made. Anal canal carcinoma is highly correlated with HPV infection, especially HPV-16. Immunosuppression, whether by HIV infection or iatrogenically (e.g., in the setting of renal transplantation), increases the relative risk of precursor high-grade AIN and anal carcinoma. Increasingly severe immunodeficiency (e.g., CD4 counts less than 200/ $\mu$ L) also increases the risk of developing anal cancer.

## ANIMAL STUDIES

Animal studies offer some clues to the genesis of anal tumors. In mice, anal carcinomas may be induced by chemical carcinogens.<sup>31,32</sup> In a study by Kingsnorth and colleagues, the induction of anal squamous cell carcinomas (but not colon tumors) was promoted by epidermal growth factor (EGF).<sup>32</sup> The frequency of anal squamous cell carcinomas induced by dimethylhydrazine alone was only 10%, whereas in mice treated with both dimethylhydrazine and EGF, the frequency was 33% ( $P < .05$ ). It was postulated that this potentiation was a result of EGF-stimulated squamous cell hyperplasia, with the EGF thus acting as a cocarcinogen.

## ANATOMY

A clear anatomic distinction between the anal canal and the anal margin is needed because of the different natural histories of cancers that arise in these two distinct anatomic areas. Considerable confusion exists when comparing series in the literature because of the use of different definitions of the anal canal and the anal margin. The anatomic components of the anal canal and anal margin are illustrated in [Figure 33.9-1](#).

**FIGURE 33.9-1.** Anatomy of the anal canal. A tumor in location A is always considered anal canal cancer; in location C, it is anal margin cancer. A tumor in location B has been called *canal* or *margin cancer*, depending on institutional preference, but now should be called *anal canal cancer* by the American Joint Committee on Cancer and the Union Internationale Contra le Cancer definition.

The upper or proximal limit of the anal canal is accepted as commencing at the anorectal ring. The anorectal ring is defined as the muscle bundle formed by the junction of the upper portion of the internal sphincter, the distal portion of the longitudinal muscle, the puborectalis, and the deep portion of the external sphincter. This ring can be identified on digital examination. The epithelium lining the anal canal at this level is columnar. The anal columns, vertical folds of mucous membranes

lined by cuboidal epithelium, start just distal to the anorectal ring and extend to the dentate line. The dentate line is defined as the demarcation between the columnar epithelium of the proximal canal and the stratified squamous epithelium of the lower canal and is the site where the anal glands empty. The junction is not an abrupt histologic change but rather a transition zone that extends for 6 to 12 mm and contains columnar, cuboidal, squamous, and transitional epithelia. The stratified squamous epithelium extends from just below the dentate line to the anal verge, which is defined as the junction of the squamous epithelium with the perianal skin, which is a keratinized squamous epithelium containing hair follicles.

Definitions of the proximal and distal extent of the anal canal have varied among authors. A number of authors have defined the distal limit of the anal canal as the dentate line and all tumors below this as anal margin cancers.<sup>33,34,35</sup> and <sup>36</sup> Some have defined the distal extent of the anal canal to reach to the anal verge.<sup>37,38</sup> and <sup>39</sup> Others refer to anal margin tumors as tumors that arise within 5 cm of the anal verge.<sup>37,40</sup> The anatomic boundary used for distinguishing anal canal from anal margin tumors alters their incidence. When the anal verge is used as the distal margin of the anal canal, 15% of tumors arise from the anal margin, but this number climbs to 30% when the dentate line is used as the distal limit. To clarify this issue, the American Joint Committee on Cancer (AJCC) and the Union Internationale Contra le Cancer (UICC) have formed a consensus that the anal canal extends from the anorectal ring (dentate line) to the anal verge.<sup>41,42</sup> This is an important distinction, as these two governing bodies agree that anal margin tumors behave in a similar fashion to skin cancers and therefore are to be classified as skin tumors and treated as such.

The arterial supply to the distal rectum and anal canal is supplied by the superior, middle, and inferior hemorrhoidal arteries, which arise from the inferior mesenteric, hypogastric, and internal pudendal arteries, respectively. Venous drainage follows the inflow patterns. The internal rectal sphincter motor innervation is supplied by sympathetic fibers, whereas the sacral parasympathetics mediate the sensation of distention. The external rectal sphincter is innervated by the inferior hemorrhoidal nerve, which is derived from the internal pudendal nerve. The lower rectal wall is supplied by the rectal plexus composed of the pelvic sympathetic and parasympathetic nerves. The sensory component of the hair-bearing skin beyond the anal verge is innervated by the inferior hemorrhoidal branches of the internal pudendal nerve.

The anal canal has a rich supply of lymphatics, which drain via three main routes, including the inguinal, pelvic visceral, and hypogastric nodes.<sup>43</sup> The lymphatics of the anal margin drain into the inguinal-femoral nodes, which subsequently drain into the external iliac to the common iliac nodes. The lymphatic drainage of the anal canal is primarily to the perirectal and superior rectal lymphatics, which drain to the inferior mesenteric nodes and eventually to the paraaortic nodes. Lymphatic drainage may also drain laterally into the obturator and hypogastric nodes. Extensive interconnections exist between the lymphatic channels, which explains why patients with distal lesions may have mesenteric nodal involvement.

Squamous tumors may arise from the entire length of the anal canal as well as develop from the anal margin. Basaloid carcinomas, which are a variant of squamous carcinoma, arise from the epithelium just above the dentate line and are commonly referred to as *cloacogenic carcinomas*. The adenocarcinomas in this region arise from the glands at the dentate line. Small cell carcinomas in this region are of neuroendocrine origin and are rare. Tumors of the anal margin include squamous carcinoma, basal cell carcinoma, Bowen's disease, Paget's disease, verrucous carcinoma, and Kaposi's sarcoma. Malignant melanomas may arise from either location, but more commonly from below the dentate line.

## **PATHOLOGY**

Many different histologic cell types may occur in the anal area.<sup>44</sup> In addition to the more common types seen in [Table 33.9-1](#), other rare histologic entities can arise, such as small cell carcinomas similar to those in lung,<sup>45</sup> and lymphoma. Melanomas constitute 1% to 2% of all anal cancers.<sup>46</sup>

Type	Percentage of Patients
Squamous cell carcinoma	47
Transitional (cloacogenic) carcinoma	27
Adenocarcinoma	15
Carcinoma, not otherwise specified	3
Papillary villous (adeno) carcinoma	3
Mucinous adenocarcinoma	2
Melanoma	1
Other	2

(Adapted from Young JL, Percy CCL, Asire AJ. Surveillance, epidemiology, and end results: incidence and mortality data, 1973-77. *Natl Cancer Inst Monogr* 1981;57.)

**TABLE 33.9-1.** Distribution of Histologic Types in Patients with Anal Carcinoma (Surveillance, Epidemiology, and End Results Data)

Some pathologists divide anal canal tumors into those that exhibit keratinization and those that do not<sup>33</sup> and further subdivide nonkeratinizing tumors into basosquamous, basaloid, and cloacogenic carcinomas. Other investigators have found no difference in clinical outcome with such subdivisions and believe that all histologic varieties are subsets of squamous cell carcinoma.<sup>47,48</sup> Most investigators currently believe that, with the exception of melanoma and sarcoma, prognosis is much more dependent on stage than on histology.<sup>49</sup>

An interesting difference in the presence of HPV DNA between cloacogenic and squamous carcinomas has been found.<sup>50</sup> When studied by *in situ* hybridization, all 14 cloacogenic carcinomas were HPV-negative, whereas two-thirds of the 21 squamous carcinomas were HPV-positive (mostly for types 16 to 18). In another study,<sup>51</sup> however, there was no difference in the percentage of HPV RNA positivity (approximately 75%) between cloacogenic and squamous carcinomas.

In the anal margin, histologies other than squamous cell carcinoma include basal cell carcinoma identical with that in skin in other areas, Bowen's disease, and Paget's disease.<sup>52</sup> Patients with Bowen's disease usually present with long-standing perianal pruritus. Raised irregular eczematous-appearing plaques are seen. Biopsy of this intraepithelial neoplasm is diagnostic with large periodic acid–Schiff-negative cells. As with Bowen's disease, patients with perianal Paget's disease frequently present with pruritus, although they may be asymptomatic or, at the other extreme, have a bleeding erythematous or eczematoid plaque.<sup>53</sup> The histologic appearance reveals characteristic periodic acid–Schiff-positive large vacuolated cells. In the absence of an underlying anal canal cancer, the origin of the cells is likely from the apocrine glands. An associated anorectal carcinoma should be excluded. Goldblum and Hart studied immunohistochemical features of specimens from 11 patients with Paget's disease and were able to distinguish two types of perianal Paget's disease.<sup>54</sup> One type has endodermal differentiation with gastrointestinal-type glands containing intraluminal necrosis, signet-ring cells, CK20 positivity, and GC-DFP15 negativity. Such cases are likely to be associated with rectal adenocarcinoma. The other type is a primary cutaneous intraepithelial neoplasm in which the Paget's cells display sweat gland differentiation, GC-DFP15 positivity, and CK20 negativity.

## **PRECANCEROUS CHANGES**

Precancerous changes have been studied by a number of investigators. In particular, the increasing incidence of anal canal carcinomas among certain populations (e.g., homosexual or bisexual men who are HIV-positive) has led to scrutiny of the role of AIN and dysplasia (see [Epidemiology and Etiology](#), earlier in this chapter).

Fenger and Nielsen studied the incidence of precancerous changes in the anal canal epithelium.<sup>55,56</sup> Of 306 specimens of the anal transition zone, seven (2.3%) showed squamous cell dysplasia, which was severe in only one. With an average follow-up of 27 months, no case of dysplasia had progressed to carcinoma. In a group of 139 patients who underwent APR (most with carcinomas of the rectum but some with anal canal tumors), 15 (10.8%) had dysplasia that was thought to be precancerous or to represent carcinoma *in situ*. Severe dysplasia or carcinoma *in situ* was seen in 13 of the 16 patients (81%) with squamous cell carcinoma of the anal canal. They concluded that most anal canal tumors arising in the anal transition zone are preceded by multicentric areas of dysplasia.

Palefsky and colleagues<sup>57</sup> studied the incidence of the premalignant condition, AIN, and its relationship to anal HPV infection among homosexual men who were HIV-positive. Infection with multiple subtypes of HPV was seen in 12% of patients; these patients had a markedly increased risk for cytologic abnormalities (RR, 39.0).

In addition, patients who had abnormal cytology were significantly more likely to have lower median T4 counts. They concluded that immunosuppressed male homosexuals may be at significant risk for the development of anal canal neoplasia, related to the presence of HPV.

Surawicz and colleagues found that in 90 homosexual men with an abnormal examination result of the anal canal, 89% had HPV-associated changes.<sup>58</sup> In a prospective study of 37 homosexual men, Palefsky and associates found a substantial increase over time in the percentage of patients with cytologic abnormalities of the anal canal (27% to 65% over an average 17-month period).<sup>59</sup> There was also an increase in the presence of AIN and of identifiable HPV infection.

Flow cytometric analysis of normal epithelium along the anal transition zone and, in smaller groups of patients, of anal canal tumors has been performed in fresh specimens by Fenger and Bichel.<sup>60</sup> A normal diploid population was seen in normal squamous epithelium in the anal transition zone, along with a small hyperdiploid peak, the relevance of which was unclear. Three patients with squamous cell carcinoma of the anal canal were studied. They had a high proliferative index but near diploid peaks. In contrast, Goldman and coworkers found that most anal tumors had an aneuploid pattern.<sup>61</sup> Scott and colleagues studied flow cytometry in 235 patients with resected tumors of the anal canal and perianal skin.<sup>62</sup> In a multivariate analysis, depth of penetration, inguinal node involvement, and DNA ploidy were of independent prognostic significance.

## SQUAMOUS CELL CANCER

### NATURAL HISTORY

Anal canal carcinomas often spread by local extension, extending cephalad to involve other organs in the pelvis. Local extension to adjacent structures and into the sphincteric muscles is common on initial presentation. Extension to the vaginal septum was seen in 9 of 76 (12%) women in the Memorial Sloan-Kettering series.<sup>43</sup> Although it is often stated that these tumors can invade the prostate, urethra, bladder, and seminal vesicles in male subjects, in this series the tumors approached these organs but did not invade them.<sup>43</sup>

Hematogenous spread appears to occur more often from tumors that arise at the dentate line or above.<sup>63</sup> This pattern of spread allows tumor cells into the portal system, and liver metastases also involve the lung in 5% to 8% of patients.<sup>43,63,64</sup> Hematogenous metastases also involve the lung in 2% to 4% of cases<sup>43,63,64</sup> and bone in 2% of cases.<sup>64</sup> Distant metastases occur with equal frequency independent of the histologic cell type involved. Distant metastases rarely, if ever, are seen with anal margin tumors.

Lymphatic spread can occur via the inguinal, pelvic, and mesenteric nodes (see [Anatomy](#), earlier in this chapter). Because routine lymphadenectomy is no longer performed in anal cancers, the data pertaining to lymph node involvement are from historic surgical series. Many interconnections exist between these lymphatic channels, and tumors arising above or below the dentate line may have mesenteric nodal involvement. Of 33 anal canal tumors arising below the dentate line, six had mesenteric nodal involvement in their abdominoperineal specimens, confirming these interconnections.<sup>43</sup>

Inguinal lymph nodes are involved in 15% to 63% of cases of anal canal tumors.<sup>43,64,65,66</sup> and <sup>67</sup> In one series, 17 of the 115 patients (15%) had inguinal nodes involved at the time of presentation, similar to the incidence reported in other series.<sup>43,63,64,66</sup> Metachronous inguinal nodes appeared in 24 of 96 patients (25%), with a median time to presentation of 12 months. Pelvic nodes are not as commonly involved, whereas mesenteric nodes are more likely to be involved if the tumors are proximal (50%) compared with distal (14%).<sup>43</sup> Anal margin tumors rarely spread to the mesenteric nodes.

Survival after lymph node dissection with positive nodes at presentation ranged from 0% to 20%.<sup>63,64,68,69,70</sup> and <sup>71</sup> However, modern combined modality therapy has greatly affected this result. Patients who have lymph node dissection for metachronous lesions have a better long-term survival, with rates up to 83%.<sup>37,63,70,72</sup> The majority of these recurrences occur by 2 years but may take up to 8 years to present.<sup>43</sup>

### DIAGNOSIS

Although anal cancers are located in one of the most accessible sites of the digestive tract, these tumors are frequently misdiagnosed and a delay in treatment often results. The initial and most common symptom is bleeding, and this occurs in more than one-half of the patients.<sup>43,66,67,73,74,75</sup> and <sup>76</sup> The bleeding is rarely substantial and is usually attributed to hemorrhoids. Other common symptoms include pain, tenesmus, pruritus, change in bowel habits, abnormal discharge, and infrequently, inguinal lymphadenopathy.<sup>43,64,73,74,76</sup> Most of these symptoms are associated with benign conditions of the anus, including fissure, fistula in ano, hemorrhoids, anal pruritus, and anal condyloma, which results in a delay of diagnosis. The diagnosis may be further confounded because benign perianal conditions may coexist in 60% of anal margin tumors and in 6% of anal canal tumors.<sup>76</sup> Patients often treat themselves for extended periods before seeking medical attention.<sup>74</sup> The duration of symptoms varies from 2 weeks to longer than 4 years, with a mean of 6 months.<sup>37,47,64,67,70,74,75</sup>

Proper treatment for these tumors is often delayed due to inappropriate diagnosis at the initial evaluation in up to one-third of patients.<sup>37,43,47,67,74,77</sup> It has been generally accepted that the delay in diagnosis has an adverse effect on the outcome, but this has been challenged.<sup>43,64,78</sup> The diagnosis may also be made indirectly in tissues examined routinely after minor anorectal procedures. The patients with these incidental tumors have the most favorable outcomes.<sup>39,43,79,80,81</sup> and <sup>82</sup> Screening of high-risk populations (i.e., HIV-positive homosexual men) may increase the percent of patients diagnosed with earlier stage tumors.

Diagnosis can be made on rectal examination, but anoscopy, proctoscopy, and transrectal ultrasound are important in the evaluation of these tumors. The most common physical finding is an intraluminal mass.<sup>64,66</sup> The physical examination should describe the location, extent, and size of the tumor and the relationship of the tumor to the dentate line. On palpation, the characteristically hard, indurated, inelastic quality of the tumor is detected, which may or may not be ulcerated. Endoscopically, the tumors may appear as flat or slightly raised lesions, as raised lesions with indurated borders, or as polypoid lesions. As the tumor enlarges, it may become fixed to adjacent structures. The use of transrectal ultrasound allows for the determination of depth of penetration and involvement of adjacent organs.<sup>83</sup> In women, the vagina may be infiltrated with tumor and, although it is commonly thought in men that the prostate and seminal vesicles are involved, this is not often confirmed pathologically.<sup>43,69</sup>

Any suspicious lesion in the anal canal should have a biopsy taken, and this can frequently be done in an outpatient procedure. If the patient has pain or spasm precluding this, then an examination under anesthesia is performed. An incisional biopsy is used to make the diagnosis. The lesion should be excised only if it is a small superficial lesion. Inguinal lymphadenopathy should be aspirated to determine tumor involvement to accurately stage the patient. Inguinal lymph node dissection is not warranted due to the associated morbidity, failure to have an effect on outcome, and the adequate control with combined modality therapy (radiation therapy plus concurrent chemotherapy).

An extent of disease workup should include computed tomography of the abdomen and pelvis to evaluate the primary tumor and to detect liver metastases. Chest radiography is performed to determine if pulmonary metastases are present.

### STAGING

In 1997 the AJCC<sup>41</sup> and UICC<sup>42</sup> developed a common staging system. This current staging system takes into account the fact that anal canal carcinoma is primarily treated by combined modality therapy (or in selected cases by radiation alone). APR is reserved for patients who fail to respond to initial treatment. Thus, the TNM classification for anal canal cancers is primarily clinical. The primary tumor is assessed for size and, for T4 tumors, invasion of local structures such as the vagina, urethra, or bladder. The TNM classification is seen in [Table 33.9-2](#). Nodal status is based on distance from the primary site rather than number of lymph nodes involved. This staging system applies to carcinomas, including cloacogenic carcinomas. Melanomas and sarcomas are not included in this staging system.

Staging System	T1	T2	T3	T4
UICC (1989)	T1	T2	T3	T4
ACME (1998)	T1	T2	T3	T4

**TABLE 33.9-2.** American Joint Committee on Cancer 1998 and the Union Internationale Contra le Cancer 1997 Joint Staging System for Anal Canal Cancer

**PROGNOSTIC FACTORS**

The most important prognostic factors in anal cancer are T stage and lymph node status. As seen in [Table 33.9-2](#), these two factors, as well as the presence or absence of metastatic disease, define the stage. The most striking difference in results is seen when comparing T1 and 2 primary cancers (smaller than or equal to 5 cm) versus T3 and 4 primary cancers (larger than 5 cm) ([Tables 33.9-3](#), [33.9-4](#), and [33.9-5](#)). The local failure rates with T3 to 4 primary cancers are approximately 50% after combined modality therapy. Because prognostic factors such as tumor size and lymph node status may be interrelated, a multivariate analysis is required to determine if they are independent prognostic variables.

**TABLE 33.9-5.** Randomized Trials of Combined Modality Therapy for Anal Cancer

**T Stage: Univariate Analysis**

Salmon and colleagues found that size was significantly related to survival in a study in which radiation therapy alone was the primary treatment. <sup>49</sup> In another radiation therapy alone series, size was prognostic for 5-year survival but not for primary tumor control. <sup>84</sup>

In a series of 118 patients treated by external-beam and brachytherapy by Peiffert et al., there was an increase in local failure with T stage (T1, 11%; T2, 24%; T3, 45%; and T4, 43%) and a corresponding decrease in 5-year survival (T1, 94%; T2, 79%; T3, 53%; and T4, 19%) ( [Table 33.9-6](#)).<sup>85</sup> Similar data were reported by Gerard and colleagues. In 95 patients treated with combined modality therapy plus brachytherapy there was an increase in 5-year colostomy-free survival with T1 and T2 tumors versus T3 and T4 tumors (T1, 83% and T2, 89%, vs. T3, 50% and T4, 54%).<sup>86</sup> Doci and associates treated 35 patients with 5-FU, cisplatin, and external-beam radiation and reported a complete response rate of 100% for T1 and T2 cancers versus 60% for T3 cancers (see [Table 33.9-4](#)).<sup>87</sup> The Intergroup randomized phase III trial of radiation, 5-FU with or without mitomycin C, reported a significantly higher complete response rate by tumor size (smaller than 5 cm, 93%, vs. larger than or equal to 5 cm, 83%; *P* = .02) (see [Table 33.9-5](#)).<sup>88</sup> Similar findings were reported by univariate analysis in the European Organization for Research and Treatment of Cancer (EORTC) randomized trial of 45 Gy with or without 5-FU/mitomycin C.<sup>89</sup>

**TABLE 33.9-6.** Brachytherapy as a Component of Treatment for Anal Cancer: Selected Series

In a series from the Princess Margaret Hospital, tumor size did not appear to have a significant effect on local failure, providing the patients received the combination of 5-FU, mitomycin C, and external-beam radiation (smaller than 4 cm, 95% vs. larger than 4 cm, 86%).<sup>90</sup>

#### **N Stage: Univariate Analysis**

In contrast to T stage, the effect of positive lymph nodes is less clear. Furthermore, although the 1997 AJCC/UICC staging system differentiates between positive inguinal and pelvic lymph nodes, most series do not report the data separately. It must be emphasized that, unlike rectal cancer, inguinal lymph nodes in anal cancer are considered nodal metastasis rather than distant metastasis, and patients should be treated in a potentially curative fashion. In the historic literature, synchronous metastases to inguinal lymph nodes have been considered an indicator of a poor prognosis.<sup>49,70,91</sup> However, the use of combined modality therapy has altered the poor prognosis previously reported with positive inguinal nodes.

In a series by Cummings et al. from the Princess Margaret Hospital (see [Table 33.9-3](#)), patients with negative nodes who received combined modality therapy had a higher 5-year cause-specific survival compared with those with positive nodes (81% vs. 57%).<sup>92</sup> The incidence of local failure was only 13% in patients with positive nodes. Doci et al. found no significant difference in the complete response rate after 5-FU, cisplatin, and external-beam radiation in patients with node-positive compared with node-negative cancers (100% vs. 92%).<sup>87</sup> In a separate report of 56 patients who received 5-FU, mitomycin C, and radiation, the eight patients who had node-positive disease all achieved a complete response.<sup>93</sup> By univariate analysis, Allal and colleagues reported a significant increase in local failure in patients with positive versus negative nodes who received 5-FU, mitomycin C, and radiation (36% vs. 19%;  $P = .03$ ); however, this difference was not found to be significant by multivariate analysis.<sup>94</sup> In patients treated with 5-FU, cisplatin, and external-beam and brachytherapy, Gerard et al. also reported no significant differences in 5-year colostomy-free and overall survival in patients with node-positive compared with node-negative disease.<sup>86</sup>

The Intergroup randomized phase III trial of radiation and 5-FU, with or without mitomycin C, reported a higher colostomy rate (which is an indirect measurement of local failure) in N1 versus N0 patients (28% vs. 13%).<sup>88</sup> In node-negative patients, and possibly node-positive patients, the addition of mitomycin C decreased the overall colostomy rates. The EORTC randomized trial of 45 Gy with or without 5-FU/mitomycin C also reported that patients with positive nodes experienced significantly higher local failure ( $P = .035$ ) and lower survival ( $P = .038$ ) rates compared with node-negative patients.<sup>89</sup> However, there was no difference in prognosis between N1 versus N2 and N3 disease.

#### **Multivariate Analysis**

In the series from Allal and associates, factors by univariate analysis associated with a significant increase in local failure included age younger than 66 years, male gender, tumor extent more than one-third circumference, lymph node involvement, overall treatment time 75 days or greater, and the use of external-beam radiation for the boost treatment.<sup>94</sup> By multivariate analysis, however, the only variable for which there was a possible effect was overall treatment time ( $P = .09$ ). In the EORTC randomized trial of 45 Gy with or without 5-FU/mitomycin C, multivariate analysis identified that positive nodes, skin ulceration, and male gender were independent negative prognostic factors for local control and survival.<sup>89</sup> Goldman and coworkers also reported by multivariate analysis that gender was also important, with women faring better than men.<sup>95</sup> In a multivariate analysis of 242 patients by Schlienger et al., T stage was the only significant prognostic factor.<sup>96</sup> In a further update with 286 patients analyzed by multivariate analysis, tumor size, clinically abnormal lymph nodes, and total irradiation dose influenced prognosis.<sup>97</sup> Constantinou and colleagues (see [Table 33.9-3](#)) reviewed 50 patients who received combined modality therapy and found that radiation dose and percent hemoglobin were independent prognostic factors for local control; radiation dose was an independent prognostic factor for disease-free survival; and radiation dose, percent hemoglobin, and T stage were independent prognostic factors for survival.<sup>98</sup>

#### **Other Prognostic Features**

Histologic cell type for squamous cancers of the anal canal (squamous vs. cloacogenic) has not been found to be of major prognostic relevance. Cloacogenic carcinomas have been considered to have a slightly better prognosis in some series<sup>49,99</sup>; however, in 243 patients with resectable anal canal tumors, Papillon and Montbarbon reported a worse prognosis for patients with nonkeratinizing and basaloid carcinoma than for patients with keratinizing lesions.<sup>84</sup> Small cell carcinomas of the anus are rare and, similar to extrapulmonary small cell cancers in other parts of the body, appear to have a worse prognosis, with a high propensity for systemic dissemination.<sup>45,100</sup>

Asymptomatic patients have a better prognosis than symptomatic patients, but this may be directly related to the size of the tumor.<sup>39</sup> Location may be of modest prognostic importance, with anal margin tumors having a better outcome than those in the anal canal (see [Treatment](#), later in this chapter).

Three studies have examined DNA content (i.e., whether tumors were diploid or nondiploid); two found no prognostic effect of this factor,<sup>61,62</sup> whereas in one large multivariate analysis,<sup>100</sup> DNA ploidy was an independent prognostic factor in the 184 patients whose tumors were analyzed for DNA. In one study,<sup>61</sup> grade was a significant prognostic factor, with low-grade tumors resulting in a 5-year survival of 75% compared with only 24% for high-grade tumors. Data from the Princess Margaret Hospital suggest the DT-diaphorase mutation is not a strong determinant of treatment outcome in patients who fail combined modality therapy.<sup>101</sup>

Tanum and Holm reported p53 expression in 34% of patients with anal carcinoma.<sup>102</sup> Pretreatment biopsies from 80 patients treated on the combined modality therapy arm of the Intergroup randomized trial were examined by immunohistochemistry for p53 expression.<sup>103</sup> For the total group, p53 protein was overexpressed in 47% of tumors. By multivariate analysis, the 4-year local disease-free survival was significantly decreased in those patients whose tumors overexpressed p53 (64% vs. 88%;  $P = .027$ ). However, significant differences were not seen in disease-free or overall survival.

In a retrospective analysis from the Princess Margaret Hospital, p53 was measured by immunohistochemistry in 49 patients who received combined modality therapy.<sup>104</sup> The incidence of p53 expression was 82%. By univariate analysis, p53 expression of 5% or greater was a poor prognostic factor for 5-year survival (78% vs. 90%) compared with less than 5%. It was an independent poor prognostic factor for disease-free survival ( $P = .01$ ).

## **TREATMENT**

### **Anal Margin**

Cancers of the anal margin are uncommon, accounting for approximately 15% of all tumors of the anal region. They account for 15% to 25% of all squamous cell cancers of the anus and, in general, have a different natural history and more favorable prognosis than squamous cell carcinomas of the anal canal.<sup>105</sup> The average age of onset is 60 to 70 years, with a wide range.<sup>106</sup> Most are well to moderately differentiated, with fewer than 10% being poorly differentiated. The 1997 AJCC/UICC staging system defines the anal margin as a cancer arising at the junction of the hair-bearing skin and the mucous membrane of the anal canal.<sup>41,42</sup> It must be

emphasized that these tumors are staged as skin cancers rather than anal canal cancers. There is confusion in the literature as a variety of other definitions has been used, the most common being an area of skin measuring from 5 cm to as wide as 10 cm centered on the anal orifice.<sup>37</sup> To further confuse the issue, some series do not report results of anal canal and margin separately.<sup>107</sup>

The lymphatic drainage of anal margin cancers is different from anal canal cancers. Cancers of the anal margin drain primarily to the inguinal lymph nodes, whereas cancers of the anal canal drain primarily to the inguinal as well as the internal iliac and superior hemorrhoidal nodes.

**SURGERY.** Squamous cell carcinoma of the anal margin, as in skin elsewhere, has a favorable prognosis and rarely requires radical surgery. Wide local excision of these lesions is an attractive approach because it can be performed with primary closure and infrequently requires a split-thickness skin graft. The use of a wide local excision implies that an adequate margin of normal tissue (1 cm) can be secured beyond the tumor without anal incontinence. If the tumor encompasses more than one-half of the circumference of the anus, local excision should be abandoned due to poor anal control; combined modality therapy or APR are advocated.<sup>34,37</sup>

Most authors recommend wide local excision for squamous cell carcinomas of the anal margin,<sup>34,36,37,65,108,109</sup> Bowen's disease,<sup>110</sup> and Paget's disease.<sup>77,111</sup> Wide excision results in control of local disease in the majority of patients.<sup>33,34,37,112,113</sup> Anal margin tumors rarely metastasize to visceral organs or regional lymph nodes, and this represents an important difference between anal margin tumors and anal canal tumors.<sup>34,68,114</sup> High-grade intraepithelial tumors (AIN III or carcinoma *in situ*) may be surgically treated.<sup>115</sup> Other options may include laser ablation<sup>116</sup> or combined modality therapy for extensive lesions that would otherwise require an APR.

Local recurrence after primary treatment of anal margin cancers is routinely treated by repeat local excision. APR or combined modality therapy is reserved for patients with extensive disease. Of the 11 local recurrences treated at Memorial Sloan-Kettering,<sup>43</sup> ten had a local excision and one had an APR.<sup>114</sup> Of the nine patients who survived longer than 5 years, two required a second procedure to control disease. In the same study, four patients had an inguinal node recurrence as the only site of failure, and all underwent inguinal lymphadenectomy. Two of these patients were long-term survivors, one died of disease, and one was lost to follow-up. The median survival exceeded 5 years. The authors concluded that few patients die from anal margin tumors.

An APR or combined modality therapy should be performed when anal margin cancers invade into deep muscle or have vascular, lymphatic, or perineural involvement. A number of series have shown no benefit to the routine use of APR for anal margin tumors, but the small number of patients in these studies combined with patient selection bias makes interpretation of these data difficult.<sup>37,74,109,117</sup>

**RADIATION THERAPY.** Squamous cell carcinoma of the anal margin tends to be early or only moderately advanced at the time of diagnosis.<sup>117,118</sup> Lymph nodes are rarely involved (0% to 15%).<sup>72,118</sup> Although early cancers of the anal margin are successfully treated by local excision, nonoperative treatment should be considered for some patients. Papillon suggested that radiation therapy should be used for patients with anal margin carcinomas that are considered unresectable or patients who have extensive or recurrent lesions; in addition, patients who are medically inoperable may be able to have radiation therapy.

Early studies of therapy for anal margin cancers used interstitial radium needle implants; however, the high incidence of radionecrosis and the relatively poor geometry suggested that external-beam therapy was better tolerated.<sup>118,119</sup> Although photons are most the frequent radiation treatment, electron-beam therapy may also be successfully used for early perianal epidermoid carcinomas.<sup>120</sup> Results of radiation therapy for perianal lesions, stage for stage, are similar to results for anal canal lesions, with more extensive lesions requiring more aggressive therapy.<sup>117,121</sup> Some authors have recommended APR for extensive lesions.<sup>117</sup> Radiation therapy with or without chemotherapy, however, appears to be an excellent alternative that yields a similar cure rate while offering sphincter preservation.

Selected series reporting the use of primary nonoperative therapy for anal margin cancers are seen in [Table 33.9-7](#). Patients received radiation therapy (external beam with or without brachytherapy) or combined modality therapy. The numbers of patients in each series are small, making it difficult to make definitive conclusions. Combining the series, the overall local control rate is approximately 75% and the 5-year survival is 65% to 70%. In a retrospective analysis from Cummings, local control with T1 and T2 disease was 100% compared with 60% for patients with T3 disease.<sup>9c</sup> Likewise, patients who received combined modality therapy had an 88% local control rate compared with 64% local control in patients who received external-beam radiation alone. Peiffert and associates reported the results of 32 patients who were treated with external-beam radiation, brachytherapy, or both. Patients with node-negative disease had a 100% 5-year survival compared with 40% 5-year survival in patients with node-positive disease.<sup>122</sup>

**TABLE 33.9-7.** Treatment of Anal Margin Cancer: Selected Series

In a retrospective comparison of 54 patients with anal margin cancers with 216 patients with anal canal cancers treated with 40-Gy external-beam radiation plus bleomycin, Friberg et al. reported better results in patients with cancers of the anal margin versus anal canal.<sup>212</sup> There was an improvement in 5-year survival (74% vs. 57%), tumor-specific survival (90% vs. 68%), relapse-free survival (83% vs. 54%), and the incidence of an intact sphincter (91% vs. 58%), respectively.

In summary, squamous cell carcinoma of the anal margin is uncommon, and the literature is limited by small numbers and the lack of a standard anatomic definition. A reasonable approach is to recommend a local excision for smaller tumors (smaller than or equal to 4 cm) that are not in direct contact with the anal verge. If the patient requires an APR due to anatomic constraints or if a local excision would compromise sphincter function, or if the tumor is larger than 4 cm, node positive, or both, then nonoperative treatment is an appropriate alternative. Based on the randomized trials from the EORTC or United Kingdom Coordinating Committee on Cancer Research (UKCCCR) revealing an advantage of combined modality therapy compared with radiation therapy alone in patients with anal canal cancers (EORTC)<sup>89</sup> or anal canal and margin cancers (UKCCCR),<sup>107</sup> combined modality therapy rather than radiation therapy alone is recommended.

### Anal Canal

**LOCAL EXCISION.** Local treatment of epidermoid tumors of the anal canal is reserved for selected patients with tumors that are smaller than 2 cm in diameter, well-differentiated tumors, or tumors found incidentally at the time of hemorrhoidectomy.<sup>36,45,70,123</sup> Local excision may also be performed for patients who are medically inoperable or who refuse a permanent colostomy.

Of 188 patients with anal canal carcinoma treated at the Mayo Clinic, 19 were treated with local excision.<sup>45</sup> For the 12 patients with tumors confined to the epithelium and subepithelial connective tissues, 11 had tumors smaller than 2 cm in size and one patient had two lesions. Overall survival for these patients was 100%. One of 12 patients had a recurrence, and this patient was without evidence of disease 5 years after an APR. Patients with tumors penetrating into muscle who refused a colostomy had a higher recurrence rate. These patients' disease often can be salvaged with an APR or combined modality therapy.

Results of local treatment for tumors smaller than 2 cm were not as favorable at Memorial Sloan-Kettering: Only three of eight patients with local excisions had prolonged survival.<sup>70</sup> For more advanced lesions, high local recurrence rates and poor overall survival mitigate against the use of local excision.<sup>37,64,66,70,75</sup>

## COMBINED MODALITY THERAPY

**Biopsy.** With the advent of combined modality therapy, surgery for the initial diagnosis and staging of anal canal tumors should be limited to a biopsy of the primary tumor and evaluation of the inguinal lymph nodes. For most distal lesions, the biopsy is performed under local anesthesia. A punch or incisional biopsy obtains adequate tissue to make a histologic diagnosis. For patients with more proximal tumors or significant pain and spasm, the biopsy may require spinal or general anesthesia. Clinically enlarged lymph nodes should be aspirated. If the cytology is nondiagnostic or demonstrates only benign disease, an open excisional biopsy of one or two lymph nodes should be performed. Under no circumstances should a formal lymph node dissection be performed for the initial evaluation of suspicious nodes.

**Therapy.** Until the late 1970s, the conventional treatment for anal canal cancer was an APR. The landmark publication that challenged this practice was a report from Nigro et al. of three patients with squamous cell cancer of the anal canal who, after preoperative 30 Gy plus concurrent 5-FU and mitomycin C, were found to have a pathologic complete response at the time of surgery.<sup>124</sup>

Since that time, increasing evidence from single-arm phase II studies has indicated that initial combined modality therapy (chemotherapy plus concurrent external-beam radiation therapy) yields a high rate of tumor regression (including a complete response rate of approximately 80% to 90%) in most patients with squamous cell cancers of the anal canal. Surgery, most commonly an APR, is reserved for salvage. Even in patients with relatively large (larger than or equal to 5 cm) primary cancers, although the complete response rates are lower (50% to 75%), the majority of patients may be spared a colostomy and has an excellent overall survival.

Given that anal canal tumors are uncommon, and because the results of phase II trials using combined modality therapy are impressive, there has been, until relatively recently, no prospective controlled randomized trials of combined modality therapy versus radiation alone or surgery alone. Results of two prospective randomized trials from Europe of combined modality therapy versus radiation alone (EORTC<sup>89</sup> and UKCCCR<sup>107</sup>) support the use of combined modality therapy. In the United States, combined modality therapy has been well established, and randomized trials focus on defining the ideal combined modality therapy regimen. For example, the Intergroup trial (RTOG 87-04/ECOG 1289)<sup>88</sup> examined the role of adding mitomycin C to radiation plus 5-FU. It is unlikely that a prospective trial of surgery versus nonoperative therapy (combined modality therapy or radiation alone) will be performed. Combined modality therapy has an acceptable toxicity profile as well as a high disease-free and overall survival and is considered the standard of care for squamous cell carcinoma of the anal canal.

The results of two randomized trials that confirm an advantage for combined modality therapy using 45-Gy external-beam pelvic radiation plus continuous infusion 5-FU and bolus mitomycin C versus radiation alone are seen in [Table 33.9-5](#). The UKCCCR trial randomized a total of 585 patients of whom 51% had T3 disease, 20% had positive nodes, and 23% had anal margin cancers.<sup>107</sup> At 6 weeks after treatment, patients with 50% or greater response had additional radiation, whereas those with less than 50% response had salvage surgery. Although the improvement in 4-year survival with combined modality therapy did not reach statistical significance (65% vs. 58%), the improvement in crude (64% vs. 41%) and 3-year actuarial local control (61% vs. 29%) was significant. The early grade 4+ toxicity was significantly higher (48% vs. 39%); however, the incidence of late toxicity was similar (42% vs. 38%).

In the EORTC trial, 110 patients, of whom 85% had T3 disease and 48% had positive nodes, underwent a similar randomization.<sup>89</sup> At 6 weeks after treatment, patients with a partial or complete response had additional radiation, whereas those with less than a partial response had salvage surgery. Patients who received combined modality therapy had a higher complete response rate (80% vs. 54%) and a significantly higher 5-year actuarial local control rate (68% vs. 50%) and colostomy-free survival rate (72% vs. 40%). The overall survival rate was not significantly different (57% vs. 52%). Patients receiving combined modality therapy had a higher incidence of ulceration.

Although neither of the randomized trials revealed a significant advantage in overall survival with combined modality therapy, given the advantage in local control and colostomy-free survival, they helped to establish combined modality therapy as the standard of care in squamous cell cancers of the anal canal.

The Intergroup trial has established that mitomycin C is an important component of combined modality therapy.<sup>88</sup> A total of 291 patients (47% with T3 disease and 17% with positive nodes) were randomized to 45 Gy plus continuous infusion 5-FU with or without mitomycin C. At 6 weeks after the completion of treatment, patients with less than a complete response had an additional 9 Gy to the primary tumor plus concurrent 5-FU and cisplatin. If there was still less than a complete response 6 weeks after the completion of this salvage therapy, an APR was performed. Patients who received mitomycin C had a higher complete response rate (92% vs. 85%) and a significantly lower colostomy rate (9% vs. 22%) and a corresponding significant increase in colostomy-free survival (71% vs. 59%). There was little difference in overall 4-year survival (75% vs. 70%). Early grade 4+ toxicity was significantly increased in the mitomycin C arm (23% vs. 7%). Although overall survival was not significantly increased given the advantage in colostomy-free survival, mitomycin C is considered a necessary component of combined modality therapy.

The combined modality therapy arm using radiation, 5-FU, and mitomycin C from the Intergroup trial is the most common treatment approach in the United States. Details are seen in [Table 33.9-5](#). Patients received continuous course pelvic radiation to a total dose of 45 Gy (30 Gy to the whole pelvis followed by 15 Gy to the true pelvis) and two cycles (weeks 1 and 5) of concurrent continuous infusion 5-FU (1000 mg/m<sup>2</sup> days 1 through 4) and bolus mitomycin C (10 mg/m<sup>2</sup> bolus day 1). If 6 weeks following completion of the initial treatment there was persistent disease, patients received 1 week of salvage therapy. Salvage therapy involved one cycle of chemotherapy (continuous infusion 5-FU, 1000 mg/m<sup>2</sup>/d 1–4; bolus cisplatin, 100 mg/m<sup>2</sup> day 2) and concurrent 900 cGy (limited to the primary tumor). If there was residual disease on biopsy 6 weeks after the salvage therapy, then an APR was recommended.

There is considerable controversy as to the need for the first biopsy at 6 weeks after initial treatment. Data from the Princess Margaret Hospital suggest that squamous cell cancers of the anus regress slowly and continue to decrease in size for 3 to 12 months after the completion of combined modality treatment.<sup>92</sup> Based on these data, an increasing number of investigators advocate a more conservative approach and do not recommend a posttreatment biopsy. In the Intergroup trial, of the 25 patients with biopsy residual disease after 45 Gy and 5-FU and mitomycin C who then received salvage therapy with 9 Gy plus 5-FU and cisplatin, 55% achieved a complete response 6 weeks later (a total of 12 weeks after the completion of the initial 45 Gy).<sup>88</sup> It is unclear if the complete response was a result of the salvage therapy or was due to an additional 6 weeks of tumor regression after initial therapy.

At the Princess Margaret Hospital, Memorial Sloan-Kettering, and other centers, if there is residual disease at the 6-week posttreatment evaluation patients do not receive the 1 week of salvage therapy. The patients are examined every 6 weeks, and providing the tumor continues to decrease in size, no salvage therapy is performed. If there is progression of disease or no response at 6 weeks after initial therapy, however, APR is necessary. In addition to careful physical examination, anal ultrasound may be helpful in following the tumor. In the current Intergroup phase III anal canal cancer protocol (RTOG 98-11) ([Fig. 33.9-2](#)), biopsy at 6 weeks after the initial 45 Gy is optional.

**FIGURE 33.9-2.** Intergroup phase III anal canal cancer protocol (RTOG 98-11). CDDP, cisplatin; 5-FU, 5-fluorouracil; LN + and –, lymph node positive and negative; MMC, mitomycin C.

There are a subset of patients who, for a variety of reasons, undergo an excisional biopsy, such as a hemorrhoidectomy, polypectomy, or local excision, first and then are referred for definitive combined modality therapy. Because the margins may be either negative or at most microscopically positive, is full-dose radiation (45 Gy) necessary? Hu and colleagues treated eight patients after excision biopsy with 30 to 34 Gy plus 5-FU and mitomycin C.<sup>82</sup> With a median follow-up of 81 months, the 5-year actuarial local control rate was 100% and the overall survival was 88%. Although the data are limited, they do suggest that combined modality therapy with 30 Gy as opposed to 45 Gy may be an adequate dose in this select group of patients.

There are a number of phase II trials of combined modality therapy with external-beam pelvic radiation plus concurrent chemotherapy. The treatment design usually involves the use of one or two cycles of 5-FU by continuous 24-hour infusion (750 to 1000 mg/m<sup>2</sup>) for 4 to 5 days plus a bolus dose of mitomycin C (10 to 15 mg/m<sup>2</sup>) given on day 1 or 2 of each cycle. If given, the second chemotherapy cycle usually begins on day 28. In those trials using cisplatin, it is substituted for mitomycin C at a bolus dose of 75 mg/m<sup>2</sup>. The group from Humboldt University in Berlin has added regional hyperthermia to combined modality therapy.<sup>125</sup> However, this approach remains investigational.

Combined modality therapy can be delivered concurrently or sequentially. In the concurrent regimen, radiation therapy and chemotherapy are initiated on the same day. In the sequential regimen, chemotherapy is given before the start of radiation therapy. Since the report from Miller et al. that reported a complete response rate of only 45% with sequential 5-FU, mitomycin C, and 30 Gy, almost all combined modality therapy trials have used concurrent chemotherapy plus radiation.<sup>126</sup> Although concurrent therapy is favored because the need for salvage APR appears lower, there are no randomized comparison trials. For certain subgroups of high-risk patients (e.g., large T4 tumors), induction chemotherapy followed by concurrent chemotherapy and radiation to higher doses may prove to be a useful option. This is currently being tested in a single-arm Cancer and Leukemia Group B trial for advanced anal canal tumors.<sup>127</sup> Combined modality therapy trials can be broadly divided into those that use either 5-FU and mitomycin C chemotherapy or, more recently, 5-FU and cisplatin chemotherapy.

*Mitomycin C versus Cisplatin.* Mitomycin C–based trials are shown in [Table 33.9-3](#). When comparing the results, it is important to consider the percentage of patients with T3 disease, node-positive disease, or both. With the exception of the series by Miller et al., which used sequential chemotherapy, the mean (average) results include a complete response rate of 84% (81% to 87%), a local control rate of 73% (64% to 86%), and a 5-year survival rate of 77% (66% to 92%). These results are comparable with the 5-FU and mitomycin C–containing combined modality arms of the three randomized trials seen in [Table 33.9-5](#). For patients with T1 and T2 disease, the complete response rates are in excess of 90%, with ultimate local control rates after surgical salvage of 80% to 90%. In patients with T3 and T4 disease, approximately 50% of patients require a salvage APR. If they achieve a complete response after the completion of combined modality therapy, then only 25% require a salvage APR.

Cummings et al. reported lower acute and late grade 3+ toxicity with split-course compared with continuous-course radiation (acute, 40% vs. 75%, and late, 17% vs. 63%). Because almost all patients receiving continuous-course radiation will need a treatment break (most commonly for grade 3+ skin or hematologic toxicity), the majority of investigators continue to recommend a continuous course, thereby giving a treatment break when needed rather than a planned break.

Although the results of 5-FU, mitomycin C, and concurrent 45 Gy are impressive, there is room for improvement, especially in patients with T3 and T4 disease. A variety of treatment approaches have been tested. These include the use of 5-FU and cisplatin (as induction therapy or concurrently with radiation) and intensifying the radiation dose beyond 45 Gy using external-beam or brachytherapy. The combination of 5-FU plus cisplatin is an attractive regimen because (1) patients who have failed 5-FU and mitomycin C still respond to 5-FU and cisplatin and (2) cisplatin is an active radiation sensitizer.

Selected trials using cisplatin-based therapy are seen in [Table 33.9-4](#). Most also use higher radiation doses compared with the mitomycin C–based trials seen in [Table 33.9-3](#). Although the numbers are small, with the exception of a similar average complete response rate (85%; range, 80% to 96%), the data suggest that the average rates of local control (87%; range, 80% to 94%), colostomy-free survival (71%; range, 56% to 86%), and overall 5-year survival (89%; range, 84% to 94%) may be higher than the mitomycin C–based regimens. It must be emphasized, however, that these differences may be due to other factors such as patient selection bias and higher radiation doses.

The Cancer and Leukemia Group B pilot trial reported by Meropol et al. was limited to patients with T3 and T4 disease. With induction 5-FU and cisplatin and concurrent 5-FU and cisplatin plus radiation, the complete response rate was 80%, colostomy-free survival was 56%, and crude survival was 78%.<sup>127</sup> The Intergroup has developed a randomized trial (RTOG 98-11) to compare this approach with conventional 5-FU, mitomycin C, and 45 Gy (see [Fig. 33.9-2](#)).

*Intensification of the Radiation Dose: External Beam.* Retrospective data from the Massachusetts General Hospital,<sup>98</sup> M. D. Anderson Hospital,<sup>128</sup> and others suggest improved local control with increased radiation dose. In an attempt to improve local control and survival, two parallel pilot trials of radiation-dose intensification were designed. In both trials, patients received 36 Gy to the pelvis (30.6 to the whole pelvis plus 5.4 Gy to the true pelvis), and, after a 2-week break, received an additional 23.4 Gy to the primary tumor with a 2- to 3-cm margin for a total dose of 59.4 Gy. The main differences between the two trials was the type of chemotherapy. The RTOG 92-08 trial<sup>129</sup> (see [Table 33.9-3](#)) used concurrent 5-FU and mitomycin C, whereas the ECOG 4292 trial<sup>130</sup> (see [Table 33.9-4](#)) used 5-FU and cisplatin.

The RTOG 92-08 trial included 47 patients, 49% with T3 and T4 and 89% with node-positive disease.<sup>129</sup> With a median follow-up of 21 months, the local failure rate was 19%, 4-year colostomy-free survival was 71%, and overall survival was 73%. Although the incidence of grade 3 to 4 toxicity (26%) was similar to a standard regimen of 45 Gy plus 5-FU and mitomycin C used in RTOG 89-04, the 2-year colostomy rate was higher (30% vs. 7%). The reason for the increase is unclear. The investigators postulate that it may be related to the higher percentage of patients requiring a treatment break of longer than 2 weeks (96% vs. 12%). The ECOG 4292 trial entered 19 patients and reported a 68% complete response rate 8 weeks after the completion of 59.4 Gy and a 79% grade 3+ toxicity rate.<sup>130</sup> In contrast, Pieffert et al.<sup>131</sup> and Gerard and colleagues<sup>86</sup> treated patients with similar doses (the boost given with either external-beam or brachytherapy) and reported higher complete response rates (96% and 89%, respectively).

*Intensification of the Radiation Dose: Brachytherapy.* Brachytherapy is an ideal method by which to deliver conformal radiation for anal cancer while sparing the surrounding normal structures such as small intestine and bladder. Much of the initial experience with brachytherapy in anal cancer was from investigators in England and France who used radium needles.<sup>132</sup> Due to radiation protection concerns and a high anal necrosis rate, afterloading <sup>192</sup>Ir catheters have replaced radium needles. However, it is not clear that <sup>192</sup>Ir has a lower rate of complications.

Selected series that use brachytherapy as a component of treatment of anal cancer are shown in [Table 33.9-6](#). In most series, patients received 30 to 55 Gy of pelvic radiation with or without 5-FU and mitomycin C or cisplatin followed by a 15- to 25-Gy boost with <sup>192</sup>Ir afterloading catheters. Most use low dose-rate; however, some investigators have advocated high dose-rate.<sup>133,134</sup> There are biologic differences between low dose- and high dose-rate brachytherapy; however, at the present time there does not appear to be a difference in efficacy.

Combining the series, the mean results include a complete response rate of 83% (73% to 91%), local control rates of 81% (73% to 89%), and a 5-year survival rate of 70% (60% to 84%). The average complete response and local control rates appear similar to those achieved with external-beam–based combined modality therapy. Furthermore, the 5-year survival rates appear lower. Of equal concern is the increased incidence of anal necrosis. Reports of anal necrosis rates include those of Papillon et al. (2%),<sup>84</sup> Gerard et al. (15%),<sup>86</sup> Peiffert et al. (25%),<sup>85</sup> and Roed et al. (76%).<sup>134</sup> The incidence of severe complications included those of Sandhu et al. (8%),<sup>135</sup> Wagner et al. (9%),<sup>136</sup> and Allal et al. (12%).<sup>137</sup>

A new technique of ultrasound-guided three-dimensional tumor reconstruction and brachytherapy has been reported by Lohnert and colleagues.<sup>138</sup> In patients receiving more than 4-Gy fractions, the incidence of severe complications was 63%; however, none were seen when the dose was limited to less than 4-Gy fractions.

In summary, it is unclear if increasing the radiation dose in patients receiving combined modality therapy improves the results compared with conventional doses of 45 to 50 Gy. Although there are no randomized data, the phase II trials suggest that even in experienced hands, brachytherapy is associated with higher complication rates than external-beam therapy.

The ideal combined modality therapy regimen and the most appropriate radiation dose to use for patients with anal canal tumors limited to the primary site have not yet been defined. At the present time in the United States, combined modality therapy with the RTOG combined modality therapy regimen of continuous-course radiation (45 Gy in 1.8-Gy fractions) plus two cycles of concurrent continuous infusion 5-FU on weeks 1 and 5, plus mitomycin C bolus on days 1 and 29, remains the standard of care. This is the control arm of RTOG 98-11 seen in [Figure 33.9-2](#). For patients with T3 and T4 disease (primary tumors larger than 5 cm) it is reasonable to boost with an additional 5.4 to 9.0 Gy. In RTOG 98-11 the experimental arm uses the same design except it adds two cycles of induction 5-FU and cisplatin as well

as 5-FU and cisplatin (CDDP) during the radiation. The posttreatment biopsy at 8 weeks is now optional.

**Radical Surgery.** With the advent of multimodality therapy for the primary treatment of patients with anal canal tumors, the role of surgery is important mostly from an historic perspective. Because of the high propensity of anal canal tumors to recur locally, a wide perineal resection was initially proposed for treatment. <sup>64,74,139,140</sup> If necessary, gluteal or perineal flaps were raised to cover the residual defect. <sup>139</sup> Some authors advocated the resection of the posterior vaginal wall to obtain clear surgical margins, <sup>30,64,66,69</sup> whereas others thought this to be unnecessary unless the rectovaginal septum was involved. <sup>43</sup> Bilateral inguinal lymph node dissection was performed in patients undergoing radical surgical resection of their primary tumor <sup>47,63,64,71,141,142</sup> until it was shown that prophylactic inguinal lymph node dissections were beneficial in only 6% of patients. <sup>34</sup> The high morbidity with little gain led others to quickly condemn the use of this procedure. <sup>34,37,64,65,69</sup> Combined modality therapy controls more than 90% of inguinal nodal disease. <sup>92,143</sup>

Recurrence develops in up to 40% of patients having an APR for primary treatment of anal canal tumors. <sup>45,63,66,70</sup> The median time to recurrence is 12 to 15 months. Local recurrence is the rule, with the majority in the pelvis and the remainder in the inguinal or pelvic nodes. <sup>45,69,70,126</sup> Distant metastases are less common but can be seen in up to 31% of patients. Greenall and colleagues observed a median survival of 10 months for patients with pelvic recurrence and 7 months with visceral metastases. <sup>70</sup>

Overall survival did not improve dramatically after the advent of radical surgery. Five-year survival rates after APR for primary treatment range from 55% to 71%. <sup>37,45,64,70,75,108,110,112,117</sup> Survival was adversely affected by the size of the primary tumor. In patients treated at Memorial Sloan-Kettering Cancer Center, 60% of patients with tumors smaller than 5 cm were alive at 5 years, whereas only 40% of those with tumors larger than 5 cm were alive at 5 years. <sup>70</sup> Miller et al. improved overall survival from 55% in historic controls to 82% for patients treated with a preoperative combined modality therapy regimen. <sup>126</sup> Of equal significance was the preservation of anal function in the majority of patients treated with combined modality therapy.

**Radiation Therapy Alone.** There is a subset of patients who have been treated with radiation therapy alone. Because both the UKCCCR <sup>107</sup> and EORTC <sup>89</sup> randomized trials have shown a significant advantage to the combined modality arm for local control (UKCCCR) and local control and colostomy-free survival (EORTC), combined modality therapy is standard of care. However, external irradiation alone is a reasonable alternative for patients who cannot tolerate chemotherapy due to medical contraindications.

Age alone is not a contraindication to combined modality therapy. Although some elderly patients may not tolerate chemotherapy well, less aggressive treatment in patients older than 65 years old appeared to jeopardize their outcome in a Canadian retrospective study. <sup>144</sup> Studies of combined modality therapy in patients 75 years old or older have been reported from both Valentini and colleagues <sup>145</sup> and Allal et al. <sup>146</sup> Rates of complete response, local control, and acute and long-term toxicity were similar to those reported for the general population. Although some chemotherapy dose attenuation and radiation field modifications may be needed, combined modality therapy in selected patients 75 years old and older should be considered.

**Radiation Alone: External Beam.** The results of major studies using external-beam radiation alone are seen in [Table 33.9-8](#). The mean results include a local control rate of 74% (61% to 100%) and a 5-year survival rate of 63% (50% to 94%). Although the series of 18 patients from Martenson and Gunderson from the Mayo Clinic had the highest survival and local control rate, they also had a high rate of complications requiring surgery (17%). <sup>147</sup> In most series, local control and survival decrease with increasing T stage. Overall, these results are comparable with those of patients who receive combined modality therapy with 45 Gy plus 5-FU and mitomycin C. However, the mean incidence of complications requiring surgery is 10% (range, 3% to 17%), which probably reflects the high radiation doses that must be delivered to the primary site to control this disease if radiation therapy is the sole treatment modality. Therefore, unless there is a compelling reason to avoid systemic chemotherapy in an individual patient, combined modality therapy should remain the standard of care.

Site	Number	Dose (Gy)	Stage	Primary T Control	Percentage Local Control	Percentage Complications Requiring Surgery

**TABLE 33.9-8.** Radiation Therapy Alone: Selected Series

**Radiation Alone: Brachytherapy with or without External Beam.** Brachytherapy (interstitial radiation) alone has the potential of curing only early lesions that are unlikely to have spread to the lymph nodes. Historically, radium needles have been used, although interstitial implants with <sup>192</sup>Ir are most common in modern series. Radium needles have been used for many years at the Christie Hospital in Manchester, England, for early anal cancers. <sup>118,121</sup> Radium needles were the exclusive treatment modality in 74 patients, 43 with anal canal lesions and 31 with anal margin lesions. <sup>121</sup> Of the 68 evaluable patients with minimum follow-up of 5 years, there were 35 locoregional failures, of which only seven were salvaged by surgery. Local control was achieved in only 64% of tumors smaller than 5 cm in diameter and in only 23% of tumors larger than 5 cm.

Radium needle implantation has also been used extensively by Papillon, but he has abandoned this technique because of painful local reactions and inability to achieve lymph node control because of the small target volume. <sup>84,119</sup> Early studies with radium needles yielded a severe necrosis rate of approximately 25%. <sup>148</sup>

Several studies with small numbers of patients have been reported in which external-beam radiation is combined with brachytherapy ( <sup>137</sup>Cs, <sup>192</sup>Ir, or radium needles). <sup>72,120,132,149,150</sup> and <sup>151</sup> Good local control was achieved, but there was a relatively high rate of complications requiring surgery or leading to death.

The largest experience is from the Centre Leon Berard in which 221 patients with anal carcinoma were treated over a 15-year period with external-beam radiation therapy (<sup>60</sup>Co) to a dose of 35 Gy, followed 2 months later by an additional 15 to 20 Gy with <sup>192</sup>Ir implant. <sup>84,132</sup> The investigators reported only a 3% rate of serious complications and achieved a 65% 5-year disease-free survival and a 79% locoregional control rate. Combined brachytherapy and external irradiation may be useful in treating extensive lesions. <sup>152,153</sup> and <sup>154</sup>

Another study from France confirmed a high 5-year survival rate (61%) and good local control (75%), but a 6% rate of complications requiring surgery. <sup>151</sup> The importance of treating the inguinal nodes prophylactically was illustrated in this study. In 28 N0 patients, two had an inguinal recurrence, neither of whom had received inguinal irradiation. Both developed distant metastases and died of disease.

In summary, radiation therapy alone with either external-beam or combined with brachytherapy may yield comparable local control and survival rates with combined modality therapy. However, it is associated with increased complication rates. In contrast to combined modality therapy in which the complications are commonly acute (i.e., diarrhea, hematologic, skin, and nadir fever), the complications with radiation therapy alone usually involve anal necrosis requiring surgery. As seen in [Table 33.9-6](#), similar toxicity has been reported in patients receiving combined modality therapy plus brachytherapy. Even in experienced hands, brachytherapy is associated with a moderate degree of anal necrosis and should be used with caution.

## RADIATION THERAPY TREATMENT TECHNIQUES

A comprehensive discussion of techniques to decrease the toxicity of pelvic radiation, such as physical maneuvers, immobilization molds, dietary supplements and

radioprotectors, three-dimensional treatment planning, and other investigational approaches, is presented in [Chapter 33.8](#) and is not discussed here. However, there are some general principles specific to the design and delivery of radiation for anal cancer that are presented in this chapter. Last, a caveat: Technique recommendations should be interpreted with caution. Radiation oncology, as with other medical specialties, is both an art and a science. Therefore, the recommendations made in this chapter should serve as a guide rather than a *cookbook*.

The design of pelvic radiation therapy fields for anal cancer is based on knowledge of the natural history of the disease and the primary nodal drainage. Because the internal iliac and presacral nodes are posterior in reference to the external iliac nodes, many of the normal structures in the anterior pelvis can be spared with the use of lateral fields. As this approach underdoses the inguinal nodes, they should be supplemented with electrons. Examples of field arrangements are seen in [Figure 33.9-3](#).

**FIGURE 33.9-3.** Idealized treatment fields for a clinical T2N0M0 squamous cell carcinoma of the anal canal. The inguinal nodes are included in the posteroanterior (PA) field and are supplemented with electrons.

## PELVIC FIELD

A prone three-field technique (posterior plus opposed laterals) is recommended. This arrangement results in the lowest dose to the anterior structures such as the genitalia and bladder. The underdosed inguinal nodes are then treated concurrently with electrons to bring the dose up to 100% of the prescription dose. An alternative method is to use an anterior/posterior technique. Although this technique treats the pelvic and inguinal nodes in the same field, it results in the highest dose to the anterior pelvic structures and skin, thereby increasing toxicity. An electron boost for the perineum is not recommended as there will be overlap between the electron and photon fields. The portion of the perineum that needs to be treated should be included in the photon fields. The whole pelvis receives 30.6 Gy followed by a 14.4-Gy cone down to the true pelvis for a total dose of 45 Gy.

## PRIMARY TUMOR BOOST FIELD FOR COMBINED MODALITY THERAPY SALVAGE AT 6 WEEKS

If the RTOG recommendations for combined modality therapy salvage are followed, then an additional 9 Gy (concurrent with 5-FU and cisplatin) are delivered. Using opposed laterals, the field includes the primary tumor plus a 2- to 3-cm margin in all directions. As an alternative, patients with T3 tumors can receive an additional 5.4 Gy to the primary tumor plus a 2- to 3-cm margin to a total dose of 50.4 Gy, which is delivered immediately after the 45 Gy of pelvic radiation.

## MEDIAL AND LATERAL INGUINAL LYMPH NODES

After treatment of the pelvis in the prone position, the patient is treated in the supine position with electrons for inguinal nodes. The medial and lateral inguinal nodes are outlined with a 2-cm margin in all directions. The inguinal nodes are included in the posterior pelvic photon field. They receive only exit dose from this field, usually approximately 30% to 40% of the pelvic field prescription. This is determined from the treatment plan. Because they need to receive a total of 1.8 Gy/d, the remaining dose should be given concurrently with electrons. The depth of the inguinal nodes can be determined from a computed tomographic scan.<sup>155,156</sup> If this is not available, then a clinical estimate may be used. If the inguinal lymph nodes are positive by biopsy, a four-field technique (anterior/posterior plus opposed laterals) is recommended as the external iliac nodes should be treated. In this setting, inguinal node dose should be 50.4 Gy.

## COMPLICATIONS AND CRITICAL NORMAL TISSUES

As seen with other cancer therapies, pelvic radiation is associated with acute and long-term toxicity. Complications of pelvic radiation therapy are a function of the volume of the radiation field, overall treatment time, fraction size, radiation energy, total dose, and technique. Large field sizes, a short overall treatment time, large fraction sizes (greater than 2.0 Gy/d), orthovoltage or low-energy megavoltage radiation (Cobalt 60), doses of greater than 50.4 Gy when there is small bowel in the field, the use of an anterior/posterior technique, treatment of only one field per day, the use of a direct perineal boost field, and the lack of computerized dosimetry all contribute to an increased incidence of radiation complications. Critical normal tissues that should be considered in the treatment of anal canal cancer include bone marrow, rectum, small bowel, bladder, and skin. The acute toxicity is due to a combination of chemotherapy and radiation therapy. Toxicities include leukopenia, thrombocytopenia, proctitis, diarrhea, cystitis, and perineal erythema. It must be emphasized that even when pelvic radiation is delivered with appropriate doses and techniques, almost all patients receiving combined modality therapy for anal cancer develop acute grade 3+ toxicity requiring a treatment break at some point in their treatment courses. Approximately 1% develop long-term severe toxicity.

Unless there is a contraindication, the most simple techniques to decrease radiation toxicity, such as the use of small bowel contrast, multiple field techniques, high-energy linear accelerators, custom blocks, avoiding a direct perineal boost, and treatment in the prone position, should be part of the standard treatment of patients receiving curative pelvic radiation therapy. Any physical maneuver beyond the use of the prone position, such as a belly board, abdominal wall compression, or a full bladder, may be associated with patient discomfort, thereby leading to increased movement and daily setup errors.

Radiation therapy can affect sphincter function. There is an increasing body of literature reporting the effect of radiation therapy on functional results in rectal cancer.<sup>157</sup> However, it is not directly applicable to anal cancer as patients do not undergo pelvic surgery. There are limited reports of functional outcome in the anal cancer literature. One series reports that full function was maintained in 93% of patients,<sup>158</sup> and a second series that used anorectal manometry reported complete continence in 56%.<sup>159</sup> Both series used brachytherapy as a component of therapy. It is hoped that new trials will include a functional analysis.

## INGUINAL NODE INVOLVEMENT

When examining the effect of positive lymph nodes on local control and survival, it is important to differentiate the site of nodal disease as well as synchronous versus metachronous nodal disease. Most series do not separate N1 versus N2 versus N3 disease. However, there are data examining synchronous versus metachronous nodal disease.

Early experience from the 1950s from Stearns et al. suggested that patients with grossly positive inguinal lymph nodes synchronous with the primary tumor were incurable.<sup>47</sup> A subsequent report indicated that 2 of 13 patients survived 5 years after an APR followed 6 weeks later by inguinal lymphadenectomy.<sup>76</sup> Older studies also demonstrated a small cure rate for surgical treatment of patients with synchronous unilateral inguinal nodes.<sup>37,65</sup>

There are conflicting reports as to the prognosis of patients with synchronous nodal disease who are treated with combined modality therapy. Compared with node-negative patients, Allal et al. report a higher rate of local failure (N1 to N3, 36%, vs. N0, 19%),<sup>94</sup> and the Intergroup randomized trial reports a higher colostomy rate (N1, 28%, vs. N0, 13%).<sup>85</sup> Although Cummings and associates from the Princess Margaret Hospital reported a local failure rate of only 13% in node-positive patients, 5-year cause-specific survival was lower (N1 to N3, 57% vs. N0, 81%).<sup>92</sup> By multivariate analysis, the EORTC randomized trial reported that positive nodes were an independent negative prognostic factor for local failure and survival.<sup>89</sup>

In contrast, in the series of combined modality therapy plus brachytherapy from Gerard et al., patients with N1 versus N0 disease had similar 5-year disease-specific and overall survival rates.<sup>86</sup> Likewise, complete response rates in the primary tumor are not affected by the presence of nodal disease. Doci and associates report similar rates in patients receiving cisplatin-based therapy (N1 to N3, 92%, vs. N0, 100%)<sup>87</sup> and in a separate series of patients receiving mitomycin C-based therapy, eight of eight patients with N1 to N3 disease achieved a complete response.<sup>93</sup> Overall, external-beam radiation alone<sup>90,96,119,151</sup> can control positive nodes in 65% of patients, and combined modality therapy<sup>88,89</sup> and<sup>90,107</sup> can achieve nodal control in approximately 90% of patients.

The current treatment recommendations for patients with positive inguinal nodes include biopsy followed by combined modality therapy with a boost of 45.0 to 50.4 Gy to the involved groin. Because the external iliac nodes should be treated in the pelvic radiation field, a four-field technique is recommended. Inguinal node dissection should not be performed as part of the initial therapy; however, it may be done for isolated inguinal recurrence.

The development of unilateral metachronous inguinal lymph nodes does not carry such an ominous prognosis. After therapeutic groin dissection, the 5- to 7-year survival rates exceeded 50% in two series,<sup>68,114</sup> but it was 0% in a small series reported from the Mayo Clinic.<sup>37</sup> Current strategies in patients with metachronous isolated inguinal node metastases after combined modality therapy include a formal groin dissection followed by chemotherapy. The use of radiation under these circumstances depends on prior dose and fields.

## RESIDUAL OR RECURRENT CANCER

### ANAL MARGIN

Locally recurrent anal margin cancers are more successfully controlled by local excision than are recurrences of anal canal cancer.<sup>105,160</sup> The largest reported series of recurrent tumors included 16 of 48 patients who, after a local excision, had local recurrences (11), in the inguinal nodes (4), or both (1).<sup>114</sup> There were no visceral failures. The median time to recurrence was 26 months. Ten of the patients with local recurrences underwent repeat local excision, and only one required an APR. Nine of these patients survived longer than 5 years. All four patients with inguinal node recurrences had inguinal lymphadenectomies, and two were long-term survivors. Although there is little reported experience with radiation therapy or combined modality therapy for patients with local recurrence after a local excision, it is reasonable for those who would otherwise require an APR.

### ANAL CANAL

After primary treatment of anal canal tumors with combined modality therapy, patients should be evaluated for response to therapy. This is usually done 4 to 6 weeks after the completion of therapy, but Nigro<sup>161</sup> recommended waiting for 8 weeks and Cummings et al. recommended at least 8 to 12 weeks.<sup>92</sup> Depending on the initial T stage and how soon the biopsy is performed after the completion of combined modality therapy, persistent disease is found in 10% to 25% of patients.<sup>161,162,163</sup> and<sup>164</sup>

Controversy exists concerning the appropriate definition and management of patients with residual disease after combined modality therapy. Whether one waits 6 or 30 weeks after the completion of therapy, if the tumor continues to decrease in size, it has been hypothesized that the cancer is in the process of responding to the therapy and therefore is not a *treatment failure*.<sup>92</sup> Selected patients with microscopic foci of tumor may undergo local excision of persistent disease. Therefore, patients who undergo salvage APR or further combined modality therapy within 8 weeks after the completion of initial therapy may be treated unnecessarily. Patients with progressive residual microscopic or gross disease are candidates for either an APR or additional combined modality therapy. There are no randomized trials to suggest which of these two alternatives are superior. APR is the most frequently reported salvage therapy, with 5-year survival rates of 30% to 58%. However, there are also reports of successful long-term salvage with combined modality therapy.<sup>88,165</sup> Because there is a maximum radiation dose that pelvic structures can safely tolerate, the decision to give additional radiation depends on careful review of the radiation fields and dosimetry.

A retrospective, nonrandomized study of patients from all of the Veterans Administration hospitals suggested that salvage surgery was superior to salvage with chemotherapy either with or without radiation therapy, with a 53% salvage rate with surgery compared with only 19% for the conservative attempts.<sup>166</sup> Nigro and others recommend a second course of combined modality therapy for patients with macroscopic disease, and several have been salvaged with this therapy.<sup>161</sup> If local failure occurs after a second course of combined modality therapy and there is no evidence of extrapelvic disease, then an APR should be done.

In the RTOG randomized study, discussed in the section [Combined Modality Therapy](#), biopsy was performed on most patients after their initial therapy.<sup>88</sup> For those with positive biopsy results, salvage chemotherapy using cisplatin and 5-FU and localized boost radiation were given. Of the 27 patients who received this salvage regimen, 24 underwent biopsy after its completion. Of these, 12 (50%) had a negative biopsy result, and five of these had no further surgery after a minimum of 3 years of follow-up. This indicates that at least some patients can have sphincter-sparing treatment despite failure to achieve a complete remission with first-line therapy.

In a French study, local failure after radiation therapy alone occurred in 50 patients of whom 26 subsequently underwent salvage APR.<sup>143</sup> Local tumor control was obtained in 12 of 26 patients (46%), and the 5-year survival was 56%. Similar local control rates and overall survival were found in 24 patients treated with APR after failure with combined modality therapy at Memorial Sloan-Kettering Cancer Center.<sup>91</sup> Others have not had such good results with salvage APR.<sup>167</sup>

The literature is confusing as investigators have used varying definitions of persistent and recurrent disease. Two series from France used different definitions of persistent versus recurrent disease and reported conflicting results.<sup>168,169</sup> When *persistent disease* was defined as a recurrence up to 6 months after combined modality therapy, surgical salvage with APR improved survival.<sup>168</sup> In contrast, when *recurrent disease* was defined as any recurrence after a clinical complete response, regardless of the disease-free interval, patients with recurrent disease had survival rates superior to those with persistent disease.<sup>169</sup> In this series, of the 27 patients who underwent salvage surgery for local failure after combined modality therapy, only 44% died of disease.<sup>169</sup>

It must be emphasized that patients should be followed closely by digital rectal examination and anoscopy (every 6 to 12 weeks) until a complete clinical response is documented. Any local progression of disease should be defined and treated as early as possible.

## METASTATIC DISEASE

Because primary combined modality therapy has been so effective, the number of patients with this uncommon malignancy who developed advanced metastatic disease is small. Perhaps as a result, the number of chemotherapeutic agents that have been tested in patients with advanced anal canal cancer is small and the reports are anecdotal.

Single-agent trials of doxorubicin (Adriamycin) and of cisplatin have been reported by several investigators. Fischer and colleagues reported a response to both doxorubicin as a single agent and cisplatin at a dosage of 2 mg/kg in an elderly man with advanced disease.<sup>170</sup> Salem and coworkers studied cisplatin as a single agent in three patients: One achieved a complete response and the other two had partial responses.<sup>171</sup> Earlier trials with 5-FU and vinblastine in small groups of patients were ineffective. Bleomycin and vincristine were used by Livingston and colleagues in a single patient, and a partial regression was observed.<sup>172</sup> Combination chemotherapy with cisplatin and 5-FU in patients with advanced disease has now been reported in small groups of patients. Responses have been reported using both systemic and regional (hepatic-arterial) routes. Of a total of six patients described in three reports, three complete and three partial responses were noted.<sup>173,174</sup> and<sup>175</sup> In a study from France using this combination and involving seven patients with local recurrence alone and 13 patients with metastasis, there were two complete and nine partial responses.<sup>176</sup> In one study, three of eight patients achieved a complete clinical response with cisplatin and fluorouracil, of whom two were 5-year survivors.<sup>177</sup>

A noncisplatin regimen was used by Wilking and colleagues.<sup>178a</sup> A total of 15 patients with advanced disease received bleomycin, vincristine, and high-dose methotrexate. Major objective regressions were seen in 3 of 12 patients with measurable tumors, but their duration of response was only 1 to 5 months. Toxicity was severe, with four patients having probable treatment-related deaths. McGill and Quan treated 24 patients using cisplatin, bleomycin, and alkaloid. Six of 21 evaluable patients (29%) responded.<sup>179</sup> Carboplatin has also been reported to have activity in this disease.<sup>178</sup>

Although response rates in patients with metastatic disease are difficult to evaluate in view of the paucity of data, the use of neoadjuvant (induction) therapy has

allowed an assessment of the effectiveness of chemotherapy alone without the confounding variable of concurrent radiation in larger groups of patients. Most more recent regimens involve the use of a platinum compound with 5-FU. Peiffert et al. reported the preliminary results of a trial involving induction cisplatin plus 5-FU chemotherapy for two cycles followed by combined modality therapy. In a group of 28 evaluable patients, 72% had complete or partial responses from neoadjuvant chemotherapy alone. The regimen used was cisplatin, 80 mg/m<sup>2</sup> on day 1, followed by a 4-day continuous intravenous infusion of 5-FU at 800 mg/m<sup>2</sup>. Other investigators have reported similar findings.

At the present time, therefore, cisplatin plus 5-FU-containing combinations appear to have a high degree of activity in patients with anal canal tumors whether used in metastatic disease or as part of induction therapy for advanced local regional disease. The high cure rate seen with primary combined modality therapy may slow the identification of newer agents. The use of agents with high degrees of activity in other squamous cell malignancies as part of a neoadjuvant approach may be a strategy to identify newer agents in this disease.<sup>180</sup>

## FOLLOW-UP

Close observation of patients after treatment of anal cancer is essential, because patients with local failure are amenable to resection and may be salvaged with long-term survival. The majority of recurrences occur within the first 3 years, and patients should be examined by physical examination and anoscopy every 6 to 12 weeks until a complete response is achieved, then every 3 months for a total of 2 years. Follow-up examinations can then be decreased to every 6 months for the next 3 years and then yearly after 5 years. The usefulness of computed tomography of the abdomen and pelvis for follow-up is unclear. Transrectal ultrasound may be of value. It must be emphasized that because the most common site of failure is at the primary tumor site, there is no substitute for physical examination. In a limited series of 33 patients, Petrelli and colleagues report a 76% sensitivity, 86% specificity, and a 62% positive predictive value of squamous cell carcinoma tumor-associated antigen.<sup>181</sup>

## ANORECTAL MELANOMA

Anorectal melanomas are relatively rare, accounting for less than 1% of all anal canal tumors. The patients present with nonspecific complaints, which are often attributed to benign anal conditions, and the correct diagnosis is seldom made accurately at the initial examination. This delay may be responsible for the advanced stage seen in most at diagnosis. The stage (tumor thickness and nodal status) at presentation is the primary determinant of survival, and distant metastasis is common.<sup>182,183,184,185,186 and 187</sup>

## CLINICAL PRESENTATION AND PATHOLOGIC FEATURES

Anorectal melanomas are slightly more common in women, and the median age at presentation is in the sixth decade. Most patients present with bleeding as the initial complaint, which is often attributed to hemorrhoids. Symptoms are often present for 1 to 3 months before evaluation and also include pain, tenesmus, pruritus, change in bowel habits, and weight loss. An initial error in diagnosis has been reported in up to 80% of patients who subsequently were diagnosed with anorectal melanoma.<sup>182,188</sup> The most common physical finding is a mass felt on rectal examination or seen extruding from the anus. It may appear pigmented in only one-third of patients.<sup>188</sup> The tumors measure 3 to 5 cm in diameter in most cases and can be as large as 12 cm. Inguinal lymph nodes are frequently positive. The primary tumor may arise from the skin of the anal verge, mucocutaneous junction, transitional epithelium of the anal canal, or rectal mucosa, but is seldom found more than 5 cm from the dentate line. The diagnosis can also be made by finding an incidental melanoma in a hemorrhoid specimen. The morphologic characteristics of anorectal melanomas are the same as for cutaneous melanomas.

## PATTERNS OF SPREAD

Anorectal melanomas spread locally by direct extension upward in the submucosal plane of the rectum, but they seldom invade bladder, vagina, sacrum, or prostate. Regional spread via the lymphatic channels is superiorly to the mesenteric system or laterally to the inguinal system. Inguinal nodes are present in 20% of patients, and mesenteric nodes are involved in up to 65% of patients undergoing radical surgery.<sup>188,189,190,191 and 192</sup> Hematogenous spread is found in up to 29% of patients at diagnosis<sup>187,190,192</sup> and overall in up to 69% of patients.<sup>191</sup> Distant metastasis is most common in the lungs, liver, and bone.

## TREATMENT AND OUTCOME

The classic surgical approach for the treatment of anorectal melanoma was APR with pelvic lymph node dissection and bilateral groin dissection.<sup>189</sup> Because those with inguinal metastases uniformly died of disease, this part of the procedure is no longer performed.<sup>189,193</sup> Because of the high systemic failure rate, several authors have questioned the wisdom of radical surgery and have advocated wide local excision for treatment of this disease.<sup>182,190,191,194</sup> In the early reports from Memorial Sloan-Kettering Cancer Center,<sup>189,195,196</sup> the only long-term survivors were patients who had undergone an APR with or without lymphadenectomy. Similar results were found at the Mayo Clinic.<sup>193</sup> Siegel and colleagues<sup>182</sup> had two long-term survivors treated with local excision and chemotherapy, and the M. D. Anderson group<sup>191</sup> had one survivor at 5 years who was treated with wide local excision alone. Despite a better local control rate with APR, no series has shown a survival advantage for patients who have had an APR compared with patients having wide local excision.<sup>182,183,190,191 and 192,197</sup> However, none of these studies was randomized, thus lending potential bias in favor of local excision, which was usually performed for smaller lesions.

Several factors have been analyzed to determine their effect on outcome. Age and race are the only factors that have consistently been shown not to affect overall survival. Size was not an important factor in the results from the study by Quan et al.<sup>189</sup> but had a direct effect on survival in the study by Goldman and colleagues.<sup>190</sup> Tumor thickness is the most important factor in determining outcome for cutaneous melanomas. Wanebo and colleagues noted three survivors at 5 years; all had tumors less than 2 mm thick, and all were treated with an APR.<sup>195</sup> Of the patients with tumors larger than 2 mm, none lived 5 years, and 85% were dead by 2 years. Another study noted three long-term survivors who had anorectal melanoma discovered incidentally at the time of hemorrhoidectomy.<sup>192</sup> Of the 18 patients with mesenteric lymph node metastases, there was only one long-term survivor.<sup>192</sup> Female gender is associated with a better prognosis.

The inability of several authors to show a survival benefit for APR compared with wide local excision can be entirely attributed to the small numbers of patients involved in the studies, selection bias, and the lack of the scientific method. Any relative advantage of adjuvant immunotherapies, chemotherapy, and radiation therapy is similarly obscured and difficult to interpret. Treatment recommendations must therefore be less than absolute. A histologic margin of at least 3 mm should be obtained if local excision is to be used. In view of probably higher local control rates, APR can still be recommended.<sup>183,184,185 and 186,190,191</sup> There is a clear need for studies of sentinel node mapping and adjuvant therapies.<sup>183,190,191</sup>

## ADENOCARCINOMA

Primary adenocarcinoma of the anal canal arising from the anal glands is a rare tumor. Most adenocarcinomas in the canal represent rectal cancer with downward spread. In general, they should be treated like adenocarcinomas of the rectum, including APR, and if T3 disease, node-positive disease, or both exist, six cycles of adjuvant combined modality therapy with 5-FU-based chemotherapy plus preoperative or postoperative concurrent radiation therapy are given. However, the radiation fields should include the inguinal nodes. Basik and colleagues treated ten patients with surgery and reported a median survival of 29 months.<sup>198</sup> Adenosquamous cancers of the anus are also rare and have an equally poor prognosis.<sup>199</sup> Given the squamous component, it is reasonable to treat these patients with combined 5-FU and mitomycin C and concurrent radiation therapy. If there is residual disease, this would be followed by a salvage APR.

## SARCOMA

Leiomyosarcomas of the large intestine are unusual neoplasms, accounting for less than 0.1% of all malignancies of the colon and rectum. Few cases of leiomyosarcoma of the anus have been reported. The optimal treatment for this neoplasm is not known. The standard surgical approach is APR. Using a technique well established for management of sarcomas of the extremities, Minsky et al. have treated several patients using local excision and <sup>192</sup>Ir brachytherapy in an attempt to preserve the anal sphincter.<sup>200,201 and 202</sup> This technique may be an alternative to APR in selected patients.

## TREATMENT OF THE HUMAN IMMUNODEFICIENCY VIRUS-POSITIVE PATIENT

Given the 40- to 80-fold increase of anal cancer in the HIV-positive population compared with the general population, HIV-positive patients have received lower doses of radiation and chemotherapy due to a concern that standard therapy may not be tolerated.<sup>7</sup> With a better understanding of the immunologic deficiencies seen in HIV-positive patients, more recent reports have recommended therapy based on clinical and immunologic parameters such as a history of prior opportunistic infections and CD4 counts.

Hoffman and associates treated 17 HIV-positive patients with a median of 51.8 Gy plus concurrent 5-FU and mitomycin C.<sup>203</sup> With a median follow-up of 17 months, the nine patients with CD4 counts greater than 200  $\mu$ L were all without evidence of disease with acceptable toxicity. In contrast, of the eight patients with a CD4 count less than 200  $\mu$ L, four had grade 4 toxicity and four required a colostomy for toxicity or local failure. Despite the increase in morbidity, the disease of seven (88%) was locally controlled after salvage surgery. They recommend treating HIV-positive patients with standard doses of combined modality therapy but minimizing the radiation fields in patients with CD4 counts less than 200  $\mu$ L. Similar results were reported from Peddada et al., who treated eight HIV-positive patients with 30 Gy plus concurrent 5-FU and mitomycin C.<sup>204</sup> Of the four with a CD4 count less than 200  $\mu$ L, three of four developed grade 4 toxicities, whereas one of the four with a CD4 count greater than 200  $\mu$ L had grade 4 toxicity. However, all achieved a complete response. With a median follow-up of 38 months, four are alive without evidence of disease, and of the four who died of HIV-related complications, all had no evidence of anal cancer at the time of death. In another report, four HIV-positive patients without evidence of other HIV-related diseases received combined modality therapy.<sup>205</sup> Only one patient required a treatment break.

Management of the HIV-positive patient is complex and requires careful attention to all aspects of the patient's medical history, coexisting medical conditions, and personal wishes. The limited experience suggests that in patients with a CD4 count greater than 200  $\mu$ L who do not have signs or symptoms of other HIV-related diseases, aggressive combined modality therapy is appropriate. They should be followed carefully, however, and frequent modifications during therapy will likely be necessary. For those patients with a CD4 count less than 200  $\mu$ L or who have signs or symptoms of other HIV-related diseases, attenuated doses of radiation, chemotherapy, or both are recommended at the start of treatment.

## FUTURE DIRECTIONS

### PREVENTION AND EARLY DETECTION

Accumulating evidence has implicated HPV as a causative and perhaps necessary factor in the development of squamous cell carcinoma of the anus. Because this is the most common histology, anal cancer may represent a preventable disease as is the case for cervical carcinoma. Both in women and in men (particularly homosexual men) increasing use of measures for safe sex, initiated to stem the spread of AIDS, may also affect the incidence of anal cancer. Early detection and screening in high-risk individuals (such as the use of anal cytology in male homosexuals and immunosuppressed patients) should be encouraged to diagnose the tumor at the earliest possible stage. The use of antiviral agents in patients with HPV infection may be another method for decreasing incidence of this disease. If the tumor is not diagnosed at a stage early enough to allow cure by surgical resection alone (the minority of cases), new approaches involving combined modality therapy have clearly been demonstrated to offer equivalent or better results when compared with an APR. APR should be reserved for patients failing to respond to combined modality therapy. New efforts aimed at finding better chemotherapeutic regimens for the higher risk patients (T4 and node-positive tumors) are under way. In addition, the identification of new noncytotoxic agents capable of curative therapy without the toxicities of chemoradiation therapy should be explored.

## KIDNEY CANCER

Kidney cancer, or renal carcinoma, affects more than 30,000 Americans annually and is responsible for nearly 12,000 deaths in the United States each year. Renal carcinoma occurs most commonly in adults between 50 and 70 years of age, although it has been reported in children as young as 3 years.<sup>1,2</sup> Renal carcinoma is responsible for approximately 3% of adult malignancies, and the male to female ratio is 1.5:1.<sup>3,4</sup> Leatherworkers and workers exposed to asbestos have an increased incidence of renal carcinoma. A strong correlation exists between cigarette smoking and the development renal carcinoma.<sup>5,6</sup> Up to 85% of renal carcinomas are of the clear cell type; 5% to 15% of renal carcinomas are a papillary histologic variant.<sup>7,8</sup> An increased incidence of renal carcinoma is seen in dialysis patients with acquired cystic disease, in which a rate 30 times higher than normal has been estimated.<sup>9</sup> A family history of this malignancy has been associated with an increased risk of developing of renal carcinoma.<sup>2</sup>

Like colon cancer, breast cancer, and retinoblastoma, renal carcinoma occurs in both a familial (hereditary) and sporadic (nonhereditary) form. It has been estimated that up to 4% of renal carcinomas may have a hereditary basis.<sup>2</sup> At least four types of hereditary renal carcinoma have been categorized: renal carcinoma associated with von Hippel-Lindau disease (VHL), hereditary papillary renal carcinoma (HPRC), hereditary renal carcinoma associated with Birt-Hogg-Dubé syndrome,<sup>10</sup> and hereditary clear cell renal carcinoma. VHL disease is a hereditary cancer syndrome with an autosomal dominant inheritance pattern in which affected individuals develop tumors in a number of organs, including the kidney. HPRC is a newly described form of inherited renal carcinoma in which affected individuals develop multifocal, bilateral, early-onset papillary renal carcinoma. Birt-Hogg-Dubé syndrome is a dominantly inherited cancer syndrome in which affected individuals are at risk to develop cutaneous, renal, and other manifestations. The cutaneous manifestation involves fibrofolliculomas; the kidney tumors can be chromophobe renal carcinoma, oncocytoma, or papillary renal carcinoma.<sup>10</sup> In the fourth, but less well understood form of inherited renal carcinoma, hereditary clear cell renal carcinoma, patients have a predisposition to develop bilateral, multifocal clear cell renal carcinoma.

### LOCATION OF A RENAL CARCINOMA GENE

The initial studies to provide information with reference to a potential location for a renal carcinoma gene came from the work of Cohen and coworkers,<sup>11</sup> who in 1979 reported a kindred in which affected individuals developed early-onset, bilateral, multifocal clear cell renal carcinoma. In this family, every member who developed kidney cancer had a germline abnormality detectable on karyotypic analysis, a balanced translocation from the short arm of chromosome 3 to the long arm of chromosome 8. Every patient who was found to have early-onset kidney cancer in this kindred had this abnormality; no patient who did not have this translocation was found to have kidney cancer.<sup>11</sup> Subsequently, Pathak and coworkers<sup>12</sup> identified another family with a chromosome 3 to chromosome 11 translocation, and Kovaks and colleagues<sup>13</sup> reported a family with a chromosome 3 to chromosome 6 translocation. In both studies, the common abnormality was on the short arm of chromosome 3 (Fig. 34.1-1).

**FIGURE 34.1-1.** Knudson's two-hit model was the model for scientists searching for the clear cell renal carcinoma gene. In accord with Knudson's model, both copies of the gene for the hereditary form of renal carcinoma associated with von Hippel-Lindau (VHL) disease are inactivated in renal carcinomas from VHL patients (germline inactivation of the VHL gene plus a somatic inactivation of the VHL gene).<sup>317,318</sup> In sporadic (nonhereditary) clear cell renal carcinoma somatic inactivation of both copies of the VHL gene has been detected in the majority of tumors.<sup>44</sup> (From ref. 319, with permission.)

### ABNORMALITIES IN SPORADIC CLEAR CELL RENAL CARCINOMA

These mutations in hereditary renal carcinoma led scientists to study nonhereditary renal carcinoma to determine if changes on chromosome 3 were also present in sporadic cases. When Zbar et al.<sup>14</sup> studied tumor tissue from 18 patients with sporadic, nonhereditary renal carcinoma by restriction fragment polymorphism analysis, loss of heterozygosity (LOH) on the short arm of chromosome 3 was detected in tumor tissue from 11 of 11 evaluable patients. LOH was detected in tumor tissue from patients with localized as well as advanced disease, suggesting the presence of a gene involved in the earliest development of this neoplasm. To more precisely define the prevalence of chromosome 3p LOH in sporadic renal carcinoma, as well as the location of a candidate gene for renal carcinoma, Anglard et al.<sup>15</sup> analyzed

DNA from normal and tumor tissue from 60 patients with various stages of renal carcinoma for losses of alleles at different chromosomal loci. LOH that was independent of tumor stage was detected at one or more of ten loci tested on chromosome 3 in tumor tissue from nearly 90% of patients.<sup>15</sup> LOH was detected in clear cell renal carcinoma but not in papillary renal carcinoma. These findings and those of others showed deletion of a segment of chromosome 3p to be a consistent finding in clear cell renal carcinoma.<sup>16,17,18,19 and 20</sup>

Although these findings pointed to the presence of a renal carcinoma gene on the short arm of chromosome 3, the chromosome 3p area of minimal deletion in the renal tumors was too large to search by conventional cloning strategies available at the time. This then led investigators to initiate studies of the familial form of renal carcinoma associated with VHL disease, with the supposition that the gene for VHL may be involved in the sporadic form of renal carcinoma.

### HEREDITARY RENAL CARCINOMA (VON HIPPEL-LINDAU DISEASE)

VHL disease is a familial cancer syndrome in which affected individuals develop tumors in a number of organs, including kidney, cerebellum, spine, eyes, pancreas, adrenal glands, inner ear, and epididymis.<sup>1,2</sup> Patients with VHL disease often develop early-onset, bilateral, multifocal renal carcinoma and multiple renal cysts. Frequently, renal tumors are found growing inside the renal cysts. The renal carcinoma in VHL patients is uniformly clear cell renal carcinoma.<sup>21</sup> It has been estimated that up to 600 clear cell renal carcinomas and 1100 benign or atypical cysts may be found per kidney in an affected VHL patient.<sup>22</sup> These kidney cancers are malignant and have been reported to metastasize in up to 40% of untreated patients. The cerebellar and spinal hemangioblastomas are multifocal and marked by extreme vascularity. Although these central nervous system tumors are benign, they can cause significant morbidity. The retinal angiomas can be the first clinical manifestation of VHL. These benign, hypervascular retinal tumors can be detected as early as 1 year of age. One identified manifestation of VHL is a tumor that develops in the endolymphatic sac of the inner ear.<sup>23</sup> These papillary tumors are low-grade malignancies that rarely metastasize but can invade locally. VHL patients can develop islet cell tumors of the pancreas and pancreatic cysts. The islet cell tumors are rarely functional; however, they can be malignant and can spread.<sup>24,25</sup> Eighteen percent to 20% of VHL patients develop pheochromocytomas.<sup>26,27 and 28</sup> These tumors can be bilateral or extraadrenal and can be malignant. The epididymal cystadenomas that VHL patients develop are frequently bilateral and are uniformly benign<sup>2,29</sup> (Fig. 34.1-2).

**FIGURE 34.1-2.** Physical (A) and genetic (B) map of the von Hippel-Lindau (VHL) region which was used to identify the VHL gene. cDNAs, complementary DNAs; Cen., centromere; Tel., telomere. (From ref. 39, with permission.)

### Localization of the von Hippel-Lindau Gene to Chromosome 3

To identify the VHL gene, studies were carried out to perform genetic linkage analysis on chromosome 3p. The VHL gene was initially mapped to a 6- to 8-centimorgan (cM) region of chromosome 3 at 3p25-26.<sup>30,31 and 32</sup> Subsequent multipoint linkage analysis localized the VHL gene to a 4-cM interval at 3p26 between RAF1 and the anonymous marker D3S18.<sup>33</sup> No evidence for genetic heterogeneity was identified.<sup>31,32,34</sup> However, early evidence was found for clinical heterogeneity; kindreds with different tumor phenotypes were identified.<sup>34</sup> The VHL gene was found to have characteristics of a tumor suppressor gene. Tory et al.<sup>35</sup> studied VHL renal carcinomas and showed loss of the chromosome 3p, which carried the wild-type allele of the VHL gene. Knudson's model<sup>36</sup> and the finding of frequent LOH in sporadic renal carcinoma<sup>14,15,16 and 17</sup> suggested that inactivation of both copies of the VHL gene was an early step in renal carcinogenesis ( Fig. 34.1-3).

**FIGURE 34.1-3. A:** Distribution of von Hippel-Lindau (VHL) gene mutations in clear cell renal carcinoma (*lower panel*) and in the germline of patients with VHL disease (*upper panel*). (Adapted from refs. 40 and 44.) **B:** Clear cell renal carcinoma is characterized by mutation of the VHL gene.

### Identification of the von Hippel-Lindau Gene

A critical step in identification of the VHL gene was the finding by Yao et al.<sup>37</sup> and Richards et al.<sup>38</sup> of overlapping germline deletions in unrelated VHL kindreds. The detection of these nested germline deletions in the VHL kindreds was crucial for detection of candidate complementary DNAs for the VHL gene. In 1993, Latif et al.<sup>39</sup> reported the identification of the VHL gene. In the initial report, rearrangements of the VHL gene were detected in 28 of 221 VHL kindreds. Eighteen of the rearrangements were due to deletions of the VHL gene, including three nonoverlapping deletions. Intragenic mutations that segregated with the disease were detected in three VHL kindreds.<sup>39</sup> The initial sequence of the VHL complementary DNA revealed a short open reading frame encoding only 284 amino acids, the remainder representing a large 3' untranslated region of the gene. Neither the predicted amino acid nor the nucleotide sequences showed any significant homology to proteins or genes in the databases.<sup>39</sup>

### Genotype and Phenotype Correlations: von Hippel-Lindau Subtype Classification

In the initial studies, Chen et al.<sup>40</sup> detected mutations in 85 of 114 families (75%). Stolle et al.<sup>41</sup> developed an improved method for detection of germline mutations in the VHL gene and reported detection of germline mutations in the VHL gene in 99% of VHL families tested. Striking correlations were noted between the germline mutations and the clinical phenotype. VHL families are classified as VHL type 1 (families without pheochromocytoma) and VHL type 2 (families with pheochromocytoma). Whereas 56% of the mutations associated with VHL type 1 were insertions or microdeletions, nonsense mutations, or length mutations, 96% of the mutations associated with VHL type 2 were missense mutations. Crossey et al.<sup>42</sup> detected missense VHL gene mutations in 9 of 11 families with pheochromocytoma, and large deletions or mutations predicted to cause a truncated protein in 36 of 53 families without pheochromocytoma. When Zbar et al.<sup>43</sup> analyzed mutations in 473 families from North America, Europe, and Japan, germline mutations were detected in 299 of 473 families (63%) tested. Mutations predicted to produce full length, mutant VHL proteins were detected in 89% of VHL families with pheochromocytoma with mutations detected. A mutation hot spot was identified at a CpG island in codon 167, where 12% of the mutations were found. The codon 167 mutations were associated with a phenotype characterized by few to

no renal carcinomas and frequent pheochromocytomas.<sup>43</sup> Thus, three distinct cancer phenotypes are associated with germline VHL gene mutations: (1) VHL type 1 (VHL without pheochromocytoma), (2) VHL IIA (pheochromocytomas, retinal angiomas, and central nervous system hemangioblastomas), and (3) VHL IIB (VHL IIA plus renal cancers and pancreatic involvement) (Fig. 34.1-4).

**FIGURE 34.1-4. A:** Hereditary papillary renal carcinoma (HPRC) is an autosomal dominant inherited cancer syndrome<sup>320</sup> characterized by the appearance of bilateral, multifocal papillary renal carcinoma. **B:** The renal tumors are uniformly of papillary histologic pattern. **C:** The gene for HPRC, c-Met, is located on the long arm of chromosome 7.<sup>321</sup> Activating mutations of the c-Met gene are detected in the germline of affected individuals. (From refs. 320 and 74, with permission.)

#### VON HIPPEL-LINDAU GENE MUTATIONS: CLEAR CELL RENAL CARCINOMA

To determine the role of the VHL gene in renal carcinoma, Gnarr et al.<sup>44</sup> analyzed tumors and cell lines from 110 patients with sporadic, nonfamilial renal carcinoma for VHL mutations and LOH. LOH was detected in 98% of the samples, and VHL gene mutations were observed in 57% of clear cell renal carcinomas analyzed.<sup>44</sup> VHL gene mutations were not detected in tumor tissue from patients with papillary renal carcinoma or with lung, breast, ovarian, cervical, prostate, or colon cancers. The somatic VHL mutations differed from the germline mutations in that a higher percentage of somatic mutations clustered in exon 2 than were detected in the germlines. VHL gene mutations were found in early- and late-stage clear cell renal carcinomas, and when multiple samples were tested from the same patient, the identical mutation was found. Shuin et al.<sup>45</sup> detected somatic mutations in 56% of primary renal carcinomas and an 84% LOH of the VHL gene. Whaley et al.<sup>46</sup> detected somatic VHL in renal carcinoma and no mutations in more than 180 sporadic tumors of other types. VHL gene mutations have been identified in clear cell renal carcinomas in Europe,<sup>42,47,48,49,50 and 51</sup> Japan,<sup>45</sup> and North America.<sup>44,52,53</sup> VHL gene mutations also have been detected in tumor tissue from patients from the 3;8 translocation family described by Cohen et al.<sup>11,44,54</sup> and from tumor tissue from patients with 2;3 translocations,<sup>55,56</sup> further supporting the conclusion that the VHL gene has an important and specific role in clear cell renal carcinoma.

#### Silencing of the von Hippel-Lindau Gene by DNA Methylation in Renal Carcinoma

Herman et al.<sup>57</sup> demonstrated that hypermethylation of a normally unmethylated CpG island in the 5' region of the VHL gene provides another important mechanism for inactivation of the VHL gene in a significant portion of clear cell renal carcinomas. In 5 of 27 (19%) of the renal tumors evaluated, hypermethylation of the VHL gene was found. The VHL gene is expressed normally in both nonneoplastic kidney and in renal carcinomas with inactivating VHL gene mutations. However, as would be predicted as a consequence of methylation of a 5' CpG island, none of the five renal tumors expressed the VHL gene.<sup>57</sup> When one of the renal carcinoma cell lines with a hypermethylated (and silent) VHL gene was treated with the hypomethylating agent (5-aza-2'-deoxycytidine), the VHL transcript was reexpressed, revealing that methylation of the gene was associated with nonexpression. Further studies are needed to determine the prevalence of hypermethylation of the VHL gene in sporadic clear cell renal carcinomas and the potential role of such hypomethylating agents as 5-aza-2'-deoxycytidine.<sup>2,57</sup>

#### The VHL Gene Has the Characteristics of a Tumor Suppressor Gene

Studies of the genetics of VHL and the VHL gene in sporadic renal cell carcinoma have determined that this kidney cancer gene fits Knudson's two-hit model for a tumor suppressor gene.<sup>58</sup> In tumors from VHL patients and from patients with sporadic renal cell carcinoma, a frequent loss of the nonmutant allele is noted, demonstrating that both copies of the VHL gene are inactivated in these tumors.<sup>35,44,59</sup>

#### CHARACTERISTICS OF THE VON HIPPEL-LINDAU TUMOR SUPPRESSOR GENE PRODUCT

##### The von Hippel-Lindau Product Is Part of a Multiprotein Complex

When the VHL gene was identified, no significant homology was identified with any known genes. The rat homologue is 88% identical to human VHL; however, it lacks the human protein's NH<sub>2</sub>-terminus acidic pentamer repeat.<sup>60</sup> Duan et al.<sup>60</sup> determined that the rat and human VHL proteins formed oligomeric complexes with a number of unidentified proteins in cultured mammalian cells. A complex containing proteins of apparent molecular masses of 9 and 16 kD and VHL was the most consistently observed.<sup>60</sup> When certain naturally occurring VHL missense mutations were introduced into the VHL gene in COS-7 cells, complete or partial loss of the p16-p9 complex was observed. When the p16 and p9 proteins were purified and sequenced, they were found to be part of the elongin (SIII) complex. Elongin (SIII) is a heterotrimer consisting of two regulatory subunits (B and C) and a transcriptionally active subunit (A) that activate transcription elongation by RNA polymerase II.<sup>61</sup> The VHL protein binds specifically and tightly to elongin B and C *in vitro*. Kibel et al.<sup>62</sup> demonstrated that the region of binding of the VHL protein to elongin B and C is in a short, colinear region of the VHL protein that is frequently mutated in renal carcinomas. These studies suggest that the tumor suppression function of the VHL protein may be associated with its ability to bind to elongin B and C.<sup>62</sup>

##### Cul-2 is a Component of the von Hippel-Lindau Complex

A series of studies have been performed to determine that Cul-2 is a part of the VHL complex.<sup>63,64</sup> Cul-2 is from a family of proteins called *cullins*, which are highly homologous to the *Saccharomyces cerevisiae* protein Cdc53p.<sup>65</sup> Based on the apparent similarity of members of the VHL multiprotein complex with yeast proteins (e.g., elongin C and Cul2 to Skp1 and Cdc53, respectively), a model for the regulation of hypoxia-inducible messenger RNAs (mRNAs) has been developed.

##### Regulation of Vascular Endothelial Growth Factor Messenger RNA by the von Hippel-Lindau Product

Angiogenesis is a marked feature in the clinical manifestation of VHL and sporadic clear cell renal carcinoma. A number of growth factors have been implicated in angiogenesis, including vascular endothelial growth factor (VEGF). VEGF is markedly elevated in renal carcinomas and in VHL-associated tumors.<sup>66,67,68 and 69</sup> The VHL gene product has been found to regulate the stability of VEGF mRNA,<sup>66,70</sup> potentially explaining the increased VEGF levels in these tumors and providing an explanation for the angiogenesis associated with their development. This fact may provide unique opportunities for treatment of patients with these tumors.<sup>53</sup>

##### Nuclear and Cytoplasmic Localization of the von Hippel-Lindau Gene Product

Duan et al.<sup>60</sup> demonstrated that the VHL protein can be found both in the nucleus and the cytosol of transiently transfected cells. To define the determinants of VHL localization, Lee et al.<sup>71</sup> showed that nuclear transport of VHL is tightly regulated and that it is determined by the density at which the cells are cultured.<sup>71</sup> When the cells in culture are sparse, the VHL protein is found predominantly in the nucleus. When the cells in culture were grown to confluence, the VHL protein is found in the cytoplasm. Deletion mutation analysis revealed that a putative nuclear localization signal is located in the N-terminal region of the VHL gene. This study suggests that VHL nuclear transport is regulated by density of the cells. Understanding this novel physiologic control mechanism could provide unique insights into the role of this multifunctional tumor suppressor gene.

## HEREDITARY PAPILLARY RENAL CARCINOMA

Papillary renal carcinoma is a histologic variant of renal carcinoma that is distinct from clear cell renal carcinoma. Whereas clear cell renal carcinoma is characterized by LOH on the short arm of chromosome 3 and mutation of the chromosome 3p VHL gene, neither chromosome 3 LOH nor VHL gene mutation are detected in tumor tissue from patients with papillary renal carcinoma. HPRC, a distinct form of hereditary renal carcinoma, has been described.<sup>72,73</sup> HPRC is an autosomal dominant form of inherited renal carcinoma that is characterized by the appearance of bilateral, multifocal papillary renal carcinoma (i.e., HPRC is distinct from VHL disease or other inherited forms of renal carcinoma).

### *Hereditary Papillary Renal Carcinoma Is Characterized by Germline Mutation of the MET Gene*

Genetic linkage analysis localized the HPRC gene to a 27-cM interval at chromosome 7q31.1-34. Missense mutations were identified in the tyrosine kinase domain of the MET gene in the germline of affected members of HPRC families.<sup>74</sup> Subsequent studies identified MET mutations in two other large North American HPRC families, confirming that the mutation in the MET protooncogene is the basis for HPRC.<sup>75</sup> Activating mutations of the MET gene have been shown to cause malignant transformation *in vitro* and *in vivo*, implicating this gene in both hereditary and sporadic forms of papillary renal carcinoma.<sup>74,75 and 76</sup>

These findings support the molecular genetic classification of renal carcinoma between clear cell and papillary renal carcinoma, with clear cell renal carcinoma being characterized by VHL gene mutation. HPRC is characterized by a germline mutation of the Met protooncogene. Understanding of the fundamental genetic basis of these forms of kidney cancer will hopefully lead to better methods for diagnosis, prevention, and therapy of patients with kidney cancer.

## PROSTATE CANCER

In 1990, prostate cancer became the most common form of cancer (other than skin cancer) diagnosed in U.S. men, surpassing lung cancer. In 1999, an estimated 200,000 new prostate cancer cases were diagnosed, accounting for more than 35% of all cancers affecting men, and more than 40,000 deaths will result from this disease.<sup>77</sup> Despite these figures, our understanding of the molecular genetics of prostate cancer is still in an embryonic stage. This section provides an overview of the efforts to define and characterize genetic alteration responsible for the initiation and progression of prostate cancer. The first part of this section describes familial prostate cancer and reviews the evidence supporting the existence of a hereditary form of the disease. The second part reviews aspects of somatic alterations found in prostate cancer cells, and the potential role of these genetic changes in the progression of prostate cancer.

## MULTISTEP CARCINOGENESIS AND PROSTATE CANCER PROGRESSION

The process of carcinogenesis is complex, requiring a number of steps. In the case of prostate cancer, evidence for this multistep requirement is readily demonstrated in the studies of experimental carcinogenesis in rodent models. In the pioneering studies of Thompson et al.,<sup>78</sup> expression of a single oncogene (ras) in normal prostate cells of the mouse is insufficient for transformation; the overexpression of a second oncogene (myc) is necessary before transformation becomes a frequent event. Even in the case of two oncogenes, not every cell expressing these becomes transformed, suggesting that further steps are necessary, presumably including inactivation of tumor suppressor genes. Although in clinical specimens of human cancers the requirement for multiple steps is less easily demonstrated, the finding of multiple genetic alterations as a common characteristic of human tumors supports this concept.<sup>79</sup>

Application of the multistep concept to carcinogenesis in the human prostate would suggest that incidental or latent cancers (i.e., clinically undetected prostate cancers found in most aged men dying from non-prostate cancer causes at autopsy) as well as putative precursor lesions [i.e., prostatic intraepithelial neoplasia (PIN)]<sup>80</sup> have undergone only a subset of the steps, "hits," or mutations necessary for the emergence of the fully malignant phenotype. Furthermore, this hypothesis would suggest that specific and discrete genetic alterations may be associated with different stages and even grades of prostate cancer. Although such a hypothesis is attractive, no definite proof has been provided to suggest that this is the case, although certain specific mutations (e.g., in the p53 gene) have been shown to be strongly associated with progression of prostate cancer.<sup>81,82,83,84 and 85</sup>

What are the molecular events responsible for the progression of prostate cancer, or, in other words, why and how does prostate cancer evolve from an indolent to a life-threatening disease? Is this evolution inevitable, or are some prostate cancers destined never to progress to advanced disease, let alone clinically detectable disease, regardless of the time frame provided? Conversely, are some prostate cancers capable of metastasis very early in their natural history? A critical issue for addressing these questions effectively is to understand the mechanisms of prostate cancer progression in molecular genetic terms, particularly if therapeutic approaches aimed at blocking this progression are to be other than empirically based.

## PROSTATE CANCER INITIATION AND PROGRESSION: GENETICS VERSUS ENVIRONMENT

The *initiation* of prostate cancer (i.e., the formation of a histologically identifiable lesion) appears to be a very frequent event, occurring in one-third of men older than 45 years.<sup>86</sup> Geographically, this rate of histologic cancer incidence is roughly the same worldwide.<sup>87,88</sup> The number of clinically manifest cases and the mortality rates, however, differ widely among various populations, strongly suggesting important environmental factors in modulating the transition between tumor initiation and progression.<sup>89</sup> This feature of prostate cancer is emphasized by studies demonstrating large increases in prostate cancer incidence in Japanese men (a low-risk population) when they move to the United States.<sup>90</sup>

On the other hand, studies of familial aggregation of this disease have suggested that between 5% and 10% of prostate cancers may be directly attributable to the inheritance of dominant prostate cancer susceptibility alleles, which may act as genetic factors driving this progression independent of environmental exposure. Thus, as with numerous other cancers, strong evidence indicates both genetic and environmental factors in the etiology of prostate cancer, with the majority of disease most likely being a result of the interaction the two.<sup>91</sup>

## HEREDITARY PROSTATE CANCER

Although not widely recognized as having a strong familial component until more recently, evidence demonstrating familial clustering of prostate cancer has been available as early as 1960 from studies of the Utah Mormon population,<sup>92</sup> and multiple subsequent studies have confirmed this observation.<sup>93,94,95,96,97 and 98</sup> Two large studies are of particular interest in answering the question of whether prostate cancer clusters in families. Cannon et al.<sup>99</sup> published a genetic epidemiologic study on prostate cancer in the Utah Mormon population. Notably, prostate cancer showed the fourth strongest degree of familial clustering after lip cancer, skin melanoma, and ovarian cancer. Prostate cancer had a higher familiarity than both colon and breast carcinoma, two solid tumors that are well recognized as having a genetic or familial component.

A case-control study of patients treated for prostate cancer at Johns Hopkins University School of Medicine was carried out to assess the extent of familial aggregation in prostate cancer.<sup>100</sup> Extensive cancer pedigrees were obtained for 691 men with prostate cancer and 640 spouse controls. A positive family history of prostate cancer was the only consistent risk factor found in this study. Men with a father or brother affected were twice as likely to develop prostate cancer as men with no relatives affected. In addition, a trend of increasing risk was found with increasing number of affected family members, such that men with two or three first-degree relatives affected had a five- and 11-fold increased risk of developing prostate cancer. Cox proportional hazards analysis in the case relatives revealed that risk was particularly increased to relatives of younger probands (younger than 55 years).

These studies suggest a familial clustering in risk to prostate cancer but do not directly address the underlying etiologic mechanism. It is important to note that familial clustering could as easily reflect a shared environmental risk factor as a genetic mechanism. To directly address this question and to test whether a Mendelian form of prostate cancer could explain the observed clustering of this disease, segregation analyses have been carried out. Carter et al.<sup>101</sup> suggested that familial clustering of prostate cancer was best explained by dominant inheritance of a rare (estimated population frequency = 0.003) high-risk allele. The estimated cumulative risk of clinically evident prostate cancer revealed that the allele was highly penetrant: By 85 years of age, 88% of the carriers are projected to be affected with prostate cancer, compared with only 5% of the noncarriers. This model suggests that the inherited form of prostate cancer may account for a significant portion (43%) of early-onset disease (disease onset before 55 years of age), although it represents only a small proportion (9% by age 85) of all prostate cancer occurrences. Furthermore, these analyses demonstrate that families with multiple affected members and early onset of disease are most likely to have a Mendelian form of prostate cancer, and thus are most appropriate for linkage analysis. Additional segregation analyses by Gronberg et al.<sup>102</sup> and Schaid et al.<sup>103</sup> provide further support for the

existence of dominantly acting prostate cancer susceptibility alleles.

These results emphasize that the genetics of prostate cancer are likely similar to those of colon and breast cancer, in which a subset of the disease occurs in persons who inherit defective copies of one of a series of critical, rate-limiting steps required for neoplastic transformation. Just as linkage studies in families with multiple members affected with these diseases were critical to the identification of colon and breast cancer susceptibility genes (e.g., APC, hMSH2, BRCA1, BRCA2), linkage analyses in prostate cancer families are an active area of study. As of 1999, four separate loci suspected of harboring hereditary prostate cancer genes have been reported (Table 34.1-1). Three of these loci are on chromosome 1, and the fourth is on the X chromosome. The finding of multiple distinct loci, along with the high likelihood that multiple additional loci will be identified, emphasizes the extensive and potentially complex genetic heterogeneity that characterizes hereditary prostate cancer. Only when these genes are cloned and characterized will their contributions to the underlying pathogenesis of this disease be assessable.

TABLE 34.1-1. Prostate Cancer Susceptibility Loci Identified by Linkage Studies

## SOMATIC ALTERATIONS IN PROSTATE CANCER

### Role of Oncogenes

A number of oncogenes have been examined in prostate cancer tissue and cell lines, primarily at the expression level, including ras, myc, sis, fos, EGFR, and ERBB2 (reviewed by Strohmeyer and Slamon<sup>108</sup>). Expression of each of these genes and, in some cases, overexpression when compared to normal genes has been detected in prostate cancer cells, but at widely varying frequencies. None of these genes have been observed to undergo mutational activation in a majority of prostate cancers, and the mechanisms responsible for their overexpression, when present, remain largely undefined. Of particular interest in this regard is the study by Bubendorf et al.,<sup>109</sup> which demonstrated that, whereas gene amplifications of ERBB2 and NMYC were never observed in any stage prostate cancer, the androgen receptor gene, myc, and cyclin D1 were observed to be amplified in 22%, 11%, and 5% of hormone-refractory, metastatic prostate cancers, respectively.

RAS. Several studies provided early evidence of a potentially important role for activated ras genes in prostate cancer, particularly in rodent models. <sup>78,110</sup> Peehl et al.,<sup>111</sup> using DNA transfection experiments, were the first to demonstrate the presence of an activated K-ras gene in a human prostate cancer specimen. Subsequent studies found low frequencies of ras gene mutations in both localized and metastatic prostate cancer (less than 4%). <sup>112,113,114</sup> and <sup>115</sup> These results, all obtained in North American patients, demonstrate that activation of ras oncogenes via point mutation is not a common event in either the initiation or progression of prostatic neoplasia.

In contrast to these studies, other reports examining prostate tissue from Japanese men suggest that ras gene mutations do occur at significant frequencies (approximately 25%) in prostate cancer, both in latent carcinoma <sup>116</sup> and clinically manifest disease.<sup>117</sup> These studies raise the interesting possibility that significant differences may exist in the genetic events associated with prostate cancer in American men compared with Japanese men (wherein the latter have an approximately fivefold lower incidence rate of clinically manifest disease).

Additionally, in this latter study,<sup>117</sup> human papillomavirus DNA was detected in more than 40% of the prostate cancer samples analyzed. The detection of human papillomavirus DNA in prostate cancer from North American men is controversial, but the most recent evidence <sup>118,119</sup> and <sup>120</sup> suggests that this family of viruses is not commonly found in prostate cancer, at least not at levels comparable to those found in cervical cancer, in which a definitive etiologic link has been established.

C-MYC. The c-myc gene has been implicated in prostate cancer since the experimental carcinogenesis studies of Thompson et al. <sup>78</sup> A role for c-myc overexpression as an important aspect of prostate cancer has been suggested by the frequent finding of increased copy number of the portion of 8q containing the c-myc gene in clinical prostate cancer specimens, particularly advanced cases. Sato et al. <sup>121</sup> observed that cases of prostate cancer characterized by fluorescence *in situ* hybridization (FISH) as having more copies of c-myc than copies of chromosome 8 centromere were highly associated with poor outcomes.

### bcl-2: An Inhibitor of Apoptosis

The bcl-2 gene is located on chromosome 18q21. It was identified because of its involvement at the breakpoint of the t(14;18) interchromosomal translocation occurring in human follicular B-cell lymphomas.<sup>122</sup> This translocation results in enhanced expression of the bcl-2 gene.<sup>123,124</sup> The bcl-2 gene encodes for a membrane-bound 26-kD protein.<sup>125</sup> bcl-2 has been demonstrated to be an oncogene, in that its induced overexpression can lead to malignant transformation.<sup>123</sup> bcl-2 is unique among oncogenes, however, in that its expression does not enhance the rate of cell proliferation, but instead decreases the rate of cell death.<sup>123,124</sup> The role of bcl-2 in the development and progression of carcinoma of the prostate has been examined by McDonnell et al. <sup>125</sup> Using immunohistochemical (IHC) techniques, bcl-2 is not usually expressed in androgen-dependent prostatic cancer cells, whereas it is expressed in androgen-independent prostatic cancer cells.<sup>125</sup> This observation has been confirmed by Colombel et al. <sup>126</sup> These findings suggest that enhanced expression of bcl-2 protein in carcinomas of the prostate is associated with the transition to androgen independence.

### Androgen Receptor

The role of androgen in normal prostate physiology is unquestioned, because these hormones are strictly required for normal development and maintenance of prostate growth and function. However, the role of androgens and androgen receptors (AR) in prostate cancer is much less clear. Studies have generated a great deal of renewed interest in this pathway and its role in the critical progression of prostate cancer to androgen independence. An initial hypothesis that loss of AR gene expression may be important in androgen-independent disease was not supported by several studies that showed continued or even elevated AR gene expression in androgen-independent tumors.<sup>127,128</sup> Newmark et al.<sup>129</sup> were the first to report a mutated androgen receptor in a clinical specimen of prostate cancer; curiously, it was found in a localized cancer before any hormonal therapy. This and other findings of mutations before hormonal therapy <sup>141</sup> would suggest that mutant AR might provide a growth advantage, even in the presence of normal androgen levels. Kelly et al. <sup>130</sup> and Sartor et al. <sup>131</sup> described a number of patients who experienced a paradoxical response to withdrawal of the antiandrogen, flutamide, in that a number of clinical parameters (e.g., prostate-specific antigen levels, bone pain) improved on cessation of drug treatment. One explanation proposed for this response is that such patients harbor AR gene mutations similar to those found in the prostate cancer cell line LNCaP (Thr to Ala change at codon 868), which alters the ligand specificity of the receptor such that both estrogens and antiandrogens, as well as androgens, act as agonists.<sup>132,133</sup> The frequency of such mutations in prostate cancer patients is unknown, but a study by Taplin et al. <sup>134</sup> found five of ten samples of hormone-refractory prostate cancer metastatic to bone had mutations of the AR gene, and at least two of these mutations resulted in a shift in hormone specificity of AR. Visakorpi et al.<sup>135</sup> demonstrated that up to 30% of prostate cancer specimens from men unsuccessful with hormonal therapy are characterized by increases in copy number of the X chromosomal region (q11-q13) containing the androgen receptor. These results suggest that instead of being insensitive to androgen, such tumors may become supersensitive to androgen by an as yet undetermined mechanism, or perhaps sensitive to a different nonandrogen steroid hormone. Furthermore, a number of studies suggest that via novel interaction with other growth factor or signaling pathways, the requirement for androgen binding to the receptor may be bypassed. <sup>136,137</sup> Thus, although the precise role of androgen and the androgen receptor is still being defined, it is possible that altered regulation of the pathway plays a fundamental role in prostate cancer progression to androgen-independent disease.

## Chromosomal Deletions in Prostate Cancer

Unlike other solid tumors, such as renal cell carcinoma, cytogenetic analyses of prostate cancer specimens have revealed few consistent chromosomal deletions.<sup>138,139</sup> An early cytogenetic study by Atkin and Baker,<sup>140</sup> however, suggested chromosomes 7q and 10q as the sites of frequent chromosomal losses in prostate cancer. Early studies of allelic loss by Carter et al.<sup>141</sup> and Kunimi et al.<sup>142</sup> confirmed frequent LOH on chromosome 10 and also highlighted portions of chromosomes 16 and 8 as being frequently deleted in clinical specimens of prostate cancer. Deletion mapping studies by Bergerheim et al.<sup>143</sup> suggested that the critical regions resided between pter and the plasminogen activator, tissue type locus at p12-q11.2 on chromosome 8 and q22.1 and qter on chromosome 16. Interestingly, loss of chromosome 8p in prostate cancer had been previously observed in a study by Konig et al.,<sup>145</sup> who found cytogenetic evidence of chromosome 8p deletions in a number of prostate cancer xenografts, and suggested a correlation existed between loss of this region and the development of androgen independence.

Of the chromosomal regions analyzed in prostate cancer, the short arm of chromosome 8 has received the most attention, because it appears to be the most frequent site of LOH, occurring in the majority of cases of prostate cancer examined. Two or possibly three distinct regions of LOH occur on this chromosomal arm, with the region 8p21-12 being deleted in the majority of prostate cancer precursor lesions (PIN). More distally, 8p22 is deleted in most adenocarcinomas.<sup>145,146,147,148,149</sup> and <sup>150</sup> In this latter region, a homozygous deletion of approximately 1 megabase has been observed.<sup>151</sup> Subregional deletion analysis of chromosome 8p in prostate cancer has been performed using a variety of molecular methods, all of which have confirmed a high frequency of loss in this region, especially, but not exclusively, within chromosome band 8p22.<sup>143,144,145,146,147,148,152,153,154,155,156</sup> and <sup>157</sup> The rate of 8p22 loss reported in these regions varies from 32% to 65% in primary tumors and from 65% to 100% in DNA derived from metastases.

Separate discrete regions of loss in more proximal regions, including 8p21<sup>147,150</sup> and 8p12,<sup>148,150</sup> have been described. Frequent loss (63%) of portions of 8p21-p12 have been identified in PIN lesions,<sup>149</sup> suggesting that a gene in this area may become frequently inactivated at a relatively early stage in prostate tumorigenesis. Evidence of heterogeneity of 8p LOH among different PIN lesions within the same gland was observed.<sup>149</sup> A combined comparative genomic hybridization (CGH), Southern, and microsatellite study has shown loss of chromosome 8p22-p12 in 80% of prostate cancer lymph node metastases.<sup>158</sup> Microcell transfer of human chromosome 8 into a rat prostate cancer cell line has been reported to suppress metastatic ability.<sup>159</sup> An association of chromosome 8p loss and higher stage has been reported.<sup>148</sup>

Several 8p candidate tumor suppressor genes have been identified, including N33, which is located in a homozygously deleted region of 8p22. This novel gene is expressed in many normal tissues but not in some cancers, most notably those of the colon.<sup>160</sup> Other candidate genes identified on this chromosomal arm include the putative transcription factor FEZ1<sup>161</sup> and an androgen-regulated homeobox gene, NKX3.1.<sup>162</sup>

The frequent loss of sequences on chromosome 8p provides a marker to determine the similarity or difference between primary prostate cancers and their metastases. This approach has been used to determine the concordance rates for 8p loss in a series of PIN, primary, and metastatic lesions obtained from the same patient.<sup>153</sup> Cases were observed in which there was a complete concordance in that all samples of cancer had retained or lost the same 8p marker, but cases also were noted in which the PIN sample would show loss, but not the primary tumor or the lymph node tumor samples. In addition, some cases showed differences among the multiple primary lesions within the prostate. These data and similar findings<sup>163</sup> demonstrate the complex genetic relationship that exists between primary and metastatic lesions and suggest that the primary prostate cancer that gives rise to a given metastatic deposit is not easily predicted on the basis of morphologic characteristics.

Concomitant with deletion of sequences from the short arm, chromosome 8 is frequently affected by gain of sequences on the long arm. First observed by Southern analysis,<sup>145</sup> a CGH study of lymph node metastases indicated that 85% of such tumors showed evidence of 8q gain, making this the most common numerical alteration observed in this study.<sup>158</sup> Van den Berg et al.<sup>164</sup> reported that gain of 8q sequences in prostate cancer was highly correlated with disease progression. Similarly, in the CGH study of Visakorpi et al.,<sup>157</sup> gain of 8q sequences was seen in 89% of tumor recurrences after hormonal therapy, whereas only 6% of primary tumors showed this alteration. An obvious candidate gene that may be the target of these amplification events in prostate cancer is the oncogene *c-myc*, which is located at 8q24, although most of the amplification events on 8q are large, suggesting that many genes are affected. In this respect, two other 8q genes, PSCA and the p40 subunit of translation initiation factor 3, are found to be frequently included in the gained regions of chromosome 8 and show increased expression in a subset of prostate cancers.<sup>165,166</sup>

## Comparative Genomic Hybridization Analysis of Prostate Cancer

Visakorpi et al.<sup>157</sup> used CGH to survey the genome of a series of both untreated, localized prostate cancers and tumors from patients unsuccessful on hormonal therapy. This important study found chromosome 8p to be the most frequently deleted, followed by 13q, 6q, 16q, 18q, and 9p. In a series of nine advanced prostate cancers from men unsuccessful with hormonal therapy, a significant increase was found in deletions of chromosome 5q and gains of chromosomes 7p, 8q, and X, when compared to untreated primary tumor samples. Evidence has been found that the androgen receptor gene may be the target of gene amplification events on this latter chromosome.<sup>167</sup> Thus, these studies confirm previous studies of allelic loss in prostate cancer and, at the same time, expand the chromosomal regions implicated as harboring "prostate cancer genes."

## Specific Gene Alterations in Prostate Cancer

A number of genes have been found to be mutated in prostate cancer, including *p53*, *PTEN*, *Rb*, *ras*, *CDKN2*, *AR*, *MXI1*, and *POLB*, although the latter two, located on chromosomes 10q25 and 8p11.2, respectively, remain to be confirmed. *ras* mutations are uncommon (fewer than 5% of cases),<sup>112,114,115</sup> as are point mutations of *Rb*,<sup>168</sup> although loss of one copy of *Rb* readily occurs. To date, the most consistently observed site of point mutations is the *p53* gene, and these mutations are common only in advanced disease. Microsatellite instability is uncommon but detectable in prostate cancer,<sup>169</sup> and the hPMS2 gene has been found to be mutated in a prostate cancer cell line that exhibits this phenotype.<sup>170</sup>

**P53.** *p53* mutations are uncommon in localized disease but become frequent in deposits of metastatic prostate cancer, particularly those to bone.<sup>81,82,83,171,172,173</sup> and <sup>174</sup> Observed heterogeneity of *p53* mutations within different tumors in the same gland, and within different regions of the same gland, appears to be a somewhat unique feature of prostate cancer.<sup>175,176</sup> Furthermore, LOH and point mutation of *p53* do not appear to be tightly coupled in this disease.<sup>177</sup> A large number of studies have examined the prognostic significance of nuclear *p53* protein immunostaining in both localized and advanced prostate cancer,<sup>178,179,180,181,182,183,184,185,186,187,188,189,190</sup> and <sup>191</sup> and although the results are somewhat disparate, two conclusions can be drawn: (1) *p53* staining tends to be very heterogeneous, resulting in problems for scoring and interpretation of staining results and in inconsistencies due to sampling biases; and (2) in general, tumors with positive *p53* staining are associated with a worse prognosis.

**PTEN.** A series of studies have examined prostate cancer specimens for alterations in the dual function phosphatase gene *PTEN* and found that this gene is inactivated by a combination of mechanisms, including hemi- and homozygous deletion,<sup>192,193,194,195,196</sup> and <sup>197</sup> point mutation,<sup>192,193,196</sup> and promoter methylation.<sup>197</sup> These changes are observed most commonly in advanced disease, and they may play a role in the acquisition of metastatic potential. However, McMenamin et al.<sup>198</sup> demonstrated that the majority of clinically localized prostate cancers had abnormal PTEN protein expression, with one in five cases being completely negative.

Wu et al.<sup>199</sup> demonstrated that, in prostate cancer cells lines with inactivated PTEN, the AKT/phosphoinositide 3 kinase pathway is constitutively activated due to increased accumulation of the PTEN substrate PIP3. Activation of this pathway results in suppression of apoptosis and increased cell survival. These findings have stimulated extensive interest in these pathways as novel therapeutic targets in advanced prostate cancer.

**Rb.** The importance of *Rb* gene inactivation in prostate cancer was initially suggested by the studies of Bookstein et al.,<sup>200,201</sup> who demonstrated the presence of inactivating mutations in the *Rb* gene in clinical specimens of prostate cancer, as well as the ability of reintroduction of a cloned copy of *Rb* to suppress the tumorigenicity of DU145 prostate cancer cells, which had been shown to produce a nonfunctional truncated *Rb* protein. Combined CGH and LOH studies reveal that one copy of *Rb* is lost in advanced prostate cancer at rates approaching 80%,<sup>158</sup> although limited sequencing studies suggest that point mutations are present in fewer than 20% of clinical samples.<sup>168</sup> IHC studies of *Rb* expression demonstrate lack of expression in 10% to 22% of tumors, with a questionable correlation between tumor LOH of *Rb* and lack of expression.<sup>202,203</sup> These data, together with LOH events on 13q that do not include *Rb*, suggest the presence of an additional or alternative

prostate tumor suppressor gene near the *Rb* locus.<sup>203</sup>

*CDKN2*. Much attention has been focused on the *p16/CDKN2* gene, a negative regulator of cell-cycle progression located at chromosome 9p21, since the finding of frequent homozygous deletions in a wide variety of cancer cell lines.<sup>204</sup> A relatively high frequency of homozygous (approximately 20%)<sup>205</sup> and hemizygous losses of *CDKN2* have been observed in clinical specimens of prostate cancer.<sup>206</sup> In the latter case, loss events in the vicinity of the *CDKN2* gene are more common in metastatic deposits of prostate cancer (43% vs. 20% in primary tumors). In a small but detectable fraction of tumors (approximately 15%), the *CDKN2* gene shows evidence of inactivation by promoter methylation.<sup>206</sup> Whether all of the allelic loss events at 9p21 in prostate cancer are associated with *CDKN2* inactivation or whether they reflect inactivation of a neighboring gene (e.g., *p15*) has not been determined.

*P27* (CDKN1B). A number of studies that reduced levels of the cyclin kinase inhibitor *p27* are associated with a more aggressive prostate cancer phenotype,<sup>207,208</sup> and<sup>209</sup> although the mechanism of this down-regulation is not clear. Interestingly, Kibel et al.<sup>210</sup> described a homozygous deletion of the *p27* gene in a lethal case of prostate cancer, and in a high frequency of LOH of *p27* in advanced prostate cancers in general. Thus, it is possible that, in prostate cancer, in addition to increased ubiquitin-mediated *p27* protein degradation, which has been demonstrated in colon and other cancers, at least a subset of lesions may inactivate this gene via deletion.

E-CADHERIN AND KAI-1. Genes whose down-regulation has been implicated in prostate cancer progression include the cell adhesion molecule genes E-cadherin and KAI-1, which are located at chromosomes 16q22.1 (a frequent site of LOH) and 11p11.2, respectively.<sup>211</sup> E-cadherin protein levels are frequently reduced in high-grade prostate cancers, and this finding has prognostic significance.<sup>212,213</sup> and<sup>214</sup> KAI-1 was identified by its ability to suppress metastasis in experimental animal studies.<sup>211,215</sup> Although the predominate mechanism for down-regulation of these genes has not been determined, in the case of E-cadherin, gene inactivation via promoter methylation has been found in prostate cancer cell lines and at a low but detectable rate in clinical specimens of prostate cancer.<sup>216</sup>

GSTP. Similarly, the gene for the phase II detoxification enzyme glutathione S-transferase *p*, has also been found to be extensively methylated in the promoter region, in a completely cancer-specific fashion, with concomitant absence of expression.<sup>217</sup> In fact, this methylation event, being found in more than 90% of all prostate cancers and in PIN lesions, is the most common genomic alteration yet observed in prostate cancer. The mechanism by which this region becomes specifically methylated in prostate cancer and the basis for its apparent selection in the carcinogenic pathway is unclear at present. Because this enzyme is a key part of an important cellular pathway to prevent damage from a wide range of carcinogens, the inactivation of this activity may result in increased susceptibility of prostate tissue to both tumor initiation and progression resulting from an increased rate of accumulated DNA damage. Indeed, reactivation of this or a similar cellular defense pathway, perhaps by dietary intervention, has been proposed as a treatment strategy aimed at blocking the progression of initiated prostate cancer foci.

## BLADDER CANCER

Approximately 90% of malignant tumors arising in the urinary bladder are of epithelial origin, the vast majority being transitional cell carcinomas.<sup>218,219</sup> Based on morphologic evaluation and natural history, urothelial neoplasms have been classified into two groups having distinct behavior and prognosis: low-grade tumors (always papillary and usually superficial) and high-grade tumors (either papillary or nonpapillary, and often invasive).<sup>220</sup> Clinically, superficial bladder tumors (stage pTa, pTis, and pT1) account for 75% to 85% of neoplasms, whereas the remaining 15% to 25% are invasive (pT2, pT3, pT4) or metastatic (N+, M+) lesions at the time of initial presentation.<sup>221</sup> More than 70% of patients affected with superficial tumors have one or more recurrences after initial treatment, and approximately one-third of those patients progress and eventually succumb to their disease.<sup>222,223</sup> Because clinical staging and morphologic evaluation determine the therapeutic modality, the pathologic assessment of tumor specimens carries significant consequences. However, it is well known that two morphologically similar tumors presenting in any assigned stage may behave in different fashions, a fact that seriously hampers the ability to accurately predict clinical outcome. For these reasons, biologic markers and new detection methods are being developed to monitor and identify recurrence and progression in patients treated for superficial disease.<sup>224</sup> The important issues in patients presenting with muscle-invasive carcinomas include metastatic potential and response to neoadjuvant regimens. The implementation of objective predictive assays will enhance our ability to assess tumor biologic activities and to design effective treatment regimens.

## CYTOGENETICS AND INTERPHASE CYTOGENETICS OF BLADDER TUMORS

Cytogenetic studies of bladder cancer cells by karyotyping have revealed a variety of chromosomal abnormalities. Nonrandom chromosomal changes consisting of monosomy of chromosome 9<sup>225,226</sup> and interstitial deletions of chromosome 13<sup>225</sup> have been observed. Other common abnormalities include trisomy of chromosome 7, deletions of chromosomes 11p and 3p, and chromosome 1 alterations.<sup>227,228</sup> and<sup>229</sup> However, most of these analyses were performed using small cohorts, lacking clinicopathologic correlations, and combining superficial and muscle-invasive lesions. In one study, Tyrkus et al.<sup>230</sup> karyotyped 17 carcinomas *in situ* of the urinary bladder and found no chromosome 9 alterations, but identified nonrandom chromosomal changes involving chromosomes 1, 5, 8, and 11.

More recent interphase cytogenetic studies have been conducted, mainly using centromeric probes, in a search for numerical alterations in bladder cancer. In addition, new telomeric and locus-specific probes are being used to identify genetic aberrations using nonisotopic detection methods. Poddighe and collaborators<sup>231</sup> reported chromosomal alterations at 1q12, as well as numerical abnormalities of chromosomes 1, 7, 9, 11, and 18.<sup>232</sup> Waldman et al.<sup>233</sup> also reported numerical aberration of chromosomes 7, 9, and 11 in 27 bladder tumors.

FISH has been used to assess *erbB-2* (17q21) gene amplification and *c-myc* (8q24) copy number gains in bladder cancer.<sup>234,235</sup> Sauter et al.<sup>234</sup> reported amplification of *erbB-2* in 10 of 141 bladder tumors using a dual labeling hybridization assay. Gene amplification was associated with protein overexpression and was found only in tumors with aneusomy of chromosome 17, and more frequently in muscle-invasive lesions.<sup>234</sup> A similar approach was used for the analysis of *c-myc* gene copy number on 87 bladder tumors. Obvious amplification was found in three cases, whereas 32 of the remaining 84 tumors showed a low-level *c-myc* copy number increase. No association was found between low-level copy number increase and protein overexpression. However, strong association was demonstrated between *c-myc* gains and tumor grade, stage, and Ki-67 labeling index, consistent with a role of chromosome 8 alterations in bladder cancer progression.<sup>235</sup> FISH assays also have been used for analyses of specific gene losses. Physical *p53* gene deletion (at 17p13) was examined by FISH in 151 bladder tumors.<sup>236</sup> 17p deletion was found to be highly correlated with tumor stage and grade ( $P < .01$ ). FISH has been used more recently to assay bladder irrigation specimens.<sup>237</sup> Labeled probes to centromeric sequences for chromosomes 1, 7, 9, 11, 15, and 17 were used on samples from 76 patients monitored for recurrent bladder tumors. Significantly, 24% of patients with history of bladder cancer but no clinical evidence of disease exhibited monosomy of chromosome 9.<sup>237</sup>

## ONCOGENES: MOLECULAR AND IMMUNOPATHOLOGY ANALYSES OF BLADDER TUMORS

The first mutation of the RAS family of oncogenes, a point mutation in codon 12 of the H-RAS gene (11p15.1), was identified in the bladder cancer cell line T24<sup>238</sup> and subsequently identified in bladder cancers.<sup>239</sup> There has been controversy regarding the mutation frequency of RAS genes in bladder tumors. Before the advent of polymerase chain reaction (PCR)-mediated DNA amplification, it was estimated that the rate of point mutations in RAS oncogenes ranged from 10% to 16% of samples analyzed.<sup>240,241</sup> and<sup>242</sup> The predominant alteration identified was codon 12 substitutions of the H-RAS gene, with a few cases presenting K-RAS mutations and no mutations detected affecting N-RAS. However, two reports by Czerniak and colleagues,<sup>243,244</sup> using a PCR-based method, revealed that approximately 40% of bladder tumors harbor H-RAS codon 12 mutations. Several studies have confirmed this high frequency of H-RAS point mutations. Ooi et al.<sup>245</sup> studied a cohort of 124 patients affected with pTa or pT1 transitional cell carcinomas. The codon 12 G to T substitution was found in nonrecurring and recurring primary tumors, as well as in initial pTa/T1 lesions from patients who had disease progression. More recently, a prospective study by Fitzgerald et al.<sup>246</sup> reported the detection of mutations in exon 1 of the H-RAS gene in urine sediments from 44 of 100 patients presenting with bladder neoplasms. It should be noted that different members of the RAS family are mutated in distinct tumor types. The frequency of K-RAS mutations in colorectal cancer is approximately 40%,<sup>247,248</sup> whereas mutations of N-RAS are commonly found in hematopoietic neoplasms.<sup>249</sup> Moreover, evidence indicates that mutant RAS alleles are involved in the earlier phases of neoplastic transformation of colorectal carcinomas.<sup>250</sup> Further studies in well-characterized cohorts of patients, using tissue microdissection techniques, are required to delineate the potential role of H-RAS mutations in bladder cancer.

Overexpression and amplification of particular growth factor receptors have been reported in bladder cancer. Neal and coworkers<sup>251</sup> observed increased expression of epidermal growth factor receptors (EGFR) in invasive versus superficial bladder tumors. This group of investigators also reported that overexpression of EGFR was associated with high-grade, high-stage bladder cancer and was an independent prognostic factor.<sup>252</sup> Messing<sup>253</sup> noticed that EGFR was expressed at detectable levels in the basal layer of the normal urothelium, whereas increased expression in basal and suprabasal layers was identified in transitional cell carcinomas. Rao et al.<sup>254</sup> also found increased expression of EGFR in urothelial samples with dysplastic changes, postulating that overexpression of EGFR may be an early event in

bladder carcinogenesis. In a more recent study, Nguyen et al.<sup>255</sup> reported that overexpression of EGFR was not an independent prognostic marker in patients with advanced bladder cancer.

Amplification of the c-erbB-2 gene was found in 1 of 14 bladder tumors in a study by Wood and collaborators.<sup>256</sup> This case also displayed overexpression when analyzed for mRNA and protein levels. In addition, five cases displayed high levels of mRNA with no signs of gene amplification, and only three of these five cases had protein overexpression. Sato et al.<sup>257</sup> observed c-erbB-2 protein (p185) overexpression in 23 of 88 bladder tumors analyzed and found a significant association with overexpression and poor clinical outcome, which is an independent prognostic factor. More recently, Underwood et al.<sup>258</sup> studied c-erbB-2 status in 236 bladder tumors. Sixteen of 89 patients with recurrent disease had evidence of c-erbB-2 amplification; however, gene amplification was not observed in the nonrecurrent tumors. A strong association with disease progression and c-erbB-2 amplification was reported. Nevertheless, protein overexpression could not be linked to disease progression. C-erbB-2 amplification was of predictive value in multivariate analysis for overall bladder cancer death; however, stage and grade remained the most significant independent prognostic parameters.<sup>258</sup>

A cellular protooncogene product, mdm2, has been shown to bind to p53 and act as a negative regulator, inhibiting its transcriptional transactivation activity<sup>259</sup> and targeting p53 for ubiquitin-mediated degradation.<sup>260,261</sup> The MDM2 gene is located on the long arm of chromosome 12 (12q13-14) and encodes a 90-kD nuclear protein.<sup>262</sup> Lianes et al.<sup>263</sup> undertook a study to determine the frequency and clinical relevance of identifying MDM2 and TP53 alterations in patients affected with bladder neoplasms. These investigators analyzed a cohort of 87 patients and observed that 26 of 87 cases had abnormally high levels of mdm2 protein; however, only one case showed MDM2 amplification. A striking association was noted between mdm2 overexpression and low-stage/low-grade bladder tumors ( $P < .01$ ). Based on these results, it was concluded that aberrant mdm2 phenotypes are frequent events in bladder cancer and may be involved in tumorigenesis or early tumor progression in urothelial neoplasms. In an independent study, Barbareschi et al.<sup>264</sup> reported mdm2 nuclear overexpression in 5 of 25 bladder tumors analyzed, but this survey lacked clinicopathologic correlations.

## TUMOR SUPPRESSOR GENES: MOLECULAR AND IMMUNOPATHOLOGY ANALYSIS OF BLADDER TUMORS

Molecular genetic studies of bladder cancer have identified abnormalities of tumor suppressor genes involved in tumor development and progression. Confirming initial cytogenetic observations, LOH on the short arm of chromosome 11 and 9q allelic losses were reported as frequent events in bladder tumors.<sup>265,266</sup> It was also observed that 17p LOH was a common event<sup>266,267</sup> in high-grade bladder cancer.<sup>267</sup>

In an attempt to define the role of molecular abnormalities of tumor suppressor genes in the pathogenesis and progression of human bladder cancer, a combined molecular genetics and immunopathology approach was undertaken by Presti et al.<sup>268</sup> In a survey of 34 unselected patients, five suspected or known tumor suppressor gene regions (3p21-25, 11p15, 13q14, 17p11-13, and 18q21) were studied. An IHC assay was also used for the analysis of the retinoblastoma gene product (pRB). This study demonstrated that tumor grade correlated with deletions of 3p ( $P = .004$ ) and 17p ( $P = .063$ ). Tumor stage was correlated with deletions of 3p ( $P = .010$ ), 17p ( $P = .015$ ), and altered pRB expression ( $P = .054$ ). Vascular invasion correlated only with deletions of 17p ( $P = .038$ ). This study also revealed that deletions of 17p (TP53 locus) and 18q (DCC gene locus) occur only in invasive tumors, whereas deletions of 3p and 11p occur in both superficial and invasive tumors.<sup>268</sup> Dalbagni et al.<sup>269</sup> followed this study by analyzing 60 paired normal and bladder tumor tissues using polymorphic DNA markers on 18 different chromosomal arms. Allelic deletions were correlated with clinicopathologic parameters. Distinct genotypic patterns were associated with early and late stages of bladder cancer. Correlation of genetic alterations with clinicopathologic data suggested the existence of two different genetic pathways for the evolution of superficial bladder tumors. Briefly, 9q deletions were found in 60% of the informative cases, confirming previous reports. Superficial papillary tumors confined to the mucosa (pTa) and almost all tumors invading the lamina propria (pT1) showed 9q alterations. In contrast, only 10 of 23 muscle-invasive tumors (pT2-4 or pT2+) had 9q deletions. A statistically significant difference was observed when comparing 9q LOH between pT1 versus pT2+ tumors ( $P = .021$ ). Moreover, 9q deletions were the sole abnormality found in some of the bladder lesions studied, suggesting the presence of a candidate tumor suppressor gene on chromosome 9q important in a subset of superficial bladder tumors. None of the pTa lesions showed 5q alterations; however, three of ten T1 tumors and 8 of 26 T2+ tumors presented with 5q LOH, indicating that 5q deletions may be involved in the transition from papillary superficial (pTa) to early invasive (pT1) tumors. Allelic loss of 17p was detected in 21 of 47 informative cases. Deletions were not identified among pTa lesions, whereas 21 of 38 invasive tumors exhibited 17p LOH. These findings support the involvement of 17p in the progression of bladder cancer. Allelic deletion of 3p was not present in any of the informative pTa neoplasms; however, 18 of 33 invasive tumors had such alterations. A statistically significant association was reported with the various pathologic parameters of poor outcome and 3p LOH. Allelic losses of 11p, 6q, and 18q were frequently detected in the corresponding informative bladder tumors analyzed. However, statistically significant differences were not observed between these abnormalities and clinical pathologic parameters of poor outcome, suggesting late involvement in bladder cancer progression. Other bona fide and putative suppressor loci analyzed in the Dalbagni et al. study showed a lower rate of LOH and lacked association with clinicopathologic parameters.<sup>269</sup>

In a subsequent allelotyping study, Habuchi et al.<sup>270</sup> investigated the role of allelic losses of seven chromosomal arms (1p, 3p, 9q, 10q, 11p, 13q, and 17p) in 49 urothelial cancers. They found 9q LOH as a common event in bladder tumors, and invasive tumors showed higher frequencies of 17p and 13q losses when compared to noninvasive lesions. Deletions of the long arm of chromosome 13, including the RB locus on 13q14, were independently reported by two groups.<sup>95,96</sup> In one of these studies, Cairns et al.<sup>271</sup> used intragenic RB probes and found 28 of 94 informative cases with LOH at the RB locus, with 26 of these 28 lesions being muscle-invasive tumors.

The relevance of RB alterations in bladder cancer was disclosed in two independent studies.<sup>272,273</sup> Using a mouse monoclonal antibody (mAb) and IHC in frozen tissue sections of 48 primary bladder tumors, Cordon-Cardo and collaborators<sup>272</sup> found normal levels of pRB expression in 34 cases. However, a spectrum of altered patterns of expression, from undetectable pRB levels to heterogeneous expression of pRB, was observed in 14 patients. Thirteen of the 38 patients diagnosed with muscle-invasive tumors were categorized as pRB altered, whereas only one of the ten superficial carcinomas had the altered pRB phenotype. The survival rate was significantly decreased in pRB altered patients compared to those with normal pRB expression ( $P < .001$ ).<sup>272</sup> Similarly, Logothetis et al.<sup>273</sup> found altered pRB expression in locally advanced bladder cancer. Forty-three patients were evaluated using the Rb-WL-1 polyclonal antiserum and IHC. These investigators reported altered pRB expression in 37% of the tumor specimens analyzed. A significant decrease in disease-free survival rate was reported for patients with documented abnormal pRB levels. Taken together, these data suggest that altered pRB expression occurred in all grades and stages of bladder cancer but was more commonly associated with muscle-invasive tumors. Moreover, altered patterns of pRB may become an important prognostic variable in patients presenting with invasive bladder cancer (Fig. 34.1-5).

**FIGURE 34.1-5.** Schematic representation of the proposed model of bladder cancer progression as it may relate to the pathologic staging of this cancer.

The clinical implications of detecting TP53 mutations and altered patterns of its encoded product (p53) in bladder tumors has been the focus of a series of investigations.<sup>274,275,276,277,278,279,280,281</sup> and <sup>282</sup> Early studies revealed that TP53 mutations were common events in bladder cancer and associated with tumor stage and grade.<sup>274,275</sup> Dalbagni et al.<sup>276</sup> correlated alterations of chromosome 17 with p53 nuclear overexpression in a cohort of 60 bladder tumors. Deletion of 17p correlated with grade ( $P = .039$ ) and stage ( $P = .004$ ), whereas p53 nuclear overexpression correlated with grade ( $P = .027$ ), stage ( $P = .008$ ), vascular invasion ( $P = .021$ ), and the presence of nodal metastases ( $P = .007$ ). A strong correlation was observed between the p53 overexpression and TP53 deletions ( $P < .001$ ). Following this study, Cordon-Cardo et al.<sup>277</sup> designed a study to evaluate the sensitivity and specificity of different laboratory assays directed to the identification of TP53 mutations, including IHC with mAb PAB1801, restriction fragment length polymorphism, PCR-SSCP (single-strand confirmation polymorphism), and sequencing.<sup>277</sup> Using this

approach, they also tested the hypothesis that p53 nuclear overexpression detected by IHC can reliably identify the presence of mutant TP53 products in bladder neoplasms. Nuclear immunoreactivities were observed in 26 of 42 bladder tumors analyzed. Abnormal shifts in mobility were noted in 14 of the 42 cases in distinct exons. A strong association was noted between p53 nuclear overexpression and 17p LOH ( $P < .001$ ), as well as p53 nuclear overexpression and detection of TP53 mutations by SSCP and sequencing ( $P < .001$ ). Using receiver operating curve (ROC) statistical analysis, the accuracy of detecting TP53 mutations by IHC was estimated to be 90.3%. In addition, this study defined as an appropriate cutoff point for IHC 20% tumor cells displaying nuclear immunoreactivities (p53-positive phenotype).

The aim of three analyses<sup>105,278,279</sup> was to investigate altered patterns of p53 expression with tumor progression in patients with superficial bladder tumors. Detection of p53 nuclear overexpression was evaluated by IHC using mAb PAb1801 on deparaffinized tissue sections in tumors from 43 patients with pT1 bladder cancer,<sup>278</sup> 54 patients with pTa neoplasms,<sup>279</sup> and 33 patients affected with pure pTis.<sup>105</sup> Nuclear p53 overexpression was correlated with clinicopathologic variables, and results were submitted to Fisher exact test, as well as univariate and multivariate analyses.<sup>105,278,279</sup> The median follow-up for these cohorts of patients was 119, 110, and 124 months, respectively. Patients in each stage were stratified into two groups, using the cutoff point identified through the ROC analysis previously conducted (20% nuclear-positive tumor cells).<sup>277</sup> A strong association was found between tumor progression and p53-positive phenotype in the three studies ( $P < .01$ ). Moreover, nuclear overexpression of p53 was an independent variable associated with disease progression and death due to bladder cancer.

Two studies dealing with p53 nuclear overexpression conducted in unselected bladder cancer patients have been reported. Lipponen<sup>280</sup> analyzed 212 bladder tumors, using IHC and 20% positive nuclear staining as the cutoff value. However, the primary antibody used was a purified rabbit polyserum (NCL-CM1, 1:150 dilution). The mean follow-up time was more than 10 years. Nuclear overexpression of p53 was associated with tumor grade and disease progression. In univariate analysis, p53 overexpression predicted poor outcome in the entire cohort. However, in a multivariate survival analysis, overexpression of p53 had no independent prognostic value over clinical stage and mitotic index. Esrig et al.<sup>281</sup> determined the relation between nuclear accumulation of p53 and tumor progression in a cohort of 243 patients treated by radical cystectomy using IHC and antibody PAb1801. These investigators noticed that detection of nuclear p53 was significantly associated with an increased risk of recurrence ( $P < .001$ ) and decreased overall survival ( $P < .001$ ). Moreover, p53-positive phenotype was an independent predictor of recurrence and survival.

The neoadjuvant use of chemotherapy offers the advantages of bladder preservation and early treatment of micrometastases in patients diagnosed with invasive bladder cancer. However, despite the chemosensitivity of invasive urothelial neoplasms, complete pathologic response in the primary lesion occurs in only 20% to 30% of patients. To determine whether aberrant p53 expression has independent significance for response, relapse, and survival in patients with muscle-invasive bladder cancer treated with neoadjuvant M-VAC [methotrexate, vinblastine, Adriamycin (doxorubicin), and cisplatin] chemotherapy, Sarkis et al.<sup>108a</sup> evaluated 90 patients who received this regimen with a median follow-up of 5.8 years. Patients whose tumors had p53-positive phenotype ( $n = 47$ ) had a significantly higher proportion of cancer deaths. Multivariate analysis revealed that p53 overexpression had independent significance for long-term survival ( $P < .001$ ).<sup>108</sup>

As already discussed, loss of genetic material on chromosome 9 is an early abnormality detected in bladder tumors.<sup>225,266,269,270,282</sup> More recently, the existence of two altered loci, one in each of the chromosome 9 arms, was postulated.<sup>283,284</sup> A detailed analysis conducted by Orlov et al.<sup>285</sup> on 73 bladder tumors showed that two regions, one on 9p at the IFN cluster (9p21) and the other on 9q associated with the q34.1-2 bands, had the highest frequencies of allelic losses. The 9p21 region has been found to be mutated frequently in a wide variety of human tumor cell lines, and the search for a putative tumor suppressor gene in this region led to the characterization of the so-called multiple tumor suppressor 1 (MTS1) gene.<sup>286</sup> It was confirmed that the MTS1 gene was the previously identified p16/INK4A/CDKN2 (p16) gene.<sup>287</sup> In addition to the p16 gene, the p15/INK4B/MTS2 (p15) gene is found in tandem at 9p21.<sup>288</sup> These genes encode members of negative cell-cycle regulators, called *cyclin-dependent kinase (cdk) inhibitory molecules*.<sup>287,288</sup> and <sup>289</sup> The initial enthusiasm over the high frequency of mutations of these genes in cell lines has been confirmed by genetic alterations mainly of p16, as well as deletions of p15, in human primary tumors, including bladder cancer.<sup>290,291,292,293,294</sup> and <sup>295</sup> Moreover, it has been shown that genetic alterations of p16 are independent of TP53 mutations, suggesting that p16 and p53 function in separate pathways of tumor suppression.<sup>294</sup>

Identification of the p14 ARF gene within the same locus as p16 and p15 links the p16/pRB and p53 pathways of tumor suppression. p16 inhibits the ability of cyclin D1 and its associated cdk to phosphorylate pRB. Unphosphorylated pRB sequesters the transcription factor E2F1, a transcription factor necessary for cell-cycle progression.<sup>296</sup> Absence of p16 (as in a homozygous deletion at chromosome 9p) allows unregulated phosphorylation of pRB and increased free E2F1. The p14ARF gene shares a portion of the p16 transcription unit and encodes a novel protein product that interacts with and causes destabilization of the mdm-2 protein.<sup>297,298</sup> Decreased mdm-2 results in increased p53 availability; increased p53 can mediate cell-cycle arrest at G<sub>1</sub> or induce apoptosis. E2F1 causes increased expression of the p14ARF gene, causing a negative feedback for cell-cycle progression. Lack of p14 ARF due to alterations at the p16 locus results in uninhibited mdm-2 and decreased p53 function. Although p16 and p53 are independent, the p16 locus encodes a gene that links the p53 and pRB pathways. Therefore, genetic alterations of the p16/p15/p14ARF locus can affect both p53 and pRB tumor suppressor function. However, it should be kept in mind that the p14ARF pathway can only modulate p53 activity via mdm-2, and mutations of the p53 or amplification of MDM2 may be more important in complete inactivation of p53 as previously discussed. Alternatively, genetic alterations that affect p16 and p15 may not affect p14ARF.

Orlov et al.<sup>295</sup> have reported an overall frequency of deletions and rearrangements for the p16 and p15 genes in bladder cancer of 19% and 18%, respectively. Moreover, this study revealed that p16 and p15 alterations were associated with low-stage, low-grade bladder tumors. It should be emphasized that only pTa and pT1, but not pTis, lesions showed deletions of either p16 or p15. Because p16 alterations occur independently of p53 mutations<sup>294</sup> and p53 mutations are frequent events in Tis bladder tumors,<sup>105</sup> data from that report further support the hypothesis that bladder carcinogenesis may develop through two distinct molecular pathways.<sup>269,299</sup> Taken together, the results suggest that p16 and p15 alterations confer selective growth advantage to urothelial tumor cells, but mutations in other genes are required to produce an overt malignant phenotype.

## BLADDER CANCER AS A MODEL FOR THE STUDY OF TUMOR PROGRESSION AND FUTURE DIRECTIONS

The molecular abnormalities reported to date, as well as the natural history of bladder cancer, have allowed the proposal of a working model for tumor development and progression of this group of neoplastic diseases.<sup>269,299</sup> It is the hypothesis of several groups of investigators that some specific chromosomal abnormalities and mutations of certain genes play a definite role in bladder tumor development, whereas other alterations seem to correlate with tumor progression. "Primary" molecular aberrations can be defined as those directly related to the genesis of cancer.<sup>300</sup> These are frequently found as the sole abnormality and often are associated with particular tumors. Primary abnormalities may have a dual nature: (1) primary events involved in the production of low-grade/well-differentiated neoplasms that destabilize cellular proliferation, but have minimal or no effects on cellular "social" interactions or differentiation, as well as rate of cell death or apoptosis; and (2) primary events leading to high-grade/poorly differentiated tumors that disrupt growth control, including cell-cycle and apoptosis regulators, and have a major impact on cellular differentiation. There are evidence and data to support the idea that a target site(s) for primary event(s) in low-grade papillary superficial bladder tumors may reside on chromosome 9. However, a candidate for the initiation of high-grade, flat carcinoma *in situ* lesions has not been yet elucidated. Novel approaches using tissue microdissection techniques and molecular genetic assays are needed to shed light on this subject. Conversely, "secondary" abnormalities may be fortuitous or may determine the biologic behavior of the tumor.<sup>300</sup> Multiple molecular abnormalities are identified in most human cancers studied, including bladder neoplasms, with the accumulation rather than the order of these genetic alterations being important and probably acting synergistically. In this regard, it is noteworthy that most of the identified genes involved in late stages of tumor progression act as major regulators of the cell cycle and apoptosis programs, such as TP53 and RB.

## HEREDITARY PREDISPOSITIONS AND UROTHELIAL CANCER

In 1993, one of the genes responsible for a hereditary cancer predisposition syndrome known as *hereditary nonpolyposis colon cancer* (HNPCC) was identified.<sup>301,302</sup> and <sup>303</sup> Although colon cancer is the predominant malignancy in this syndrome, Lynch and colleagues<sup>304</sup> previously described an increased incidence of upper tract transitional cell carcinoma (TCC) in a subset of HNPCC families. The genes responsible for HNPCC are highly conserved DNA repair genes involved in the correction of misincorporated deoxyribonucleotides formed during DNA replication known as *mismatch repair* (MMR).<sup>305</sup> Tumors deficient for MMR display a characteristic pattern of genetic alterations termed *microsatellite instability* (MSI) or *replication errors*.<sup>306,307</sup> and <sup>308</sup> MSI is caused by slippage of the DNA polymerase at mono-, di-, and trinucleotide tracts normally repaired by MMR proteins.<sup>309</sup> Almost all tumors from HNPCC patients display MSI, because the normal MMR allele is lost in these tumors. The instability that results can cause mutations in other genes, which leads to tumorigenesis.

Subsequent studies in sporadic bladder tumors demonstrate MSI in 6% of superficial tumors,<sup>1</sup> and immunohistochemical analysis of one of the MMR genes (hMSH2) revealed lack of expression in only two.<sup>311</sup> However, decreased expression of hMSH2 was observed in 25% of tumors, and this finding correlated with high-grade and recurrent disease. Analysis of expression of MMR genes in bladder tumors from HNPCC patients has not been reported, and it will be interesting to determine if these

tumors display MSI. The investigation of MMR genes in urothelial malignancies may be important in management of patients with bladder cancer, because HNPCC is the only cancer syndrome that predisposes affected individuals to TCC. Also, tumors with MMR deficiency are resistant to alkylating agents<sup>312</sup> sometimes used in treatment of superficial TCC, such as thiotepa. Further investigation of these genes in urothelial malignancies seems warranted.

Are other protooncogenes involved in cell-cycle control, such as cyclin D1 and Cdk4, altered in bladder tumors? Is the genetic instability observed in some uroepithelial carcinomas due to mutations of MMR genes? Is the deficiency in apoptotic signals responsible for lack of response to adjuvant therapy? Are unconstrained transcription factors, such the E2F family members in the advent of RB alterations, accountable in part for the clinical phenomenon of the resistant phenotype? To what extent do other drug resistance mechanisms, such as P glycoprotein, play a role in treatment failure? Which are the genes involved in the phenotype of metastatic bladder cancer? These clinically relevant questions await further studies. The current need is to translate newly developed scientific knowledge into diagnostic and therapeutic strategies, using well-characterized cohorts of patients and novel approaches to the analysis of available tissue samples.

## POTENTIAL CLINICAL APPLICATIONS

Inherent in the study of the fundamental genetic events leading to bladder cancer is the hope that the understanding of the molecular mechanisms of transformation in this malignancy may lead to insights for new treatment strategies for this disease. Another potential application of studies on molecular genetics of bladder cancer is that detection of alterations in certain genes may lead to improved methods for early diagnosis of uroepithelial tumors. Sidransky et al.<sup>274</sup> have shown that identification of alterations, such as p53 gene mutations in bladder tumors and urine samples, can provide a potentially extremely sensitive method for detection of bladder cancer. In one instance, genetic abnormalities could be detected years before the disease was clinically apparent.<sup>313</sup> In a series of studies, these scientists have demonstrated that microsatellite instability is associated with some bladder tumors and can occur early in bladder tumorigenesis.<sup>310,314</sup> In a blinded study in which urine samples from 25 patients with suspicious bladder lesions were analyzed by conventional cytology and genomic instability analysis, microsatellite changes identical to those in the tumors were detected in the urine sediment of 19 of 20 patients (95%) who were found to have bladder cancer.<sup>315</sup> Cytology detected cancer cells in only 9 of 18 cases (50%).<sup>316</sup> These studies suggest that molecular genetic analysis for disease gene alterations and microsatellite instability may become useful additions to current screening methods for detecting bladder cancer and may provide improved methods for prediction of clinical course in individual patients.

## RENAL CARCINOMA

Each year in the United States, approximately 31,000 cases of kidney and upper urinary tract cancer occur, resulting in more than 11,900 deaths.<sup>1</sup> These tumors account for approximately 3% of adult malignancies and occur in a male-female ratio of 1.5:1. They are more common among urban than rural residents. Although most cases occur in persons aged 50 to 70 years, renal carcinoma has been observed in children as young as 6 months. Between 1975 and 1995, a steady and significant increase in the incidence of renal carcinoma was seen, from 2% to 4% per year, an increase of 43% since 1973.<sup>2,3,4 and 5</sup>

Renal carcinoma was first described by Konig in 1826. As early as 1855, Robin concluded that the renal tubular epithelium was the most probable tissue of origin of the cancer, an observation that was confirmed by Waldeyer in 1867. In 1883, Grawitz, noting that the fatty content of the cancer cells was similar to that of adrenal cells, concluded that the tumors arose from adrenal rests within the kidney and introduced the term *stroma lipomatodes aberrata renis* for these clear cell tumors. The term *hypernephroid tumors* was introduced in 1984 by Birch-Hirschfeld. Since then the conceptually incorrect term *hypernephroma* has frequently been applied to renal tumors.<sup>6,7</sup>

Renal carcinoma occurs in both a sporadic and a hereditary form. There are four main forms of hereditary renal carcinoma (HRC). The most studied form of HRC is von Hippel-Lindau (VHL) syndrome. VHL syndrome is a hereditary cancer syndrome in which affected individuals are at risk to develop tumors in a number of organs, including the kidney.<sup>8</sup> A recently described form of HRC is hereditary papillary renal carcinoma (HPRC).<sup>9,10</sup> Another recently described form of hereditary kidney cancer is familial renal oncocytoma (FRO),<sup>11</sup> which has been found to be associated with the cutaneous condition Birt-Hogg-Dubé syndrome.<sup>12</sup> Hereditary clear cell renal carcinoma is a rare condition that is inherited in an autosomal dominant fashion in which patients develop clear cell variant renal carcinoma. In the hereditary syndromes, the kidney cancer is often bilateral and tends to occur in a younger age group.<sup>8</sup> An increased incidence of renal carcinoma has also been observed in patients with autosomal dominant polycystic kidney disease and tuberous sclerosis.<sup>13</sup>

## ETIOLOGY

A number of environmental, hormonal, cellular, and genetic factors have been studied as possible causal factors in the development of renal carcinoma. In studies of risk of renal carcinoma, cigarette smoking has been found to be a definite risk factor.<sup>14,15 and 16</sup> A statistically significant dose response has been observed in both genders for pack-years of cigarette use.<sup>17</sup> It has been estimated that 30% of renal carcinomas in men and 24% in women may be directly due to smoking.<sup>18</sup> Obesity is associated with an increased risk of development of renal carcinoma, particularly in women.<sup>19</sup> Analgesic abuse, which is known to be associated with renal pelvis cancer, is also associated with an increased incidence of kidney cancer. The increased risk for the development of renal carcinoma is observed primarily in patients who abuse phenacetin-containing analgesics and develop analgesic nephropathy.<sup>5,16,20</sup>

Environmental and occupational factors have also been associated with the development of kidney cancer. Brauch et al.<sup>21</sup> demonstrated an association between the development of renal carcinoma and long-term exposure to high levels of the industrial solvent trichloroethylene. There is an increased incidence of renal carcinoma among leather tanners, shoe workers, and workers exposed to asbestos.<sup>22</sup> Exposure to cadmium is associated with an increased incidence of kidney cancer, particularly in men who smoke.<sup>23</sup> An association between gasoline exposure and kidney cancer has been observed in animal studies. Although there is an increased incidence of renal carcinoma reported with exposure to petroleum, tar, and pitch products, studies of oil refinery workers and petroleum products distribution workers do not identify a definite relationship between gasoline exposure and renal cancer. There may be an increased risk of kidney cancer in older workers or in workers exposed to gasoline for prolonged periods.<sup>24</sup>

An increased incidence (100-fold) of renal carcinoma has been noted in patients with end-stage renal disease who develop acquired cystic disease of the kidneys.<sup>25</sup> Acquired cystic disease is a recently described phenomenon in which patients on long-term dialysis for renal failure develop cysts in their native kidneys. Renal carcinoma has been found in association with the papillary hyperplasia observed in the cyst epithelium of these kidneys. The risk of developing kidney cancer has been estimated to be greater than 30 times higher in dialysis patients with cystic changes in their kidney than in the general population.<sup>26</sup> It is estimated that 35% to 47% of patients on long-term dialysis will develop acquired cystic disease and that nearly 5.8% of the patients with acquired cystic disease will develop renal cancer. Kidney cancer can develop at any time in patients with end-stage renal disease, and it can occur in kidney transplant recipients as well. It can develop in patients with end-stage renal disease who are undergoing either hemodialysis or chronic ambulatory dialysis, but it also has been reported to occur in patients with end-stage renal disease who are not being dialyzed.<sup>25</sup> Although many of these cancers are clinically insignificant and are found incidentally at autopsy or after bilateral nephrectomy, some will follow an aggressive course.<sup>27</sup> Careful surveillance of patients with end-stage renal disease with ultrasonography and computed tomography (CT) is recommended.<sup>14</sup>

## HEREDITARY FORMS OF RENAL CARCINOMA

Like breast cancer, colon cancer, and retinoblastoma, renal cancer occurs in both a sporadic (nonhereditary) and a hereditary form. At least four forms of HRC are

recognized: VHL, HPRC, FRO, and HRC ([Table 34.2-1](#)).<sup>224,225,226 and 227</sup>

Form of Carcinoma	Abbreviation	Studies
Renal carcinoma associated with von Hippel-Lindau disease	VHL	8,224,225
Hereditary papillary renal carcinoma	HPRC	9,10
Hereditary renal carcinoma associated with Birt-Hogg-Dubé syndrome	BHDS	12
Hereditary renal carcinoma (clear cell)	HCRC	226,227

**TABLE 34.2-1.** Hereditary Forms of Renal Carcinoma

### von Hippel-Lindau Syndrome

The VHL syndrome, which is predicted to occur in 1 in 36,000 live births, is a familial cancer syndrome in which affected individuals have a predisposition to develop tumors in a number of organs, including the kidneys, brain, spine, eyes, adrenal glands, pancreas, inner ear, and epididymis.<sup>2,8,28</sup> Forty percent of VHL patients develop multiple, bilateral tumors or cysts in the kidneys. The renal carcinoma acquired by VHL patients is clear cell renal carcinoma.<sup>29</sup> These patients can have hundreds of small clear cell tumors and cysts in their kidneys. The tumors, which tend to occur early in life, can metastasize, and the affected individual may succumb to the malignancy. VHL patients can also develop pheochromocytoma, pancreatic cysts and islet cell tumors, retinal angiomas, central nervous system hemangioblastomas, inner ear tumors (endolymphatic sac tumors), and epididymal cystadenomas ([Table 34.2-2](#)).<sup>8</sup>

Type	Description
I	VHL syndrome without pheochromocytomas
II	VHL syndrome with pheochromocytomas
IIA	Pheochromocytomas, retinal angiomas, and central nervous system hemangioblastomas
IIIB	VHL IIA syndrome plus renal cancers and pancreatic involvement

**TABLE 34.2-2.** Classification of von Hippel-Lindau (VHL) Syndrome

**THE VHL GENE.** Identification of the VHL gene by Latif et al.<sup>30</sup> in 1993 was an important step for physicians managing patients with VHL disease. Critical to management of VHL patients is the knowledge of who is affected and who is not. Early identification of at-risk individuals is essential for initiation of early intervention with the potential to prevent of life-threatening complications of the disease, such as metastatic kidney cancer.<sup>2,8</sup>

**VHL GERMLINE MUTATION TESTING.** Identification of the VHL gene has allowed the detection of germline mutation in nearly 100% of VHL families.<sup>31,32</sup> The VHL clinical features can be heterogeneous, and manifestations such as kidney cancer occult. In some families, VHL syndrome can be confused with other hereditary cancer syndromes, such as multiple endocrine neoplasia type 2. The availability of germline mutation screening can aid the physician in making the correct diagnosis as well as in performing presymptomatic screening in at-risk individuals. (See [Chapter 34.1.](#))

**ROLE OF THE VHL GENE IN CLEAR CELL RENAL CANCER.** The VHL gene has been found to be mutated in a high percentage of tumors and cell lines from patients with sporadic (nonhereditary) clear cell renal carcinoma.<sup>33,34</sup> VHL gene mutations have not been detected in either tumors from patients with papillary renal carcinoma or from the germline of patients with HPRC. This has led to the development of a molecular genetic classification of renal carcinoma of papillary versus clear cell (nonpapillary) renal carcinoma,<sup>8,35</sup> with clear cell renal carcinoma being characterized by inactivation of the VHL gene.<sup>33,34</sup> The determination that VHL gene mutations can be detected in formalin-fixed tissue from patients with clear cell renal carcinoma provides a potential method for significantly improving clinicians' ability to diagnose this disease, by analysis of either tissue blocks or tissue aspirates from patients suspected of having this disease.<sup>36</sup>

### Hereditary Papillary Renal Carcinoma

HPRC is a recently described form of HRC.<sup>9,10</sup> HPRC is an inherited disorder with an autosomal dominant inheritance pattern in which affected individuals develop bilateral, multifocal papillary renal carcinoma ([Fig. 34.2-1](#)). These tumors, which are often detected incidentally, can spread in a fashion similar to sporadic renal carcinoma. Abdominal CT is recommended for evaluation of at-risk individuals, as even large papillary renal tumors are frequently undetectable by renal ultrasound evaluation.<sup>37</sup>

**FIGURE 34.2-1. A:** Abdominal computed tomography scan of a patient with hereditary papillary renal carcinoma, demonstrating bilateral, multifocal papillary renal carcinoma.<sup>9,10</sup> **B:** Hereditary papillary renal carcinoma kindred. The black boxes and circles represent individuals found to have kidney cancer. The circles below these represent the result of germline testing for the c-Met mutation. (From ref. [39](#), with permission.)

**THE HPRC GENE: MET.** Genetic linkage studies in HPRC kindreds localized the HPRC gene and led to the identification of the c-Met protooncogene as the gene

responsible for HPRC.<sup>38</sup> Germline mutations in the tyrosine kinase domain of the MET gene have been found in affected individuals in HPRC kindreds.

**HPRC GERMLINE TESTING.** Germline MET mutation testing is recommended for patients at risk for HPRC. Individuals in HPRC kindreds, those with bilateral, multifocal papillary renal carcinoma (Fig. 34.2-2), or those with a family history of papillary kidney cancer are considered candidates for germline testing.<sup>39</sup>

**FIGURE 34.2-2.** **A:** A kidney from an asymptomatic man who was found to have hereditary papillary renal carcinoma (HPRC), demonstrating multifocal papillary renal carcinoma. HPRC is a hereditary cancer syndrome in which affected individuals are at risk to develop multifocal papillary renal carcinoma. **B:** The histology of HPRC renal tumors is uniformly papillary. **C:** Hundreds of small tumors and adenomas may be present in each kidney. HPRC is characterized by a germline mutation of the c-Met gene, and germline testing is recommended for at-risk individuals. (From ref. 9, with permission.)

### Familial Renal Oncocytoma and Birt-Hogg-Dubé Syndrome

A new, recently described form of HRC is FRO.<sup>11</sup> Affected individuals can develop bilateral, multifocal oncocytoma or oncocytic neoplasms in the kidney. Similar renal manifestations have been found to occur in patients with a hereditary cutaneous syndrome, Birt-Hogg-Dubé syndrome (BHDS). BHDS patients have a dominantly inherited predisposition to develop fibrofolliculomas, benign tumors of the hair follicle that appear predominantly on the face, neck, and upper trunk. Affected BHDS individuals are at risk to develop fibrofolliculomas, renal tumors, colon polyps or tumors, and pulmonary cysts.<sup>12</sup> Individuals in BHDS kindreds are at risk to develop renal tumors. The renal tumors that occur in BHDS can be clear, papillary, chromophobe, or oncocytomas and are malignant and can metastasize if not detected and treated. Studies are currently under way to identify the gene for this hereditary cancer syndrome and to develop a test for germline testing of at-risk individuals.

### PATHOLOGY

Immunohistologic and ultrastructural analysis has established that the proximal renal tubular epithelium is the true tissue of origin of renal carcinoma. Renal tumors tend to be spherical but may vary widely in size. The average diameter is approximately 7 cm; however, renal tumors can often grow to fill the entire retroperitoneum. Previously, renal lesions 2 cm or less in diameter were considered to be renal adenomas, while lesions 2 cm or more in diameter were considered to be carcinomas. The distinction between benign and malignant tumors is no longer made on the basis of size but on the basis of classic histologic criteria.<sup>40</sup> Although renal carcinoma tends to arise in the cortex of the kidney, it can originate in the interior of the kidney. Often a pseudocapsule is formed around the tumor by compression of surrounding tissue. Hemorrhage and necrosis may be present and, frequently, large areas of sclerosis and fibrosis are found within the tumor. Calcification and single or multiple fluid-filled cysts may be seen within the tumor also. Sporadic renal carcinoma appears in either kidney with equal frequency; it is most often solitary and unilateral.

Renal tumors can be of five main cellular types: clear cell, papillary, chromophobe, oncocytoma, and collecting duct (for review, see Zambrano et al.<sup>40</sup>). Clear cell carcinomas contain lightly staining cells with vacuolated cytoplasm containing cholesterol-like substances, neutral lipids, phospholipids, and glycogen; these constitute 85% of kidney cancers.<sup>40,41</sup> Papillary renal carcinoma makes up approximately 10% of all kidney cancers,<sup>42</sup> with the remainder being chromophobe, collecting duct, and miscellaneous histologic types. Papillary renal carcinoma has been divided into two morphologic subtypes, types 1 and 2.<sup>42</sup> Collecting duct carcinoma is an unusual variant of renal cell carcinoma (RCC) that is characterized by a very aggressive clinical course. It is not uncommon for a patient with collecting duct carcinoma to present with locally or widespread advanced disease.<sup>43</sup> Chromophobe carcinoma, described by Thoenes et al.<sup>44</sup> in 1985, is characterized by large polygonal cells with pale reticular cytoplasm. Renal oncocytoma, which consists predominantly of eosinophilic cells in a characteristic nested or organoid pattern, is considered to be predominantly a benign lesion.<sup>45</sup> Whether oncocytoma can occur in a malignant form or whether so-called malignant oncocytoma is actually a variant of chromophobe renal carcinoma is not completely understood.<sup>40,46</sup>

The sarcomatoid variant, which can occur with any histologic subtype,<sup>47</sup> is associated with a significantly poorer prognosis than are nonsarcomatous renal carcinomas.<sup>48</sup> A median survival of only 6.6 months is reported for patients with sarcomatoid-type renal carcinoma, as compared to a 19.0-month median survival for patients with nonsarcomatous renal carcinoma.<sup>49</sup> Although infrequently used in renal carcinoma, tumor grading may correlate with survival, particularly in patients with nonmetastatic cancer.

### CLINICAL PRESENTATION

Renal carcinoma may remain clinically occult for most of its course. The classic presentation of pain, hematuria, and flank mass occurs in only 9% of patients and often is indicative of advanced disease.<sup>50</sup> A tumor in the kidney can progress unnoticed to a large size in the retroperitoneum until a metastasis appears. Approximately 30% of patients with renal carcinoma present with metastatic disease, 25% with locally advanced renal carcinoma, and 45% with localized disease. Some 75% of patients with metastatic renal carcinoma have metastases to the lung, 36% to soft tissues, 20% to bone, 18% to liver, 8% to cutaneous sites, and 8% to the central nervous system.<sup>51</sup>

A considerable number of patients with renal carcinoma develop systemic symptoms of this disease (Table 34.2-3).<sup>52</sup> Hypochromic anemia, due to either hematuria or hemolysis, has been observed in 29% to 88% of patients with renal carcinoma. Pyrexia is observed in 20% and cachexia, fatigue, and weight loss in 33%. Nonmetastatic hepatic dysfunction, initially described by Stauffer in 1961, is a reversible syndrome associated with renal carcinoma that tends to occur in association with fever, fatigue, and weight loss and resolves when the primary tumor is removed. Nonmetastatic hepatic dysfunction, which is usually associated with poor long-term prognosis, occurs in up to 7% of patients with renal carcinoma. Abnormal hepatic function is observed in up to 40%.<sup>53</sup>

Presenting Symptom, Abnormal Laboratory Findings, or Abnormalities on Physical Examination	Patients (n = 309)	Patients Surviving 5 Y
Classic triad (gross hematuria, abdominal mass, pain)	29 (9%)	9/29 (31%)
Hematuria	183 (59%)	74/183 (40%)
Pain	127 (41%)	56/127 (44%)
Abdominal mass	139 (45%)	49/139 (35%)
Fever	21 (7%)	8/21 (38%)
Weight loss	85 (28%)	29/85 (34%)
Anemia	64 (21%)	24/64 (38%)
Erythrocytosis	10 (3%)	4/10 (40%)
Hypercalcemia	11 (4%)	4/11 (36%)
Acute varicocele	7 (2%)	3/7 (43%)
Tumor calcification on x-ray film	39 (13%)	18/39 (46%)
Symptoms of metastases	31 (10%)	1/31 (3%)
Cancer, incidental finding	20 (6%)	13/20 (65%)

(Modified from ref. 228.)

**TABLE 34.2-3.** Presenting Symptoms, Laboratory Abnormalities, or Abnormalities on Physical Examination and Their Relation to Survival Rate in 309 Consecutive Patients Undergoing Nephrectomy for Renal Carcinoma

One to five percent of patients with kidney cancer have polycythemia.<sup>54</sup> Renin levels often are elevated in patients with renal carcinoma but tend to return to normal after the kidney is removed. Whether the tumor itself produces renin or whether it induces renin production by compression of adjacent tissue is unclear. Immunocytochemical studies suggest that renal carcinoma may produce renin, which, however, may be biologically inactive.<sup>55</sup> Plasma fibrinogen levels may be elevated in patients with renal carcinoma and may correlate with tumor stage, disease activity, and response to therapy. Acquired dysfibrinogenemia has also been reported in association with renal carcinoma and can be a sensitive plasma marker for the disease and for tumor progression.<sup>56</sup>

### SYSTEMICALLY ACTIVE TUMOR-PRODUCED FACTORS

In many patients with RCC, there is evidence of tumor-produced factors that have systemic effects. Pyrexia, cachexia, abnormal liver function, increased alkaline phosphatase levels, hypercalcemia, polycythemia, neuromyopathy, and amyloidosis have all been reported in association with RCC.<sup>57</sup>

Humoral hypercalcemia of malignancy, frequently observed in patients with advanced RCC, is believed to be caused by a tumor-produced, systemically active bone-resorbing factor. A number of investigators have demonstrated that kidney cancer produces a factor with parathyroid hormone–like bioactivity.<sup>58</sup> A parathyroid hormone–related protein that has been implicated in malignant hypercalcemia has been cloned from a human lung cancer cell line and is expressed in mammalian cells.<sup>59</sup> Whether the parathyroid hormone–like factor induces paracrine or endocrine effects, such as bone resorption or hypercalcemia of malignancy, in patients with RCC is currently being studied (Table 34.2-4).

Type of Lesion	No. of Lesions	% of Total No. of Lesions
Cystic lesions		50
Benign cysts	515	
Benign hemorrhagic cysts	4	
Hydronephrosis	8	
Cystic dysplastic kidney	3	
Polycystic kidney	17	
Malignant neoplasms		5.5
Hypernephroma	21	
Other malignant neoplasms	31	
Benign neoplasms	40	4.2
Inflammatory lesions (pyelonephritis, abscess)	215	25
Intrarenal hematoma	7	0.7
Pseudotumors	81	8.6

(Modified from EK. Lang. Asymptomatic space-occupying lesions of the kidney: a programmed sequential approach and its impact on quality and cost of health care. *South Med J* 1977;70:277.)

**TABLE 34.2-4.** Underlying Pathologic Conditions in 940 Asymptomatic Space-Occupying Lesions of the Kidney

### RADIOGRAPHIC EVALUATION

Determining whether a space-occupying renal mass is benign or malignant can be difficult. A number of diagnostic modalities are used to evaluate and stage renal masses, including excretory urography, CT, arteriography, venography, ultrasonography, and magnetic resonance imaging (MRI). Excretory urography is infrequently used in the initial evaluation of renal masses but, because it is neither sensitive nor specific in RCC, a small to medium-sized tumor may be present when the excretory urogram appears normal. Excretory urography does provide important information about the location and function of the contralateral kidney and, while this is particularly useful when surgery is being considered, CT has replaced excretory urography in the evaluation of renal masses.<sup>60,61 and 62</sup>

Ultrasound examination provides excellent staging and diagnostic information and can provide accurate anatomic detail of extrarenal extension of tumor, adrenal involvement, involvement of lymph nodes, and infiltration of adjacent viscera.<sup>60,63</sup>

Renal arteriography is infrequently used in the evaluation of patients with a suspicious renal mass (Fig. 34.2-3). In a renal carcinoma, the arteriogram often will show neovascularity, arteriovenous fistulas, pooling of contrast medium, and accentuation of capsular vessels. Epinephrine may be used as an aid in the diagnosis of an equivocal renal mass. When epinephrine is infused into a normal kidney during arteriography, the renal vessels constrict; in contrast, the vessels in a renal carcinoma do not constrict, owing to lack of musculature in the tumor vessels.<sup>64</sup> A renal arteriogram may be useful in evaluating an indeterminate small renal mass and as an aid to the surgeon in defining the vasculature during the surgical removal of a large tumor.<sup>65,66</sup> Although renal arteriography can be performed with minimal risk, false aneurysms, arterial emboli, hemorrhage, and decreased renal function secondary to contrast agent injection have been reported.<sup>67</sup> Dual-phase three-dimensional magnetic resonance angiography can be a useful technique in depicting renal vessels before surgical therapy. This technique is very accurate for the detection of the renal arteries, renal vein involvement, and extension into the inferior vena cava.<sup>61</sup>

**FIGURE 34.2-3.** Angiographic appearance of a renal carcinoma. **A:** Computed tomography demonstrates a right renal carcinoma (m) with a large contralateral adrenal metastasis (a). **B:** Early phase of the arteriogram demonstrates vascular changes indicative of a malignancy, with puddling and tortuosity (arrows). **C:** Late phase of the arteriogram demonstrates that the tumor (M) is relatively avascular despite its early appearance.

CT is a useful imaging technique for renal carcinoma (Fig. 34.2-4).<sup>37,60</sup> CT and ultrasonography have become the main modalities used to characterize renal masses.<sup>63,68</sup> Although arteriography and CT are equivalent in depicting renal vein involvement, CT is better for demonstrating local nodal involvement. The use of contrast agent enhancement has greatly increased the sensitivity of CT for abnormal renal masses.<sup>37</sup> Contrast-enhanced CT allows the clinician to detect very small changes in the density of a renal lesion that might indicate the presence of an early neoplastic lesion. In a comparison study, dynamic CT was superior to standard CT arteriography, ultrasonography, and radionuclide scanning. Dynamic CT correctly demonstrated tumor involvement of the kidney, involvement of the renal fascia, or extension into adjacent organs in all of the 22 patients studied (see Fig. 34.2-4).<sup>69</sup>

**FIGURE 34.2-4.** Renal vein invasion by a renal carcinoma as shown by computed tomography (CT) and magnetic resonance imaging. **A:** Nonenhanced CT scan shows large left renal mass with calcification (m) invading the left renal vein (arrow). **B:** T1-weighted magnetic resonance image demonstrates tumor (m) and vascular invasion (arrow). Flowing blood (v) in the left renal vein is black on this scan.

Inferior venacavography may be performed when a large renal tumor is present or when there is uncertainty about tumor involvement of the vena cava. Ultrasonography, CT, and MRI can provide information about tumor involvement of the vena cava (Fig. 34.2-5)<sup>61,63</sup>; however, the inferior venacavogram is the most reliable means of accurately determining the precise extent of vena caval involvement by tumor. This information is important to the surgeon in planning the vascular aspect of the operative procedure. MRI is very useful for staging renal carcinoma.<sup>70,71</sup> MRI can produce a unique three-dimensional picture of the tumor, which, in the case of a large lesion, may be an invaluable aid to the surgeon in planning the operative approach. In patients with tumor involving the inferior vena cava, transesophageal echocardiography has been shown to be an accurate diagnostic technique for tumor imaging to document the extent of involvement of the vena cava (see Fig. 34.2-5).

**FIGURE 34.2-5.** Invasion of inferior vena cava (IVC) by renal carcinoma demonstrated by magnetic resonance imaging and venography. **A:** Axial T1-weighted image demonstrates a large left renal carcinoma with extension into the left renal vein (m) with protrusion into the IVC (v). **B:** Sagittal T1-weighted image shows the relation of the tumor thrombus (m) to the IVC (v) in the lateral projection. **C:** An anteroposterior image of the inferior cavogram demonstrates tumor (arrows) in the medial aspect of the inferior vena cava.

No single imaging technique is best for all patients with renal carcinoma. Depending on the size of the primary tumor and the extent of extrarenal disease, excretory urography, CT, ultrasonography, arteriography, venography, and MRI each can provide unique information in an individual case. Because CT, MRI, and ultrasonography are outpatient procedures and are less invasive than arteriography, arteriography now is infrequently used. Multiple imaging modalities often are combined to provide the most complete information, particularly when surgical removal of a large tumor is being considered.

## STAGING AND PROGNOSIS

### Robson Classification

The staging system used in the past by most physicians in the United States is the Robson modification of the system of Flocks and Kadesky (Table 34.2-5).<sup>72</sup> In the Robson classification, stage I renal carcinoma is confined to the kidney. Stage II carcinoma extends through the renal capsule but is confined to Gerota's fascia, and stage III carcinoma involves the renal vein or inferior vena cava (IIIA) or the local hilar lymph nodes (IIIB). In stage IV renal carcinoma, the tumor has spread to local, adjacent organs (other than the adrenal gland) or to distant sites. The Robson staging system is uncomplicated and widely used. A disadvantage of this system is that it combines stages that may have significantly different survival prognoses. In this classification system, renal inferior vena caval involvement (IIIA) is staged the same as is local lymph node metastasis (IIIB). Although patients with stage IIIB renal carcinoma experience a greatly decreased survival,<sup>73,74</sup> the prognosis for patients with stage IIIA renal carcinoma is not markedly different from that for patients with stage I or stage II renal carcinoma. Patients who have disease that involves the inferior vena cava often have either locally advanced or micrometastatic disease. However, patients who are found to have no evidence of metastatic disease and who undergo complete surgical excision can expect to have a reasonable chance for 5-year survival.

Findings	TNM Classification (1997)	Robson Classification
Small tumor, no enlargement of kidney	T1	A (I)
Large tumor, cortex not broken	T2	A (I)
Perinephric or hilar extension	T3a	B (II)
Renal vein involved	T3b	C (III)
Vena cava involved	T3b,c	C (III)
Extension to neighboring organs	T4	D
Nodal invasion	N+	C (III)
Distant metastases	M+	D

TNM, tumor, node, metastasis.  
(From ref. 76, with permission.)

**TABLE 34.2-5.** Comparison of the Two Classification Systems for Staging of Renal Carcinoma

### Tumor, Node, Metastasis Classification

The TNM (tumor, node, metastasis) classification proves a more accurate method for classifying the extent of tumor involvement. In the TNM classification, *T1* denotes a tumor 7 cm or less confined to the kidney, *T2* denotes a tumor more than 7 cm in greatest dimension but that is still confined to the kidney, *T3* denotes tumor that extends into the major veins or invades the adrenal gland or perinephric tissues but not beyond Gerota's fascia, and *T4* denotes tumor that has extended beyond Gerota's fascia (Table 34.2-6).

PRIMARY TUMOR (T)	
TX	Minimum requirements cannot be met
T0	No evidence of primary tumor
T1	Tumor confined to kidney, <7.0 cm in greatest diameter
T2	Tumor confined to kidney, >7.0 cm in greatest diameter
T3a	Tumor involving perinephric tissues, inside Gerota's fascia
T3b	Tumor involving renal vein or vena cava below the diaphragm
T3c	Tumor involving vena cava and extending above the diaphragm
T4	Tumor invasion of neighboring structures (e.g., muscle, bone)

NODAL INVOLVEMENT (N)	
TX	Minimum requirements cannot be met
N0	No evidence of involvement of regional nodes
N1	Single, homolateral regional nodal involvement
N2	Metastasis in more than one regional lymph node

DISTANT METASTASIS (M)	
MX	Not assessed
M0	No (known) distant metastasis
M1	Distant metastasis

(From ref. 76, with permission.)

**TABLE 34.2-6.** TNM Classification of Kidney Cancer

N1 denotes metastasis in a single regional lymph node; N2 denotes metastasis in more than one regional lymph node. M1 indicates distant metastasis.<sup>75</sup> The 1997 TNM classification of renal carcinoma appears to provide improved stratification according to survival and may have enhanced clinical utility as compared with previous classification systems.<sup>76</sup>

## SURVIVAL

The 5-year survival initially reported by Robson et al.<sup>72</sup> in 1969 was 66% for stage I renal carcinoma, 64% for stage II, 42% for stage III, and only 11% for stage IV. Except for stage I carcinoma, these survival statistics remained essentially the same for a number of years (Table 34.2-7). However, it has since been noted that while renal vein involvement does not have a markedly negative effect on prognosis, the 5-year survival for patients with stage IIIB RCC is only 18%. Recent studies have reported better survival for patients with tumor confined to the kidney: approximately 95% 5- and 10-year disease-specific survival for T1 renal carcinoma and an 88% 5-year and an 81% 10-year disease-specific survival for stage T2 disease.<sup>76</sup> Patients with T3 renal carcinoma had a 59% 5-year survival, and those with T4 disease, a 20% 5-year disease-specific survival.<sup>76</sup>

Study	Survival (y)	Survival Rate by Stage (%)			
		I	II	III	IV
Robson et al. <sup>72</sup>	5	66	64	42	11
	10	66	67	38	0
Skinner et al. <sup>73</sup>	5	65	47	51	8
	10	56	20	37	7
Becker et al. <sup>74</sup>	5	36	100	60	8
	10	20	66	25	0
McNichols et al. <sup>75</sup>	5	67	51	34	14

	10	95	81	45	14

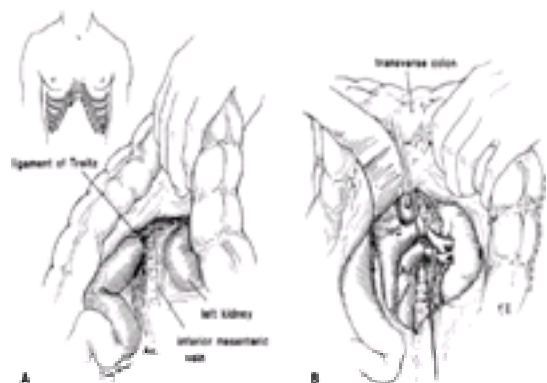

**TABLE 34.2-7.** Summary of Published Survival Rates in Renal Carcinoma Demonstrating Improvement in Survival Over Time

In patients with N0M0 tumors, studies have detected no statistically significant difference in survival in relationship to the T stage of the disease.<sup>77</sup> The 5-year survival for patients with metastatic renal carcinoma continues to be low, from 0% to 20%.<sup>77</sup>

With the expanded use of CT scans and ultrasonography, the rate of incidentally found carcinomas of the kidney has increased. The prognosis for patients whose tumor was diagnosed incidentally is more favorable than that for patients who present with symptoms, as the former group consists of patients with smaller tumors that usually tend to be confined to the kidney.<sup>78</sup> Patients with metastatic renal carcinoma who present with humoral hypercalcemia of malignancy have a poor prognosis. Fahn et al.<sup>79</sup> reported the median survival of patients with stage IV kidney cancer to be fewer than 50 days. Most studies show increased survival in patients in whom metastatic disease has been diagnosed and in whom the following conditions obtain: (1) a long disease-free interval between initial nephrectomy and the appearance of metastases, (2) presence of only pulmonary metastases, (3) good performance status, and (4) removal of the primary tumor.<sup>51</sup>

## SURGICAL TREATMENT

Surgery is the only known effective therapy for localized renal carcinoma. The first nephrectomy was performed by Eratus B. Walcott in Milwaukee on June 4, 1861, on a 58-year-old man with a kidney tumor who died 15 days after surgery.<sup>80</sup> Professor Gustave Simon, after completing a number of experimental nephrectomies on dogs, undertook the first deliberate, planned, and successful nephrectomy in Heidelberg on August 2, 1889, in a patient with a persistent ureteral fistula. The first successful nephrectomy in a patient with kidney cancer was performed in 1883 by Grawitz.<sup>80</sup> The standard procedure today for treatment of localized renal carcinoma is radical nephrectomy (Fig. 34.2-6). Radical nephrectomy involves complete removal of Gerota's fascia and its contents, including the kidney and the adrenal gland, and provides a better surgical margin than simple removal of the kidney.<sup>81</sup> Owing to the rarity of ipsilateral adrenal metastasis and the potential morbidity associated with adrenalectomy, many surgeons believe that a macroscopically normal ipsilateral adrenal gland should not be removed with the kidney (see Fig. 34.2-6).<sup>82,83</sup>

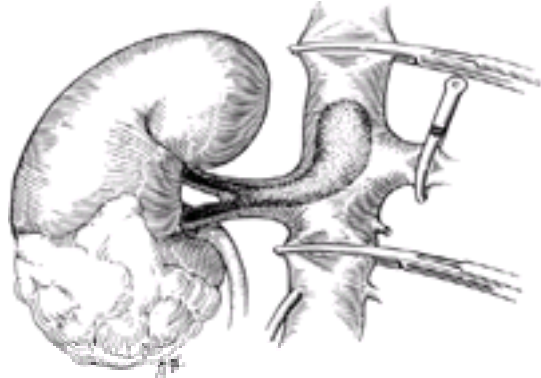

**FIGURE 34.2-6.** A: Area of lymph node dissection for radical nephroureterectomy should be from the superior mesenteric artery to the level of the inferior mesenteric artery, with the anatomic structures identified. B: The left colon can be reflected from the anterior surface of Gerota's fascia with exposure of the renal artery before ligation and division. The dotted line to the right of the descending colon indicates a line of incision on the left pericolic gutter that should extend superiorly to include division of the splenocolic attachments. Ao, aorta; IVC, inferior vena cava. (From ref. 262, with permission.)

A number of different surgical approaches have been described for removal of kidney cancer. Common approaches are the anterior transperitoneal approach, the flank approach, and the thoracoabdominal approach. The choice of surgical approach depends on the location and size of the tumor and the body habitus of the patient. The type of incision is chosen to ensure that the tumor may safely be removed. A flank incision, with or without removal of a portion of the tenth or eleventh rib, often is used for small tumors without venous involvement. A subcostal transabdominal incision may be used when a large tumor occupies the middle or lower

aspect of the kidney or when vascular involvement is anticipated and access to the major vessels is essential. A thoracoabdominal incision often is required when a large middle or upper pole tumor is present.

In a thoracoabdominal incision, a rib is removed, the thoracic cavity is opened, and the diaphragm is incised. The incision then is carried down transabdominally to allow maximal exposure of the upper abdominal region and the great vessels. In removal of a right-sided tumor, the hepatic flexure of the colon is mobilized toward the midline away from the kidney and duodenum. The duodenum is also dissected up anteriorly and medially to the great vessels, and the renal artery and vein are identified. The renal vessels are divided and ligated early in the surgical procedure to decrease the vascularity of the tumor so that it may be removed with a minimum of blood loss. Following ligation of the vessels, Gerota's fascia is incised away from the posterior abdominal wall, diaphragm, and liver (pancreas and spleen on a left-sided tumor) (see Fig. 34.2-6). Once Gerota's fascia and its contents have been dissected away from the surrounding structures and the vasculature has been ligated with nonabsorbable suture, the specimen can be lifted out of the retroperitoneum. When there is tumor in the renal vein, the renal vein can be ligated distal to the tumor thrombus. If there is tumor extension into the vena cava, the vena cava may need to be partially resected. If the tumor has grown into the sidewall of the vena cava or if the vena caval involvement is too extensive for a simple partial wall resection, a portion of the vena cava itself may be resected. When the tumor is in the right kidney, the adjacent vena cava can often be resected safely. If, however, the tumor in the left kidney and the adjacent vena cava are resected, vascular reconstruction of the right renal vein may be needed to establish adequate venous drainage. If the suprahepatic caval extension of a renal tumor thrombus extends up to the right atrium, cardiopulmonary bypass may be required for tumor removal ( Fig. 34.2-7).

**FIGURE 34.2-7.** Surgical removal of a kidney tumor in which there is tumor extension through the renal vein into the inferior vena cava.

Laparoscopic nephrectomy has been evaluated as a less invasive procedure for the removal of kidneys with a small volume of RCC. <sup>84,85</sup> Walther et al. <sup>86</sup> have also evaluated the use of laparoscopic cytoreductive nephrectomy in patients with advanced RCC as preparation for interleukin-2 (IL-2) treatment.

Regional lymphadenectomy often is performed at the time of radical nephrectomy, although its role in prolonging survival has not been demonstrated. In a regional lymphadenectomy, ipsilateral nodal tissue from the diaphragm to the bifurcation of the aorta as well as nodal tissue in the interaortocaval region at the hilum of the kidney is removed. Proponents of regional lymphadenectomy point out that 5-year survival in patients with node-positive renal carcinoma is greatly decreased, and there is no known effective therapy for metastatic renal carcinoma. If local nodes were the first site of metastasis, resection of microscopic disease might be of benefit. Long-term survival in patients with node-positive disease who underwent lymphadenectomy has been reported. <sup>87</sup> The ultimate role of regional lymphadenectomy remains to be determined in further randomized trials. In patients with locally advanced RCC (node-positive), no evidence to date supports the theory that adjuvant, postsurgical treatment of patients with an agent such as IL-2 or interferon- $\alpha$  (IFN- $\alpha$ ) increases survival. In patients in whom all visible disease has been resected surgically, most physicians recommend treatment when residual or recurrent disease becomes detectable.

#### **Bilateral Renal Carcinoma or Tumors in Solitary Kidneys**

The treatment of patients with either bilateral renal carcinoma or renal carcinoma in a solitary kidney is challenging. Patients with tumor in a solitary kidney may be treated by either partial nephrectomy or nephrectomy followed by dialysis or transplantation (or both). In selected patients, nephron-sparing surgery may be recommended for patients with sporadic renal cell cancer, particularly those with a small tumor ( $\leq 4$  cm) or a tumor in a solitary kidney. <sup>88,89</sup> Extracorporeal partial nephrectomy plus autotransplantation is an infrequently used technique that allows the surgeon accurately to remove large tumors from the center of a solitary kidney. This *ex vivo* procedure entails radical excision of the kidney and division of the ureter. The kidney then is placed on a table and is intermittently perfused with a chilled solution to enhance viability. Under optical magnification, the tumor is carefully dissected from the surrounding renal parenchyma. Care is taken to preserve the vasculature of the normal kidney, which has been defined by preoperative arteriography. A small rim of normal tissue is removed along with the tumor to provide a tumor-free margin of resection. After the kidney has been surgically reconstructed, it is autotransplanted back into the iliac space. Vascular anastomosis of the renal artery and vein to the iliac vessels and ureteroureterostomy are performed.

#### **Surgical Management of Patients with Hereditary Forms of Renal Carcinoma**

Patients with hereditary forms of renal carcinoma are often challenging to manage. Individuals with VHL syndrome or HPRC can have widespread renal involvement. <sup>29,90,91</sup> Surgical management in these patients involves careful parenchyma-sparing surgery, which is recommended when the renal tumors reach a certain size threshold, generally 3 cm. The use of parenchyma-sparing surgery in these patients is based on a strategy designed to maintain the patient's renal function as long as possible while decreasing the risk for metastasis. <sup>92</sup>

#### **Radiotherapy as an Adjuvant to Nephrectomy**

The value of adjuvant external-beam radiotherapy for patients with RCC remains unclear. Previous reports have demonstrated increased complication rates using conventional radiotherapeutic techniques. <sup>93,94,95,96,97</sup> and <sup>98</sup> In addition, several randomized studies performed 20 to 30 years ago showed no apparent survival benefit with adjuvant therapy. <sup>93,94</sup> These considerations led to an overall lack of enthusiasm for using radiotherapy in this disease. However, recent studies have suggested that the use of more sophisticated radiation techniques is less likely to result in treatment-related complications. <sup>99,100</sup> In addition, previous trials testing preoperative or postoperative radiotherapy for this disease may not have been designed in an optimal fashion to evaluate its potential benefit fully for improving outcome in high-risk patients.

Though some retrospective reports have indicated an improvement in local tumor control or overall survival with the addition of postoperative radiotherapy, <sup>95,101,102</sup> subsequent randomized prospective trials could not confirm any benefit. In one randomized study reported by Finney et al., <sup>95</sup> the incidence of local recurrence was 7% in both the adjuvant radiotherapy and control arms. In addition, no survival advantage was detected in the radiotherapy arm. In fact, a trend for an inferior 5-year survival outcome was observed for the adjuvant radiotherapy group (36% as compared to 47% for patients with nephrectomy), owing to a higher complication rate observed in these patients. Ten years later, a second randomized prospective trial comparing nephrectomy and postoperative radiotherapy to nephrectomy alone demonstrated identical results. <sup>94</sup> In that study, the incidence of local recurrence was reduced from 25% to 3% with adjuvant local radiotherapy. Further, the incidence of treatment-related morbidity in these two randomized trials was unacceptably high. Severe complications were experienced in 20% to 44% of treated patients, with an associated increased mortality rate due to radiation-related toxicities. The potential value of preoperative radiotherapy has also been tested in two randomized trials, <sup>97,98</sup> neither of which could demonstrate any advantage for improved local control or survival with adjuvant radiotherapy.

However, it is difficult to draw any meaningful conclusions about the safety and value of adjuvant therapy for patients with RCC who are at increased risk for local recurrence. Previously published postoperative studies used relatively crude radiation techniques, and the radiation dose per fraction of 250 cGy to cumulative doses of 5000 to 5500 cGy used in some reports likely directly contributed to the high gastrointestinal and liver-related toxicities observed. In addition, a significant percentage of patients treated in these trials did not have prognostic features indicating a high risk for local recurrence for which adjuvant radiotherapy may have been potentially beneficial. Based on patterns-of-failure studies after nephrectomy alone, <sup>103,104</sup> the overall local recurrence rate is low, and routine administration of adjuvant local therapy for all patients on the basis of advanced stage only would not be expected to improve outcome. Rabinovitch et al. <sup>103</sup> reported on 172 patients treated with nephrectomy alone to identify patterns of failure and risk factors for local recurrence. In that report, the 7-year actuarial local failure rate was 5%.

However, among patients with positive surgical margins or positive lymph nodes, the incidence of local recurrence was 21%. Advanced T-stage disease in the absence of these prognostic features did not predict for local recurrence and thus is not necessarily an indication for local adjuvant therapy.

More recent reports have demonstrated that with the application of more sophisticated radiotherapeutic planning techniques, the incidence of treatment-related complications has been minimal. Using CT-based treatment planning, Kao et al.<sup>95</sup> at the University of Pennsylvania retrospectively reported the outcome of postoperative radiotherapy for selected patients with positive surgical margins or perinephric disease extension. Doses ranged from 4140 cGy to 6300 cGy using conventional fractionation. The overall local failure and survival rates were 100% and 75%, respectively, as compared to 30% and 62%, respectively, for similar patients at the University of Pennsylvania who underwent nephrectomy alone. Despite the higher radiation doses used, no late complications were observed.

An additional limitation of prior studies is the relatively low postoperative doses used secondary to concerns of late radiation sequelae. Several reports have suggested that higher doses may be necessary in this disease to overcome the relative radioresistance of the renal cell histology.<sup>105,106</sup> With the introduction of three-dimensional conformal radiotherapy and intensity-modulated treatment delivery systems, it now is possible to deliver higher radiation doses in the adjuvant setting with less potential toxicity. The use of intraoperative radiation for high-risk patients may prove to be an effective approach for the delivery of high radiation doses, with the ability to easily shield the adjacent normal gastrointestinal structures. Eble et al.<sup>107</sup> and Frydenberg<sup>108</sup> reported the results of a phase I study in 11 patients with advanced-stage or locally recurrent RCC that incorporated intraoperative radiotherapy (15 to 20 Gy) in combination with fractionated external-beam radiotherapy. The 4-year survival outcome was 75%, and no local relapses or complications were noted. In a limited number of patients with recurrent RCC, other investigators have reported the feasibility of postoperative, hyperfractionated, high-dose-rate brachytherapy using iridium 192 as a means of effectively delivering a high radiation dose to the postoperative bed.<sup>109</sup>

The aforementioned studies would suggest that adjuvant radiotherapy may be of benefit for selected patients with high-risk features predicting for local recurrence after nephrectomy. Using modern external-beam and brachytherapy techniques, higher radiation doses can now be delivered more safely and may further improve the efficacy of radiotherapy for selected patients. Nevertheless, randomized trials limited to high-risk patients will be required to assess fully the local control benefit of postoperative radiotherapy in this clinical setting.

### **Metastatic Renal Carcinoma**

#### **NEPHRECTOMY AND RESECTION OF METASTASES**

*Cytoreductive Nephrectomy.* Adjuvant or palliative nephrectomy is not infrequently performed in patients with metastatic RCC particularly those with pain, hemorrhage, malaise, hypercalcemia, erythrocytosis, or hypertension. Removal of the primary tumor may alleviate some or all of these abnormalities.<sup>110</sup> Although there are isolated reports of regression of metastatic renal carcinoma after removal of the primary tumor, only 4 (0.8%) of 474 patients in nine series who underwent nephrectomy experienced "regression" of metastatic foci.<sup>111</sup> deKernion et al.<sup>112</sup> reported results in 26 patients with metastatic renal carcinoma who underwent palliative or adjuvant nephrectomy and found no increase in survival, as compared with survival in the entire group of 79 patients with metastatic renal carcinoma. Adjuvant nephrectomy is not recommended for the purpose of inducing spontaneous regression; rather, it is performed to decrease symptoms or to decrease tumor burden in preparation for subsequent therapy in carefully controlled environments.<sup>113</sup> The recent use of laparoscopic nephrectomy<sup>86</sup> provides a potentially less invasive method for cytoreduction as preparation for administration of systemic therapies such as IL-2.

*Resection of Metastases.* Of the approximately 30% of patients with RCC who present with metastases, fewer than 4% have solitary metastases.<sup>114</sup> Patients with a solitary metastasis synchronous with a primary lesion experience decreased survival when compared with patients who develop metastasis after the primary tumor is removed.<sup>115</sup> Surgical resection is recommended in selected patients with metastatic renal carcinoma. In a study of 59 patients with renal carcinoma who underwent surgical resection for a solitary metastasis, 45% had a 3-year survival, and 34% survived 5 years.<sup>114</sup> O'Dea et al.<sup>115</sup> reported on patients who presented with primary tumor in place and a solitary metastasis. Of the patients who underwent nephrectomy and who later developed metastasis, 23% lived more than 5 years after removal of the metastatic lesions. Three of the 26 patients were alive 58, 94, and 245 months after resection of the metastatic lesions.<sup>115</sup> Nephrectomy and resection of metastases will render few cures but frequently will produce some long-term survivors.

**ROLE OF RADIOTHERAPY.** Palliative radiotherapy for patients with symptomatic metastatic osseous lesions can be effective. Previous reports have noted response rates of 50% to 70% after local palliative radiotherapy for patients with metastatic RCC.<sup>105,116</sup> In a randomized trial assessing various fractionation schemes for the palliation of symptomatic bone metastases, renal cell histology was found to respond less favorably to standard palliative radiation regimens as compared to metastatic breast and prostate cancers.<sup>117</sup> In light of the relative radioresistance of this histology, higher radiation doses are critical to achieve adequate palliation. In general, doses of at least 50 Gy are required to achieve durable palliation. To deliver these higher doses safely, complex treatment planning often is necessary to minimize treatment-related toxicity. Investigators from the Jefferson College of Medicine have shown that higher radiation doses were associated with an improved palliative response.<sup>106</sup> In a multivariate analysis, a higher baseline performance status and the use of higher radiation doses predicted for a greater likelihood for significant pain relief after radiotherapy for painful osseous lesions. Large-volume metastatic lesions such as those found within the renal bed require higher radiation doses to achieve palliation and, in general, this therapy is successful in fewer than 50% of treated patients.

Brain metastases from RCC are often hemorrhagic in nature, and the rapid initiation of palliative radiotherapy may be necessary to halt potential neurologic progression. Surgery should be considered for solitary lesions of the brain or spine, followed by postoperative radiotherapy. The results of routine administration of short-course whole brain radiotherapy using the conventional fractionation program of 3000 cGy in ten fractions has been disappointing.<sup>118,119</sup> Investigators from the M. D. Anderson Cancer Center have reported that, in the majority of treated patients with short-course whole brain radiotherapy, the cause of death was neurologic deterioration.<sup>119</sup> For selected patients with good performance status or solitary lesions, radiosurgery alone or in combination with whole brain radiotherapy provides an opportunity to deliver higher doses and should be considered.<sup>120,121</sup> Pomer et al.<sup>120</sup> have shown that for patients with metastatic RCC, radiosurgery was more effective among those with a Karnofsky performance score in excess of 70 and among those with a greater than 1-year interval from diagnosis to manifestation of central nervous system metastases.

Osseous lesions in weight-bearing areas such as the femora should be considered for initial orthopedic stabilization, followed by postoperative radiotherapy. Treatment with radiotherapy alone should be exercised with some caution owing to the potential for posttreatment fracture.

#### **SYSTEMIC CHEMOTHERAPY FOR RENAL CELL CARCINOMA**

Limited options are available for the systemic therapy of RCC, and no hormonal or chemotherapeutic regimen is accepted as a standard of care. Reviews surveying phase II clinical trials for RCC have appeared at intervals (1967, 1973, 1983, 1995, and 2000),<sup>263,264,265,266,267</sup> and <sup>268</sup> without a change in the final conclusion: No systemic chemotherapeutic or hormonal approach has provided a reasonable level of activity.

A comprehensive review by Yagoda et al.<sup>267</sup> encompassed 4542 patients enrolled in 83 clinical trials published from 1983 through 1993. Among 4093 evaluable patients, a 6.0% response rate was recorded, with 53 complete responses (CRs; 1.3%) and 192 partial responses (PRs; 4.7%). Response rates in excess of 25% were noted in eleven trials; in each case another trial incorporating the same or a comparable treatment regimen reported lower or zero response rates.

Three agents warrant particular mention: floxuridine, 5-fluorouracil (5-FU), and vinblastine. One of the most intensively studied agents has been infusional floxuridine, which, studied in both standard and circadian schedules, appears to have a level of activity above the background. Fourteen trials yielded response rates ranging from 0% to 43%, with an average rate of 12%. Seven trials had response rates of less than 10%, and four had response rates exceeding 20%. For 5-FU, which has been primarily used in combination with immunotherapy, responses were somewhat fewer, with an overall response rate of 10% for infusional 5-FU alone and 19% for 5-FU in combination with interferon. Similar results were reported for vinblastine, an agent initially thought to have activity in RCC. In the Yagoda series,<sup>267</sup> seven trials incorporating infusional vinblastine yielded an overall response rate of 7%, whereas three trials reported no responses. Since 1993, further results with vinblastine have been equally discouraging. As the control arm for a multidrug resistance modulator trial, vinblastine produced one PR in 80 patients; as the control arm for an interferon trial, vinblastine produced one complete and one PR among 81 patients.<sup>269,270</sup>

The 83 trials reported in the review by Yagoda<sup>267</sup> included compounds from every class of anticancer agent: antimitotics (paclitaxel and docetaxel); vinca alkaloids (vinblastine, vindesine, and vinorelbine); anthracyclines (epirubicin, doxorubicin, and idarubicin); anthracenediones (mitoxantrone, bisantrene); alkylating agents (both nitrosoureas and sulfonyleureas, as well as ifosfamide and melphalan); metals (carboplatinum and gallium nitrate); pyrimidines (floxuridine, 5-FU, and gemcitabine);

and purines (6-thioguanine, fludarabine, and 2-deoxycoformycin). Yagoda et al.<sup>267</sup> concluded that the responses may be mediated by an indirect effect on the immune system. Considering that the response rates in these trials are higher than the frequency of spontaneous remissions, and observing the occasional complete remission, one could speculate that the responses involve an effect triggered by the chemotherapy but mediated by the immune system. However, scientific evidence to support this thesis is lacking. Although the majority of patients experiencing a complete remission were noted in trials including cimetidine, vinblastine, 5-FU, and floxuridine, the CR rate ranges between 2% and 4%, which is not very different from the 1.3% CR rate noted in the entire series. These considerations favor a conclusion that little, if any, cytotoxic activity has been exerted in renal cell cancer. It can be concluded that the best recommendation for patients with this disease, after immunotherapy, is participation in clinical trials studying new agents or new approaches.<sup>271,268</sup>

### Hormonal Therapy in Renal Cell Cancer

Hormonal agents have also been used in systemic therapy. This strategy had its origins in studies showing that progesterone could inhibit the development of estrogen-induced renal cell cancers in Syrian hamsters<sup>272</sup> and in the observation that both estrogen and progesterone receptors could be found in a portion of human kidney cancers.<sup>273</sup> Subsequently, medroxyprogesterone acetate (Megace) became conventional treatment for renal cell cancer. However, multiple studies have concluded that hormonal therapy is of no definite benefit. A series of studies collected from 1967 through 1976, using progestins or androgens included 644 patients.<sup>265</sup> Response rates were highest (17%) in the earliest studies. With more stringent response criteria used in the studies conducted after 1971, an overall rate of 2% was observed. Except for its value in appetite stimulation, the use of Megace cannot be recommended in the treatment of renal cell cancer today.

Studies with antiestrogens in more recent years have yielded similar results. An overall response rate of 7% (three patients with CR) was identified in four studies treating 146 patients with high-dose tamoxifen (100 mg/m<sup>2</sup>/d or more).<sup>121a</sup> More recently, two CRs (3%) were reported in 63 patients receiving 40 mg of oral tamoxifen daily in the control arm of a randomized study.<sup>275</sup> Similar activity was suggested also in a pilot study of high-dose toremifene (300 mg/d), a novel antiestrogen with activity in breast cancer.<sup>276</sup> Thus, reported responses to treatment with hormonal therapy most likely mimic the same level of inactivity identified with most chemotherapeutic agents.

### Recent Chemotherapy Trials in Renal Cell Cancer

More recently, an effort has been made to identify new treatment targets in cancer. A limited search for phase II single agents examined in renal cell cancer and reported since 1993 (and thus not included in earlier reviews) identified 23 published studies. These compounds, shown in [Table 34.2-8](#), are from various pharmaceutical classes, including taxanes, camptothecins, anthracyclines, antifolates, and alkylating agents. In recent abstracts from the American Society of Clinical Oncology, an additional nine new agents were tested. Once again, the refractory nature of renal cell cancer is observed. One new study—the combination of gemcitabine and 5-FU—warrants mention. In a study reported by Vogelzang at the University of Chicago, 7 PRs (17%) were observed among 39 patients receiving gemcitabine at 600 mg/m<sup>2</sup> on days 1, 8, and 15 and continuous-infusion 5-FU at 150 mg/m<sup>2</sup>/d for 21 days in 28-day cycles.

**TABLE 34.2-8.** Phase II Studies in Renal Cell Cancer: 1993–1999

To some extent, the refractory nature of renal cell cancer highlights a general problem with anticancer agents developed over the last three decades. A review of cytotoxic drugs introduced into clinical trial by the National Cancer Institute between 1970 and 1985 found that half of the 47 new agents adequately studied in phase II trials could be rated as having anticancer activity.<sup>277</sup> Among these active compounds, 74% were active in lymphoma, 35% in leukemia, 22% in breast cancer, and 18% in ovarian cancer. Only one drug was active in colon cancer; no activity was reported with any of the 25 drugs properly tested in renal cell cancer. These data suggested that the prevailing screening strategies for anticancer agents were biased toward agents active in leukemia and lymphoma and were not likely to identify agents active in solid tumors.<sup>278</sup> Thus, the drug screen was reorganized and a 60–cell line *in vitro* screen was established in 1990 with cell lines derived from solid tumors including RCC.<sup>279</sup> It is hoped that this effort, along with compounds under development for defined intracellular and extracellular targets, will identify agents with activity in those tumors that are most difficult to treat. The antiangiogenesis agents currently being developed are examples of compounds with a novel approach to this difficult problem.

### Chemotherapy Combined with Interferon in Renal Cell Cancer

Interferon, one of two immunotherapeutic agents widely used in the treatment of renal cell cancer (as discussed later, in [Biologic Therapy](#)), has a modest response rate and confers a survival advantage as a single agent.<sup>122,122a,123</sup> Numerous trials have been conducted combining interferon with cytotoxic chemotherapy in the hope that the immunologic benefit from interferon would improve the response to chemotherapy. Wirth<sup>280</sup> identified response rates ranging from 0% to 45% among 315 patients in 11 trials combining vinblastine with IFN- $\alpha$ . The response rates were highest in the oldest trials, where less stringent response criteria were used. Randomized studies have failed to provide any evidence for combining interferon with vinblastine ([Table 34.2-9](#)).

Study	No. of Patients	% Response	Median Survival (mo)	Median Survival (mo) for Combination
Krupnik et al. <sup>281</sup>	4	25	—	18
Mohr et al. <sup>282</sup>	35	4	—	18
Pyhonen et al. <sup>283</sup>	70	15	12	17
Finn et al. <sup>284</sup>	44	18	11	—
Wirth et al. <sup>285</sup>	33	15	11	—
Wirth et al. <sup>286</sup>	42	12	—	—
Saper et al. <sup>287</sup>	70	12	11	1
Mason et al. <sup>288</sup>	47	15	11	1
Mason et al. <sup>289</sup>	19	11	—	11
Mason et al. <sup>290</sup>	16	6	—	11

**TABLE 34.2-9.** Randomized Phase III Trials with Interferon and Chemotherapy

Interferon has also been combined with floxuridine or 5-FU in multiple studies, with several reporting higher response rates than usually reported with either agent alone.<sup>281</sup> However, more recent, nonrandomized, multiinstitutional studies have been disappointing, suggesting little or no benefit from combining interferon with floxuridine given over 14 days<sup>282</sup> or with 5-FU.<sup>283,284</sup>

A similar evolution occurred with the combination of interferon and *cis*-retinoic acid; Motzer et al.<sup>285</sup> originally observed a 30% response rate for the combination.

However, when this trial was taken forward to a combination with IL-2, only 8 of 47 patients (17%) responded.<sup>286</sup> Preliminary results of a randomized trial comparing IFN- $\alpha$  plus *cis*-retinoic acid with IFN- $\alpha$  alone suggest no significant difference between the two arms.<sup>287</sup>

One potential confounding factor in all these trials may be the inclusion of patients with varying prognoses. In future studies, evaluation of data taking into account clinical prognostic factors may help to eliminate the variation in results long observed in renal carcinoma trials.<sup>288</sup> To date, there is no convincing evidence that chemotherapy adds to the effectiveness of single-agent IFN- $\alpha$ .<sup>122</sup> The combination of interferon with a cytotoxic agent in patients whose disease progressed after treatment with IL-2 must be considered unproven, and enrollment in clinical trials is the most logical alternative.

### Drug Resistance in Renal Cell Cancer

The ineffectiveness of chemotherapy can be ascribed to the primary, or intrinsic, resistance to chemotherapy, which, although poorly understood, is a hallmark of RCC. Overexpression of the 170-kD drug transporter P glycoprotein (P-gp) and its encoding gene, *MDR-1*, has been most frequently cited as a mechanism of resistance. Expression of P-gp in RCC is related to its normal tissue expression in the cell of origin, the renal proximal tubule; and the level of expression correlates with differentiation.<sup>289,290</sup> and <sup>291</sup> Fojo et al.<sup>292</sup> reported high levels of expression of this transporter in kidney cancer and *in vitro* sensitization of kidney cancer cell lines to vinblastine with the antagonists verapamil and quinidine. Chemosensitivity studies with fresh tumor specimens demonstrated high levels of resistance in 30 of 35 samples, and overexpression of P-gp in 70% of cases.<sup>293</sup> Together, these findings suggest that P-gp expression could explain, at least in part, the notorious resistance of RCC.

However, efforts to modulate P-gp by treating patients with antagonists have met with disappointing results to date. Except for a single phase I study with doxorubicin,<sup>294</sup> most of the trials have attempted modulation of vinblastine (Table 34.2-10). Though the studies, at face value, suggest no role for P-gp in RCC, it can be argued that this question is not fully resolved.<sup>295</sup> Most of the reversal agents used in the trials were first-generation agents with low potency, selected because they were already in clinical use for other indications. Most of the trials incorporated vinblastine. Although vinblastine is a substrate for P-gp, renal cell cancers may have other mechanisms of resistance to vinblastine that were not addressed by these studies. P-gp may represent an avenue to increase intracellular concentrations of an agent, but that agent must have intrinsic activity for successful resistance reversal.

Study	IP	Reversal	Treatment Schedule	CR/CR <sup>1</sup> PR/PR <sup>1</sup>
Shawmon et al. <sup>294</sup>	14	Verapamil 20 mg PO qd d1-5	1 mg/m <sup>2</sup> IV d1 qd	0/0
Wang et al. <sup>295</sup>	15	Quinidine 15 mg PO qd d1-4	1.2 mg/kg IV d1 qd	0/0
Wang et al. <sup>295</sup>	15	Dexamethasone <sup>2</sup> 10 mg PO qd d1-4	1.2 mg/kg IV d1 qd	0/0
Wang et al. <sup>295</sup>	15	Cyclosporin A 1 mg/kg PO x 1, 10-17 mg/kg PO qd d1-4	1.2 mg/kg IV d1 qd	0/0
Agarwal et al. <sup>296</sup>	17	Quinidine 200-400 mg PO qd	1 mg/m <sup>2</sup> IV d1	1/0
Sawyer et al. <sup>297</sup>	18	Cyclosporin A (CS) 100 mg PO qd d1-4	1.2 mg/m <sup>2</sup> IV d1 qd	0/0
Regnier B	18	Quinidine 400 mg PO x 1, 100 mg PO x 10 d1-11	1.2 mg/m <sup>2</sup> IV d1 qd	1/0

CR, complete remission; CR<sup>1</sup>, complete response; PR, partial response.  
 Number assessable for response.  
 Dexamethasone (CS) dose before day 1.  
 Twelve patients received a dose of 200 mg x seven of quinidine.  
<sup>1</sup>May indicate a variable for resistance to combination with vinorelbine, where only 1 fully infused vinorelbine in combination with cyclosporin A.

TABLE 34.2-10. Trials Testing the Reversal of P-glycoprotein–Mediated Resistance

ABC TRANSPORTERS. The broad nature of clinical resistance in renal cell cancer suggests that P-gp may be one of multiple resistance mechanisms. Recent studies have identified the existence of an increasing number of ATP-binding cassette (ABC) transporters, of which P-gp is the prototype.<sup>296</sup> These include the family of multidrug resistance–associated proteins (MRP1 through MRP6), which have organic anion transport activity<sup>297,298,299,300,301</sup> and <sup>302</sup> and a half-ABC transporter designated *MXR/BCRP/ABCP1*,<sup>303,304</sup> and <sup>305</sup> which confers mitoxantrone and camptothecin resistance, bringing to three the number of transporter families expressed in renal cell cancer and potentially linked to drug resistance. If these transporters are confirmed as being active in renal cell cancer, their inhibition offers a future strategy for increasing drug accumulation in kidney cancer cells.

INTRACELLULAR MECHANISMS. While drug transporters would directly affect intracellular concentrations of drug, other mechanisms of drug resistance have been identified that confer resistance at the levels of cell survival pathways, drug metabolism, and the drug target. Many of these have been examined in renal cell cancer, but the findings are preliminary and must be validated. Cell survival in RCC may be linked to the frequently observed overexpression of the epidermal growth factor receptor and its homologue, ErbB2.<sup>306,307,308,309</sup> and <sup>310</sup> or to overexpression of the antiapoptosis protein, Bcl-2.<sup>124,311</sup> Alternatively, increased metabolism of anticancer agents may be promoted by higher levels of enzymes of the cytochrome P-450 family in concert with glutathione and glutathione transferases.<sup>312,313</sup> Finally, decreased levels of topoisomerase II have been observed in RCC, which could confer resistance to agents that impair cell division through inhibition of topoisomerase II.<sup>314,315</sup> Thus, ample evidence for intracellular mechanisms of resistance exists in RCC. The challenge is to determine the importance of such mechanisms and to identify strategies for their circumvention.

DRUG DELIVERY. To some, the generalized resistance just described supports an argument that drug resistance in RCC is not based primarily on cellular mechanisms. Although investigators have worked principally in other model systems, studies evaluating tumor drug delivery may cast light on the problem of drug resistance in kidney cancer. Factors that influence drug delivery include blood flow, permeability of tumor vasculature, and drug diffusion into the interstitium, which is affected both by properties of the drug and by interstitial pressure within the tumor.<sup>316,317,318</sup> and <sup>319</sup> Strategies aimed at identifying and reducing these physiologic barriers to drug delivery are under investigation and could have a particular relevance to the very large tumor masses seen in renal cell cancer.

### Prognostic Factors

Clinical prognostic factors relating to survival after nephrectomy have been well defined. Molecular prognostic factors that may reflect chemosensitivity have been examined but, without reliable and effective therapy for RCC, their value cannot be determined. It could be predicted from experience in other cancers that correlations obtained for good and poor prognosis would generally relate to the inherent biology of the tumor cell in the absence of effective therapy. Thus, markers of differentiation and indolent biology will confer a better prognosis at the present time because of the limitations of current therapy. A frequently identified poor prognostic factor is expression of PCNA [proliferating cell nuclear antigen] or MIB-1/Ki-67, antigens associated with cell proliferation. Disease-free and prolonged survival is more likely in tumors with a low proliferation index.<sup>320,321,322,323</sup> and <sup>324</sup> Patients with diploid tumors are more likely to have longer disease-free intervals.<sup>125</sup> Interestingly, response to interferon treatment is also more likely to occur in patients whose tumors manifest a more indolent biology.<sup>322</sup> That finding is in contrast to laboratory observations with chemotherapy in which a slower growth rate is associated with increased drug resistance. When effective treatment for renal cell cancer is identified, tumor markers relevant to response to treatment can then be identified.

Although patients who have stage IV disease experience a reported median survival of 12 to 24 months, the range of survival times in this group of patients is very broad. A variety of studies have looked at the parameters that predict survival in patients with metastatic renal cancer, and performance status is the most commonly identified predictive parameter. Other factors that have been identified in some studies as predictors of poorer survival of patients with stage IV disease are a short interval from initial diagnosis, multiple organ involvement, recent weight loss, previous chemotherapy, anemia, and an elevated serum lactate dehydrogenase level.<sup>288,325</sup> Such factors should be considered in evaluating survival in nonrandomized studies.

### Summary

In conclusion, RCC is a remarkably refractory solid tumor. More resistant than most other cancers, new phase II agents have failed time and again. The explanation for this drug resistance may lie within the tumor as an entity or within the individual cells. The broad spectrum of drugs to which RCCs are resistant suggests tumor-based mechanisms, while resistance in even the tiniest pulmonary nodule suggests cellular mechanisms. A detailed understanding of drug resistance in renal cell cancer is a major challenge for the new millennium. It is most likely that new agents directed against novel targets will be subject to the same mechanisms of

resistance that have plagued treatment of this disease for decades.

## BIOLOGIC THERAPY

The primary therapies for widespread metastatic RCC involve the use of biologic agents. IFN- $\alpha$  and IL-2 are the predominant agents used, yet several major questions remain about their application. The optimal dose and schedule have not been determined for either agent, the relative efficacy of combination therapy versus single-agent therapy is not known, and the factors that predict or produce dramatic, durable responses in a minority of patients have not been elucidated. There has even been debate as to whether these agents truly have benefit for patients with metastatic renal cell cancer or whether long-term survival results from chance or spontaneous tumor regression. The experience from two decades of biologic therapy for renal cancer has clarified this latter issue, made biologic agent administration safer, and defined the role of a number of cellular agents used in renal cancer therapy. The principle that immunotherapy can cause the complete and durable regression of large burdens of metastatic renal cancer and melanoma in some patients has been conclusively established. The most significant goal not yet accomplished is to increase significantly the percentage of patients who achieve these regressions. This objective will require improvements in our understanding of current agents as well as the development of new modalities that target different biologic mechanisms.

### Spontaneous Tumor Regression

Although it does not represent a bona fide treatment modality, much has been made of the phenomenon of spontaneous tumor regression in patients with advanced renal cancer, and the mechanism is presumed to be immunologic. The practice of nephrectomy in patients with metastatic disease in the hope of inducing a spontaneous regression has been largely abandoned owing to the disappointingly low incidence of success of this method.<sup>126</sup> In reviews of spontaneous tumor regression, another striking feature is that the majority of regressions are short-lived. In one randomized study of IFN- $\alpha$  in patients with RCC, the placebo control population demonstrated a singularly high response rate of 6%, but the duration of these regressions were 2 to 13 months with only one ongoing response of 9 months at the time of publication.<sup>127</sup> Other larger reviews show that the true incidence of this phenomenon is probably less than 1% and that the vast majority of documented spontaneous regressions will relapse with progressive metastatic disease and require other therapy.<sup>128,129</sup> In addition, the few well-documented cases of durable regressions often occurred in patients in whom life-threatening infectious or inflammatory events were possible instigators of their regression.<sup>130</sup> These data indicate that spontaneous regression of RCC often is transient and is not a phenomenon that should be relied on as therapy. Furthermore, spontaneous regression clearly cannot account for the consistent fraction of patients who achieve complete and durable regressions with some immunotherapies.

### Interferons

Early studies of leukocyte interferon in the treatment of cancer reported sporadic responses in patients with RCC.<sup>131</sup> Subsequently, increased dosages and larger studies were possible using recombinant IFN- $\alpha$ , and this experience was repeated and confirmed. The response rates in the largest studies ranged from 0% to 29% (Table 34.2-11), with few CRs and few long-term survival data.<sup>132,133</sup> In a review of the literature in 1989, Quesada<sup>134</sup> reported an overall response rate of 16% for 654 patients. Factors that seemed to increase the likelihood of responding included good performance status, prior nephrectomy, and metastases confined to the lungs. Nevertheless, these factors could not be used to identify patients without a significant possibility of response, and so they should serve only as general guidelines. Few data exist on the long-term results from interferon therapy but, from the very small number of completely responding patients, it is safe to conclude that interferon has no significant curative potential in RCC.

Study	IFN	Route and Schedule	N	RR (%)	CR (%)

IFN, interferon; MU, million units; RR, response rate.  
 CR, complete response; all responses were partial or complete.

TABLE 34.2-11. Treatment of Metastatic Renal Cell Cancer with Interferon

Recently, randomized prospective studies have been performed to measure the benefit of IFN- $\alpha$  in patients with advanced renal cancer. A randomized comparison of IFN- $\alpha$  versus medroxyprogesterone acetate in 335 patients demonstrated a significant prolongation of median survival (6 months for medroxyprogesterone acetate and 8.5 months for IFN- $\alpha$ ).<sup>135</sup> This modest, albeit statistically significant, prolongation of survival was offset by greater symptoms and lesser quality of life in patients receiving IFN- $\alpha$ . In addition, responses did not appear durable, with estimated progression-free survival at 2 years of 5% or less for both groups.

Many different types and preparations of interferons have been used in clinical trials. Early trials with “natural” interferon produced from donor leukocytes and subsequent trials with several different subtypes of recombinant IFN- $\alpha$  have not suggested a difference in efficacy among these preparations. Recent trials using IFN- $\beta$  and IFN- $\gamma$  have indicated that these agents have either similar or less activity than IFN- $\alpha$ .<sup>136</sup> A randomized comparison of IFN- $\alpha$  and placebo showed no difference in response rates or survival.<sup>127</sup>

Interferon is one of the few biologic agents that has been tested in a randomized adjuvant study after nephrectomy. Two hundred and ninety-four patients with completely resected T3 or T4a or N1, N2, or N3 disease were randomized to observation or to 9 months of subcutaneous lymphoblastoid interferon.<sup>137</sup> With a median follow-up of 4.4 years, patients receiving interferon had similar recurrence rates and significantly worse survival than patients randomized to observation only. In view of the limited response rate to biologic therapy and the absence of any indication that responses are related to lesser tumor burdens, there is currently no rationale for recommending adjuvant biotherapy outside of a protocol setting.

One important consideration in evaluating interferon therapy is that the optimal dose, schedule and route of interferon administration is not yet known. Although refinement of schedules may have the potential of increasing response rates somewhat, in view of the small benefit demonstrated to this point, it is unlikely that randomized studies will ever be done to effectively optimize these parameters. In summary, disseminated renal cell cancer shows a small but consistent response rate to interferon (primarily IFN- $\alpha$ ), but these benefits must be weighed against the toxicity of chronic therapy and the lack of documented long-term benefit.

### Interleukin-2

After its discovery in 1976 and the demonstration of its activities as a T-cell growth factor and activator of T cells and natural killer cells, IL-2 was used in clinical trials against a variety of malignancies. From the first trials in 1984, renal cell cancer was identified as a tumor that could respond to IL-2 ( Fig. 34.2-8, Fig. 34.2-9, and Fig. 34.2-10).<sup>138,139</sup> These early trials rapidly escalated the dose of IL-2 to the maximum tolerated dose and then added lymphokine-activated killer (LAK) cells to the therapy, based on preclinical results. These trials initially reported response rates of 33% in RCC and, in a subsequent multicenter experience, the response rate was 16%.<sup>140</sup> The remarkable feature of many of these responses is that they appear complete and durable. Median follow-up of greater than 10 years is available from those early studies, and a review of the follow-up data indicates that 7% to 9% of all patients (nearly half of all those responding) had a CR and the majority of those completely responding patients have never relapsed (see Fig. 34.2-8).<sup>141,142</sup> and <sup>143</sup> This constitutes the most convincing evidence that IL-2 has clinical benefit in the treatment of metastatic renal cell cancer and led to the approval of IL-2 by the U.S. Food and Drug Administration as the only currently approved therapy for this disease in the United States. It should be emphasized that it is the curative potential of these responses and not their frequency that is of value ( Fig. 34.2-11).<sup>254,255</sup>

**FIGURE 34.2-8.** Radiographs of two patients with long-term complete regressions of pulmonary metastases from renal cancer in response to high-dose therapy with interleukin-2 alone. In most studies, patients with only pulmonary metastases appear to have a slightly higher probability of response.

**FIGURE 34.2-9.** Abdominal computed tomography scans of a patient with a durable, ongoing complete response to high-dose interleukin-2 therapy, which included the regression of extensive liver metastases.

**FIGURE 34.2-10.** Regression and recalcification of a large lytic metastasis of the lateral femoral condyle in a patient with widely metastatic renal cell cancer. This patient also had a durable complete response of all soft tissue metastases with interleukin-2–based immunotherapy.

**FIGURE 34.2-11.** Complete responses to high-dose interleukin-2 in patients with metastatic renal carcinoma are typically durable. An actuarial curve of response duration for patients with metastatic renal cell carcinoma responding to high-dose bolus interleukin-2 is shown. Among completely responding patients, 81% have not experienced relapse (median follow-up, 7 years), and no patients have experienced relapse beyond 3 years. Partial responses can be sustained for years but, in this study, all partially responding patients eventually experienced relapse. (Adapted from ref. 143.)

Since those early studies, several developments have occurred. The use of LAK cells with IL-2 has been critically examined in randomized studies, and many investigators have explored the use of lower-dose IL-2 regimens to avoid the toxicity of high-dose IL-2. Although murine models predicted that the addition of LAK cells to IL-2 would substantially increase therapeutic efficacy, this has not proved to be true in clinical studies. A randomized comparison of high-dose intravenous bolus IL-2 with and without LAK cells showed an insignificant difference in response rate (21% for IL-2 and 31% for IL-2 combined with LAK cells) with no difference in survival.<sup>144</sup> Other studies have confirmed this<sup>145</sup> and, currently, there is no evidence to support the use of LAK cells in patients with RCC.

The initial rapid escalation of IL-2 to its maximum tolerated dose identified as the maximum tolerated dose 600,000 to 720,000 IU/kg by intravenous bolus given every 8 hours. On that schedule, patients tolerated approximately seven to nine consecutive doses before treatment had to be stopped for vascular leak syndrome, hypotension, multiorgan dysfunction, and a variety of other toxicities.<sup>146</sup> These effects rapidly reversed after therapy was stopped but, with hypotension requiring vasopressor support, pulmonary edema, and potential infectious complications, a 2% to 4% treatment-related mortality was initially encountered (see Fig. 34.2-10). Since then, increased experience with IL-2, prophylactic antibiotics (when indicated), and patient screening for occult coronary disease have dramatically decreased this mortality rate. A recent report cites 809 consecutive patients who received high-dose bolus IL-2 without a treatment-related mortality,<sup>147</sup> a statistic unattainable with most multiagent chemotherapeutic regimens.

Nevertheless, the expense of intensive care unit care and the precipitous nature of toxicities on high-dose IL-2 led many investigators to try lower-dose regimens. In particular, daily subcutaneous self-administration was adopted as a convenient and inexpensive route. In a scenario that has been replayed many times during the development of IL-2, a multitude of small phase II studies were performed that reported short-term response rates similar to those seen with high-dose IL-2. An outpatient, daily, self-administered regimen using an initial week (Monday through Friday) of 18 million IU (fixed dose) followed by 5 weeks at half that dose was well tolerated and produced a response rate of 23% in 26 evaluable patients.<sup>148</sup> Later, continued experience with a modification of this regimen showed a 20% overall response rate, with one ongoing CR in 47 patients<sup>149</sup>; another group of investigators achieved an 18% response rate with a similar regimen.<sup>150</sup> Others reported on the use of continuous-infusion IL-2, describing a similar response rate with less toxicity (and less overall IL-2 given over the same period).<sup>151</sup> A review of the literature

(Table 34.2-12) shows response rates to IL-2 monotherapy or IL-2 and LAK cells, delivered on many different schedules and at different doses, ranging from 8% to 35%, and it is clear that smaller, nonrandomized studies cannot discern whether one schedule is more effective than another. Nevertheless, lower-dose schedules have been widely adopted before being critically evaluated. There is no question that patients with metastatic RCC can respond to these regimens and that patients with other significant medical conditions may not be able to tolerate high-dose IL-2. In these cases, lower-dose options represent a reasonable therapeutic choice. For those patients who are able to tolerate any of the published IL-2 regimens, it remains crucial to determine whether the added toxicity of high-dose IL-2 is associated with any improvement in clinical efficacy.

TABLE 34.2-12. Therapy with IL-2 Alone or with LAK Cells

Such a study is under way, and an interim analysis is available.<sup>152</sup> This study randomized patients to receive IL-2 at either 720,000 IU/kg or 72,000 IU/kg every 8 hours by intravenous bolus to maximum tolerance (up to 15 consecutive doses). The lower dose was selected as the maximum dose that still resulted in a well-tolerated regimen not requiring intensive care unit care and vasopressor support. This two-arm comparison constitutes the most precise determination of whether the dose of IL-2 is important. Subsequently, a third arm was added to the trial to evaluate the widely used subcutaneous route of administration. This arm delivered 250,000 IU/kg/d for 5 days in the first week and then half that dose 5 days per week for the subsequent 5 weeks. Of course, only concurrently randomized patients are compared in this two-phase trial. With 228 randomized patients of a projected study population of 400, it is evident that the two lower-dose regimens are associated with lower toxicity, especially in the areas of hypotension requiring pressors (43% of courses of high-dose intravenous IL-2 vs. 4% of courses of low-dose intravenous IL-2 and 0% with subcutaneous IL-2), thrombocytopenia, pulmonary distress, and disorientation. It is important to note that there have been no deaths in any of the treatment arms. The interim response rates are shown in Table 34.2-13. In the two-arm comparison of high- and low-dose intravenous bolus IL-2, the respective response rates are 19% and 10% ( $P = .06$ ). The durations of the responses bear watching, as seven of nine patients completely responding to high-dose IL-2 remain in CR beyond 2 years, whereas two of five patients completely responding to low-dose IL-2 maintained their response at 2 years. The three-arm comparison including subcutaneous IL-2 is still preliminary, with response rates of only 16%, 4%, and 11% for high-dose intravenous, low-dose intravenous, and subcutaneous IL-2 reported.<sup>152</sup>

TABLE 34.2-13. A Randomized Study of High-Dose versus Low-Dose Interleukin-2 in Patients with Metastatic Renal Cell Cancer

Because the clinical benefit of IL-2 resides in the long-term CRs achieved, any interpretation of this study will require prolonged follow-up and survival analyses after full accrual. As a drug that conveys great benefit to a minority of patients (who happen to possess the unidentified tumor or immune system qualities that allow them to respond), IL-2 is unlikely to affect the median survival of patients in randomized studies, and study design must take this into account.

Other studies have addressed the issue of continuous-infusion IL-2 versus bolus IL-2. The initial nonrandomized studies using continuous-infusion IL-2 reported response rates similar to those for bolus IL-2 but with lesser toxicities.<sup>151</sup> In a subsequent randomized study in which all patients received LAK cells, there was a randomization to receive either continuous-infusion IL-2 at 18 to 22.5 million IU/m<sup>2</sup>/d or 600,000 IU/kg/dose by bolus every 8 hours (the cumulative daily dose by bolus was more than three times the dose by continuous infusion).<sup>153</sup> Both of these doses represented the respective maximally tolerated doses for these regimens, and the few significant differences in toxicities did not favor either regimen. In this study, patients receiving LAK cells and bolus IL-2 had a 20% major response rate, as compared to a 15% response rate for patients given LAK cells and continuous-infusion IL-2; the difference was not significant. Fortunately, it has been established that the CRs to high-dose continuous-infusion IL-2 can be of long duration. A single-institution study of 123 patients (some also receiving LAK cells) with follow-up of 1 to 109 months reported an overall response rate of 19%, with 7% CRs and 78% of those patients sustaining their CRs at 42 to more than 109 months.<sup>154</sup>

A more complex issue is whether any combination of cytokine or chemotherapy added to IL-2 is superior to IL-2 alone. Here again, small, nonrandomized phase II studies have clouded this issue. Innumerable small studies have combined IL-2 with interferon and chemotherapy, and sometimes both agents, and reported improved short-term response rates with large, overlapping confidence intervals (see Table 34.2-9). The combination of IFN- $\alpha$  and IL-2 is especially appealing because both agents have independent activity against RCC, and preclinical animal models predict synergistic benefit from combining these agents. Early reports suggested that the response rate for patients with metastatic RCC might rise from 18% to 20% with high-dose IL-2 alone to as much as 31% with high-dose IL-2 plus interferon.<sup>155</sup> However, further accrual and long-term follow-up of the patients in this study did not show sufficient improvement in either response rate or survival (when compared to historical controls from the same institution) to warrant the additional toxicity seen (see Fig. 34.2-11).<sup>156</sup>

Other investigators have been using this combination of cytokines to reduce the dose of IL-2 needed for a response and, thus, to limit toxicity. Most have employed outpatient, subcutaneous schedules, as widely described by Atzpodien et al.<sup>157</sup> The initial nonrandomized reports on this regimen emphasized lesser toxicities but similar response rates to high-dose IL-2 monotherapy. Yet when others have tried the same or similar regimens, their response rates as well as their toxicity profiles have not been as favorable. Without randomized studies, it is impossible to reconcile these disparate results.

Some experience in randomized evaluations of IL-2 and interferon is available. Negrier et al.<sup>158</sup> randomized 425 patients to receive continuous-infusion, high-dose IL-2 alone, subcutaneous IFN- $\alpha$  three times weekly, or both agents simultaneously. There was a significantly higher response rate to the combination (18.6%) than to only IL-2 (6.5%) or interferon (7.5%), but this increased response rate did not translate into improved survival. This study demonstrated an unusually low response rate to IL-2 alone, and patients with tumor progression crossed over between therapy arms. Other small randomized studies of IL-2 and interferon have also failed to demonstrate an advantage to combination therapy, but these studies are largely underpowered.<sup>159,160</sup>

In a further effort to enhance the efficacy of IL-2 by adding other agents, investigators have tried to exploit the reported synergy between 5-FU (which has a low single-agent response rate against RCC) and interferon by adding this agent to IL-2 and interferon. Again, early phase II studies reported major increases in response rates,<sup>161</sup> but later studies did not always substantiate these findings.<sup>162</sup> In fact, an attempt to reproduce the initial studies exactly with 5-FU, IFN, and IL-2 (which had a

reported response rate of 49%) resulted in a PR and CR rate of 16%—exactly the same as with IL-2 alone. <sup>163</sup>

One issue rarely addressed in evaluating these combinations is the durability of the responses. Long-term follow-up with sufficient patients to evaluate response durations in the minority of patients showing regression is crucial to evaluating IL-2 therapies. Dutcher et al. <sup>163</sup> have raised a possible red flag by reviewing their sequential use of IL-2, IL-2 plus interferon, and IL-2 plus interferon plus 5-FU. Not only did they fail to see an increased response rate as the dose of IL-2 was moderated and other agents were added to IL-2, but their percentage of patients attaining durable CRs seemed to decrease. Although their numbers still are small and patients were not randomized, this is a potentially important issue. If IL-2's durable responses are indeed forfeited by these combinations, then these regimens are indistinguishable from the many ineffective chemotherapeutic agents with 15% to 25% partial or transient responses and should not be advocated.

## VACCINES AND CELLULAR THERAPY

An effort to identify immune cells with reactivity to renal cancer is ongoing. The use of nonspecific activated killer cells (natural killer or LAK cells) has largely been ineffective, but current efforts have concentrated on T cells and the induction of a T-cell response via vaccination. After the lead of melanoma research, tumor-infiltrating lymphocytes (TIL) isolated from renal cancer specimens and cells from mixed lymphocyte-tumor reactions were examined for antitumor reactivity. With some notable exceptions, <sup>164,165,166</sup> and <sup>167</sup> little specific tumor reactivity was seen. <sup>168</sup> Attempts to use TIL clinically have showed some promising early results (usually combined with IL-2 and IFN- $\alpha$ ), <sup>169</sup> but a randomized trial of IL-2 with and without CD8-enriched TIL was fraught with technical difficulties and showed no augmentation in response rate or survival with cell transfer. <sup>170</sup> Another study of the use of peripheral blood cells nonspecifically activated by anti-CD3-stimulated mononuclear cell supernatant (autolymphocyte therapy) appeared to be beneficial in a small randomized trial <sup>171</sup> but, despite the undertaking of a large multicenter trial, no confirmatory data for this approach have been produced since that trial.

Because of the relative scarcity of tumor-reactive specific T cells against renal cancer, another approach has been the use of vaccines. Typically, whole tumor preparations have been used because of the failure to identify broadly applicable, common tumor antigens expressed by RCC. In one study, the gene for granulocyte-macrophage colony-stimulating factor (GM-CSF) was introduced into autologous cultured renal cell cancer lines by retroviral transduction in a concept based on preclinical studies. <sup>172</sup> Patients then were immunized with irradiated tumor cells secreting large amounts of GM-CSF (or control nontransduced cells) and were evaluated for immune responses and clinical tumor regression. One PR was seen in 16 evaluable patients, and evidence was seen of cutaneous delayed-type hypersensitivity responses generated against tumor as well as an antitumor T-cell response in the responding patient. This approach is limited by the requirement for an autologous cultured tumor line. Other approaches are investigating the use of tumor lysates and whole tumor cells co-incubated with autologous dendritic cells to vaccinate patients. Data on the clinical and laboratory responses generated by dendritic cell vaccines should be forthcoming soon.

Another recent early-phase trial has used a nonmyeloablative allogeneic peripheral blood stem cell transplant, hypothesizing that a graft-versus-tumor response may lead to regression of metastatic renal cancer. It appears, in the single patient presented, that tumor regression did not occur until the onset of complete donor chimerism, tapering of immunosuppression, and the appearance of mild graft-versus-host disease, supporting an immunological mechanism of action related to the allograft. <sup>173</sup> Still not clear is whether there is specific recognition of tumor-associated antigens by the matched sibling allograft or whether generalized graft-versus-host disease is leading to *in situ* production of cytokines, which then can treat an intrinsically cytokine-sensitive tumor (i.e., renal cancer). This is an interesting approach, given the magnitude of the few responses seen thus far, but it remains to be confirmed by a larger experience, and the mechanism of action requires further investigation.

## ANTIANGIOGENIC AGENTS

The field of angiogenesis and its role as a target for cancer therapy has burgeoned in the last decade. New inhibitors of angiogenesis such as endostatin and angiostatin have been discovered, <sup>174</sup> and old compounds such as thalidomide have found new life as antiangiogenic agents. RCC presents an attractive target for these agents for two reasons. First, it is a tremendously vascular tumor consisting largely of capillaries and blood sinuses surrounded by malignant clear cells. In addition, there appears to be a highly angiogenic environment within clear cell cancers, driven by tumor-elaborated vascular endothelial growth factor (VEGF). As described in [Chapter 34.1](#), the elaboration of VEGF by RCC in response to a variety of stimuli appears to be linked to the functional mutation of the VHL protein found in nearly all clear cell renal cancers. Thus, the common genetic event that leads to clear cell RCC involves a deregulation of the VEGF pathway and, presumably, angiogenesis is a consequence. One ongoing randomized trial is studying the use of a neutralizing antibody to human VEGF that is highly effective in slowing the growth of VEGF-secreting human tumors implanted into nude mice. <sup>175</sup> The clinical trial is a blinded, placebo-controlled trial designed to determine whether survival or time to progression are altered by the chronic administration of this antibody. A small trial of thalidomide (the highly teratogenic sedative now thought to cause deformities via an *in utero* antiangiogenic mechanism) in patients with metastatic renal cancer was recently reported to produce tumor regression in some patients (R. Amato, unpublished data). Another agent, endostatin, which showed broad preclinical activity in mice, has also just been entered into highly anticipated clinical trials. Although this is a field of intense activity and interest, it is not yet clear whether a single antiangiogenic agent will be sufficient to interrupt the vascular supply of a tumor. It may be that tumors use a variety of angiogenic pathways and that only with carefully combined multiagent therapy will clinically significant tumor arrest or regression be accomplished.

### Summary

In the last two decades, a burgeoning supply of new biologic agents has been made available in amounts sufficient for clinical trials by recombinant gene technology. Most of these proteins did not meet the unrealistic expectations generated by preclinical work and entrepreneurial publicity. In the face of these disappointments, several important principles were established in the treatment of renal cell cancer and melanoma that should not be overlooked. It has been established that purely immunologic therapy, which has no direct, intrinsic antitumor activity, was able to cause the regression of large, metastatic tumors by stimulating host immune cells. Even more crucial was the demonstration that some of these regressions were potentially curative, with a small but consistent fraction of patients maintaining their CRs to IL-2 beyond 10 years. These results argue effectively that predicted pitfalls to immunotherapy such as tumor heterogeneity and antigen loss, immunosuppression by the cancer-bearing state or tumor microenvironment, and a lack of tumor-specific antigens in human cancers are not insurmountable problems. To increase the frequency of successful immune attack on renal cell cancer, it will be important to understand the mechanisms and cellular elements that are responsible for these few dramatic responses. Both immune effector factors as well as tumor characteristics are likely to be involved in the successful interplay that occurs in responding patients. The treatment of patients with renal cell cancer is likely to contribute to our future understanding of these factors and to continue at the forefront of progress in biologic therapies for cancer.

## CARCINOMA OF THE RENAL PELVIS AND URETER

### CARCINOMA OF THE RENAL PELVIS

Carcinoma of the renal pelvis is a relatively rare tumor that accounts for 5% of all renal tumors. It occurs more frequently in men than in women (2:1 to 3:1). Upper urinary tract carcinoma is a multifocal process; patients with cancer at one site in the upper urinary tract are at greater risk of developing tumors elsewhere. <sup>256,257</sup> and <sup>258</sup> The probability of multifocal occurrence is greater in patients with larger lesions and in those with carcinoma *in situ*. A patient with one upper tract urothelial tumor has a 30% to 50% chance of developing a bladder tumor as well. Some 2% to 4% of patients with an upper tract urothelial tumor develop bilateral renal pelvic tumors. If a patient has both a renal pelvic tumor and a ureteral tumor simultaneously, there is a 75% chance that a bladder tumor will develop in this patient. Alternatively, a patient with a bladder tumor initially has a 2% to 3% chance of developing an upper tract tumor. <sup>176</sup>

### Etiologic Features and Genetics

Recent studies have demonstrated that the major cause of cancer of the renal pelvis is smoking and that cessation of smoking can eliminate a large number of these tumors. <sup>177</sup> A significant increase in risk for upper genitourinary (GU) tract urothelial cancer is found in smokers, the risk being highest among the heaviest smokers. <sup>22</sup> In 1965, Hultengren et al. <sup>178</sup> first identified a connection between epithelial tumors of the renal pelvis and abuse of compound analgesics. Since then, a number of other reports <sup>179,180</sup> and <sup>181</sup> from Sweden, <sup>182</sup> Australia, <sup>183</sup> the Netherlands, <sup>184</sup> Denmark, <sup>185</sup> Italy, <sup>186</sup> Germany, <sup>187</sup> and the United States <sup>22</sup> have demonstrated an association between analgesic abuse and renal pelvic tumors. <sup>188</sup> Most of the patients ingested a significant amount (5 kg) of compound analgesic, usually containing phenacetin, phenazone, and caffeine. <sup>189,190</sup> Typically, upper GU tract tumors occur in patients in whom prolonged and heavy analgesic ingestion is followed by renal papillary necrosis. <sup>190</sup>

There is also an association between cancer of the renal pelvis and danubian endemic familial nephropathy (Balkan nephropathy). Balkan nephropathy is a slowly

progressive inflammation of the interstitium of the kidney that ultimately results in renal failure.<sup>191</sup> This disorder, which is prevalent in the Balkan countries (Yugoslavia, Romania, Bulgaria, and Greece), is associated with multifocal, slow-growing, superficial, low-grade tumors of the renal pelvis. The cause of Balkan nephropathy is unclear; however, a number of potential etiologic agents such as fungal toxins, viruses, silicates, and heavy metals have been studied.<sup>192</sup>

An association has been observed between renal pelvic tumors and urban residence as well as occupation in the aniline dye, textile, plastics, and rubber industries.<sup>189,192</sup> Chronic inflammation and irritation are associated with the development of renal pelvic tumors, particularly in patients who have upper urinary tract stones.

There are reports of kindreds exhibiting a hereditary pattern in the development of transitional cell carcinoma of the urinary tract.<sup>193,194</sup> Of the affected family members, 22% had upper GU tract tumors, 59% had bladder cancer, and 18% had both upper and lower GU tract tumors.<sup>193</sup> Upper GU tract urothelial tumors are found in patients with hereditary nonpolyposis colorectal cancer, which is associated with a germline abnormality in DNA mismatch repair genes.<sup>195</sup> Studies of the molecular and cellular aspects of urothelial transformation should provide further insight into the etiology and mechanisms of progression and metastasis of this disease.

### Pathology

Transitional cell carcinoma accounts for 90% of the tumors of the renal pelvis and can be *in situ*, papillary, or planar (Table 34.2-14). Squamous cell carcinoma, which usually is associated with chronic inflammation or infection of the renal pelvis, accounts for 7% of renal pelvic tumors.<sup>196</sup> Squamous cell cancer of the renal pelvis often is deeply invasive and is associated with a worse prognosis than is transitional cell carcinoma. Adenocarcinoma of the renal pelvis has been reported in few patients and occurs in association with inflammation, infection, or calculi.<sup>197</sup>

### Diagnosis and Staging

Hematuria is the initial pelvic presenting symptom in the majority of patients with renal pelvic carcinoma. Gross hematuria is present in 62% to 75%, and microscopic hematuria is seen in 10%. The triad of flank mass, pain, and hematuria is encountered infrequently, in 20% or fewer cases, and often is associated with advanced disease. Excretory urography frequently is used in the initial evaluation of patients with renal pelvic tumors and will often reveal a filling defect in the collecting system. There may also be either a hydronephrotic or a nonfunctional kidney due to obstruction by a blood clot or mass. Retrograde pyelography (in which contrast medium is injected into the ureter through an endoscope) accurately delineates upper GU tract filling defects. If there is uncertainty about the nature of a renal pelvic lesion, CT performed before and after administration of intravenous contrast material will differentiate a tumor from another radiolucent mass such as a stone.<sup>198,199</sup> and <sup>200</sup> Angiography is not used often in the diagnostic evaluation of a suspected renal pelvic tumor. However, a renal mass that lacks the characteristic neovascularity of a renal carcinoma may be the first indication of a renal pelvic tumor invading the renal parenchyma.

Urine cytology is useful in evaluating a renal pelvis mass, and endoscopically obtained barbotage specimens allow an accurate diagnosis to be made in approximately 80% of cases.<sup>201,202</sup> Tissue can also be obtained by introducing a biopsy brush into the ureter and removing a specimen for cytologic or histologic examination. Brush biopsy increases diagnostic accuracy to between 80% and 90%. Endoscopic ureteroscopy and percutaneous nephroscopy are techniques that have dramatically improved the diagnosis of upper tract tumors.<sup>203,204</sup> and <sup>205</sup> Endoluminal sonographic evaluation may also be useful for diagnosis and staging.<sup>206,207</sup> With currently available endoscopic instruments, the renal pelvis can be inspected visually in more than 90% of patients.

The most significant prognostic factors for survival of patients with renal pelvic carcinoma are stage and grade of tumor. Renal pelvic upper urinary tract cancer is divided into four stages by the TNM classification (Table 34.2-15). The primary tumor is classified as low-stage (Ta, limited to mucosa; T1, lamina propria invasion) and high-stage (T2, muscularis involvement; T3, tumor beyond the muscularis).<sup>75</sup> Renal pelvic tumors are graded from 1 to 3. The median survival for patients with high-grade tumors is 14 to 16 months as compared with 67 months for patients with low-grade tumors. Median survival for patients with high-stage tumors is 13 months, whereas median survival for patients with low-stage tumors is 91 months.<sup>176</sup> Invasion of the renal hilum occurs in 95% of patients who ultimately develop metastases.<sup>208</sup>

Stage	Description
<b>TUMOR</b>	
Ta (stage 0/I)	Limited to mucosa
T1 (stage A/II)	Lamina propria invasion
T2 (stage B/III)	Confined to the muscularis propria
T3 (stage C/IV)	Invasion of perirenal or peripelvic tissue or renal parenchyma
T4 (stage D/IV)	Invasion of contiguous structures
<b>NODE</b>	
N1	Single node ≤ 2 cm
N2	Multiple nodes ≤ 5 cm
N3	Multiple nodes > 5 cm
<b>METASTASES</b>	
M	Hematogenous or distant nodal metastasis

TABLE 34.2-15. Staging of Ureteral and Pelvic Tumors

### Surgical Treatment

Carcinoma of the renal pelvis may be treated with a radical nephrectomy that includes removal of Gerota's fascia and its contents, total removal of the ipsilateral ureter, and removal of a cuff of bladder.<sup>209,210</sup> When transitional cell carcinoma of the renal pelvis invades the renal vein or vena cava, an extensive surgical procedure including thrombus extraction or partial vena cava resection may be required.<sup>211</sup>

More conservative endourologic surgical excision is advocated by some who note that renal pelvic carcinoma can be bilateral and that survival of patients with low-stage, low-grade renal pelvic carcinoma treated with a conservative surgical procedure is approximately the same as in patients treated with more radical surgery.<sup>203,212</sup> The incidence of low-grade, low-stage renal pelvic carcinoma is approximately 8%, and that of bilateral disease is 2%. Often there is also a long latent period prior to recurrence. Papillary, low-grade, low-stage tumors of the upper urinary tract often are considered amenable to endoscopic resection. However, most clinicians offer radical surgery to patients with high-grade endoscopically defined lesions.<sup>203</sup> Currently, most clinicians consider that local, partial excision is potentially

appropriate for patients with a solitary kidney, with bilateral renal pelvic carcinoma, or with renal insufficiency. Treatment strategies involving percutaneous or ureteroscopic resection of renal pelvic tumors followed by either laser irradiation or supplemental intracavitary therapy are currently being evaluated. [213,214](#) and [215](#)

### Follow-Up

Conscientious follow-up after surgery for renal pelvic carcinoma is essential. Urinalysis, urine cytology, and cystourethroscopy are performed every 3 months for 2 to 3 years and then less frequently. For patients who undergo a conservative upper tract procedure, periodic retrograde pyelography and ureteroscopy also are performed. [203](#)

## URETERAL CARCINOMA

Ureteral carcinoma is an uncommon neoplasm that accounts for only 1% of all malignancies of the upper GU tract. Ureteral carcinoma was first described by the French pathologist Rayer in 1841; the first ureteral carcinoma to be removed by nephroureterectomy was reported by Vorphl in 1905. Ureteral carcinoma tends to occur in the older age groups, predominantly in the sixth, seventh, and eighth decades of life. The male-female ratio is 2:1. The most common site for the occurrence of a ureteral tumor is in the lower one-third of the ureter, with a lesser incidence higher up.

### Histology and Etiology

Ninety percent of malignant tumors of the ureter are transitional cell carcinomas; 20% have squamous or glandular differentiation. Eight percent of the tumors are pure squamous cell carcinomas, and 1% are adenocarcinomas. Tumors of the ureter share embryologic, morphologic, and etiologic characteristics with renal pelvic tumors. As with renal pelvic tumors, there is an increased incidence of ureteral carcinoma associated with Balkan nephropathy, prolonged exposure to phenacetin, or prolonged exposure to environmental agents such as aniline dyes. [216](#)

### Clinical Presentation: Grade and Stage

Hematuria is the most common presenting symptom and is present in 75% of patients with ureteral carcinoma. The hematuria is usually painless; however, colicky pain due to obstruction by clot or by tumor occurs in up to 35%. Urinary frequency or dysuria, present in only 10% of patients with renal pelvic carcinoma, occurs in up to 50% of patients with ureteral carcinoma. [216](#)

As in pelvic carcinoma, the primary ureteral carcinoma is classified as grades 1 through 3 and stage Ta (limited to the mucosa), T1 (lamina propria invasion), T2 (muscularis involvement), or T3 (invasion beyond the muscularis). [75](#) Although up to 100% of grade 1 tumors and 85% of grade 2 tumors may be noninvasive, only 30% of grade 3 and 8% of grade 4 tumors are noninvasive. [176,216](#)

### Diagnosis

Excretory urography is an initial part of the evaluation of a suspected ureteral mass lesion. On excretory urography, the upper tract above the tumor may be completely normal or there may be hydronephrosis or complete nonfunction. Retrograde pyelography may be performed to delineate accurately the precise location of the ureteral lesion. Urine is collected for cytologic examination, and brush biopsy may be performed to obtain tissue for histologic examination. Advances in ureteroscopic techniques have revolutionized the diagnosis and treatment of upper tract transitional carcinomas. [217](#) The flexible endoscope has greatly improved the surgeon's ability to visualize and perform a biopsy of ureteral lesions, and its use is now part of the standard management of this disease. [217,218](#) Abdominal CT also provides useful staging information, particularly with regard to extension of the tumor outside the ureter.

### Treatment

Carcinoma of the ureter has historically been treated by either nephroureterectomy or partial ureterectomy. The advantage of a partial ureterectomy is that the more conservative procedure preserves the kidney. However, mapping studies of the urothelium have demonstrated that carcinoma of the upper urinary tract is a multifocal disease. Often atypia and carcinoma *in situ* are noted in multiple areas of the urothelium, particularly in high-grade, high-stage carcinomas. Small, solitary, low-grade tumors are most often treated by endoscopic resection, fulguration, or laser photocoagulation, which allows acceptable survival and renal preservation, particularly in patients with a solitary kidney, bilateral tumors, a poor operative risk, or impaired renal function. [203,217,218](#) Nephroureterectomy is recommended for patients with high-grade or high-stage tumor and for those with disease at an unresectable location.

The surgical procedure of radical nephrectomy plus ureterectomy entails removal of the kidney and the entire contents of Gerota's fascia, the ureter, and a cuff of bladder including the ureteral orifice and intramural ureter ( [Fig. 34.2-12](#)). Regional lymph nodes may be removed, particularly if there is indication that they are involved. This surgical procedure may be performed using one or two incisions, depending on the patient's body habitus and the surgeon's preference. When partial ureterectomy is performed, urinary tract continuity is reestablished with either ureteroureterostomy or ureteroneocystostomy.

**FIGURE 34.2-12.** The patient who will undergo a nephroureterectomy with lymph node dissection should be placed in a modified flank position and an incision made through either line a or line b. The area of dissection is as indicated in the middle panel, being divested from the superior mesenteric artery to the bifurcation. The ureter is removed by opening the bladder, circumscribing the orifice, and sharply dissecting the ureter from the surrounding detrusor muscle. The defect in the bladder then is closed appropriately. (From ref. [262](#), with permission.)

### Results of Therapy

The 5-year survival of patients with ureteral carcinoma is determined primarily by the grade and stage of the disease. Thorough endoscopic follow-up is essential at regular intervals to rule out recurrences. [205](#) Endourologic techniques combined with conservative treatment of ureteral transitional cell carcinoma can be effectively and safely used as first-line therapy for selected individuals. [212](#) Patients with Ta or T1 ureteral carcinoma can experience a 90% to 100% 5-year survival rate; those with T2 disease, a 45% to 85% 5-year survival rate; and patients with T3 disease, a 25% to 30% 5-year survival rate. The 5-year survival for patients with metastatic disease is currently 0% to 5% ( [Table 34.2-16](#)).

Tumor Stage	5-Y Survival Rate (%)
T1 (stage A/II)	92
T2 (stage B/III)	40-70
T3 (stage C/IV)	25-43
T4 (stage D/IV)	0

(From refs. 257 and 258, with permission.)

**TABLE 34.2-16.** Correlation of Survival Rate with Stage of Ureteral and Pelvic Tumors

### ADJUVANT RADIOTHERAPY FOR CARCINOMA OF THE RENAL PELVIS AND URETER

In the absence of randomized prospective data, there is no consensus regarding the need for adjuvant radiotherapy for patients with renal pelvis or ureteral cancers. Brookland and Richter<sup>219</sup> reported on 23 patients with stage III to IV transitional cancers of the upper GU tract. Postoperative radiotherapy (45 to 50 Gy) was given to 11 patients. Among these 11, 5 patients (45%) developed a local recurrence, as compared to 1 of 9 patients (11%) treated with a nephroureterectomy alone ( $P = .23$ ). Cozal et al.<sup>220</sup> reported on 67 patients with stage I through IV upper tract transitional cell tumors. Though the authors demonstrated a reduction in the crude local relapse rate with the administration of 45 to 50 Gy of postoperative radiotherapy as compared to patients who did not receive adjuvant therapy (26% vs. 10%), these differences were not significant ( $P = .42$ ). Other recent retrospective reports could not demonstrate a significant benefit for adjuvant therapy for advanced-stage disease.<sup>221,222 and 223</sup> These authors have highlighted the systemic nature of stage III and IV disease—namely, the high risk of distant metastases and the relative infrequent incidence of isolated local recurrences after initial local aggressive surgical therapy, which likely explain the lack of conclusive evidence that adjuvant radiotherapy is of any benefit. Nevertheless, as most patients in these reports were followed without the benefit of routine CT evaluations, the true incidence of a local failure for advanced-stage patients remains unclear. Until more effective systemic regimens are available for patients with locally advanced disease, distant metastasis appears to be the predominant mode of failure, and routine administration of adjuvant local radiotherapy is not recommended.

### CHEMOTHERAPY FOR METASTATIC CARCINOMAS OF THE RENAL PELVIS AND URETER

Except for its role in the conservation and preservation of the bladder, considerations for systemic treatment of cancer of the ureter and renal pelvis are identical to those of bladder cancer. It is believed that the biology of transitional cell carcinomas of the renal pelvis, ureter, and bladder is the same, with comparable etiology, pathology, and pattern of spread. This paradigm is supported by the frequent occurrence of multifocal neoplastic sites in the transitional epithelium. Systemic chemotherapy for upper urinary tract cancers mirrors that for bladder cancer and has been administered in the metastatic, adjuvant, and neoadjuvant setting. Indeed, patients with carcinomas of the renal pelvis and ureter usually are included in clinical trials for bladder cancer, because the chemoresponsiveness of both upper and lower urothelial cancers is considered to be comparable. A retrospective review of 203 patients in five trials of methotrexate, vinblastine, doxorubicin (Adriamycin), and cisplatin (M-VAC) from the Memorial Sloan-Kettering Cancer Center could identify no difference in response or survival between patients with bladder and nonbladder primary sites (Table 34.2-17).<sup>326</sup> Because the incidence of cancer of the upper urinary tract is a fraction of that of cancer of the bladder, chemotherapeutic trials do not address the upper urothelium separately. Hence, this section will briefly outline the issues relating to systemic treatment of upper urinary tract cancer, drawing from the bladder cancer literature. For a more extensive discussion, the reader is referred to Chapter 34.3.

Primary Site	No. of Pts.	CR (%)	CR + PR (%)	Median Survival (mo)	5-Y Survival
Renal pelvis	21			19.7	10
Ureter	12			13.7	28
Urethra	10			17.5	20
Nonbladder	43	31	67	17.8*	16
Bladder	160	22	66	15.1*	13

CR, complete responders; M-VAC, methotrexate, vinblastine, doxorubicin (Adriamycin), and cisplatin; PR, partial responders. \* $P = .56$ .

Note: Data from 203 patients with unresectable or metastatic transitional cell cancer in five previously reported trials of M-VAC chemotherapy from Memorial Sloan-Kettering Cancer Center, New York, was retrospectively reviewed to determine whether primary site adversely affects response or survival (D. F. Bagaria, personal communication, 2000). There was no significant difference in response to M-VAC, in median survival ( $P = .56$ ) or in 5-year survival when the outcome for patients with bladder or nonbladder primary site were compared.

**TABLE 34.2-17.** Effect of Nonbladder Primary Site of Transitional Cell Carcinoma on Response to M-VAC

### CHEMOTHERAPY FOR ADVANCED CANCER OF THE RENAL PELVIS AND URETER

Urothelial cancers are highly responsive to chemotherapy. After local recurrence or metastasis has developed, systemic chemotherapy is indicated. While combination chemotherapeutic regimens, including cisplatin, are most widely used, the single-agent activity for a variety of agents is solid. Response rates ranging from 25% to 35% have been reported for cisplatin, methotrexate, cyclophosphamide, and paclitaxel.<sup>327</sup> Most recently, single-agent activity of 28% for gemcitabine has been reported.<sup>328</sup> Table 34.2-18 includes results from both combined and single-agent chemotherapy trials.

**TABLE 34.2-18.** M-VAC and New Agents for Urothelial Cancer

As with other cancers that are responsive to chemotherapy, combination regimens elicit a higher response rate than do single-agent regimens. Although others have been described, the most widely accepted regimen for bladder and other urothelial cancers has been M-VAC (methotrexate, 30 mg/m<sup>2</sup> on days 1, 15, and 22; vinblastine, 3 mg/m<sup>2</sup> on days 2, 15, and 22; Adriamycin, 30 mg/m<sup>2</sup> on day 2; and cisplatin, 70 mg/m<sup>2</sup> on day 2, in a 28-day cycle), originally described in 1985 with a 70% overall response rate.<sup>329,330</sup> A single-institution randomized trial comparing M-VAC with cisplatin, cyclophosphamide, and Adriamycin (CISCA) confirmed a 65% response rate for M-VAC, including 35% of patients with a complete remission.<sup>331</sup> Among 110 patients enrolled in the study, 81 had a primary bladder tumor, 14 had cancer of the renal pelvis, and 6 had cancer of the ureter. The site of origin of the tumor had no influence on response rate. A randomized intergroup study comparing

M-VAC with cisplatin monotherapy also demonstrated M-VAC to be significantly superior with regard to both response rate (39% vs. 12%) and survival (median 12.5 vs. 8.2 months).<sup>332</sup> Long-term follow-up of this trial at 6 years confirmed the superiority of M-VAC over cisplatin alone.<sup>333</sup> Escalation of methotrexate to 1000 mg/m<sup>2</sup> failed to improve response rate or median survival.<sup>334</sup> M-VAC is associated with significant hematologic toxicity, and studies aimed at ameliorating the toxicity or supporting dose escalation with GM-CSF or granulocyte colony-stimulating factor have shown little benefit.<sup>335,336</sup>

Patients experiencing a CR survive longer<sup>337</sup> but, despite the regular occurrence of CRs, there is a high relapse rate. In the intergroup study, only 5 of 17 patients with CR remained disease-free from 8.5 to 39.5 months.<sup>332</sup> Similarly, Igawa et al.<sup>337a</sup> reported that among 51 patients who received M-VAC, 10 patients experienced CRs, but 8 relapsed, with a median duration of response of 11.9 months. These considerations have urged the pursuit of treatment that would provide more durable benefit with less toxicity.

For patients whose tumors progress after treatment with M-VAC, several newer agents have shown single-agent activity in urothelial cancer (see [Table 34.2-18](#)). Both paclitaxel and gemcitabine have response rates in the 20% to 30% range. Phase II combination studies of paclitaxel with carboplatin or gemcitabine with cisplatin have shown reproducible response rates, generally 50% to 60% in previously untreated (or adjuvant-only treated) patients.<sup>337t</sup> Although the response rates are lower than those seen in the original M-VAC trials,<sup>330,331</sup> the results are comparable to the findings of the large intergroup trial of M-VAC, which demonstrated a 39% response rate and improved survival.<sup>332</sup> A recently reported phase I trial incorporated a sequential approach: doxorubicin plus gemcitabine for six 2-week cycles followed by ifosfamide, paclitaxel, and cisplatin in four 3-week cycles.<sup>223a</sup> A sequential approach such as this may allow the use of multiple known active agents without compromising doses, while minimizing toxicity.

Enrollment has been completed in a large randomized study comparing gemcitabine plus cisplatin with M-VAC in metastatic transitional cell carcinoma.<sup>337c</sup> A second randomized study conducted by the Eastern Cooperative Oncology Group is ongoing, comparing M-VAC with carboplatin and paclitaxel.<sup>337d</sup> Patients must be previously untreated and have advanced or metastatic urothelial cancer (from the renal pelvis, ureter, bladder, or urethra). This study should help to determine whether M-VAC can be challenged as front-line therapy in urothelial cancer.

## PROGNOSTIC FACTORS IN UROTHELIAL CANCER

The randomized trial comparing M-VAC with cisplatin alone, encompassing 255 patients, was examined for prognostic factors.<sup>333</sup> Factors that predicted a poor outcome included nontransitional cell histology, poor performance status, and liver or bone metastases. Overall, fewer than 4% of patients treated with M-VAC for advanced urothelial cancer were alive and disease-free at 6 years. Among 99 patients treated with M-VAC or CMV [cisplatin, methotrexate, and vinblastine], good performance status, low metallothionein expression, and high tumor grade were significant predictors of response to chemotherapy.<sup>337e</sup> Molecular factors important in tumor progression—p53, the retinoblastoma gene product (Rb), E-cadherin, and epidermal growth factor receptor—have also been identified in urothelial cancer.<sup>338</sup> It is not known whether, beyond tumor progression, these factors may play a role in determining chemosensitivity.

## ADJUVANT AND NEOADJUVANT CHEMOTHERAPY FOR CANCER OF THE RENAL PELVIS AND URETER

The responsiveness of urothelial cancer to chemotherapy offered the possibility that adjuvant or neoadjuvant chemotherapy could improve survival in patients undergoing curative resections. However, evidence for benefit of either strategy is limited, in part because of the large trial size that would be required to prove it. As in advanced disease, it is believed that upper urinary tract cancers have the same responsiveness to chemotherapy as do bladder cancers. A small adjuvant trial supporting this included 18 patients with bladder cancer and 10 patients with upper urinary tract cancer treated postoperatively with a combination of methotrexate, vincristine, cisplatin, cyclophosphamide, Adriamycin, and bleomycin.<sup>339</sup> Disease-free survivals were comparable for both groups of patients.

Randomized adjuvant chemotherapy trials in bladder cancer have not provided clear support for the benefit of adjuvant treatment.<sup>340,341,342</sup> and <sup>343</sup> Several factors can be cited for the failure of some trials to show benefit, including use of weaker chemotherapeutic regimens such as single-agent cisplatin,<sup>340</sup> treatment of node-negative populations,<sup>343</sup> and small trial size. Neoadjuvant chemotherapy before cystectomy has also been studied in bladder cancer. A study from the M. D. Anderson Cancer Center compared neoadjuvant M-VAC (two cycles before cystectomy and three cycles afterward) with adjuvant M-VAC (five cycles after cystectomy).<sup>344</sup> Randomizing 98 patients, no survival difference (60% vs. 63%) between the two strategies could be seen when the study was analyzed at 31.7 months. Neoadjuvant trials in bladder cancer have also failed to provide conclusive evidence for the benefit of chemotherapy,<sup>327,345</sup> including a recently reported study from an international collaboration of trialists in which 976 patients were randomized between no chemotherapy and neoadjuvant chemotherapy consisting of three cycles of cisplatin, methotrexate, and vinblastine prior to curative local therapy.<sup>346</sup> Median survival in the no-chemotherapy group was 37.5 months and, in the chemotherapy group, was 44 months. The absolute difference in 3-year survival was 5.5% (50% vs. 55.5%), an insufficient number to allow a broad recommendation for the inclusion of chemotherapy in the initial treatment of patients with urothelial cancer. One goal of neoadjuvant therapy is the downstaging of tumor size, potentially allowing bladder preservation. In this regard, neoadjuvant therapy seldom is applicable to patients with upper urinary tract cancer, as the only candidates for conservative surgery are patients with low-grade, superficial, noninvasive tumors in whom the prognosis is better (85% at 5 years) and the likelihood of benefit from chemotherapy is difficult to prove.<sup>347,348</sup> and <sup>349</sup>

Most authors conclude that further randomized studies are required to prove a survival benefit for adjuvant or neoadjuvant chemotherapy in urothelial cancer. However, some clinicians administer adjuvant chemotherapy in the absence of convincing data because of the responsiveness to chemotherapy that has been observed in advanced disease and the incurability of recurrent or metastatic disease. Indeed, the current Eastern Cooperative Oncology Group trial for adjuvant chemotherapy in bladder cancer is not a randomization with or without chemotherapy but rather an assignment to treatment with M-VAC or carboplatin and paclitaxel.<sup>337d</sup> In the absence of randomized data and specific data from upper urinary tract cancers, a decision in favor of adjuvant chemotherapy seems reasonable, particularly in patients in whom the risk of relapse is high, in whom tumors are invasive, nodal metastases are present, or the tumor grade suggests an aggressive biology.

## SUMMARY

Cancer of the renal pelvis and ureter most frequently is a transitional cell carcinoma, as in carcinoma of the bladder. Because the biology of these urothelial cancers is considered to be identical, treatment recommendations have followed those for bladder cancer. At present, M-VAC is the mainstay of systemic chemotherapy for urothelial cancer; however, hematologic toxicity is significant and often results in reduced dosing. Thus, regimens with equal efficacy and less toxicity have been pursued, and several randomized trials are currently being evaluated. Insufficient data are available to define clearly subgroups of patients who will or will not benefit from adjuvant chemotherapy; many physicians opt for adjuvant treatment in the absence of randomized data because of the poor survival that results from tumor recurrence.

#### INTRODUCTION

Urinary bladder cancers represent a spectrum of neoplasms that can be grouped into three general categories: superficial, invasive, and metastatic. Each differs in clinical behavior, prognosis, and primary management. For treating superficial tumors, the aim is to prevent recurrences and progression to an incurable stage. For treating invasive disease, the issue becomes how to determine which tumors can be cured with single-modality therapies (e.g., surgery), which can be treated without surgical removal of the bladder, and which, by virtue of a high metastatic potential, require an integrated systemic approach to achieve cure. For treating metastatic disease, combination chemotherapy is the standard; yet, despite responses in more than 50% of cases, overall cure rates remain low. Recent progress with evolving chemotherapeutic regimens suggest that cure rates may improve in the future.

A unique aspect of bladder cancer treatment is that repeated surgical biopsy is an integral part of routine patient management, thus permitting molecular genetic studies of tumors from specific stages of the disease. The results of these studies suggest that bladder cancers develop and progress along at least two discrete pathways, which may account for differences in invasiveness and metastatic potential.<sup>1</sup> It may also explain why some tumors recur on the surface, without invasion, while others metastasize with minimal infiltration below the epithelial layers. These considerations, along with identifying several chemotherapeutic agents active in patients who have progressed on cisplatin-based combinations, have led to clinical trials seeking to define new standards of care. It is hoped that incorporating molecular genetic factors into the currently used staging systems will change the paradigm of treatment so that the probability of cure is optimized and the quality of life maintained.

#### EPIDEMIOLOGY

Bladder cancer is the fourth most common cancer in men and the seventh most common in women. More than 54,000 cases (in 29,500 men and 14,900 women) were diagnosed in 1999, and 12,500 individuals (8400 male and 4100 female) succumbed.<sup>2</sup> Bladder cancer, primarily a disease of men older than age 65, is rarely diagnosed before the age of 40. White men receive diagnoses twice as often as black men. Additionally, the diagnosis rate is higher in urban than in rural areas. Bladder cancer death rates declined substantially for both whites and blacks of both genders from 1973 to 1996, approximately 24% overall.<sup>3</sup> This decrease is likely to be the result of more cases being diagnosed at a noninvasive stage and more effective therapies.

Cigarette smoking is the most important risk factor, although work in the dye, rubber, or leather industries is also strongly associated with bladder cancer.<sup>4</sup> The latency period from initial exposure to the development of a urothelial tumor is a median of 18 years. Cigarette smoking is believed to contribute to upward of 50% of the cancers in men and 33% of the cancers in women.<sup>5</sup> Overall, smokers have a two- to fourfold higher relative risk of bladder cancer than nonsmokers. Smoking contributes to the field change of the urothelium, because the urothelium from individuals who “never smoked” shows atypia in only 4% of cases versus up to 50% in “smokers.”<sup>5</sup> Discontinuing smoking decreases risk, although a higher risk than nonsmokers remains for up to 10 years after smoking cessation. A high fluid intake is associated with a decreased incidence of bladder cancer in men, and lesser intake of daily fluids proportionally increases the risk of bladder cancer.<sup>6</sup>

Dietary components consumed in high quantities, such as fried meats and fats, are associated with bladder cancer. Vitamin A supplements appear to be protective.<sup>7</sup> Coffee consumption and artificial sweeteners confer little or no risk.<sup>8</sup> Several drugs (e.g., phenacetin) are implicated in the development of urothelial tumors, and cyclophosphamide, used as an oncolytic or immunosuppressive agent, can increase risk ninefold.<sup>9</sup>

Exposure to *Schistosoma haematobium*, a parasite found in many developing countries, is associated with an increased risk of both squamous and transitional cell carcinomas of the bladder.<sup>8</sup> A link between a history of urinary tract infection and squamous cell carcinoma of the urinary bladder has been shown,<sup>10</sup> particularly in paraplegics and those with bladder stones or indwelling Foley catheters. An association is not identified between infection and transitional cell tumors.

#### CLINICAL PRESENTATION AND DIAGNOSIS

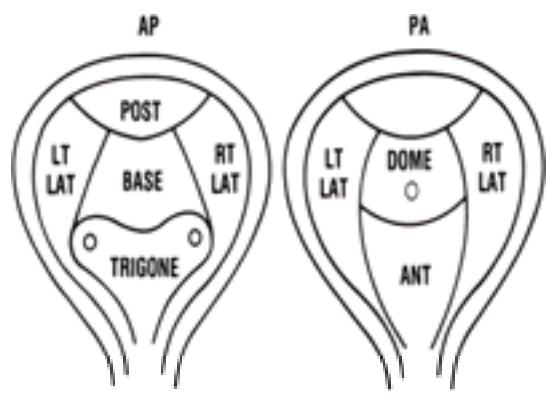

The frequencies of a specific symptom at diagnosis parallel the occurrence of the three clinical subtypes. At presentation, 75% of tumors are superficial, 20% are invasive, and up to 5% have *de novo* metastases. Although hematuria is the presenting sign in 80% to 90% of cases, urinary frequency, the result of irritative symptoms or a reduction in overall bladder capacity, is common. Depending on a lesion's location and depth of invasion, ureteral obstruction may develop, resulting in flank pain, discomfort, and overall reduced renal function. In rare cases, pain from a metastatic bone lesion or local progression of disease is the presenting sign.

Individuals older than 40 years of age who develop hematuria should have a urine specimen for cytology and undergo cystoscopy and imaging of the urinary tract with an intravenous pyelogram or computed tomographic (CT) scan. Screening of asymptomatic subjects for hematuria has not been shown to affect overall survival, although it does increase the probability of diagnosing the disease at an earlier stage.<sup>11</sup> Prospective studies are ongoing to assess the role of screening in high-risk populations. Other urine assays have been used to diagnose disease and to follow up patients, including flow cytometry, blood group antigens (i.e., Lewis X), cytokeratins, the bladder tumor–associated test, and tests for nuclear matrix protein, fibrin degradation product, and telomerase. None is sensitive or specific enough to replace cystoscopy and urine cytology.

#### CYSTOSCOPY

The cystoscopic evaluation forms the mainstay of diagnosis and staging. It begins with an examination under anesthesia to determine whether a palpable mass is present and, if present, whether it is movable. A cystoscope is then inserted into the bladder, and urine is obtained to determine the presence or absence of malignant

cells. The bladder is inspected visually, and a detailed notation of the size, number, location, and growth pattern (papillary or solid) of all lesions is recorded. The status of uninvolved mucosa is also noted. These data are recorded on a detailed bladder map for future reference ( Fig. 34.3-1). Biopsy specimens are taken from visible tumors or resected in stages to determine the histologic subtype and depth of invasion into the submucosa and muscle layers of the bladder. In cases where there is suspected or minimal tumor invasion, a repeat biopsy is advised to ensure that all visible tumor is completely resected and to detect the presence of muscle invasion.<sup>12</sup>

**FIGURE 34.3-1.** Bladder cancer map. AP, anteroposterior; ANT, anterior; LT LAT, left lateral; RT LAT, right lateral; PA, posteroanterior; post, posterior.

Selected biopsy specimens from the “apparently” normal transitional cell epithelium and prostatic urethra are also performed to assess whether a field change has occurred. The presence of carcinoma *in situ* (CIS) provides important information if organ preservation is being considered because it portends frequent tumor recurrences. For patients with a positive cytology and no apparent tumor within the bladder, selective catheterization of the ureters is required, with retrograde studies to evaluate for the presence of upper urinary tract disease.

The cystoscopic evaluation is also used after treatment to assess the response to therapeutic intervention. For an invasive tumor, cystoscopic biopsy is considered *clinica* (T) evaluation and does not constitute *pathologic* (P) staging because of the recognized inability of cystoscopy to predict with certainty residual disease in the bladder after treatment. The results of the posttreatment cystoscopy are, nevertheless, being used with increasing frequency to help to select the type of treatment required to eradicate disease within the bladder and to determine the feasibility of bladder preservation.

The decision whether to perform additional diagnostic studies is based on the results of the cystoscopy and the pathologic studies of the tumor. An intravenous pyelogram or CT scan is used to evaluate the upper urinary tracts. A CT scan or magnetic resonance imaging assists in distinguishing between a tumor that is confined to the bladder (stage T2) and one that extends into perivesical fat (stage T3) and documents whether regional lymph nodes are involved (N+). None of these can precisely predict the depth of invasion within the bladder wall.<sup>13</sup> The presence or absence of distal metastases can be documented with physical examination, CT, a chest radiogram, and a radionuclide bone scan. Because bladder tumors occur in elderly individuals, a general medical evaluation is essential to document significant comorbid conditions.

## **PATHOLOGY AND NATURAL HISTORY**

Transitional cell carcinomas (TCCs) constitute 90% to 95% of the urothelial tumors in the United States.<sup>14</sup> They occur anywhere along the urinary tract from the renal pelvis to the ureter, bladder, and proximal two-thirds of the urethra, at which point a squamous epithelium predominates. More than 90% of tumors originate in the urinary bladder and 8% in the renal pelvis; primary tumors of the ureter and urethra constitute the remaining 2% of tumors in these locations. Pure squamous cell tumors, defined by the presence of keratinization in the pathologic specimen, comprise 3%, adenocarcinomas 2%, and small cell carcinoma fewer than 1% of tumors that develop in this region. Tumors of mixed histology, consisting of transitional cell and squamous or adenocarcinomatous elements, can also be identified. These are considered variants of the transitional cell lesion, and they do not portend a worse prognosis. Adenocarcinomas may occur in the embryonal remnant of the urachus on the bladder dome or in the periurethral tissues, or they may assume a signet cell histology. In rare cases, a lymphoma or melanoma develops in the bladder.

Approximately 70% of newly diagnosed cases have exophytic papillary tumors that are confined to the mucosa (stage Ta) or invade the submucosa (stage T1). They tend to be friable, with a high propensity to bleed. These tumors may recur at the same part or in other portions of the bladder and at the same or at a more advanced stage and grade. They are generally managed endoscopically by complete resection. An estimated 50% to 70% of patients with a tumor confined to the mucosa have a recurrence or a new occurrence of a TCC within 5 years, whereas 5% to 20% of superficial tumors progress to a more advanced stage. An important area of research is determining which tumors will recur, which will progress to a higher stage, and which will metastasize.

## **GRADING**

Bladder tumors are classified as low-grade (G1) or high-grade (G2, G3).<sup>15</sup> Grading is more important for noninvasive tumors because almost all invasive neoplasms (T1 or greater) are high-grade. The epithelium has a thickness of less than five to seven layers, normal polarity of nuclei, and no pleomorphism. Papillary carcinomas of low grade are considered to be relatively benign tumors that closely resemble the normal urothelium. They have more than seven layers of urothelium, normal nuclear polarity in more than 95% of the tumor, and no or only slight pleomorphism. More important, they rarely progress to a higher stage.<sup>16</sup> High-grade papillary tumors show loss of polarization of the nuclei and moderate or prominent pleomorphism. Progression to higher-stage lesions is frequent. For invasive tumors, stage is the most important independent prognostic variable for progression and overall survival.

Primary CIS (Tis), without a concurrent exophytic tumor, constitutes 1% to 2% of newly detected cases of bladder cancer.<sup>16</sup> CIS is found in more than one-half the bladders with multiple papillary tumors, either adjacent to or involving mucosal sites remote from papillary lesions. CIS is, by definition, high-grade and believed to be a predominant precursor of invasive tumors.<sup>17</sup> Left untreated, CIS will develop invasive disease in 5 years in more than 50% of patients.

## **STAGING**

The most commonly used staging systems are the Jewett-Strong-Marshall and TNM (tumor-node-metastasis) systems.<sup>18,19</sup> They were developed from pathologic studies of cystectomy specimens in which the association between depth of invasion and clinical course was first identified. They are contrasted in Table 34.3-1 and Table 34.3-2. The major difference is that the TNM system provides for the two patterns of growth and clinical behavior of superficial lesions and delineates more clearly the extent of extravesical spread. Because of this, it is more widely used.

Depth of Invasion	Jewett System	Union Internationale Contre le Cancer
Limited to the mucosal surface	0	T <sub>0</sub>
	0	T <sub>is</sub> (carcinoma <i>in situ</i> )
Invasion of the lamina propria	A	T <sub>1</sub>
Invasion of the muscle (<50% of the depth)	B1	T <sub>2a</sub>
Invasion of the muscle (>50% of the depth)	B2	T <sub>2b</sub>
Perivesical fat	C	T <sub>3</sub>
Growth into adjacent structures (prostate, uterus, vagina, bowel) but still mobile	C	T <sub>4a</sub>
Tumor is fixed to the pelvic wall	C	T <sub>4b</sub>
Nodal metastases	D1	N <sub>+</sub>
Distant metastases	D2	M <sub>+</sub>

**TABLE 34.3-2.** TNM Staging System for Bladder Cancer

Ta lesions grow as exophytic lesions and tend to recur but generally do not invade. If a tumor invades the layer below the mucosa, the submucosa, or lamina propria, it is a T1 tumor. A breakpoint in both classifications is invasion into muscle, at which point surgical removal of the bladder is considered standard therapy ( [Table 34.3-3](#)). Once invasion into the muscle layer is documented, the risk of nodal and subsequent distant metastases increases. The TNM system divides muscle-infiltrating (T2) disease into superficial (T2a) or deep (T2b) invasion but confined within the bladder. In clinical practice, the accuracy of determining the degree of muscle infiltration is modest, at best. Even in experienced hands, the correlation between depth of invasion, based on the cystoscopic evaluation, and the final bladder removed by cystectomy is only 70%. As treatment outcomes are further evaluated, it is becoming apparent that the most important determination is whether the tumor is organ-confined (T2 or less) or non-organ-confined (T3 or greater).<sup>20</sup> The T3 category includes tumors that extend to the perivesical fat. In some cases, surgeons take specimens from deep in the bladder wall, rendering it possible for the pathologist to determine the boundary between muscle and perivesical fat. CT scans or magnetic resonance imaging may help to identify disease that has spread outside the bladder.

**TABLE 34.3-3.** Treatment Options for Muscle-Infiltrating Disease

The TNM system differentiates tumors extending into adjacent organs from those extending into perivesical fat. A tumor that grows into the prostate, vagina, uterus, or bowel is classified as T4a, and a tumor fixed to the abdominal wall, pelvic wall, or other organs is a T4b lesion. Urothelial tumors may also grow into the prostate, along the prostatic ducts—noninvasive lesions with a good prognosis when resected—or directly invade the prostatic stroma, which harbors a worse prognosis.<sup>21</sup> The TNM system categorizes nodal disease based on the number and size of involvement. It also accounts for metastases to specific sites. Once invasion outside the bladder<sup>20</sup> or nodal disease<sup>22</sup> is documented, outcomes without systemic therapy are poor, with overall survival rates ranging from 4% to 35% at 5 years ( [Table 34.3-4](#) and [Table 34.3-5](#)).<sup>20,22</sup> A similar bleak prognosis is also apparent for patients with metastases, whose median survival rates range from 6 to 9 months; few patients survive 5 years.

## PATHOGENESIS

The natural history of a urothelial tumor is recurrence. Recurrences may develop at any time, at the same or separate site of the urothelial tract, and at the same or a more advanced stage. This is termed *polychronotopism* and has led investigators to postulate that a field defect occurs in the urothelial tract, resulting in a genetically unstable urothelium that facilitates the continued development of new lesions. The observation of atypia in the urothelial lining of smokers is consistent with this view. An area of controversy is whether tumors that occur in separate sites in the urothelial tract are derived from the same clone or are polyclonal in origin. Reports by Sidransky et al.,<sup>23</sup> demonstrating the clonality of multiple bladder tumors from different sites, and by Miyao et al.,<sup>24</sup> showing concordant genetic alterations in asynchronous tumors from individual patients, suggest that disparate urothelial tumors are derived from the same neoplastic clone.

Studies of different stages and grades of bladder cancer have shown a higher frequency of genetic abnormalities in advanced-stage lesions. The changes are classified as primary chromosomal aberrations if they are associated with the development of the disease or as secondary if they are associated with progression to a more advanced stage.<sup>1</sup> These changes represent the activation of protooncogenes by point mutation, amplification, or translocation that results in a gain of function and the inactivation of tumor suppressor genes, primarily by allelic deletion and point mutation of the contralateral allele, which results in a "negative" event. In general, deletions of *17p* (the TP53 locus) and the *RE* gene locus are seen in patients with invasive disease, whereas aberrations of *9q* occur predominantly in superficial tumors.<sup>25</sup>

Several studies report associations between specific pathologic and molecular markers and prognosis.<sup>26</sup> More significantly, tumor markers are beginning to be incorporated into clinical practice. Caution is advised when interpreting the results of different studies because of the different sensitivities of the technique used, the specific stage of the tumor included, the number of patients, and the follow-up interval on which the conclusions are based. An example of the differences is provided by the reported results evaluating *p53* alterations. These have variably been assessed by immunohistochemical staining, single-strand conformational polymorphism analysis, and direct sequencing of different gene exons. With a panel of antibodies that recognize the mutated *p53* protein, nuclear overexpression correlated with grade, stage, vascular invasion, and the presence of nodal metastases. Multivariate analyses showed that *p53* mutation is associated with a higher frequency of progression to a more advanced stage and a higher rate of death from bladder cancer.<sup>27,28 and 29</sup> The status of *p53* is currently being used to stratify patients for risk of metastasis, probability of nonmetastasis, and response to specific chemotherapeutic regimens. Whether determinations of *p53* can provide more information than staging and grade for the choice between different treatment modalities remains to be investigated in comparative trials.

## TREATMENT

Treatment selection is based on the extent or stage of disease. For certain patients, one therapeutic modality is sufficient. For others, a combined-modality approach is required. For superficial tumors, cystoscopic resection with and without intravesical therapy is preferred. Once invasion into muscle is documented, the standard treatment is surgical removal of the bladder. After cystectomy, and depending on whether disease is documented outside the bladder, systemic therapies may be advised. Developing standards of care beyond single-modality approaches has been hampered by inconclusive clinical trials. Demonstrating the superiority of one treatment approach over another requires large numbers of patients and long follow-up to be clinically meaningful. Furthermore, the higher the morbidity of the "new" approach, the greater the reluctance to offer it to patients.

## SUPERFICIAL DISEASE

The standard initial treatment of superficial bladder tumors is a complete cystoscopic resection. The majority of patients develop new tumors over time, 30% of which progress to a higher stage. As a result, vigilant follow-up with cystoscopy, urine cytology, and repeat transurethral resections (TURs) as needed are performed every 3 to 6 months, at least for the first 5 years of follow-up. Depending on the number of lesions, the size, the depth of invasion, and the number of prior tumors in that individual, intravesical therapy may or may not be recommended. Intravesical treatment is rarely advised for the first Ta tumor that is low-grade, although it is recommended for high-grade Ta, Tis, and T1 lesions.

Intravesical therapies are used for two indications: therapeutic and adjuvant or prophylactic. The former refers to the clinical situation in which residual disease remains in the bladder despite an attempt at a complete endoscopic resection. This is relatively infrequent except in cases with CIS. Prophylactic or adjuvant therapy is applied when a patient has shown a repeated tendency to develop new lesions in the bladder. The recurrences may represent new papillary lesions, CIS, or a combination of both.

Intravesical instillations have been performed with chemotherapeutic agents, such as thiotepa, doxorubicin (Adriamycin), and mitomycin C; immunologic agents, such as bacille Calmette-Guérin (BCG); and cytokines, such as interferon and interleukin.<sup>30,31 and 32</sup> For all agents, the mechanism of action is debated. Although the rationale for instilling chemotherapeutic agents initially was a postulated direct toxic effect on the tumor cells, a nonspecific inflammatory reaction is also believed to be contributory. Side effects include the local toxicities based on the instillation itself and whether the drug is systemically absorbed. The latter depends partly on the size of the molecule, the pH at the time of instillation, and the timing of the instillation relative to the diagnostic and therapeutic cystoscopy. All intravesical treatments have some side effects in common, especially those related to bladder irritation, such as dysuria and frequency, but also other unique side effects specific to a particular drug, such as myelosuppression or contact dermatitis. BCG differs in one important aspect from the chemotherapeutic agents: A small proportion of patients develop a systemic "BCGosis" requiring treatment with tuberculostatic agents and steroids. Deaths have been reported. Allowing 2 to 3 weeks for healing after the endoscopic resection has been performed and before chemotherapy or BCG is administered reduces the chance of severe local or systemic toxicities.

Indications for intravesical instillations vary. Generally, the indications for adjuvant therapy include two or more tumor recurrences in a given year, the presence of diffuse Tis or multiple papillary tumors, or the identification of T1 disease that carries a high risk of stage progression. The risk of tumor recurrence and progression is associated with tumor type (Ta, T1, or Tis), tumor grade (low vs. high), length of follow-up (5 or more years), and treatment (TUR alone or TUR plus chemotherapy or BCG). The majority of papillomas and TaG1 tumors recur within 5 years, but they rarely invade or cause a cancer death. Recurrent tumors are treated with TUR or fulguration (as outpatient procedures) and are a low biologic risk. On the other hand, almost all high-grade (G3) Ta tumors recur within 2 to 3 years, 20% progress in stage within 5 years, and 30% to 40% progress by 10 years. All adjuvant treatments using thiotepa, doxorubicin, mitomycin C, or BCG decrease the probability of tumor recurrences over TUR alone. BCG has been shown to delay tumor progression to a more advanced stage, to decrease the need for cystectomy, and to improve survival.<sup>33,34 and 35</sup>

Tis is generally treated by a combination of endoscopic resection followed by the intravesical instillation of BCG.<sup>36</sup> This recommendation is based on the results of large-scale randomized comparisons showing its proven superiority relative to doxorubicin<sup>37</sup> and mitomycin C.<sup>38</sup> In the past, thiotepa was the most widely used agent, but it is now used less frequently because of limited efficacy and high frequency of myelosuppression. BCG is typically instilled weekly for 6 weeks. BCG eradicates Tis for more than 1 year in 70% of cases and prevents subsequent disease for 5 years in 60% of cases and for up to 10 years in 40% of cases.<sup>36</sup>

Treatment-predictive information is provided by follow-up evaluation after 3 and 6 months and whether the bladder has been rendered tumor free, both endoscopically and cytologically.<sup>35</sup> If it is not, some urologists recommend a repeat course of treatment. The maintenance role of BCG treatments has been debated. Some feel that regular treatment beyond the initial 6-week course further delays tumor recurrence and progression. Others believe that continued BCG not only increases the frequency of complications but fails to reduce tumor progression.<sup>39</sup> Patients who have recurrent or persistent tumors after one or two cycles of intravesical therapy are often considered for cystectomy.

TUR alone is generally sufficient for noninvasive papillary (Ta) tumors. In some patients, the disease does not recur and, if no disease is documented after several sequential 3-month evaluations, the follow-up can be restricted to a yearly examination. In other cases in which recurrences are documented, more frequent and longer follow-up is essential. In these cases, intravesical therapy has been shown to diminish both the probability of recurrences and the number of tumors documented at a given recurrence.<sup>40</sup> Because the probability of progression to a more advanced stage is low, however, no definitive benefit of delayed progression or improved survival has been shown. The decision to administer such therapy must be balanced by the adverse effects and potential benefit of therapy. Intravesical therapy is commonly recommended if the number of recurrent episodes during a 24-month period exceeds two<sup>41</sup> and if a large part of the urinary bladder wall is covered with tumors. Repeat cystoscopic examinations are generally advised at 3- to 6-month intervals, depending on the number of tumor recurrences, for the first 5 years, and annually thereafter in the absence of tumor recurrence.<sup>42</sup>

Were it possible to determine which tumors were destined to progress to an invasive stage, early cystectomy would be preferred. Currently, no single factor or combination of factors has been useful in guiding treatment selection for patients with superficial disease. Some surgeons suggest radical surgery in patients with

multiple tumors and frequent recurrences, especially if such tumors recur despite BCG therapy. Other agents undergoing clinical trials for BCG-refractory bladder tumors include gemcitabine, taxanes, broperimine, and valrubicine (AD 32).

Recurrences after intravesical treatment can develop anywhere that transitional epithelium exists, including the renal pelvis, ureters, and urethra. In fact, one consequence of the “successful” treatment of tumors in the bladder is an increase in the frequency of extravesical recurrences.<sup>43</sup> In patients with multifocal CIS, the risk of developing an upper tract tumor is 15% at 5 years, 25% at 10 years, and 33% with 15-year follow-up. Tumor involvement of the prostatic urethra and ducts may be detected in 10% to 15% of cases in 5 years and in 20% to 40% within 10 years. Patients with a positive cytology and no obvious tumor in the bladder need careful monitoring of the upper tracts.<sup>44</sup> Tumors of the upper tract are particularly difficult to manage, because contact between a topical therapeutic agent and the diseased urothelium is limited. The development of tumors in extravesical sites is cited as evidence of the “field change” theory of carcinogenesis. Selected tumors in the ureter or renal pelvis may be managed by ureteroscopic resection or, in some cases, by instilling BCG through the renal pelvis. Tumors of the prostatic urethra are frequently managed by cystectomy, particularly if a complete resection cannot be accomplished.

The prevalence of panurothelial tumor diathesis suggests that chemoprevention strategies will be needed as an adjunct to active therapy directed against the primary bladder tumors. Broperimine, an interferon inducer, and fenretinide (4-HPR), a synthetic retinoid, are being investigated as oral chemoprevention agents, but neither appears to be effective (National Cancer Institute and Bladder Cancer Italian Trial Group [BLINST], unpublished data, 1999).

## T1 DISEASE

The T1 tumor is an invasive (lamina propria) neoplasm. Virtually all are high-grade, and one-half the cases have associated Tis. Recurrence rates are 50% by 1 year, 80% by 3 years, and 90% within 5 years.<sup>45</sup> Considering progression, 50% of T1G3 cases develop invasive disease within 5 years; this number rises to 80% if associated Tis is in the pathologic specimen. Because of the high risk of progression, T1 tumors are generally treated with intravesical therapy. BCG reduces tumor recurrence in 50% of patients and reduces the progression rate to 15% at 5 years and 50% at 10 years. These rates mean that 50% of patients with T1 tumors will develop a muscle-invasive cancer in 10 years, despite the best available conservative therapy. Each present and recurrent T1 tumor has a 5% to 10% probability of distant metastasis. The survival rate is 70% at 5 years with BCG therapy and resembles that achieved after immediate radical cystectomy. On the other hand, patients who relapse with recurrent T1 tumors within 6 months to 1 year after an adequate trial of TUR and BCG (one or two courses) are best treated currently with cystectomy.<sup>46</sup>

## MUSCLE-INVADING TUMORS

Therapies for muscle-infiltrating disease can be divided into bladder-sparing and non-bladder-sparing (see [Table 34.3-3](#)). The standard treatment is surgical removal of the entire organ by radical cystectomy. In appropriately selected cases, an aggressive TUR may be adequate, although this is controversial.<sup>47</sup> In other cases, a resection is combined with radiation or chemotherapy. These combined-modality approaches are limited to selected cases. End points include time to recurrence, in either the primary or a distant site, disease-free status, and overall survival.

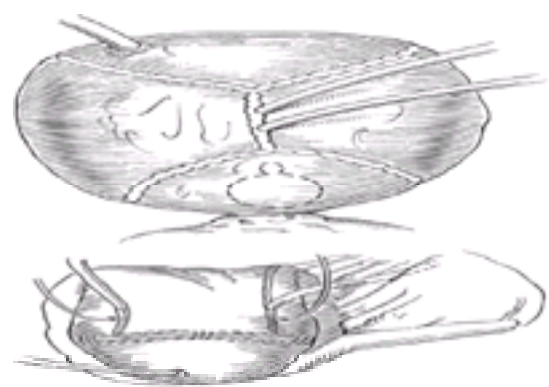

Radical cystectomy achieves the best local control of invasive bladder cancer. The exact indications vary between institutions. Most physicians recommend cystectomy for (1) muscle-invasive tumors unsuitable for segmental resection, (2) low-stage tumors unsuitable for conservative management (i.e., because of multicentric and frequent recurrences resistant to intravesical instillations), (3) high-grade tumors (T1G3) associated with Tis, or (4) bladder symptoms, such as frequency or hemorrhage, rendering the patient a “bladder cripple.” Survival distributions are expected to vary for patients who undergo treatment for these indications.

## SURGICAL APPROACHES

Radical cystectomy in men involves the *en bloc* removal of the bladder, prostate, seminal vesicles, and proximal urethra, with a wide margin of pelvic adipose tissue and peritoneum. Loss of sexual function is often a consequence of the operation. In women, the procedure involves an anterior exenteration to remove the bladder, urethra, uterus, fallopian tubes, ovaries, anterior vaginal wall, and surrounding fascia. Pelvic lymph nodes are also removed.

Urinary flow is directed through a conduit diversion or a continent reservoir, a bladder substitute. In the standard ileal conduit, urine drains directly from the ureters through a segment of ileum to the skin surface, where it is collected. No internal reservoir is created. A few patients with this form of diversion develop hypochloremic acidosis, hyperkalemia, hyponatremia, and uremia. Ureteral obstruction and urinary tract infection are also relatively common.

Continent reservoirs are becoming increasingly popular and include external continent stomas, which the patient self-catheterizes at regular intervals, and internal, orthotopic neobladders that can be fashioned in both men and women. All involve the creation of a low-pressure reservoir from a detubularized segment of bowel that is then anastomosed to either abdominal wall (Indiana pouch) or the urethra (neobladder) ([Fig. 34.3-2](#)).<sup>48,49</sup> When an anastomosis to the urethra is created, primarily in men without urethral disease, the patient can void in the natural position. Complication rates are acceptable and most patients achieve urinary continence. An indication for urethrectomy precludes the creation of a urethral anastomosis, such as documented CIS or exophytic tumor in the urethra but also tumors that involve the bladder neck, rendering spread to the urethra likely. In addition, elderly or infirm patients or those with locally extensive tumors who are at high risk of local recurrence are better served with an ileal conduit. An ileal stoma has fewer complications than continent diversions and is less demanding on the patient for daily care.

**FIGURE 34.3-2.** The ileoneobladder (A) and the Indiana reservoir (B).

Medical clearance before cystectomy is essential and includes optimizing cardiac medication and nutritional status. Complications of the operation include those typical for major surgery and those specific to the cystectomy. Among the former are adverse reactions to the agents used during anesthesia, blood loss and complications secondary to blood transfusions, pulmonary depression, myocardial damage secondary to prolonged anesthesia time or blood loss, and wound infection. Complications specific to cystectomy include rectal perforation and pelvic abscesses. Early and late complications associated with the urinary diversion procedure include intestinal obstruction, acute pyelonephritis, ureteral obstruction, stomal stenosis, intestinal fistula, renal calculus, and ureteroileal urinary leakage. Outcomes are usually reported on the basis of 5-year survival rates. As [Table 34.3-4](#) and [Table 34.3-5](#) show,<sup>20,22</sup> survival rates vary inversely with depth of invasion and lymph node status. In most cases, patients succumb to distant disease, believed to be the result of the continued growth of micrometastases present at the time of surgery. This, in turn, has led to the integration of systemic chemotherapy to manage these tumors. Survival is also improved and complications are minimized in patients who undergo cystectomy by experienced surgeons in centers that treat a high volume of bladder cancer.<sup>50</sup>

## RADIOTHERAPY AS DEFINITIVE TREATMENT

In some countries, external-beam radiotherapy is considered standard but not in the United States. It is also recommended for patients deemed unfit for cystectomy, based on either comorbid conditions or disease extent. In most series, despite negative selection, results are inferior to those observed with radical surgery. These

results are partially because of the difficulty of rendering the bladder tumor-free by external-beam radiation alone and the continued risk for developing new tumors in the retained bladder.

In most cases, treatments are delivered in five daily fractions a week, ranging from 2.0 to 2.5 Gy to a total treatment dosage of 55 to 65 Gy without interruptions. In designing the radiation fields to treat a patient with bladder cancer, the target is best defined by information from the planning cystogram, the CT scan, the cystoscopic and bimanual examinations, and having the bladder empty to assist setup reproducibility and adequate coverage of the tumor at each treatment. Even with these efforts, a prospective CT study from Manchester reported significant movement in the bladder target volume, with possible underdosing of the tumor in one-third of the evaluated patients.<sup>51</sup> Thus, care must be taken to ensure that the target volume is well defined and adequate margins are included, especially posteriorly.<sup>52,53</sup>

The initial complete response (CR) rate (T0), based on clinical restaging with a cystoscopy and biopsy after conventional radiation, is 40% to 52% ( [Table 34.3-6](#) ).<sup>54,55,56,57</sup> and <sup>58</sup> For patients who do not respond completely or whose disease progresses locally without metastases and who are medically fit, a salvage cystectomy is performed. When radiation is used in patients with T2 to T4 disease, the probability of keeping the bladder free of disease at 5 years ranges from 35% to 45%; overall survival is from 23% to 40%. Toxicities are classified as acute or chronic, with radiation delivery to the rectum and bladder being dose-limiting, and include symptoms of an irritated bowel and bladder, inflammation of the skin, and fatigue. A persistent proctitis, with bleeding and secretion of mucus, is rare but does occur, and bowel obstruction may be severe enough to require a colostomy. A markedly reduced bladder capacity resulting from fibrosis may render a cystectomy or urinary diversion necessary. Sexual function can also be impaired. Occurrence of secondary tumors in the urinary bladder or the surrounding tissue is a potential late complication. Radiation techniques have evolved with surgical techniques, encouraging the therapeutic index to improve in both increased radiation dosage to tumor and decreased exposure of normal tissue with three-dimensional treatment planning.

Series	Patients	Stage	5Y Survival Rate (%)	5Y Rate of Local Control in the Bladder (%)

## EVOLVING STANDARDS OF CARE FOR MUSCLE-INVASIVE DISEASE: COMBINED-MODALITY APPROACHES

Developing treatment guidelines for tumors of a specific stage is easier than applying guidelines to an individual patient. For example, although the standard treatment of an invasive bladder tumor is radical cystectomy, numerous reports in the literature of selected series of patients treated by TUR alone, partial cystectomy, external-beam radiotherapy, chemotherapy, or combinations of these appear to have comparable survival rates. Given the choice, most patients prefer a bladder-sparing approach, yet cumulative results suggest that some of these alternatives produce inferior survival rates as compared to radical surgery if salvage cystectomy for local recurrence is not done promptly. Refining the choice of treatment to optimize quality of life without compromising cure is difficult, because preservation of a tumor-free bladder still has some risk of the subsequent development of a superficial or an invasive tumor.

In the 1970s and 1980s, four randomized phase III trials compared preoperative irradiation and immediate cystectomy to external-beam radiotherapy with cystectomy deferred for recurrence. Three of the four trials (involving a total of 442 patients from the United Kingdom, Denmark, and the United States National Bladder Cancer Group) found no significant difference in survival.<sup>59,60</sup> and <sup>61</sup> However, a trial of 67 patients from the M. D. Anderson Cancer Center (MDACC) is the only phase III study, to our knowledge, that shows a statistically significant survival advantage to immediate versus deferred cystectomy.<sup>62</sup> Combined-modality treatment with bladder preservation as an alternative to cystectomy is still investigational, and we recommend that such therapy be administered by dedicated multimodality teams. This treatment may be considered a reasonable alternative, if careful cystoscopic surveillance is conducted, in patients who are deemed unfit for cystectomy and for those definitely seeking an alternative to radical cystectomy.

Strong inferential data also suggest improved outcomes for which randomized trials are not truly definitive. The role of postoperative or adjuvant chemotherapy is one such scenario. Difficulties are encountered in interpreting both negative and positive outcomes. In a negative-outcomes trial designed in 1980 with the best available therapy at the time, for example, only 19% of patients enrolled actually received full doses of the planned chemotherapy.<sup>63</sup> Not administering treatment virtually guarantees failure. Furthermore, instead of being representative of the population of bladder cancer patients as a whole, many trials enroll only highly selected patients. This situation is illustrated in a study in which only 17 of 41 randomly selected patients completed therapy in a specific treatment program; these patients were derived from 453 patients with invasive disease seen at the treating institution over the same interval.<sup>64</sup> Extrapolating these results to all patients can be misleading. If a treatment is associated with significant morbidity or may increase mortality, the question becomes: What is the level of benefit a physician requires to adopt the approach as a standard? Considering the difficulties encountered in completing clinical trials in this disease, a more effective developmental strategy might be conducting trials in populations who have specific high-risk factors for developing metastatic disease and in whom treatment effects can be discerned rapidly.

### Preoperative Radiotherapy

In the 1970s, moderate-dose preoperative radiation, either 20 Gy by accelerated fractionation or 40 to 50 Gy with conventional fractionation, was the standard. The results showed that radiotherapy alone could eradicate disease in the resected specimen and the regional lymph nodes in a small but definite proportion of patients.<sup>65,66</sup> The technique was largely abandoned when no survival benefit was observed in randomized comparisons.<sup>67</sup>

A recent trial at the MDACC identified a clinical subset for whom radiotherapy might be beneficial. The trial included 135 patients with clinical stage T3 tumors who were treated by either preoperative radiotherapy and cystectomy (92 patients) or cystectomy without irradiation (43 patients), using modern-day surgical techniques and adjunctive multiagent chemotherapy.<sup>68</sup> Although no survival benefit was observed, the results showed a significant decrease in pelvic recurrence rates from 28% to 9% at 5 years for patients with T3 disease who received radiation. No difference was observed for patients with T2 disease. Because the true rate of pelvic recurrences after radical surgery is not known, as disease in most patients who experience relapse systemically is not restaged locally, the study raises the question whether precystectomy radiation might be an option for patients who present with extravesical tumors. With drawbacks including the potential effect on the ability to create internal urinary reservoirs with irradiated bowel, the question requires prospective evaluation.

### Postoperative Radiotherapy

When a positive surgical margin is documented after cystectomy, local recurrence rates are high with or without chemotherapy. However, no randomized trial has evaluated the use of postoperative radiation for patients with transitional cell tumors. A Radiation Therapy Oncology Group (RTOG) phase II trial of postoperative irradiation reported the incidence of small bowel obstruction or fistula in 30% of patients.<sup>69</sup> Recently, investigators using multivariate analysis in a retrospective study of 92 patients from Milan reported that patients without evidence of nodal metastases receiving 50.4 Gy after radical cystectomy had significantly improved cancer-specific and disease-specific survival rates.<sup>70</sup> With a median follow-up of 36 months, one of 32 irradiated patients has required reoperation for bowel toxicity. While encouraging, this result requires longer follow-up to be considered for further prospective evaluation. One randomized trial evaluating postoperative radiotherapy has been completed in Egypt for patients with squamous cell carcinomas.<sup>71</sup> In this trial, the rate of pelvic recurrences was reduced from 50% to 10% in the irradiated patients. It must be noted that squamous cell tumors seen in the Middle East tend to recur locally and have a low metastatic rate as compared to the transitional cell tumors that occur in North America, which have a high metastatic rate.

**Deferred Cystectomy: Treatment with External-Beam Radiation and Salvage Cystectomy**

Four randomized trials have addressed the question of whether a regimen of preoperative radiation and immediate cystectomy compares with one of external-beam radiotherapy followed by a salvage cystectomy for radiation failures. A small trial with 67 patients showed a difference in survival at 5 years, <sup>62</sup> and a second showed a lower frequency of pelvic recurrence but no survival difference with combined modality therapy. <sup>59</sup> Based on the sample sizes, a 25% difference, either negative or positive, could not be excluded (Table 34.3-7; S. D. Cutler, personal communication, 1983).<sup>59,60,62</sup> Nevertheless, the trials do suggest that deferring a cystectomy until local progression is documented does not appear to affect adversely the rate of metastases or to compromise overall survival.

Site	Treatment	No. of Patients	5Y	
			Survival Rate (%)	Distant Recurrence (%)
M. D. Anderson Cancer Center <sup>a</sup>	30 Gy + cystectomy	35	23	46
	40 Gy + salvage cystectomy	32	22	—

**TABLE 34.3-7.** Randomized Trials of Irradiation Plus Cystectomy versus Radiation and Deferred (Salvage) Cystectomy

**INTEGRATING SYSTEMIC CHEMOTHERAPY**

The major cause of death in patients with invasive bladder cancer is metastatic disease. In most cases, the course of tumor relapse supports the concept that micrometastases are present at the time of initial therapy. The primary role for chemotherapy in the perioperative setting is to increase survival. Additionally, a substantial number of studies address the use of chemotherapy alone and concurrent with radiotherapy to preserve the native bladder. Specific considerations in evaluating chemotherapy's role in patients presenting with invasive disease include the activity of the various combinations of multiagent therapy—as judged by the proportion of patients with known metabolic diseases who achieve complete remissions and are ultimately cured—and the number of patients needed to prove the benefit of currently available therapies. Reviewing the activity of chemotherapy in metastatic disease provides insight into the studies exploring perioperative chemotherapy.

**Chemotherapy**

Urothelial cancer is a chemotherapy-sensitive neoplasm. A broad number of single agents with different mechanisms of action are effective (Table 34.3-8).<sup>61,72,73,74,75,76,77</sup> and <sup>78</sup> Complete responses using older agents are rare; most produce partial responses, with response durations of approximately 3 to 4 months. Recently, several agents were identified as active in phase I and II studies, including docetaxel, paclitaxel, gemcitabine, piritrexim, and ifosfamide. Observations distinguishing these new, active agents from older drugs are moderate activity as both first- and second-line therapy <sup>79,80</sup>; favorable toxicity profiles<sup>73,76</sup>; drug metabolism independent of renal excretion<sup>61</sup>; and CR in metastatic disease to a single agent.<sup>73,76</sup>

Agent	No. of Patients	Response (%)	95% Confidence Intervals
Cisplatin	522	24	20-28
Carboplatin	327	14	10-18
Methotrexate	295	29	24-34
Doxorubicin	274	17	13-22
Vinblastine	38	16	4-28
Cyclophosphamide	98	31	23-40
5-Fluorouracil	141	17	11-25
Mitomycin C	42	13	2-22
Ifosfamide	101	28	19-37
Docetaxel	29	31	17-50
Paclitaxel	35	46	28-65
Gemcitabine	112	22	15-30

Note: Data are compiled irrespective of trial design (i.e., phase II or phase III dose and schedule).  
(Data compiled from refs. 61 and 72-78.)

**TABLE 34.3-8.** Cumulative Results with Single-Agent Chemotherapy Used in Metastatic or Unresectable Disease

**Combination Chemotherapy: Randomized Trial Results**

Clinical outcomes (i.e., response and survival) are better for multiagent therapy than those observed with single-agent treatment in advanced TCC. The regimens most extensively studied in the 1980s were cisplatin, cyclophosphamide, and Adriamycin (CISCA); cisplatin, methotrexate, and vinblastine (CMV); and methotrexate, vinblastine, Adriamycin, and cisplatin (M-VAC; Table 34.3-9).<sup>74,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98,99,100,101,102,103,104</sup> and <sup>105</sup> These regimens demonstrate strikingly similar CR and overall response proportions in 20% to 22% and 50% to 60% of patients, respectively. The comparable efficacy and toxicity of the various regimens were discerned by randomized trial results. The CMV combination was superior to methotrexate and vinblastine without cisplatin; CMV was associated with significantly longer progression-free survival (4.5 months vs. 2.5 months) and 1-year survival (28% vs. 16%). <sup>83</sup> M-VAC was superior to single-agent cisplatin in both response and survival.<sup>84</sup> In the only direct comparison of cisplatin-based combinations, M-VAC was superior to CISCA. <sup>85</sup> Despite the popularity of the CMV regimen, median survival in one randomized trial was only 7 months; CMV has not been directly compared with M-VAC. It is concluded from these studies that cisplatin-based therapy should be the primary consideration for all patients requiring chemotherapy, and that M-VAC should be the regimen of choice.

Phase	Regimen	No. of Patients	Response (%)		Median Survival (months)	Comments
			CR	OR		
Phase III	CISCA	100	20	50	16	Superior to single-agent cisplatin
	CMV	100	22	50	28	Superior to methotrexate and vinblastine
	M-VAC	100	22	50	28	Superior to single-agent cisplatin
Phase II	CISCA	100	20	50	16	Superior to single-agent cisplatin
	CMV	100	22	50	28	Superior to methotrexate and vinblastine
	M-VAC	100	22	50	28	Superior to single-agent cisplatin

**TABLE 34.3-9.** Cisplatin - and Carboplatin-Containing Regimens Used to Treat Urothelial Carcinoma

Undermining the favorable response data for M-VAC in advanced TCC are the toxicity of the regimen and the disappointing long-term survival. Approximately 20% to 30% of patients develop neutropenia and fever, and 10% to 20% experience mucositis.<sup>84</sup> Diminished renal function, a decrease in auditory acuity, and peripheral neuropathy may also be seen. Death as a complication of M-VAC therapy occurs in 3% to 4% of patients.<sup>81,84</sup> Despite promising overall response proportions, the median survival for patients receiving M-VAC is consistently reported to be approximately 1 year,<sup>81,84,85</sup> and follow-up of the intergroup trial reported that only 3.7% of M-VAC patients remained continuously relapse-free at 6 years.<sup>106</sup>

### **Impact of Pretreatment Prognostic Factors and Postchemotherapy Surgery**

Several analyses demonstrated that pretreatment prognostic features affect the outcome of patients treated with M-VAC chemotherapy for metastatic TCC.<sup>84,106,107</sup> Prognostic factors predicting poor response and survival are bone or liver metastases (determined either by radiographic abnormality or by an elevated baseline alkaline phosphatase) and poor performance status. The intergroup study by Loehrer et al.<sup>84</sup> reported a median survival of 18.2 months for patients with the most favorable combination of prognostic features, compared with only 4.4 months for patients with the least favorable combination; none of the patients with liver or bone metastasis and only one patient with Karnofsky performance score (KPS) of less than 80% survived for 6 years.<sup>106</sup> The impact of prognostic features on survival was further emphasized in an analysis of more than 200 patients with metastatic or unresectable disease treated with M-VAC in Memorial Sloan-Kettering Cancer Center (MSKCC) phase I and II trials. The median survival was 14.8 months at a median follow-up of 40 months, and 5-year survival was 17%; at the time of the report, 19 of the 203 patients (9%) were alive. Three strata with distinctly different long-term survival rates were developed using the presence of any visceral metastasis and a KPS of less than 80.<sup>108</sup> No patient with both a poor KPS and visceral metastases experienced long-term survival, in contrast to an 11% 5-year survival in patients with either a poor KPS or visceral disease and a 33% likelihood of 5-year survival in patients with none of these poor-risk features.

Several studies show that postchemotherapy resection of persistent viable cancer in selected patients after M-VAC and CMV chemotherapy for unresectable or metastatic disease enhances long-term survival in patients who would have otherwise succumbed to their disease.<sup>109,110</sup> and <sup>111</sup> Criteria to select the optimal candidates are not uniform. However, retrospective analysis from MSKCC suggests that benefit is greatest in patients who have had a major response to chemotherapy and have persistent disease restricted to the primary lesion or a single site of metastatic disease in a lymph node or lung.<sup>111</sup>

### **Dose-Intensity Studies**

One strategy for improving therapeutic response is to increase drug delivery (or dose intensity in milligrams per square meter per week). This approach appeared promising because of a dose-response relationship suggested for cisplatin and doxorubicin and evidence of benefit in patients failing standard-dose therapy when hematopoietic growth factors were given to increase drug dose in the salvage setting.<sup>112</sup> Trials have reported dose-intensive therapy with M-VAC using either recombinant human granulocyte-macrophage colony-stimulating factor or human granulocyte colony-stimulating factor.<sup>113,114,115</sup> and <sup>116</sup> These studies demonstrated that it is possible to increase drug delivery by as much as 60% over standard-dose M-VAC either by increasing the doses of the individual agents or decreasing the cycling intervals (or both). Toxicities seen with the dose-intense regimens range from side effects that resemble standard-dose M-VAC to substantially increased toxicity and an increased toxic death rate.<sup>113,116</sup> Despite more intensive chemotherapy, the CR proportions for these studies still approximate 20%, suggesting no meaningful impact on survival. A randomized trial in the European Organization for Research and Treatment of Cancer (EORTC) is evaluating whether dose-intense M-VAC improves survival over standard-dose therapy.

**NEW CHEMOTHERAPEUTIC REGIMENS.** Developing new agents and combining agents is necessary if improvement in long-term survival or reduction of chemotherapy-associated toxicity (or both) is to be achieved. In combination chemotherapy trials, several cytotoxic agents introduced in this decade are undergoing evaluation for treating urothelial tumors. The most extensively studied agents are gemcitabine, a deoxycytidine analog with structural similarities to cytarabine, and the taxanes: paclitaxel and docetaxel.

Most combination regimens include a platinum analog, either cisplatin or carboplatin, in part because of the reported complementary or synergistic actions of these new agents with platinum analogs. The single-agent activity of carboplatin in urothelial cancer appears less than that observed with cisplatin (see [Table 34.3-8](#)).<sup>61,72,73,74,75,76,77</sup> and <sup>78</sup> Controversy exists as to whether the efficacy of carboplatin combinations compares favorably with cisplatin combinations. A small, randomized phase II trial compared M-VAC with the carboplatin-based regimen of methotrexate, carboplatin, and vinblastine.<sup>117</sup> Relative to M-VAC, the carboplatin-containing regimen produced a lower response proportion (52% vs. 39%) and shorter median survival (16 vs. 9 months). Criticisms of the trial included the phase II nature of the study (i.e., a small number of patients) and the lack of doxorubicin in the carboplatin arm.

Cisplatin combinations are associated with greater renal, neurologic, and auditory toxicity; they are more difficult to administer to patients who have renal impairment or other medical comorbidities. In contrast, carboplatin is not only more feasible in the patient with impaired renal function or medical comorbidities, it is more easily administered in the outpatient setting. Although carboplatin has greater myelosuppression, this toxicity is easily managed by adjusting the dose according to the patient's creatinine clearance to provide a predetermined area under the plasma concentration–time curve (AUC) of the drug. The controversy surrounding the efficacy of carboplatin- versus cisplatin-containing therapy in phase II trials is being addressed by ongoing and planned randomized phase III trials.

**NEW TWO- AND THREE-DRUG COMBINATIONS AS FIRST-LINE THERAPY.** The combinations of either paclitaxel (42% to 55% single-agent activity)<sup>61,76</sup> or docetaxel (31% activity)<sup>78,118</sup> with cisplatin (at 70 to 75 mg/m<sup>2</sup>/course) have been evaluated in four phase II trials.<sup>86,87,88</sup> and <sup>89</sup> Three trials evaluating paclitaxel at 135 to 175 mg/m<sup>2</sup> over 3 hours in combination with cisplatin produced overall response rates ranging from 62% to 72% and CR rates ranging from 10% to 34%.<sup>86,87</sup> and <sup>88</sup> Responses were predominantly in lymph node and lung metastases; however, some patients with liver or adrenal metastases also responded.<sup>87</sup> A median survival of 13 months was reported in one of the trials.<sup>86</sup> Myelosuppression and neurotoxicity were the most common toxicities. This two-drug combination is active, generally well tolerated, and can be given in the outpatient setting. Docetaxel (75 mg/m<sup>2</sup>) and cisplatin had a major response in 60% of patients; 7 of 25 (28%) patients achieved CR, with a median survival rate of 13.6 months.<sup>89</sup> The most predominant toxicity was granulocytopenia, but fluid retention, neuropathy, and mucositis were also observed. No plans exist to compare further either the paclitaxel-cisplatin or the docetaxel-cisplatin doublet to standard therapy.

The paclitaxel-carboplatin doublet has been evaluated in numerous phase II trials. The initial phase I–phase II trial exploring paclitaxel doses of 150 to 225 mg/m<sup>2</sup> in a 3-hour infusion plus carboplatin at an AUC of 6 every 3 weeks reported an overall response rate of 51%.<sup>9c</sup> Trials 90 through 97 of more than 200 patients treated with paclitaxel (150 to 225 mg/m<sup>2</sup>) and carboplatin (AUC of 5 to 6) have provided several important observations. The regimen is well tolerated; myelosuppression is the most common toxicity, but granulocytopenic fever and cycling delays for hematologic toxicity are uncommon. Neurotoxicity is commonly observed but is not severe. Response rates vary, ranging from 14% to 65%, with CR rates ranging from 0% to 40%. Efficacy is highest among patients with lymph node metastases, but patients with lung and liver metastases also respond. No clear dose-response correlations exist for either paclitaxel or carboplatin. Mature results are not available for all studies, but the survival rate ranges from 8.5 to 9.5 months in the three trials reporting survival data.<sup>95,96</sup> and <sup>97</sup> It is as yet unclear whether this doublet has survival inferior to the approximately 1-year survival seen with M-VAC or that the reported phase II results are affected by pretreatment prognostic factors,<sup>88</sup> the small number of patients resulting in wide confidence intervals of efficacy parameters, or the inclusion of previously treated patients.<sup>95,96</sup> and <sup>97</sup>

Gemcitabine (single-agent activity of 22% to 28%)<sup>73,74</sup> and <sup>75,79</sup> has been examined in combination with cisplatin. Von der Maase et al.<sup>98</sup> reported on 37 assessable patients using a weekly regimen of both gemcitabine and cisplatin. Although the response rate was 41%, toxicity was severe, with granulocytopenia of at least grade 3 in 46% and thrombocytopenia of at least grade 3 in 71% of patients. The schedule of gemcitabine at 1000 mg/m<sup>2</sup> on days 1, 8, and 15 and cisplatin on day 1 was explored in two separate trials conducted in the United States and Canada.<sup>99,100</sup> Kaufman et al.<sup>99</sup> explored this schedule with an initial cisplatin dose of 100 mg/m<sup>2</sup>. Toxicity was excessive, so the dose of cisplatin was reduced to 75 mg/m<sup>2</sup>, resulting in better patient tolerance. The overall response proportion in 38 assessable patients was 59%. Moore et al.<sup>100</sup> reported a 57% overall response rate with a 21% CR proportion using the same dose and schedule of gemcitabine and a cisplatin dose of 70 mg/m<sup>2</sup>. This regimen is well tolerated, with predominantly hematologic toxicity and a reported median survival of 14 months. The gemcitabine-carboplatin combination is also active, with a 68% overall response proportion.<sup>101</sup>

The three-drug combination of ifosfamide, paclitaxel (Taxol), and cisplatin (platinum) (ITP) recycled every 4 weeks was reported by MSKCC investigators to be effective and tolerable in previously untreated patients with advanced TCC.<sup>102,103</sup> Thirty of 44 (68%) assessable patients (95% confidence interval, 52% to 81%) demonstrated a major response (10 complete [23%], 20 partial [45%]), with durations of response ranging from 4 to 36 months. At a median follow-up of 28 months, the median survival was 20 months.<sup>103</sup> Eleven (25%) patients are disease-free. The median survival of 20 months in this trial is the best reported result for unresectable or metastatic TCC patients receiving chemotherapy and is greater than previously observed experiences with M-VAC (median survival, 12 to 13

months).<sup>81</sup> The possibility exists that adding ifosfamide to a cisplatin-based combination may enhance survival; alternatively, the improved survival may be a consequence of favorable pretreatment prognostic factors and aggressive postchemotherapy surgery.

The combinations of gemcitabine, paclitaxel, and either cisplatin or carboplatin have been reported in two separate trials.<sup>104,105</sup> The cisplatin-containing triplet, reported for 29 assessable patients, demonstrated a 79% response proportion.<sup>104</sup> Myelosuppression and asthenia were the predominant toxicities. Investigators at Wayne State University explored the paclitaxel-gemcitabine-carboplatin regimen, building on prior experience with the paclitaxel-carboplatin regimen. In 19 assessable patients, 11 (58%) had a major response.<sup>105</sup>

Tu et al.<sup>119</sup> evaluated paclitaxel, cisplatin, and methotrexate every 3 weeks in 25 previously treated patients. Partial responses lasting from 2 to more than 9 months were achieved in ten patients (40%), including three of seven patients with liver metastases. The primary toxicity was hematologic, with 9 of 25 patients experiencing severe neutropenia, resulting in six episodes of neutropenic fever requiring hospitalization. Severe thrombocytopenia, defined as grade 3 or greater, occurred in 8 of 25 patients. Meyers et al.<sup>120</sup> evaluated the triplet of paclitaxel-carboplatin-methotrexate in 23 assessable patients. Adjunctive care included leucovorin and granulocyte colony-stimulating factor (G-CSF). Fourteen of 23 patients (61%) responded, including four complete responses, resulting in a median survival of 16 months. The primary toxicities were neutropenia and neurotoxicity. Leucovorin was subsequently eliminated from the regimen, and reduction of the carboplatin dose to AUC 5 allowed deletion of G-CSF.<sup>121</sup>

Gallium nitrate as second-line therapy sponsored first-line combinations. The initial report of the three-drug regimen of vinblastine, ifosfamide, and gallium nitrate had a 67% major response rate.<sup>122</sup> Activity was confirmed in the Eastern Cooperative Oncology Group (ECOG) trial, with 44% of patients responding.<sup>123</sup> Toxicity was substantial; ocular blindness, arrhythmias, and myelosuppression were reported. A separate randomized phase II study examined the efficacy of gallium nitrate plus fluorouracil versus dose-intense M-VAC, finding only marginal activity for the gallium combination (12% major response proportion).<sup>124</sup> The toxicity profile and the cost of administering gallium nitrate on a 5-day inpatient schedule limit further study. Seven of 15 (47%) patients obtained a major response to the combination of paclitaxel, vinblastine, and cisplatin.<sup>125</sup> Calvo et al.<sup>126</sup> evaluated the paclitaxel-cisplatin-fluorouracil triplet in both chemotherapy-naïve and previously treated patients. Among 12 patients, eight partial (67%) responses were observed, for an overall response rate of 75%. Grade 3 or 4 toxicity included neutropenia, thrombocytopenia, mucositis, diarrhea and vomiting, and paralytic ileus.

**SECOND-LINE THERAPY AND FIRST-LINE REGIMENS WITHOUT PLATINUM ANALOGS.** Regimens devoid of a platinum analog have not been extensively studied. Sweeney et al.<sup>80</sup> reported the combination of ifosfamide, 1000 mg/m<sup>2</sup> days 1 to 4, plus paclitaxel, 135 mg/m<sup>2</sup> by 24-hour infusion on day 4 of a 3-week cycle, using G-CSF support. Twenty-six patients were evaluable for response: Two of 13 patients (15%) treated in a second-line setting responded with CR, as did 4 (1 CR, 3 partial responses) of 13 (31%) previously untreated patients. The authors concluded that ifosfamide did not add to paclitaxel activity as first-line therapy and that paclitaxel did not increase the second-line activity of ifosfamide. The ECOG is currently exploring the combination of docetaxel and gemcitabine in chemotherapy-naïve patients, and the Hoosier Oncology Group is evaluating the combination of paclitaxel and gemcitabine.

Limited experience exists for the paclitaxel-carboplatin combination in patients with prior therapy or preexisting renal impairment. Otto et al.<sup>127</sup> performed a phase II trial of this doublet in combination with an antimotility agent (acellular pertussis vaccine) in 18 patients with cisplatin- and methotrexate-resistant metastatic cancer; 4 (22%) patients responded, including 2 CR (11%). It is implied from these studies that multiple-agent regimens offer no advantage over single-agent therapy in patients eligible for second-line therapy.

#### **Randomized Trials: Developing a New Standard of Chemotherapy for Advanced Disease**

Initiatives to develop a new standard of therapy with greater efficacy, better tolerance, or both are essential to improve conventional therapy. Randomized comparison to M-VAC is a critical step in this process, and two randomized comparisons to M-VAC recently have been reported. Preliminary data for improved drug delivery with dose-intense M-VAC prompted a large, prospective trial conducted by the EORTC that compares dose-intense M-VAC with conventional M-VAC to evaluate response and survival differences. A preliminary analysis demonstrated that the response rate was slightly higher in the high-dose M-VAC arm, but no statistical differences in the median survival were observed, suggesting no substantial benefit by increasing drug delivery of all four drugs simultaneously.<sup>128</sup> Longer follow-up is necessary to determine whether dose-intense M-VAC results in any meaningful impact on long-term survival. The second international, multicenter randomized trial compared the gemcitabine-cisplatin doublet, a combination with identified activity and good patient tolerance, to the M-VAC combination. Preliminary analysis in this trial with more than 400 patients demonstrated that the complete and overall response proportions were similar, with no statistical differences.<sup>129</sup> The survival distributions with early follow-up were also comparable, but long-term survival rates were not available. Drug tolerance and toxicity profiles favored the gemcitabine-cisplatin doublet. The two-drug combination was associated with delivery of a greater number of chemotherapy cycles, a smaller incidence of treatment-related death, and a lower incidence of infectious complications. Based on the results of this randomized trial, gemcitabine and cisplatin should be considered a conventional chemotherapy standard for TCC.

Two randomized trials are ongoing. 5-Fluorouracil (5-FU) combined with interferon- $\alpha$  alone and together with cisplatin has been reported to be active.<sup>130</sup> A randomized comparison of the 5-FU, interferon- $\alpha$ , and cisplatin combination and M-VAC regimens in chemotherapy-naïve patients is ongoing at the MDACC. The second trial ongoing in the ECOG compares the paclitaxel-carboplatin regimen with M-VAC. Carboplatin and paclitaxel is a regimen that has a favorable toxicity profile; it is easy to administer, has activity in phase II studies, and is frequently used in clinical practice. However, questions remain regarding the efficacy of this regimen in relation to M-VAC; this controversy is being addressed by comparing the paclitaxel-carboplatin regimen to standard M-VAC to determine whether this new doublet has similar efficacy with less toxicity. The phase II data for combination of gemcitabine, paclitaxel, and cisplatin have been encouraging.<sup>104</sup> An international randomized trial has been proposed to compare this triplet to standard therapy.

A chemotherapy hypothesis novel to urothelial cancer is being tested at MSKCC. The Norton-Simon model, a mathematical prediction of chemotherapy sensitivity based on gompertzian growth rates displayed by malignant tumors, predicts that efficacy is increased with sequenced "dose-dense" therapy using either single agents or combination regimens compared to either alternating chemotherapeutic regimens or combination chemotherapy in which maximal doses of each agent are limited by overlapping toxicity.<sup>131,132</sup> The sequence of Adriamycin plus gemcitabine (AG) followed by the ITP combination is under evaluation for treating unresectable or metastatic TCC. A phase I study explored the feasibility of doxorubicin at 30 to 50 mg/m<sup>2</sup> plus gemcitabine at 1000 to 2000 mg/m<sup>2</sup> every 2 weeks for six treatment cycles with G-CSF in the AG/ITP sequence.<sup>133</sup> Among the 14 patients assessable for response to the entire sequence, complete regression was observed in 3 (21%), and more than 50% regression occurred in 6 (43%), for an overall response rate of 64%. All six patients at the highest dose levels responded. The most common grade 3 and grade 4 toxicities were anemia and neutropenia. A preliminary report of an MSKCC phase II trial of AG at a doxorubicin dose of 50 mg/m<sup>2</sup> and gemcitabine dose of 2000 mg/m<sup>2</sup> followed by ITP is associated with an encouraging CR proportion of more than 30%.<sup>134</sup> An attempt to confirm the high CR proportion of this sequenced approach has been proposed in the cancer and leukemia group B.

**NEOADJUVANT AND ADJUVANT CHEMOTHERAPY ROLES IN MUSCLE-INVASIVE DISEASE.** Given the chemosensitivity of urothelial cancer, attempts to improve the survival of patients with muscle-invasive disease have focused on administering chemotherapy at the time of definitive treatment of the primary tumor, most commonly in the perioperative setting. This approach attempts to enhance cure based on the putative advantages of greater efficacy in a smaller volume of disease and greater cure rate in patients whose disease is restricted to nodal sites rather than visceral sites.<sup>84,108</sup>

Several considerations arise in analyzing the trial data. First, the odds of reducing mortality by perioperative chemotherapy are independent of the absolute odds of that event occurring in the absence of chemotherapy. For example, a group of pT4 or N+ patients (or both) would be expected to have an 80% death rate. A hypothetical 20% chemotherapy benefit in mortality will reduce the actual mortality from 80% to 64% (i.e., survival improves from 20% to 36%). However, the same 20% chemotherapeutic benefit would reduce mortality of pT2 patients from the expected 25% to only 20% (i.e., survival improves from 75% to 80%). Therefore, the heterogeneity of patient accrual will significantly affect the number of patients necessary to prove efficacy. Second, the trials should be large enough to detect important differences. A trial of adequate power and acceptable false-positive rate to detect a 10% survival advantage of one approach over the other (i.e., the demonstration of a 60% survival rate for patients receiving chemotherapy as compared to a 50% survival in those who receive local therapy alone) requires randomly selecting 1000 patients. Four hundred patients are required to detect a 15% difference and 200 to detect a 20% difference. Studies that are substantially underpowered but detect a survival difference must be reviewed with caution, since the demonstration of survival benefit may reflect a false-positive result. Third, optimal trial design requires studying optimal chemotherapy to assess survival benefit.

**DILEMMA: ADJUVANT OR NEOADJUVANT CHEMOTHERAPY.** If a survival benefit is conferred by perioperative chemotherapy, that benefit should be evident whether the chemotherapy is administered in an adjuvant or neoadjuvant setting. Lessons learned in treating other malignancies show that if chemotherapy is effective, survival benefit is conferred in either setting. However, such data do not exist for urothelial cancer, and advantages and disadvantages of each approach

exist.

**Adjuvant Chemotherapy.** The major advantages for adjuvant chemotherapy are the following: (1) The risk of relapse is best predicted by pathologic stage, (2) the removal of the bladder eliminates the risk for new tumors, and (3) any potential risk of delay in surgery that may compromise cure is reduced. Radical cystectomy allows the treatment decision regarding chemotherapy to be based on the pathologic risk of recurrence, restricting chemotherapy to patient subsets most likely to benefit from chemotherapy, such as patients with pT3 to pT4 or positive lymph node (N+) disease. In addition to removing the bladder and reducing the risk of new tumor formation, repeated cystoscopy is not needed to evaluate for recurrent tumor.

The major disadvantages are that (1) drug delivery may be more difficult after surgery and (2) response to chemotherapy cannot be objectively measured. Clinical trials evaluating adjuvant therapy do not have a surrogate end point for response; therefore, long patient follow-up is necessary to determine disease recurrence and survival. Historically, patients have had more difficulty in tolerating adjuvant chemotherapy after a radical cystectomy, so drug delivery, particularly cisplatin-based therapy, may be more difficult to give in the adjuvant setting.

Nonrandomized data suggest a survival benefit for adjuvant chemotherapy.<sup>135</sup> In a study performed at MDACC, patients who did not receive adjuvant chemotherapy (not referred for chemotherapy, refused chemotherapy, or were considered medically unfit) were subdivided into a high-risk subgroup (defined as having resected nodal metastases, extravesical involvement of tumor, lymph-vascular permeation of the primary tumor, or pelvic visceral invasion) and low-risk subgroup (having none of the above). These untreated patients were compared to those in a second high-risk group that received adjuvant chemotherapy with cisplatin, doxorubicin, and cyclophosphamide. The 5-year, disease-free survival for the treated high-risk group was twice that of the untreated high-risk group and equaled that observed for the low-risk group. These data imply that adjuvant chemotherapy is beneficial for high-risk treated patients, but the absence of randomization and patient selection may have biased the results.

Five randomized trials have examined adjuvant therapy in muscle-invasive disease (Table 34.3-10).<sup>64,136,137,138</sup> and <sup>139</sup> Three trials have not shown benefit of single-agent cisplatin; the combination of cisplatin, vinblastine, and methotrexate; or a regimen of 5-FU and doxorubicin. Two trials suggest a benefit for chemotherapy over observation alone after cystectomy.<sup>64,139</sup> In a University of Southern California (USC) trial, patients with pT3 or pT4 or node-positive disease were randomly assigned to either observation or four cycles of cyclophosphamide, doxorubicin, and cisplatin.<sup>64</sup> A significant delay in time to progression was observed for patients who received chemotherapy (70% compared to 46% disease-free survival at 3 years;  $P = .001$ ), and the improvement in survival (4.3 years vs. 2.4 years) was also statistically significant ( $P = .0062$ ). Flaws in this trial include (1) low numbers of patients, (2) premature termination of the study, (3) the statistical methodology, and (4) the use of nonstandardized chemotherapy. Investigators in the Mainz trial<sup>139</sup> studied 49 patients with pT2 to pT4 or node-positive TCC who were randomly chosen to receive M-VAC or CMV and either doxorubicin or epirubicin or to undergo observation. However, patients in the observation arm did not routinely receive chemotherapy at relapse. A significant reduction in the risk of tumor recurrence was observed in the adjuvant chemotherapy arm: 3 of 18 (17%) patients who received chemotherapy experienced relapse as compared to 18 of 23 (78%) untreated patients ( $P = .0007$ ). A survival benefit was reported in a follow-up report with additional patients entered into the study.<sup>140</sup>

First Author Year	No. of Patients	Investigational Arm Therapy and Primary Tumor Management	Investigational Arm Survival	Control Arm Therapy	Control Arm Survival	Comment
United Kingdom <sup>64</sup>	129	Relaxin plus 5-FU, methotrexate	33%	Relaxin	27%	No
United States <sup>136</sup>	55	Cyclophosphamide and CMV	45%	Cyclophosphamide	39%	No
New Group for Clinical Cancer Research <sup>137</sup>	77	Cyclophosphamide and cisplatin	37%	Cyclophosphamide	34%	No
University of Mainz <sup>139</sup>	49	Cyclophosphamide and 5-FU, CMV	85%	Cyclophosphamide	35%	Yes
University of Southern California <sup>138</sup>	51	Cyclophosphamide and CMV	70%	Cyclophosphamide	46%	Yes

CMV, cyclophosphamide, doxorubicin (Adriamycin), and cisplatin (platinol); CMV, cyclophosphamide, methotrexate, and 5-FU; CMV, cyclophosphamide, methotrexate, and cisplatin; 5-FU, methotrexate, and cisplatin; 5-FU, methotrexate, and cisplatin; 5-FU, methotrexate, and cisplatin. Estimated survival from published survival distribution when proportions are not provided.

**TABLE 34.3-10.** Randomized Trials of Adjuvant Chemotherapy versus Observation in Patients with Muscle-Invasive Urothelial Cancer

Collectively, these trials fail to prove definitively that adjuvant chemotherapy provides a survival benefit in muscle-invasive TCC. The trials performed to date are substantially flawed. Problems encountered in the interpretation of results include (1) insufficient numbers of patients, raising the possibility of false interpretation, (2) inadequate chemotherapy, or (3) premature closure. Despite the reported activity of cisplatin-based chemotherapy in more advanced disease over the last 15 years, the hypothesis that multiagent chemotherapy may be beneficial after cystectomy for muscle-invasive disease has not been adequately tested.

Both nonrandomized and randomized data suggest that adjuvant chemotherapy delays tumor progression; however, a survival benefit has not been definitively proven. The MSKCC approach for nonprotocol patients with muscle-invasive disease is to consider four cycles of adjuvant M-VAC for patients with at least T3,N0 primary tumors and any patients with node-positive disease provided that they can tolerate aggressive chemotherapy. If such patients cannot tolerate M-VAC therapy, surveillance is recommended. These treatment recommendations are based on the following data: (1) Cure can be achieved in patients with node-positive disease treated with chemotherapy followed by cystectomy<sup>111</sup>; (2) M-VAC must be considered the most efficacious regimen based on randomized comparisons to single-agent cisplatin and to the combination of cisplatin, doxorubicin, and cyclophosphamide<sup>84,85</sup>; and (3) independent prognostic factors for survival in the advanced disease setting are a good performance status (reflecting lower tumor burden) and disease restricted to lymph nodes; cure is greatest in patients with both features.<sup>108</sup>

**Neoadjuvant Chemotherapy.** The major advantages of the neoadjuvant approach are the response of the primary lesion, which has prognostic importance, and the degree of response, which can be used to recommend further treatment.<sup>141,142</sup> Response of a primary lesion to combination therapy is associated with improved long-term survival. In a report of 125 patients on multiple trials of cisplatin-based therapy followed by definitive surgery, 91% of the responders (pT1 at cystectomy) were disease-free, in contrast to only 37% of nonresponders (pT2 at cystectomy).<sup>143</sup> A major response to neoadjuvant chemotherapy can also result in preservation of the bladder by repeated and aggressive transurethral resections or by a partial cystectomy.<sup>144,145</sup> Patients whose disease is not responding appropriately can be referred for definitive cystectomy.

Major disadvantages of neoadjuvant chemotherapy include a marked discordance between the clinical and pathologic response to chemotherapy and persistent risk of new bladder tumor formation in the preserved bladder. Approximately 30% of bladder tumors staged as T0 after completing neoadjuvant chemotherapy will have persistent muscle-invasive disease if a cystectomy is performed.<sup>146</sup> Second, even in the patient whose tumor is in complete pathologic response after chemotherapy, the bladder remains at risk for new muscle-invasive bladder tumors that may result in the need for cystectomy. Herr et al.<sup>147</sup> reported a 56% incidence of new bladder tumors in patients 10 years after bladder preservation with neoadjuvant M-VAC and conservative surgery; 30% of the patients had invasive disease requiring a cystectomy.

Studies evaluating chemotherapy in the neoadjuvant setting include both phase III trials examining survival advantage and phase II studies examining response or potential bladder preservation (or both). The latter studies are not controlled for patient selection, cystoscopic resection, staging and restaging techniques, and chemotherapeutic regimens. Most randomized studies of neoadjuvant chemotherapy failed to show a survival benefit for chemotherapy (Table 34.3-11).<sup>55,148,149,150,151,152,153,154,155,156,157,158</sup> and <sup>159</sup> Similar to the adjuvant trials, these studies suffer from suboptimal regimens of chemotherapy or small sample size. The only reported trial with enough power to detect a 10% difference in survival is the intergroup trial performed by the Medical Research Council and the EORTC evaluating CMV for three cycles followed by the participating institutions' recommended management of the primary lesion versus similar primary tumor management without neoadjuvant chemotherapy.<sup>159</sup> Primary tumor management in this trial included cystectomy, radiotherapy, or both. With an accrual of 976 patients, a 5.5% advantage in 3-year survival for patients receiving neoadjuvant CMV was observed. The survival advantage was not statistically significant, because the trial was powered to detect a 10% survival advantage, the minimal benefit discerned by these collaborating investigators to substantiate the routine use of chemotherapy. Trial interpretation is difficult, as not all patients underwent similar treatment of the primary tumor; it is possible that benefit might be different in patients treated with cystectomy versus those treated with radiotherapy.

76%.<sup>170,171,172</sup> and <sup>173</sup> The approach has not been widely adopted in the United States because it is judged more invasive than transurethral surgery followed by chemotherapy and radiotherapy.

### Results with Chemotherapy Alone

The demonstration of CRs in advanced disease led to subsequent trials evaluating preoperative or neoadjuvant chemotherapy in patients with invasive disease in the 1980s.<sup>174</sup> A prerequisite for safe bladder preservation is eradicating the tumor in the bladder. Published reports based on clinical (cystoscopic) staging showed CRs in up to 50% of cases; however, when the same reports are evaluated for the proportion of tumors free of disease at cystectomy, a more modest 20% to 30% rate based on pathologic grounds alone, pathologic complete response (PCR) is observed.<sup>173,174</sup> Of equal concern is that the ability to predict which bladders clinically free of tumor by cystoscopic staging (T0) will actually be pathologically free of tumor at cystectomy (P0). Understaging in up to 30% to 40% of cases has been observed in selected series.<sup>174</sup> Thus, cumulative data show that chemotherapy alone is inadequate therapy to control the primary tumor for most patients. Analyses also show that the proportion of bladders rendered free of tumor varies inversely with T stage.<sup>175</sup> PCR rates are less than 10% in patients with pT3 to pT4 disease or a palpable mass at presentation. Cumulatively, the data show that chemotherapy alone is inadequate as monotherapy if the primary goal is to preserve bladder function.

### Bladder Sparing: Combined-Modality Approaches

The 20% to 40% success rates achieved with single-modality approaches are, when used nonselectively, inferior to contemporary cystectomy series in which local control rates for pelvic disease approach 90%. The evolution of combined-modality approaches aimed at bladder preservation began with reports suggesting that the combination of an aggressive TUR followed by radiation alone or in combination with multidrug systemic chemotherapy could increase the proportion of bladders that are rendered tumor-free. These strategies are based on the principle that final treatment of the bladder is determined by the response to initial therapy, whether unimodality or multimodality.<sup>141,148,163,174,176,177,178,179,180</sup> and <sup>181</sup>

Table 34.3-12<sup>142,144,178,179,182,183,184,185,186</sup> and <sup>187</sup> shows results of combined-modality therapies for survival and survival with a bladder preserved.<sup>181,182,183,184,185,186,187,188,189,190,191</sup> and <sup>192</sup> The ideal candidate for bladder preservation has clinical stage T2 primary tumor, no associated ureteral obstruction, visibly complete TUR, and a documented CR after induction by chemotherapy or chemoradiation. Combined-modality treatment as an alternative to cystectomy is still investigative; it is recommended that such therapy be administered by dedicated multimodality teams.

Series	Therapy	No. of Patients	5Y Survival Rate (%)	5Y Survival Rate with Bladder Preservation (%)
Scop <sup>174</sup>	Cisplatin/5-FU/RT	40	32	45
Scop <sup>174</sup>	TUR plus concurrent 5-FU/RT	79	32	45
Scop <sup>174</sup>	CMV plus concurrent 5-FU/RT	91	42	46
Klein <sup>174</sup>	TUR plus CMV plus concurrent 5-FU/RT	38	32	45
Geer <sup>174</sup>	TUR plus CMV plus concurrent 5-FU/RT	35	31	38
Scop <sup>174</sup>	MVAC plus sequential cisplatin	36	33	38
Scop <sup>174</sup>	MVAC plus TUR	46	—	37
MWCC <sup>174,175</sup>	MVAC plus conservative surgery	11	48	36

5-FU, 5-fluorouracil; CMV, cyclophosphamide, methotrexate, and cisplatin; MVAC, methotrexate, cisplatin, vinorelbine, and ifosfamide; RT, radiotherapy; TUR, transurethral resection of tumor; RT, external beam radiation.  
 \*Bladder preservation performed selectively, based on initial tumor response and stability in response.  
 †Based on local follow-up.  
 ‡Median follow-up of 39 months at time of report.

TABLE 34.3-12. Recent Results of Various Combined-Modality Therapies for Survival and Survival with Bladder Preserved

### Chemotherapy Followed by Partial Cystectomy

Only 5% to 10% of invasive tumors present in a location amenable to a curative resection by partial cystectomy at diagnosis.<sup>165</sup> In appropriately selected cases, the approach has the advantage of surgically removing the diseased portion of the bladder, with definitive staging of the bladder and lymph nodes. After a response to chemotherapy, less extensive surgery may be necessary to achieve control. The proportion of tumors that could be removed by partial—as opposed to radical—cystectomy increased to 27% after M-VAC was used.<sup>178</sup> Early results, confirmed by Sternberg et al.,<sup>179</sup> were excellent for this highly selected patient group. However, the long-term risk of recurrent disease is substantial. Herr et al.<sup>147</sup> reported that salvage cystectomy was necessary in one-third of the patients, owing to new muscle-invasive neoplasms.

### Chemotherapy Combined with Radiotherapy

The strategy of combining chemotherapy and radiotherapy evolved from clinical trials performed in the 1980s, which showed the importance of a complete endoscopic resection of the tumor within the bladder before radiation<sup>163</sup> and, in a randomized comparison, a higher rate of local control in the bladder using concurrent cisplatin and radiotherapy versus radiotherapy alone.<sup>148</sup> At the same time, laboratory studies demonstrated that several cytotoxic agents, particularly cisplatin and 5-FU, could sensitize tumor tissue to radiation and increase the killing of tumor cells in a synergistic fashion.<sup>180</sup>

Chemotherapy has been combined with radiotherapy in concurrent, sequential, and alternating fashions.<sup>181</sup> No optimal schedule has been defined. Nevertheless, several reports<sup>182,183,184,186,187,188,189</sup> and <sup>190</sup> show that radiation adds to TUR and systemic chemotherapy to maintain the bladder free of tumor. These reports suggest a higher response rate after TUR and chemoradiation therapy (74%) than after TUR and chemotherapy (20% to 30%) as well as 5-year survival rates with the bladder (range, 36% to 44%), which are within the limits of comparing nonrandomized series. These survival rates appear to be superior to those reported with conservative surgery and chemotherapy alone [20% at 5 years and 33% at 30 months (median follow-up)]. When the results are analyzed, the number of patients with tumor-free bladders must be considered in the context of the total number of patients entered into a study, as was done in the previously mentioned series (see Table 34.3-12).<sup>142,144,178,179,182,183,184,185,186</sup> and <sup>187</sup> Considering the number of retained bladders relative to the number of patients who complete therapy artificially inflates the outcome. Finally, it must be remembered that the results of contemporary trials, though encouraging, do not exclude the possibility that a bladder-sparing approach may result in reduced survival compared to radical surgery.<sup>147</sup>

The highly selective nature of patients treated with combined modality approaches the limits of comparisons of survival distributions between these patients and those treated by more conventional means. These caveats notwithstanding, in contemporary combined-modality series, 5-year survival rates in the range of 45% to 52% have been reported.<sup>182,184,190,191</sup> Three included radiation with a cisplatin-based regimen. Perhaps a reason why the survival rates with complete TUR of the bladder and chemoradiation are higher than those of other reported experiences is that patients who are at high risk for local failure are identified early and are referred for immediate cystectomy. At what point the patient is designated to have experienced failure of treatment and is referred for cystectomy is controversial. For example, in the Massachusetts General Hospital (MGH) series, patients first undergo an aggressive TUR followed by two cycles of CMV chemotherapy. A cystoscopy is performed 8 weeks from the initial TUR, and the response is assessed. All patients then receive radiation to a maximum of 40 Gy and two concurrent doses of cisplatin. A third cystoscopy is performed and, if residual disease is documented, the patient is referred for cystectomy. In this series, 41% of the patients without a CR (T0) after TUR and chemotherapy at cystoscopy were rendered tumor-free by concurrent radiation of 40 Gy.<sup>175</sup> The policy of referring nonresponding patients for surgery before definitive radiation doses has been effective and used successfully by other groups.<sup>182,184,191</sup> No increase in surgical complications has been observed. In any case, it is unlikely that the “window of surgical curability” would be closed with monitoring at these frequent time intervals. This practice differs from a treatment policy of salvage cystectomy, in that tumor regrowth is not required before a patient is referred for surgery.

Evidence that the optimal dose and schedule of chemoradiation have not been developed is provided by a nevertheless encouraging report from Paris evaluating cisplatin and 5-FU with concomitant twice-daily high-dose-fraction pelvic irradiation.<sup>191</sup> To evaluate the efficacy and safety of the regimen, initially all patients were restaged both clinically and pathologically. All 18 patients who were clinically T0 proved to have no tumor at cystectomy (P0). As a result of this experience, the group changed their treatment policy to focus more on selective bladder preservation. This high rate (100%) of PCR in patients who were CRs (T0) appears to be a marked improvement over the experience of others using neoadjuvant chemotherapy, in which approximately 50% of patients judged to be clinically T0 after induction are confirmed pathologically at cystectomy.<sup>141</sup> In an update of the Parisian experience, 74% of referred patients have retained their bladders. Equally encouraging is that

only 10% of these have developed new tumors within the preserved bladder. In the MGH, RTOG, and Erlangen studies, CR rates at cystoscopic rebiopsy after induction range from 70% to 80%, of which 83% to 89% (representing 58% to 72% of all referred patients) remain free from invasive recurrence. The RTOG has recently evaluated the Paris approach in 34 patients and found a 65% clinical CR (T0) rate. <sup>193</sup>

The concern that a conserved, irradiated bladder functions poorly has also been answered by recent reports after modern radiation techniques. In the Erlangen experience, only three cystectomies were necessary for bladder shrinkage among 192 preserved bladders, for an incidence of 1.6%. <sup>183</sup> An analysis of bladder function in 72 patients successfully treated with 60 Gy in 30 fractions found no differences in urinary and rectal function as compared with an age- and gender-matched control group. Similarly, the MGH reported excellent tolerance in 21 women treated by bladder conservation using chemoradiation. <sup>192</sup> With a median follow-up of 56 months, all patients were continent and free of dysuria and hematuria. Bladder function improved or was unchanged after treatment in 91% of the patients, and no patients reported a compromise in bowel or sexual function. In an update of 106 consecutively entered patients on prospective protocols at the MGH, including induction by TUR of tumor, two cycles of methotrexate, cisplatin, and vinblastine chemotherapy followed by 64.8-Gy irradiation with concomitant cisplatin, none of the 76 patients whose bladders were preserved had to undergo a cystectomy for shrinkage or bleeding. The median follow-up of the 76 patients who had no cystectomy for tumor was 59 months.

After multimodality organ-preserving therapy, 20% to 30% of patients may subsequently develop superficial tumors. These tumors are usually amenable to standard management with TUR and intravesical agents. Of 18 patients (24%) who developed either Ta or CIS among the 76 patients with initial bladder presentation at MGH, 14 have been maintained in remission by TUR and intravesical drug therapy, with 15 to 49 months of follow-up after development of their new superficial tumor. <sup>181</sup> Obviously, all patients treated by multimodality bladder-preserving therapies must be willing to return to the urologist for regular cystoscopic follow-up so that TUR, intravesical chemotherapy, or cystectomy can be used at the earliest opportunity, if necessary.

## CASE SELECTION

Developing a coherent strategy for treating invasive bladder tumors will ultimately require designing and completing comparative trials. The Medical Research Council–EORTC international study, involving almost 1000 patients, was a landmark trial in that it was the first study with a sufficient number of patients to detect a survival difference for chemotherapy. Similarly, the SWOG intergroup trial evaluating neoadjuvant chemotherapy is also important because it tests M-VAC, shown to be the most active chemotherapeutic regimen, with a sufficient number of patients to detect a survival difference.

A novel approach in selecting patients for perioperative chemotherapy is incorporating prognostic markers of the primary tumor to allow a more precise definition of metastatic risk. Clinical prognostic factors predicting adverse outcome include depth of invasion, presence or absence of a palpable mass, and presence or absence of hydronephrosis. Several molecular markers have also been investigated. <sup>190</sup> Invasive bladder tumors that have a dysfunctional retinoblastoma (*Rb*) gene product or mutant p53, <sup>25,194,195</sup> and <sup>196</sup> implied by immunohistochemistry assays, <sup>197,198</sup> are at increased risk of metastatic disease. These molecular markers must be validated in clinical trials of appropriate sample sizes to determine their clinical utility.

Two ongoing investigational trials explore the use of p53 mutations in urothelial cancer. Studies at USC determined that patients whose tumors had mutant p53 were more likely to have disease recurrence and death ( $P < .0001$ ) than patients whose primary tumor had wild-type p53. <sup>26</sup> At MSKCC, the p53 status of the tumors in patients treated with neoadjuvant chemotherapy showed similar results. Patients whose primary tumors had nuclear staining of p53 protein by immunohistochemistry, which implied mutant p53, were three times more likely to die from disease than were those patients whose tumor staining was consistent with wild-type p53. <sup>195</sup> In the latter study, the use of both clinical stage and p53 status could predict patients with a favorable outcome. Patients with good prognostic features [i.e., wild-type p53 and low stage of disease (T2 tumors)], had a 77% survival at 5 years after neoadjuvant chemotherapy; bladder preservation and survival were more frequent in patients whose tumors had wild-type p53. <sup>199</sup> A prospective trial attempts bladder preservation in patients with wild-type p53 tumors. USC investigators are testing a different hypothesis; preliminary retrospective data from their center suggest that adjuvant chemotherapy enhances survival in patients whose tumors have mutant p53. <sup>200</sup> Based on these data, patients with mutant p53 tumors are randomly assigned to receive either adjuvant M-VAC chemotherapy or observation after cystectomy to assess a survival advantage associated with adjuvant chemotherapy.

## SUMMARY

Urinary bladder cancer is a common disease, with increasing incidence but a decreasing mortality. Several carcinogens of the urothelium and risk groups have been identified, such as aromatic amines, combustible gases, a dietary component in meat or fat, the drug phenacetin, and tobacco smoking. An understanding of the pathogenesis of the disease is evolving, and at least two pathways lead to urinary bladder cancer. Mutations in *p53*, *Rb*, and as yet uncharacterized genes on chromosome 9 are common and probably important. Urinary bladder cancers typically present with macroscopic hematuria. The clinical course of the disease is strongly heterogeneous. Superficial TaG1 lesions almost never progress and can easily be handled with an endoscopic resection. Recurrent and high-grade superficial bladder tumors can be controlled in most cases with repeated TURs and intravesical BCG, with cystectomy reserved for refractory tumors.

Muscle-invasive disease may require both a locally aggressive therapy and systemic therapy of micrometastases for cure. Metastatic urinary bladder cancer is a fast-growing and often lethal malignancy. In the latter stage, only a small proportion of patients are currently cured with chemotherapy. Newer chemotherapeutic regimens may improve survival of patients with advanced disease. Current refinements in therapy include identifying subgroups of patients with superficial disease in whom the intensity of follow-up can be reduced or intravesical therapy is needed. For muscle-invasive disease, efforts are being made to identify patients for whom organ preservation is possible without compromising overall survival, as well as those with subclinical micrometastases for whom systemic therapy is needed for cure. Efforts to improve therapy include better surgical techniques, computed three-dimensional treatment planning for more precise delivery of external-beam radiotherapy, and the incorporation of newly identified chemotherapeutic agents into combination regimens.

For most patients, combined-modality approaches are essential to optimal management. It is likely that the improved overall survival observed during the last two decades will continue. With the increasing focus on preventive measures, such as the cessation of smoking <sup>201</sup> and reducing exposure to known carcinogens, the incidence of the disease is likely to decrease, and the current trend of reduced bladder cancer mortality is likely to continue.

## INTRODUCTION

Prostate cancer is a significant health care problem in the United States due to its high incidence and mortality, the costs associated with its detection and treatment, and the fact that no consensus exists on what constitutes the best form of treatment for any stage of this disease. Excluding superficial skin cancers, prostate cancer is the most common malignancy afflicting American men.

Since the advent in the late 1980s of prostate-specific antigen (PSA) level as an effective screening test, the medical community has witnessed a dramatic increase in the incidence of prostate cancer cases. Between 1985 and 1992, the age-adjusted incidence in the United States more than doubled, reaching a peak of more than 190 cases per 100,000 in 1992.<sup>1</sup> Perhaps reflecting stage migration or more effective treatment for localized disease, 5-year cancer survival rates have increased from approximately 70% in the early 1980s to more than 90% a decade later.<sup>1</sup> Since 1992, the incidence rate has steadily declined.

To date, no conclusive data confirm that screening reduces disease morbidity and mortality. Observations that support screening and early detection include the following: PSA screening improves detection of clinically important tumors without significantly increasing the detection of unimportant tumors; the disease is more burdensome at later stages; most PSA-detected tumors are curable using current techniques; and there is no cure for metastatic disease. However, until properly conducted trials of screening are completed, the benefits and risks of prostate cancer's early detection and the associated treatment methods should be discussed carefully with patients.

## NORMAL PROSTATE ANATOMY AND HISTOLOGY

The prostate is an ovoid structure located between the urinary bladder superiorly and the pelvic floor inferiorly ( [Fig. 34.4-1](#)). The urethra traverses this gland, entering its base below the bladder neck and exiting at the narrowed apex at the level of the urogenital diaphragm. The anterior surface of the prostate is attached to the pubis, and the posterior surface is flattened with a midline depression that lies against the rectal ampulla. The lateral and inferior surfaces of the gland are in contact with the levator ani muscles. The levator ani muscles have an almost vertical orientation, funneling inferiorly to surround the rectum and bracket the striated urethral sphincter and middle and apical portions of the prostate.<sup>2</sup> The ejaculatory ducts enter the posterior surface laterally and pass obliquely toward the midline, where they end at the verumontanum on the posterior surface of the prostatic urethra. Because of the gland's location deep within the pelvis behind the pubic bone, surgical as well as radiation-based approaches to expose and target the prostate and protect surrounding structures may be challenging.

FIGURE 34.4-1. Prostate and regional anatomy.

The prostate's anterior surface and the adjacent lateral pelvic floor are covered by the periprostatic fascia, which is formed by the prostatic and levator fasciae. Lateral to the gland, this layer is called the *endopelvic fascia*, and it covers both the pelvic floor and important underlying neurovascular structures. The prostatic venous plexus (of Santorini), a rich network of tributary veins that serve as the primary penile drainage, is seen within this fascial covering. Erectile nerves to the corpora cavernosa travel outside the prostatic capsule in the lateral pelvic fascia between the prostate and the rectum (see [Fig. 34.4-1](#)). The cavernous nerves arise from the pelvic plexus, contain both sympathetic and parasympathetic fibers, and pass beneath the arch of the pubis to supply the corpora cavernosa and the corpus spongiosum. These end in a network of nerve fibers around the cavernous vessels at the penile hilum. Appreciating these anatomic relationships intraoperatively is essential to avoid unnecessary injury and bleeding.<sup>3</sup> The prostatic capsule, composed of condensed smooth muscle and connective tissue, blends with the prostatic sheath on the anterior and anterolateral surfaces of the gland and with the anterior lamella of Denonvilliers' fascia on the posterior gland surface.<sup>4</sup> The puboprostatic ligaments extend anterolaterally from the surface of the gland to fix the apex of the prostate to the pubis.<sup>5</sup> At both the apex and base, no clear capsule separates the prostate from the striated urethral sphincter or bladder neck, respectively. Prostatic glands can be seen in the substance of the urethral sphincter, and smooth muscle fibers from the detrusor blend with the muscular coat of the prostate. Separating the prostate from the rectum is a layer of fascia, Denonvilliers' fascia, derived from two layers of pelvic peritoneum in the retrovesical space.

While voluntary control of voiding begins with relaxation of the striated sphincter in the membranous urethra, smooth muscle components of the bladder neck and prostate contribute to continence in men.<sup>6</sup> The preprostatic sphincter is composed of muscle elements from the bladder. These muscles encircle the urethra and travel along and insert into the urethra more distally. The preprostatic sphincter provides resistance to urine leakage and retrograde seminal ejaculation. A passive prostatic sphincter is located distal to the verumontanum and is related closely to the striated muscle elements of the prostatomembranous sphincter.<sup>7</sup>

The prostatic striated sphincter forms a thick muscle layer over the anterior surface of the gland. Distally, these fibers almost completely surround the gland, except for a posterior gap at the apex, and merge with muscles of the membranous urethral sphincter. Fibers of the membranous striated sphincter encircle the urethra, originating at the anterior decussation of the prostatic sphincter and inserting at the perineal body at the level of the perineal membrane. These sphincteric fibers insert broadly over the surface of the prostatic fascia near the apex and play an important role in regaining continence after radical prostatectomy.<sup>8,9 and 10</sup>

The primary arterial supply to the prostate comes from the prostatovesical artery that descends inferiorly along the bladder base. The origin of this artery is variable, but it usually comes from the anterior division of the internal iliac artery. The prostatic artery divides at the base of the prostate into the large posterolateral branch and the smaller anterior branch. The superolateral gland may receive arterial supply from the middle and superior rectal arteries. Urethral branches from the prostatic artery enter the capsule posterolaterally below the bladder neck to supply the transitional zone and periurethral glands. Capsular branches, traveling in the neurovascular bundle posterolaterally to the gland, enter the capsule more distally and laterally, to supply the central and peripheral zones. Prostate parenchymal veins, as well as veins draining all deep pelvic structures, intercommunicate with the prostatic venous plexus lying within the periprostatic fascia on the anterior surface of the gland.<sup>11</sup> The deep dorsal vein of the penis emerges beneath the symphysis pubis between the puboprostatic ligaments to join this plexus. The majority of venous blood drains directly into the prostatic and inferior vesical veins to the internal iliac veins.

Seminal emission is a neural process mediated within the prostate. With sexual activity, parasympathetic nerves stimulate the prostatic acini to produce secretions. Sympathetic nerve activity closes the preprostatic sphincter, preventing retrograde ejaculation, and increases smooth muscle tone in both the prostatic parenchyma and capsule to deposit secretions in the urethra (emission).<sup>12,13</sup> Ejaculation occurs with contraction of the striated bulbospongiosus muscle.

Preganglionic sympathetic nerves to the preprostatic sphincter and smooth musculature of the prostate gland originate at spinal level L2-3 and pass through the sympathetic chain ganglia to the superior hypogastric plexus. Here they synapse with postganglionic noradrenergic nerves, the cell bodies of which lie in the pelvic plexus lateral to the bladder and prostate. Parasympathetic innervation to the prostatic epithelium originates in the pelvic splanchnic nerves from spinal levels S2-4. These preganglionic neurons synapse in the prostatic plexus, located between the seminal vesicles and the prostate, and send short postganglionic fibers into the prostate stroma. Somatic motor output from the pudendal nerve arises from S1-3 and innervates the pubococcygeus muscle of the external striated sphincter. Some contribution to external sphincter tone may also come from the pelvic nerve.<sup>14,15,16 and 17</sup> The prostatic nerve, which includes sympathetic, parasympathetic, and somatic fibers, travels with the neurovascular bundle and sends off main branches at the level of the prostate base. This nerve continues posterolaterally along the prostate and divides into apical branches and a branch to the ejaculatory duct. The main branches pierce the prostatic capsule, then travel along the fibromuscular trabeculae as acinar branches before reaching their terminals at muscular and glandular cells. Afferent nerves from the prostate travel through the pelvic plexus to reach sensory tracts in the spinal cord.

Lymph capillaries emerge from the fibrous stroma and anastomose to form a lobular network of channels. The major route of lymphatic drainage occurs along the prostatic artery to the obturator and internal iliac nodes. Secondary lymphatic drainage originates at the base of the prostate, where lymphatic trunks travel along the medial border of the seminal vesicles to drain into the external iliac nodes. Two more minor routes are along capsular lymphatics on the posterior surface of the gland to the sacral and internal iliac lymph nodes.

The internal structure of the prostate has been organized into *lobes* or *zones*. Early descriptions of five lobes were based on the embryologic concept of the prostate beginning as five groups of epithelial buds that branch off of the urogenital sinus between gestational weeks 11 and 16. By successively branching and rebranching, a complex system of ducts is formed circumferentially around the urethra, forming anterior, posterior, median, and two lateral lobes. However, the zonal description of prostate structure is more commonly used in clinical practice today.<sup>18</sup> According to this scheme, the prostate consists of two primary areas: the peripheral zone and the central zone. In the normal gland of young adults, these two zones make up 95% of the prostate mass. The remaining 5% of the gland is made up of the transitional zone, an anterior fibromuscular segment, and a preprostatic sphincter zone. It is well recognized that prostate cancer occurs primarily in the peripheral zone, while the adenomatous growth of benign prostatic hypertrophy occurs primarily in the transitional zone.

The prostatic parenchyma is composed primarily of glandular epithelium, yet 30% of its mass is composed of muscular elements. The secretory epithelium of the prostate is contained within tubuloalveolar glands with a simple branching architecture. These glands are lined with simple cuboidal or columnar epithelium under which lie flattened basal cells. Stromal smooth muscle and connective tissue surround most of the acini. Ducts draining each gland enter the urethra in several locations. Periurethral glands, not connected to the deep network of acini, drain into the urethra.

## **PATHOLOGY AND PATTERNS OF PROGRESSION OF PROSTATE CANCER**

Approximately 75% of prostate cancers will arise in the peripheral zone of the gland. Another 15% may occur in the central zone, and 10% to 15% will be located in the transitional zone. Carcinoma within the peripheral zone of the gland may be palpable, on digital rectal examination (DRE), as firm nodules or induration. However, it is not uncommon for cancers to be nonpalpable. Gross examination of cancerous tissue in prostatectomy specimens often reveals a similarly firm and gritty texture on palpation; however, lesions can be extremely difficult to differentiate visually from the surrounding normal prostatic parenchyma.<sup>19</sup> Histologically, 95% of prostate cancers or more are adenocarcinomas derived from prostatic acinar cells. Carcinomas tend to be multifocal and show heterogeneous glandular patterns of malignant growth.<sup>20</sup> The glands are typically small or medium-sized, lined with a single layer of cuboidal or low columnar epithelium. The outer basal layer, found in normal and hyperplastic glands, usually is absent in carcinoma. In suspicious lesions, immunohistochemical staining for basal cells can assist in diagnosis.<sup>21</sup> Cancerous acini are irregularly shaped and packed closely together with varying amounts of stroma. In some poorly differentiated tumors, cells in cords or sheets may replace the glandular pattern. Perineurial, lymphatic, and vascular invasions are common and are reliable signs of malignancy. The mechanism of transformation from benign to malignant adenocarcinomas is unclear; however, androgen stimulation appears to play an important role in pathogenesis.<sup>22</sup>

Similar to other cancers, prostate adenocarcinomas are graded histologically. Pathologic interpretation of needle biopsy and prostatectomy specimens focuses on the degree of glandular differentiation, cytologic atypia, and nuclear abnormalities. Several grading systems have been proposed, of which the Gleason system is the most commonly used.<sup>23,24</sup> This grading system recognizes the fact that prostate cancer is a multifocal disease with heterogeneous glandular patterns. Thus, two individual scores, each ranging from 1 to 5, are given to the two most predominant histologic patterns of prostate cancer. The two scores are added together to give the Gleason sum. Sums of 2 to 4 represent well-differentiated disease; 5 to 7, moderately differentiated disease; and 8 to 10, poorly differentiated disease ( [Fig. 34.4-2](#)). In well-differentiated cancers, groups of small acini are spaced closely "back to back," with little intervening stroma and a loss of the normal myoepithelium that surrounds the glandular elements. Histologically, glands may show luminal distention with mucin (so-called colloid carcinoma) or may take on a cribriform or papillary organization.<sup>25,26</sup> Moderately differentiated cancers are characterized by more haphazardly organized acini, more pronounced nuclear anaplasia, and infiltration of surrounding normal glands. In poorly differentiated adenocarcinoma, cells appear to be in sheets or cords, and glandular components may not be discernible. There is pronounced nuclear anaplasia, and invasion of surrounding tissue may be seen. When comparing patients with similar Gleason sums, it is important to note that the major Gleason pattern score may have additional prognostic value. For instance, patients with 3+4 disease tend to do better than those with

4+3 disease. In our experience, 3-year actuarial PSA failure-free survival rates in patients treated with prostatectomy are approximately 82% for the former group and 77% for the latter.

**FIGURE 34.4-2.** Prostate cancer histology. **A:** Gleason grade 2 (200×). Glands are medium-sized and well developed, with only mild variation in gland size and shape, luminal blue mucin, and no basal cell layer. The glands are tightly packed with minimal intervening stroma and grow in circumscribed nodules, with a minimal peripheral infiltrative pattern. Nuclear features of malignancy include mild nuclear enlargement, granular chromatin, and nucleoli. **B:** Gleason grade 3 (200×). Glands are well developed, with more profound variation in contour and morphology. The glands grow in an infiltrative pattern as seen here, with extension into extraprostatic tissues. **C:** Gleason grade 4 (200×). Malignant cells have trabecular and glandular growth pattern, forming small solid nests and abortive, fused glandular lumens. This tumor has a highly infiltrative pattern with scattered small angulated nests. Malignant nuclear features include marked nuclear enlargement and macronucleoli. **D:** Gleason grade 5 (200×). Highly infiltrative growth pattern with single cells and small nests of malignant epithelial cells. Cytologic features include marked nuclear pleomorphism and anisonucleosis with irregular contours, coarse irregular chromatin distribution, and macronucleoli.

The histology of the remaining 5% of prostate cancers is heterogeneous, arising from stromal, epithelial, or ectopic cells. Nonadenocarcinoma variants can be categorized into two groups—epithelial and nonepithelial—based on the cellular origin. Epithelial variants consist of endometrioid, mucinous, signet-ring, adenoid cystic, adenosquamous, squamous cell, transitional cell, and neuroendocrine carcinoma and comedocarcinoma. Among the nonepithelial variants are rhabdomyosarcoma, leiomyosarcoma, osteosarcoma, angiosarcoma, carcinosarcoma, malignant lymphoma, and metastatic neoplasms (Table 34.4-1). An appreciation of histologic variants is important, because treatment and prognosis may be different.

Epithelial	Nonepithelial
Endometrioid	Rhabdomyosarcoma
Mucinous	Leiomyosarcoma
Adenoid cystic	Osteosarcoma
Signet-ring	Angiosarcoma
Adenosquamous	Carcinosarcoma
Squamous cell	Fibrosarcoma
Transitional cell	Malignant fibrous histiocytoma
Neuroendocrine	Malignant lymphoma
Comedocarcinoma	Metastatic neoplasms

**TABLE 34.4-1.** Examples of Nonadenocarcinoma Prostate Cancer Cell Types

Endometrioid carcinoma involves the prostatic urethra and periurethral prostatic ducts in the region of the verumontanum. Histologically, it resembles endometrial adenocarcinoma of the uterus with complex glands lined by stratified columnar epithelium.<sup>27,28</sup> Clinically, this variant is more aggressive than simple adenocarcinoma and often is associated with metastases and a poorer prognosis. Another epithelial variant is mucinous adenocarcinoma. It is characterized by large accumulations of extracellular mucin and luminal distention.<sup>26,29</sup> Overall prognosis is similar to that of adenocarcinoma. Signet-ring cell carcinoma is characterized by large cytoplasmic vacuoles that displace the nucleus and frequently is associated with poorly differentiated and aggressive adenocarcinoma.<sup>30</sup> Associations with mucinous adenocarcinoma are not uncommon, and vacuoles may or may not be filled with mucin. The prognosis for patients with primary signet-ring cell carcinoma is poor, with a 3-year survival rate of 27%.<sup>31</sup> Comedocarcinoma is characterized by nests of cells with central necrosis. Comedocarcinoma resembles poorly differentiated adenocarcinoma (Gleason grade 5) and usually carries a poor prognosis.<sup>32</sup> A rare variant with a better prognosis is adenoid cystic carcinoma. Histologically, lesions resemble basal cell hyperplasia, and disease usually is organ-confined.<sup>33,34</sup>

Squamous cell carcinoma of the prostate accounts for 0.5% to 1% of all prostate cancers and sometimes is difficult to differentiate from disease originating from the bladder and urethra.<sup>35</sup> Such histologic features as keratinization and intercellular bridging are seen, as is the lack of glandular differentiation. Clinically, patients present in fashions similar to those with adenocarcinoma; however, serum tumor markers such as acid phosphatase and PSA will remain normal.<sup>35,36,37</sup> and <sup>38</sup> This epithelial variant is more aggressive than adenocarcinoma, with an average survival after diagnosis of approximately 14 months.<sup>38</sup> Primary transitional cell carcinoma (TCC) of the prostate has also been reported, although secondary spread from the bladder is much more common.<sup>40</sup> Primary prostatic TCC does not respond to hormonal therapy but has been shown to respond to combination therapy.<sup>41</sup> Prognosis is variable, and TCC is best treated with primary surgery or combinations of chemotherapy, radiation therapy, and surgery. Neuroendocrine tumors of the prostate are rare and can present with paraneoplastic syndromes.<sup>42,43</sup> Most patients tend to present with advanced disease at the time of diagnosis.<sup>44</sup>

Nonepithelial nonadenocarcinomas of the prostate are rare. Sarcomas represent fewer than 0.1% of prostate cancers and tend to occur in younger patients.<sup>45</sup> The two most common types are rhabdomyosarcoma and leiomyosarcoma. The former is the most common prostatic tumor in the pediatric age group, whereas the latter tends to occur in adults.<sup>46</sup> Both are extremely aggressive and tend to invade locally and hematogenously. Pathologically, rhabdomyosarcomas are solid neoplasms, with a histologic appearance that ranges from primitive mesenchyma to well-differentiated, myofiber-type cells.<sup>47</sup> Leiomyosarcomas tend to be bulky, with diffuse infiltration into the periprostatic soft tissues. Histologically, lesions show interlacing spindle cells, eosinophilic cytoplasm, and nuclear atypia accompanied by necrosis and hemorrhage.<sup>48</sup> A multidisciplinary approach to treatment, including surgery, chemotherapy, and radiation therapy, is usually recommended.<sup>44</sup> A third nonepithelial cancer of the prostate is malignant lymphoma. It usually affects young men and frequently is associated with non-Hodgkin's and Hodgkin's lymphoma.<sup>49</sup> On histologic examination, lesions resemble lymph nodes consisting of small-cleaved lymphocytic cells or large diffuse lymphomas. Prognosis is usually poor, and prostatectomy may not prolong survival. Other metastases to the prostate include leukemia and local extension from rectal or bladder primary cancers. Metastases from other organs are rare.<sup>45</sup>

Prostate cancer may spread locally or distantly. Cancers can invade the seminal vesicles and bladder base proximally and the urethra distally. Extension through the prostatic capsule and into the periprostatic tissues is not uncommon; however, rectal invasion posteriorly is rare, owing to separation of the two organs by Denonvilliers' fascia. Lymphatic spread most often occurs in a stepwise manner and follows the normal pattern of lymphatic drainage. The obturator nodes are the primary sites of lymphatic metastases, followed by the perivesical, hypogastric, iliac, presacral, and paraaortic nodes. Hematogenous metastases primarily affect the bones and occur in up to 85% of patients who die of prostate cancer.<sup>50</sup> The axial skeleton is particularly vulnerable, as the preprostatic and periprostatic venous complex communicates with Batson's plexus of the presacral veins. Osseous sites of involvement, in decreasing order of frequency, include the lumbar spine, proximal femur, pelvis, thoracic spine, ribs, sternum, and skull. Bone metastases are typically osteoblastic (80%). Osteolytic (5%) and mixed osteoblastic-osteolytic (15%) lesions are less common. Hematogenous spread to viscera can occur, but widespread visceral dissemination is rare. Lung and liver metastases are seen in approximately 25% and 20% of patients, respectively, with end-stage prostate cancer. The current tumor, node, and metastasis (TNM) staging system for prostate

Taiwan over the past three decades has been attributed mainly to aging of the population. <sup>76</sup>

Ethnic and racial differences are also seen in disease incidence and mortality. African Americans are in the highest-risk group, with an incidence of 224.3 cases per 100,000 for the period between 1990 and 1995. The incidence in white and Asian counterparts during that same period was considerably lower at 150.3 and 82.2 (per 100,000), respectively.<sup>1</sup> In addition, African Americans tend to present with more advanced disease and may have poorer overall prognosis than their white counterparts. It has been reported that African Americans are 1.3 to 1.8 times more likely to present with distant disease and, stage for stage, African Americans have lower survival rates.<sup>77,78</sup> The underlying cause for this difference has been attributed to social, economic, educational, hereditary, and dietary differences. <sup>78,79,80,81</sup> and <sup>82</sup> Conlisk et al.<sup>83</sup> reported that among African Americans, disease stage at presentation was inversely correlated with income and health insurance status. When one controls for access to medical care, the difference in disease stage at presentation and survival persists. <sup>77,84,85</sup> Recent reports from nations with a large concentration of black patients demonstrate a high incidence of the disease nationally, suggesting a genetic association. <sup>86,87</sup> Several investigators have shown that differences in testosterone levels or androgen receptor gene activity may contribute to the racial differences observed in prostate cancer. <sup>88,89,90,</sup> and <sup>91</sup>

Migrant studies, particularly of Asian men, also suggest an environmental, social, or dietary etiology in prostate cancer. When migrants from a low-risk country such as Japan move to the United States, a high-risk nation, their prostate cancer incidence and mortality become severalfold higher than native Japanese counterparts.<sup>92,93</sup> Other investigators have found a positive correlation between the number of years since migration to the United States and cancer risk. <sup>80</sup> Although diagnostic biases exist between countries, the upward shift in risk nevertheless seems real. This rise in clinically detectable disease may be related to differences in diet. High fat intake has been positively associated with increased risk in these studies and may, in part, explain the rising incidence of prostate cancer in Japan, as dietary habits become more Westernized.<sup>94</sup>

Family history of prostate cancer also contributes to risk. It has been reported that men with prostate cancer are two to three times more likely than controls to have at least one first- or second-degree relative with prostate cancer. <sup>95,96</sup> and <sup>97</sup> Keetch et al.<sup>95</sup> reported that a patient with prostate cancer is 3.1 and 4.3 times more likely than a control to give a history of prostate cancer in his father and brother, respectively. Together with the observation that clustering of prostate cancer cases exists in some high-risk families, a hereditary component clearly exists. <sup>98,99</sup> However, the role of specific gene activity and molecular mechanisms of disease remains largely unsolved and continues to be an area of active research. A word of caution is warranted in interpreting family history studies, however, as they are subject to recall, self-selection, and socioeconomic biases. <sup>100,101</sup> and <sup>102</sup>

The role of vasectomy and prostate cancer risk remains controversial. Retrospective and prospective cohort epidemiologic studies have demonstrated a relative risk of approximately 1.6 in men who underwent vasectomy. <sup>103,104,105</sup> and <sup>106</sup> However, others could not confirm these findings and suggest that earlier studies were flawed by detection, control selection, and publication biases. <sup>95,107,108,109</sup> and <sup>110</sup> In a recent metaanalysis that included five cohort and nine case-control studies, no causal association was found.<sup>108</sup>

In summary, prostate cancer is a disease of older men worldwide. It is more common in Westernized countries, in those with a family history of the disease, and in African Americans. The cause is likely multifaceted, with genetic, dietary, and social modifiers. Further investigation is necessary to elucidate the role and significance of each factor in prostate cancer induction and progression.

## CHEMOPREVENTION AND DIET

Chemoprevention is the administration of medicines or other agents to prevent, slow, or reverse cancer progression. The concept of primary chemoprevention for prostate cancer has gained much interest in the 1990s because of the disease's high prevalence, slowly progressive nature, and long latency period. <sup>111,112</sup> and <sup>113</sup> The ideal therapeutic intervention would arrest disease progression during this latency period and decrease the incidence of clinical disease. The success of chemoprevention, however, depends on consideration of several important factors. First, because "healthy" men are treated, the therapeutic agent must offer low to no toxicity and no side effects and must require a simple dosing regimen. Second, epidemiologic and laboratory evidence should support the agent's efficacy. Finally, the ideal patient is one at high risk for developing clinical disease and motivated to adhere to chronic dosing of chemopreventive agents. <sup>114</sup>

To date, several promising chemopreventive agents have been identified and are under laboratory and clinical investigation. <sup>115,116,117,118,119</sup> and <sup>120</sup> Finasteride is among the agents now being tested in a large, phase III, randomized clinical trial, the Prostate Cancer Prevention Trial (PCPT). <sup>115,121,122</sup> A joint effort of the Southwest Oncology Group (SWOG), the Eastern Cooperative Oncology Group (ECOG), and the Cancer and Leukemia Group B (CALGB), the PCPT is a 10-year study of 18,882 men, aged 55 or older, with normal DRE and a PSA level of less than 3.0 ng/mL, who have been randomized to either placebo or the 5 $\alpha$ -reductase inhibitor finasteride (5 mg/d).<sup>123</sup> Given prostate cancer's slowly progressive nature, the end point of prostate cancer mortality will not be pursued because of long study duration and large sample size requirements. Instead, the primary end point of prostate cancer period prevalence, as determined by sextant prostate biopsy, is used. The PCPT is designed to have greater than 90% power in detecting a 25% reduction in period prevalence of biopsy-proven disease when it reaches its end point in mid-2004.

The use of finasteride to prevent disease seems rational, given that prostate cancer is androgen-responsive. <sup>124,125,126</sup> and <sup>127</sup> An inhibitor of 5 $\alpha$ -reductase, finasteride blocks the conversion of testosterone to its active metabolite dihydrotestosterone (DHT) and lowers the prostatic androgen levels. <sup>128</sup> Bologna et al. <sup>124,129</sup> have shown that finasteride can attenuate *in vitro* prostate cancer cell growth in a dose-dependent manner, and others suggest that the lower incidence of prostate cancer among Japanese men may be associated with lower 5 $\alpha$ -reductase activity. In addition, as a chemopreventive agent taken chronically, finasteride is well absorbed orally and does not appear to have any clinically relevant drug interactions or toxicity. <sup>130</sup> The frequency of side effects is low and includes decreased libido, impotence, and decreased ejaculate volume.<sup>123,128</sup>

Dietary manipulations have also gained much interest. <sup>131,132</sup> and <sup>133</sup> Epidemiologic studies have shown that the incidence of clinically significant prostate cancer is much lower in parts of the world where people eat a predominantly low-fat, plant-based diet. <sup>95,134</sup> In addition, migrant studies demonstrate that when men from a low-risk country move to the United States and begin eating a Westernized diet, their rates of prostate cancer increase severalfold and approach that of the host country. <sup>92</sup> However, which component of a certain diet increases prostate cancer risk remains unclear. Researchers have suggested fat, soy, green tea, lycopene, selenium, and vitamins, among others, as modifiers of prostate cancer risk.

Dietary fat intake is positively associated with prostate cancer risk and may be a rational target for chemoprevention. In a case-control study from the Physicians' Health Study, those who had higher plasma  $\alpha$ -linolenic acid levels (a fatty acid found in animal fat) had a two- to threefold increase in prostate cancer risk as compared to those with lower  $\alpha$ -linolenic acid levels. <sup>135</sup> Similarly, in a prospective cohort study of more than 47,000 men, Giovannucci et al. <sup>136</sup> found that fat intake was directly correlated with risk of advanced disease and, specifically, animal fat, red meat, and  $\alpha$ -linolenic acid were associated with the greatest risk [relative risk (RR) = 1.63, 2.64, and 3.43, respectively].<sup>136</sup> Others have studied saturated fat and reported an attributable risk of 13% for saturated fat intake in excess of 26 g/d as compared to diets with less than 13 g/d. This suggests that 13% of prostate cancer cases may be preventable by reducing saturated fat intake to less than 13 g/d. <sup>137</sup> In a recent prospective case-control study of men in whom prostate cancer was diagnosed, Fradet et al. <sup>138</sup> found that survival was inversely associated with saturated fat intake. As compared to men ingesting less than 10.8% of dietary calories from saturated fat, those ingesting more than 13.2% had three times the risk of dying from prostate cancer (RR = 3.13) and were more likely to develop bone metastasis (RR = 3.4) at a median follow-up of 5.2 years. <sup>138</sup>

Evidence supporting a relationship between prostate cancer and dietary fat also comes from animal studies. Wang et al. <sup>139</sup> injected prostate cancer cells (LNCaP) into mice and placed them on a "typical American" diet containing 40% fat. In 3 weeks, prostate tumor growth was noted. The researchers then divided the animals into subgroups receiving diets containing approximately 40%, 30%, 20%, 10%, and 2% of calories as fat. Progression of prostate cancer ceased or was reversed in some animals placed on 10% to 20% fat diets. This was in contrast to continued tumor growth in groups ingesting higher amounts of fat. PSA levels were also lower in mice on the 2% fat diet as compared to those on the 40% fat diet. <sup>139</sup>

On a molecular level, much remains unknown. Myers and Ghosh<sup>140</sup> recently postulated that the risk seen with high fat intake may be linked to 5-lipoxygenase products of arachidonic acid (a ubiquitous fatty acid found in animal fat) and that inhibition of 5-lipoxygenase could lead to prostate cancer cell death and apoptosis. However, the significance of genetic polymorphisms for 5-lipoxygenase and the role of other fatty acid metabolic pathways in prostate cancer risk remain elusive.

The worldwide difference in prostate cancer incidence may also be associated with dietary intake of soy proteins. In Asian countries such as Japan and the Republic

of Korea, where prostate cancer incidence and mortality are just a fraction of that in North America, consumption of soy in the form of tofu, soy milk, tempeh, and miso is noted to be up to 90-fold higher than soy consumption in the United States.<sup>134</sup> In a cross-national study of more than 40 nations, Hebert et al.<sup>134</sup> found soy, on a per-calorie basis, to be the most protective dietary factor. This protective role may be associated with soy's phytoestrogenic components genistein and daidzein. Genistein and daidzein are isoflavonoids with weak estrogenic effect that may have the ability to delay growth of precancerous prostate lesions and prostate tumors.<sup>116,141</sup> Davis et al.<sup>141</sup> showed that genistein inhibits prostate cancer cell growth in culture and induces apoptosis through cell-cycle gene regulation in a dose-dependent manner. Others have demonstrated that genistein is an inhibitor of tyrosine kinase and suggest that genistein may act through inhibition of up-regulated tyrosine kinases in proliferative cancerous states.<sup>131,142,143</sup> Although the association between soy and cancer risk seems convincing, a causal role remains obscure and awaits the rigors of prospective randomized studies. However, given that soy products are generally well tolerated and provide a cost-effective source of isoflavonoids, the scientific community's interest in soy as a chemopreventive agent will likely continue.<sup>120</sup>

To explain the difference in cancer incidence and mortality between nations, researchers have also suggested a chemopreventive role for green tea, a beverage consumed in high quantities in Asia.<sup>117,144</sup> *In vitro* studies by Yang et al.<sup>145</sup> showed that polyphenol extracts from tea inhibited growth of cancerous cell lines and induced cellular apoptosis in a dose-dependent manner. Furthermore, *in vivo* studies by Mohan and Gupta et al.<sup>146,147</sup> found that tea polyphenols inhibited ornithine decarboxylase, a testosterone-induced enzyme that is up-regulated in prostate cancer. Tea polyphenols' inhibition of ornithine decarboxylase in effect attenuates testosterone in the prostatic milieu and may be an important target for chemoprevention.

Tomatoes are rich sources of the carotenoid lycopene. With its potent antioxidant activity, lycopene may protect cellular components from reactive oxygen radical species and lower prostate cancer risk. Epidemiologic data show that lycopene consumption is associated with decreased risk as well as a possible reduction in prostate tumor growth.<sup>148</sup> In a cohort study of approximately 14,000 Adventist men over a 6-year period, consumption of tomato products was associated with lower prostate cancer risk.<sup>149</sup> This finding was substantiated in a prospective cohort study from the Health Professionals Study, where lycopene intake from tomato-based foods was found to be inversely associated with risk.<sup>150</sup> The investigators reported that men ingesting two or more servings of tomato sauce per week had a 36% reduction in cancer risk as compared to counterparts who did not consume tomato sauce. Little is known, however, regarding lycopene's exact mechanism of action or the specific role of different isomers in prostate tissue metabolism.

The role of another antioxidant, vitamin E, as a chemopreventive remains controversial. Epidemiologic and *in vivo* data are often conflicting, despite promising *in vitro* studies.<sup>118,151,152,153</sup> and <sup>154</sup> Part of the difficulty in elucidating vitamin E's effect in chemoprevention is that oral supplements frequently contain different forms of vitamin E than that found naturally in foods. Given the fact that vitamin E exists as potentially eight different compounds, and that isoforms such as  $\alpha$ -tocopherol have been shown to have greater inhibitory effects on prostate cancer cell growth than  $\gamma$ -tocopherol, further evaluation of vitamin E is warranted.<sup>154</sup>

Selenium has also been reported to lower prostate cancer risk. In a double-blinded clinical trial designed to determine whether selenium could lower skin cancer recurrences, Clark et al.<sup>155</sup> found that men randomized to receiving selenium had a 63% reduction in prostate cancer incidence as compared to those randomized to receiving placebo. Similar findings were demonstrated in a nested case-control trial of the Health Professionals Follow-Up Study. The investigators found that higher selenium intake, as reflected in nail selenium levels, was significantly protective (odds ratio = 0.35 when comparing the highest and lowest quintile).<sup>156</sup> *In vivo* studies in the human prostate cancer cell lines have also shown that selenium inhibits cancer cell growth at physiologic doses and that its protective effect may be mediated through an androgen-sensitive gene that encodes for a selenium-binding protein.<sup>157,158</sup>

Attention has also focused on vitamin D's antiproliferative and prodifferentiation effect on the prostate.<sup>159,160</sup> Investigators have demonstrated that 1,25-dihydroxyvitamin D<sub>3</sub> [1,25(OH)<sub>2</sub>D<sub>3</sub>], the active metabolite of vitamin D, inhibits cellular proliferation in primary prostate cancer tissue cultures and in prostate cancer cell lines such as PC3, DU145, and LNCaP.<sup>119,161,162</sup> Moreover, epidemiologic evidence shows an inverse relationship between prostate cancer risk and ultraviolet radiation, the primary source of endogenous vitamin D synthesis.<sup>163,164</sup> This observation has led some to suggest that higher rates of prostate cancer in the elderly may be due in part to decreased sun exposure or a decline in the body's ability to synthesize 1,25(OH)<sub>2</sub>D<sub>3</sub> with aging.<sup>160</sup> Similarly, others have proposed that the higher risk in men of African descent may be related to higher skin melanin content, which would decrease endogenous vitamin D production.<sup>114</sup> Taken together, vitamin D and its synthetic analogues may prove to be useful chemopreventive agents for prostate cancer.

Although a relationship between diet and prostate cancer is apparent, whether manipulating the diet will lead to changes in cancer risk is the subject of ongoing clinical trials. In considering the future development of rational chemoprevention trials and test compounds, one must appreciate the interdependence between the practical aspects of clinical trial design and the mechanisms in disease progression.<sup>165,166</sup> A better understanding of the latter may lead to clinical trials that are less restrained by the need for large sample populations and prolonged follow-up. For example, it has been shown that urokinase-mediated cell surface proteolysis and angiogenesis in human prostate cancer cells are important in metastasis and that specific inhibition could decrease the metastatic potential of cancerous cells.<sup>167,168</sup> From this work, one could postulate the design of a chemopreventive agent aimed at preventing metastasis in patients who present with localized disease. As compared to primary chemoprevention, this may be easier to implement clinically as patients are more likely to be motivated and compliant with chronic therapy. Thus, a multidisciplinary approach that reflects our understanding of prostate carcinogenesis and tumor invasion is critical to study design of future chemoprevention trials.

## PROSTATE CANCER EARLY DETECTION

Prostate cancer screening or early detection has been accomplished using DRE, measurement of serum PSA (and its various forms), transrectal ultrasonography (TRUS), and combinations of these tests. Although DRE can detect prostate cancer, it detects fewer cancers than does PSA testing and, unfortunately, many cancers detected using DRE are either locally or regionally advanced.<sup>169</sup> Although serum PSA is a better screening test than DRE, DRE should not be abandoned, as it may detect some cancers associated with a normal serum PSA level. Therefore, DRE should be combined with serum PSA testing. TRUS should not be used a first-line screening study as it lacks high specificity, is relatively expensive, and adds little information to that already gained by the use of serum PSA testing and DRE.<sup>170</sup> TRUS is used to guide prostate biopsy in those patients who have an elevated serum PSA level, an abnormal DRE, or both ( Fig. 34-4.3).

**FIGURE 34.4-3.** Transrectal ultrasound image showing a characteristic hypoechoic abnormality (arrow) consistent with prostate cancer.

PSA is a serine protease produced by benign and malignant prostate tissues. Although it is produced in small amounts elsewhere, including breast tissue, endometrium, and in a few malignancies other than prostatic cancer, it should be considered to be organ-specific clinically.<sup>171,172,173,174</sup> and <sup>175</sup> PSA circulates in the serum as uncomplexed (free or unbound) or complexed (bound) forms.<sup>176,177</sup> and <sup>178</sup> Serum PSA is largely complexed by endogenous protease inhibitors, the most common being  $\alpha_1$ -antichymotrypsin. Other proteins bind a smaller fraction.

Serum PSA may be elevated transiently in cases of prostatitis and after endoscopic urethral manipulation, prostatic biopsy and, to a more limited extent, ejaculation.<sup>179,180</sup> Routine DRE actually has little effect on serum PSA, but most physicians defer PSA testing after such an examination.<sup>181</sup> The half-life of serum PSA is 2.2 to 3.2 days.<sup>182,183</sup> Therefore, one should wait approximately 4 to 8 weeks after significant prostate manipulation, such as that which occurs with prostatitis or prostate biopsy, before obtaining serum PSA. It should be emphasized that the most common cause for an elevated serum PSA level is BPH, the incidence of which

increases with age, as does the incidence of prostate cancer.

Serum PSA concentrations can be decreased by treatment with agents that lower serum testosterone, such as luteinizing hormone–releasing hormone (LHRH) agonists and antagonists, antiandrogens such as flutamide, and the 5 $\alpha$ -reductase inhibitor finasteride, which is used for the management of presumed BPH and male-pattern baldness. Finasteride also lowers PSA levels by an average of 50%.<sup>184</sup> Therefore, one can correct for the effect of finasteride on PSA by doubling the PSA level.<sup>185</sup> Use of  $\alpha$ -adrenergic antagonists such as terazosin (also used to manage obstructive voiding symptoms) has no appreciable effect on serum PSA levels.<sup>186</sup>

### USE OF TOTAL SERUM PROSTATE-SPECIFIC ANTIGEN LEVEL AND DIGITAL RECTAL EXAMINATION FOR PROSTATE CANCER EARLY DETECTION

The risk of prostate cancer correlates with serum PSA concentrations and DRE findings. The positive predictive value of a serum PSA level between 4.0 ng/mL and 10 ng/mL is approximately 20% to 30%.<sup>187,188,189,190</sup> and <sup>191</sup> For levels in excess of 10 ng/mL, the positive predictive value increases to 42% to 71.4%. The use of DRE complements serum PSA testing (Table 34.4-3).

Study	PSA <4.0 ng/mL		PSA >4.0 ng/mL	
	-DRE	+DRE	-DRE	+DRE
Cooner et al. <sup>188</sup>	9%	17%	25%	62%
Catalona et al. <sup>189</sup>	—	10%	32%	49%
Hammerer and Huland <sup>190</sup>	4%	21%	12%	72%
Ellis et al. <sup>191</sup>	6%	13%	24%	42%

**TABLE 34.4-3.** Probability of Prostate Cancer Based on Serum Prostate-Specific Antigen and Digital Rectal Examination

The majority of cancers (>80%) detected by serum PSA are clinically significant as defined by cancer grade and volume.<sup>192</sup> In contrast to the use of DRE alone for early detection of prostate cancer, the majority of PSA-detected cancers are confined *clinically*. However, as many as 40% of cancers detected by the use of serum PSA and DRE may have evidence of ECE, usually capsular penetration, if the prostate is removed surgically and examined pathologically.<sup>192</sup>

The frequency of PSA testing remains a matter of some debate. In men with a normal DRE and a PSA level in excess of 2.5 ng/mL, PSA testing should be performed annually, as approximately 50% of these patients may convert to having a PSA level exceeding 4.0 ng/mL.<sup>193,194</sup> The test can be performed biannually in those with a normal DRE and serum PSA level lower than 2.5 ng/mL, as conversion in this group is much less likely. The likelihood of curable prostate cancer, either organ-confined or with ECE associated with low to intermediate cancer grade, is similar in men who have prostate cancer associated with serum PSA levels lower than 4.0 ng/mL and in those with levels of 4.0 to 5.0 ng/mL. Therefore, cure is not likely to be compromised in those with very low serum PSA levels initially who experience a limited rise in the PSA level over time.

#### Enhancing Prostate-Specific Antigen Test Performance

A number of different strategies have been developed to enhance PSA test performance, by increasing sensitivity in certain populations or specificity in others. These strategies include use of age-specific reference ranges, PSA velocity, PSA density, and the molecular forms of PSA (free or complexed PSA).

PSA density is a measurement that attempts to correct for elevated PSA levels due to BPH. *PSA density* is defined as the total serum PSA level divided by the prostate gland volume (in milliliters) measured by TRUS.<sup>195</sup> As prostate gland volume increases with increasing amounts of BPH, PSA should rise as well. Prostate cancer releases more PSA into the serum than does BPH.<sup>196</sup> The use of PSA density is limited by the need to perform TRUS, variations in the accuracy of TRUS to measure volume, and the fact that PSA levels due to BPH are a product of the ratios of both the stromal and epithelial components of BPH, which vary from patient to patient. Some have suggested that a PSA density cutoff of 0.15 may better discriminate between patients with elevated serum PSA levels due to BPH and those with elevated levels due to cancer.<sup>197</sup> Catalona et al.<sup>198</sup> showed that as many as 50% of prostate cancers may be missed if one uses this PSA density cutoff to determine the need for prostate biopsy. Still others have failed to show any utility for the use of PSA density in men with a normal DRE and PSA levels between 4.0 and 10.0 ng/mL.<sup>199</sup> As BPH tends to occur in the transitional zone of the prostate and not in the central or peripheral zones, attempts to improve prostate cancer detection using transitional zone PSA density have been developed.<sup>200,201</sup> However, like PSA density, these calculations are subject to error, require TRUS, and do not seem to be superior to the use of PSA testing alone in most patients. In addition, the failure to identify prostate cancer in those with larger prostate glands may simply be a product of biopsy sampling errors rather than true absence of the disease.

*Age-specific PSA reference ranges* are an attempt to compensate for the fact that the standard reference range of 0.0 to 4.0 ng/mL does not reflect age-related volume changes in the prostate due to BPH. A single cutoff may, therefore, be inappropriate for all ages. Many investigators have proposed age-related reference ranges to improve test sensitivity in younger men (who have less BPH and, therefore, would be expected to have lower levels of PSA) and to improve test specificity in older men (who are more likely to have BPH and higher PSA values that accompany it).<sup>202</sup> Race may also have an impact on PSA levels, an issue that has been addressed by several authors (Table 34.4-4). Using age-specific reference ranges, cancer detection rates will increase 8% to 18% in men younger than 60 years and will decrease 4% to 22% in older men. Use of age-specific reference ranges decreases the overall biopsy rate in men undergoing screening. The biopsy rate has been shown to decrease approximately 21% in older men undergoing screening if age-specific reference ranges are used. However, the overall cancer detection rate will also decrease, as fewer elderly men, the group most likely to have prostate cancer, will undergo prostate biopsy. In one series, the overall cancer detection rate fell from 5.7% using the standard PSA cutoff point of 4.0 ng/mL to 3.8% using age-specific reference ranges. Of the T1c or nonpalpable cancers missed in the older patient population, the vast majority have favorable pathologic features suggesting that they may be of low biologic potential in this age group and that failure to detect them may have little impact on patient mortality or morbidity. Use of age-specific reference ranges remains controversial: Some investigators have shown no benefit to their use as compared to use of the standard cutoff point of 4.0 ng/mL. Others have also argued cogently the likelihood that organ-confined cancers are similar in men with serum PSA values between 2.5 and 6.0 ng/mL, suggesting that any lead time gained by use of age-specific reference ranges will not likely translate into improved outcomes and that the increased costs—monetary, physical, and psychological—associated with the increased biopsy rates in men younger than 60 years may not be justified.

Age Range (y)	Hispanic <sup>22</sup>		African American <sup>22</sup>		Caucasian <sup>22</sup>	
	Reference Range (ng/mL)	Specificity (%)	Reference Range (ng/mL)	Specificity (%)	Reference Range (ng/mL)	Specificity (%)
6-9	0.4-1.5	95	0.4-1.0	95	0.4-1.0	95
10-19	0.4-1.5	95	0.4-1.0	95	0.4-1.0	95
20-29	0.4-1.5	95	0.4-1.0	95	0.4-1.0	95
30-39	0.4-1.5	95	0.4-1.0	95	0.4-1.0	95

(Adapted from ref. 202.)

**TABLE 34.4-4.** Age-Adjusted Prostate-Specific Antigen Reference Ranges

PSA velocity refers to the rate of changes in serum PSA over time. PSA velocity is calculated using the following equation:  $1/2 (PSA_2 - PSA_1 / \text{time } 1) + (PSA_3 - PSA_2 / \text{time } 2)$ , where  $PSA_1$  is the first,  $PSA_2$  the second, and  $PSA_3$  the third PSA measurement. Time represents the interval (in years) between PSA measurements. At least three PSA measurements obtained over 24 months or at least 12 to 18 months apart are required for maximal accuracy. In the initial study, significant differences in PSA velocity were noted in patients found to have cancer and BPH many years before cancer diagnosis. Carter et al. <sup>203,204</sup> found that a PSA velocity exceeding 0.75 ng/mL was highly predictive of prostate cancer using one assay (sensitivity 72% and specificity 95%). The use of PSA velocity is limited by the fact that multiple measurements using the same assay over a relatively long period are necessary for accuracy. In addition, there is substantial biologic and laboratory variability in serum PSA testing, and some suggest that only increases in serum PSA greater than 25% are likely to represent changes due to prostatic disease (BPH or cancer).

Perhaps the greatest enhancement of PSA testing has been based on the knowledge that PSA exists in the serum in both free (or unbound) and complexed forms (bound to serum proteins). Stenman et al. <sup>176</sup> made the observation that the free form of serum PSA exists in a higher fraction in men without prostate cancer than in those with the disease. Others observed that the specificity of PSA testing for the detection of prostate cancer could be enhanced by calculating the free-to-total PSA ratio as compared to using total PSA alone. <sup>205</sup> Partin et al. <sup>206</sup> conducted a multiinstitutional trial evaluating the performance of both total and free-to-total PSA for the detection of prostate cancer in men with serum PSA levels between 4.0 and 10.0 ng/mL using the Hybritech assay (Hybritech, Inc., San Diego, CA). All men had a normal DRE and underwent systematic TRUS-guided prostate biopsy. Of 773 men, 379 (49%) were ultimately found to have prostate cancer. As expected, the total PSA was higher and free fraction was lower in those with prostate cancer as compared to those without the disease. Using a free PSA cutoff of 20% to provide 95% sensitivity, these researchers could achieve a specificity of 20%, eliminating 20% of unnecessary biopsies. For patients who had a normal DRE and total PSA concentration between 4.0 and 10.0 ng/mL, the probability of prostate cancer was 56%, 20%, and 8% for those with free PSA fractions of 0% to 10%, 15% to 20%, and more than 25%, respectively. Catalona et al. <sup>206</sup> also demonstrated that the use of the percentage of free PSA in men with total serum PSA concentrations between 4.0 and 10 ng/mL could eliminate 29% of unnecessary biopsies, if a cutoff of 20% free PSA was used as an indicator for prostate biopsy. Others have performed similar studies using the same or different assays and patient populations (i.e., ranges of total PSA). <sup>205,207,208,209,210,211,212</sup> and <sup>213</sup> In these studies, the sensitivity and specificity for cancer detection varied from 71% to 100% and 24% to 95%, respectively, using cutoff points ranging from 14% to 28%.

As 13% to 20% of men with serum PSA concentrations between 2.6 and 4.0 ng/mL (upper limit of normal) will be found to have prostate cancer within 5 years, some have examined the usefulness of percentage of free PSA for the early detection of prostate cancer in these men. <sup>171,176,214</sup> Catalona et al. <sup>208</sup> used percentage of free PSA to screen 914 men aged 50 years or older who had normal DREs and total PSA concentrations between 2.6 and 4.0 ng/mL. Using a cutoff point of 27% free PSA, 90% of cancers were detected and 18% of unnecessary biopsies were eliminated. The positive predictive value of percentage of free PSA at this cutoff point was 24%, and 81% of 52 men who underwent radical prostatectomy were found to have organ-confined cancers. Of these cancers, 83% were considered to be clinically significant based on cancer volume, stage, and grade. Others have shown similar findings using a different PSA cutoff point. <sup>215</sup>

The percentage of free PSA may also be of value in predicting cancer aggressiveness. Carter et al. <sup>216</sup> measured both total and percentage of free PSA serially in men from whom serum had been stored before the diagnosis of prostate cancer. Stored sera from men with aggressive cancers as defined by stage (T3, nodal or bone metastases), grade (<sup>37</sup>), or positive margins at the time of radical prostatectomy were compared to sera from men with less aggressive cancers (none of the previously mentioned features). Although total PSA levels were not different between both groups measured serially before the diagnosis, a statistically significant difference between the two groups with respect to percentage of free PSA was noted. All eight patients with aggressive cancers from whom serum was available for testing 10 years before diagnosis had free PSA fractions of 14% or less.

Clinicians should be aware of several issues when determining whether to use percentage of free PSA and in interpreting results of the assay. Age, prostate volume, and method of serum storage before processing may influence PSA ratios. Samples should be processed within 3 hours or stored at  $-70^{\circ}\text{C}$  if processing is delayed; otherwise, the free PSA fraction may be degraded. <sup>217</sup> Lower free PSA cutoff points may be possible in smaller gland volumes (i.e.,  $<40\text{ cm}^3$ ) while still maintaining an acceptable detection sensitivity of 90%. <sup>207</sup> Several analytical issues must be understood. Assays performed by different methods may yield different results. <sup>191,218,219</sup> The percentage of free PSA cutoff point advised by manufacturers of these assays varies. Therefore, clinicians must be well acquainted with the methods used for free PSA testing before interpreting the results. Finally, it must be emphasized that use of percentage free PSA improves specificity of detection; some cancers will be missed. Both physicians and patients must be aware of this, as some will find any decrement in sensitivity unacceptable. Percentage of free PSA testing may be used best when determining the need for a second prostate biopsy in patients with a normal DRE, a total serum PSA between 4.0 and 10 ng/mL, and a previously negative biopsy.

### Future Refinements

Similar to use of percentage of free PSA, several investigators have assessed the measurement of complexed PSA (PSA bound to a  $\alpha_1$ -antichymotrypsin) for the detection of prostate cancer. Brawer et al. <sup>220</sup> measured total, complexed, and free PSA in 75 men with prostate cancer and in 225 who had benign findings on prostate biopsy. At 95% sensitivity, the specificities of total, free, and complexed PSA were 21.8%, 15.4%, and 26.5%, respectively. Sokoll et al. <sup>221</sup> reported similar findings and improved specificity for complexed PSA as compared to total PSA in men with total serum PSA concentrations between 4.0 and 10.0 ng/mL.

The ProstAsure Index (Horus Global HealthNet, Hilton Head Island, SC) examines the relationships between several variables, such as PSA, age, and prostatic acid phosphatase, using an artificial neural network to predict the risk of prostate cancer. Babaian et al. <sup>222</sup> compared the ProstAsure Index with percentage of free PSA for prostate cancer detection in 54 men with prostate cancer, 77 with BPH, and 94 with no evidence of either. A comparison of the receiver operating characteristics curves for both tests demonstrated that the area under the curve for the ProstAsure Index was higher than that for percentage of free PSA (0.95 vs. 0.86, respectively), suggesting a small but significant advantage for the index.

Other serum proteins have been identified that may, in the future, play a role in prostate cancer detection and evaluation. Prostate-specific membrane antigen (PSMA) is a 750–amino acid type 2 transmembrane glycoprotein distinct from PSA. Serum levels of PSMA are increased in patients with prostate cancer. Human kallikrein-2 is a serum protease that bears considerable homology to PSA. Neither PSMA nor human kallikrein-2 currently is being used routinely for prostate cancer early detection, but refinements in development of serum assays, as well as novel imaging and treatment techniques targeting these and yet-to-be discovered proteins, may have a significant impact on prostate cancer early detection, staging, and treatment.

### PROSTATE BIOPSY AND ITS IMPACT ON RISK ASSESSMENT

Prostate biopsy is indicated in men with an elevated serum PSA level, an abnormal DRE, or a combination of the two. Prostate biopsy is best performed under TRUS guidance using a spring-loaded biopsy device coupled to the transrectal probe. <sup>223,224</sup> Although prostate biopsy can be done using a transperineal approach, the transrectal approach facilitates more accurate needle placement and tissue sampling. Rather than just sampling an area abnormal on the basis of DRE or TRUS imaging, systematic biopsy strategies have been developed that improve cancer detection and risk assessment. DRE and TRUS each lack the sensitivity and specificity to guide performance of lesion-directed biopsy only. Traditionally, six (sextant) biopsies have been taken in most patients along a parasagittal line between the lateral edge and the midline of the prostate at the apex, midgland, and base bilaterally ( Fig. 34.4-4).<sup>225</sup> Recently, several investigators have assessed the impact of increasing the number of biopsies as well as sampling specific portions or zones of the prostate. <sup>225,226</sup> and <sup>227</sup> Investigators have shown that more laterally directed biopsies of the peripheral zone will increase detection rates by 14% to 20% over the more traditional sextant technique. Chang et al. <sup>225</sup> analyzed a biopsy scheme that involved tissue from a minimum of eight sites, including bilateral apex, midlobar midgland, parasagittal midgland, and lateral base (see Fig. 34.4-4). They found that the parasagittal biopsies at the base added very little unique information to this scheme.

**FIGURE 34.4-4.** Prostate biopsy schemes. **A:** Traditional sextant (six-biopsy) technique. **B:** More contemporary technique, which samples the peripheral zone more laterally and improves cancer detection rates. (From ref. 225, with permission.)

As up to 30% of lesions may originate in the transitional zone, many investigators have examined the utility of specific transitional zone biopsies. <sup>228,229,230</sup> and <sup>231</sup> Most have found that routine transitional zone biopsies add little unique information to that gained from routine peripheral zone biopsy schemes. Therefore, transitional zone biopsy should be considered in those with a high suspicion of prostate cancer based on serum PSA level and who have undergone previous peripheral zone biopsy without cancer detection. Patients should be advised that a negative prostate biopsy does not completely exclude cancer, as 13% to 31% of patients with an initially negative biopsy will be found to have cancer on subsequent biopsy. <sup>232,233</sup>

Although the primary goal of prostate biopsy is cancer detection, the information gained from the results, if positive, can be of considerable value in initial risk assessment. The number of cores with cancer as well as the cancer grade determined by biopsy correlate with the risk of ECE and cancer progression. As biopsy samples only a portion of the prostate, accurate grading may be hampered by sampling errors. Grade as measured by biopsy will correlate exactly with that determined by analysis of the entire prostate after radical prostatectomy 31% to 59% of the time. <sup>234,235</sup> Most often, needle biopsy underestimates cancer grade. Grading errors appear to be more limited with the use of contemporary biopsy schemes, which have increased (>6) the number of cores taken. <sup>236</sup>

Prostate cancer volume correlates with both the risk of extracapsular disease and outcome after treatment. Although cancer volume currently is not well assessed by imaging, analysis of the number of biopsy cores involved with cancer as well as the extent of cancer within each core appears to be of value in this regard. Patients with multiple positive biopsies are at an increased risk of both ECE and recurrence after initial therapy. One series reported on 257 consecutive radical prostatectomy patients and demonstrated that the number of positive sextant biopsies and the Gleason score correlated with ECE ( $P < .0001$  and  $P = .0004$ , respectively) in a comparison of patients with and without ECE. <sup>237</sup> With respect to serologic recurrence, patients with fewer than three positive biopsies and a Gleason score of less than 7 were at a low risk for recurrence irrespective of preoperative PSA levels (14% risk with a mean follow-up of 2 years). <sup>237</sup> Other investigators have substantiated these findings, noting that patients in whom more than 50% of biopsy cores are involved with cancer are at an increased risk of both ECE and disease recurrence after radical prostatectomy. <sup>238,239</sup> and <sup>240</sup> Knowledge of the number of cores involved may give important information not provided by analysis of the PSA level, Gleason grade, and local T stage alone. <sup>241</sup>

Although TRUS-guided prostate biopsy usually is very well tolerated by patients, approximately 24% of those undergoing the procedure will find it very painful. Hematospermia and hematuria are common, occurring in approximately 40% to 50% of patients. <sup>242,243</sup> and <sup>244</sup> High fever is rare, occurring in 2.9% to 4.2% of patients. Antibiotic prophylaxis is commonly given, although the necessity for it has been questioned by some. <sup>242</sup> Recent use of aspirin or nonsteroidal antiinflammatory agents is not a contraindication for this procedure. <sup>244</sup>

#### TO SCREEN OR NOT TO SCREEN?

The case for prostate cancer screening is supported by the following facts: The disease is burdensome; PSA testing improves detection of clinically important tumors without significantly increasing the detection of unimportant tumors; most PSA-detected tumors are curable using current techniques; and there is no cure for metastatic disease. In addition, several investigators have shown a reduction in cause-specific mortality with screening. <sup>245,246</sup> and <sup>247</sup> In a community-based, prospective, randomized trial of men between the ages of 45 and 80 years, Labrie et al. <sup>245</sup> showed that patients randomized to PSA screening had a cause-specific mortality equal to one-third that of unscreened men. However, this study must be interpreted with caution, as fewer than 20% of men in this study were randomized to screening. In an independent, population-based, case-control study that looked at screening with DRE, Jacobsen et al. <sup>246</sup> showed an association between decreased mortality and screening. However, the causal relationship between screening and decreased mortality remains to be proven. In the Prostate, Lung, Colon, Ovarian Trial supported by the National Cancer Institute, men are randomized to screening (with DRE and PSA testing) and to no screening, with cancer-specific mortality as the end point. However, the fact that therapy is not standardized and that screening will occur over only a limited period may make interpretation of results difficult. The efficacy of treatment also is currently being examined in Scandinavia, where two randomized trials compare watchful waiting with radiation or radical prostatectomy. A similar trial, Prostatectomy Versus Observation for Clinically Localized Carcinoma of the Prostate (PIVOT), is accruing patients in the United States. Patients must be informed of the risks and benefits of screening before it is carried out. It appears that many men who undergo screening in certain health care settings have no knowledge of having the test performed, suggesting that more discussion of this test with patients must occur. <sup>248</sup> If screening and eventual treatment are to be offered to asymptomatic patients, they should be offered to those whose age and health status are such that they may benefit from early detection of a disease that may have a protracted natural history (Table 34.4-5). An algorithm for early detection is outlined in Figure 34.4-5.

Age (y)	Average Life Expectancy (y)	Good-Excellent Range (y)	Fair-Poor Range (y)
65	15	17-20	11-15
70	12	13-17	8-11
75	10	10-14	6-8
80	7	8-11	3-6

(From ref. 374, with permission.)

**TABLE 34.4-5.** Average Life Expectancy and Life Expectancy Correlated with Patient's Perception of Health Status

**FIGURE 34.4-5.** Algorithm for the early detection of prostate cancer. \*Whether one uses total prostate-specific antigen (PSA) or its variations (i.e., percentage free or age-referenced prostate-specific antigen testing) for the initial screening for the disease is a matter of debate (see text). DRE, digital rectal examination; PIN, prostatic intraepithelial neoplasia; TRUS, transrectal ultrasonography.

## INITIAL CANCER STAGING AND RISK ASSESSMENT

Historically, initial risk assessment was based on clinical staging—that is, the assessment of anatomic extent of the disease on the basis of physical examination and imaging. Although clinical stage (TNM) correlates with outcome, in a large percentage of patients who are believed to have organ-confined disease, evidence of disease beyond the prostate is identified at the time of radical prostatectomy. Alternatively, some patients with high-risk pathologic features may not experience disease recurrence. Therefore, many clinicians have focused their efforts on better risk assessment schemes that predict the likelihood of disease recurrence if patients are treated and the likelihood of clinical progression if patients undergo initial surveillance. This more modern concept of risk assessment is a product of the knowledge that disease may be better characterized by analyzing many criteria (e.g., serum PSA level, Gleason grade, cancer volume) in combination with clinical stage, as compared to the use of staging alone.

An accurate assessment of risk before definitive treatment is attempted would allow for a more realistic assessment of the likelihood of cure with various treatment options and, therefore, better treatment selection. In addition, such assessment would allow for more accurate prediction of who may be candidates for neoadjuvant or adjuvant treatment or novel clinical trials owing to the presence of high-risk cancer features.

## IMAGING

Imaging plays an important role in staging. Both cross-sectional imaging of the pelvis and imaging of the bones (with radionuclide bone scanning) often are performed. However, imaging can be costly, and patients at low risk of advanced disease can be spared the cost and morbidity of cross-sectional imaging and radionuclide bone scanning. With the advent of widespread screening for prostate cancer, considerable stage migration has occurred, and the incidence of metastatic and regionally advanced prostate cancer has decreased. Several investigators have proposed guidelines for prostate cancer imaging that limit costs without compromising significantly the accuracy of staging. However, a recent analysis of the use of cross-sectional imaging [computed tomography (CT) or magnetic resonance imaging (MRI)] and bone scanning in a large cohort of patients cared for by urologists suggests that bone scans, CT, and MRI are overused, certainly in low-risk patients (i.e., PSA <10 ng/mL, stage <T2c, grade <7).<sup>249</sup> In this latter group, 66% of patients were undergoing bone scans, and 24% either CT or MRI.

Radionuclide bone scanning has replaced the use of plain films for the detection of prostate cancer metastases. Although sensitive, bone scans have a low specificity. False-positive scans can occur due to trauma, degenerative disease, or Paget's disease. Lee and Oesterling et al.<sup>250,251</sup> have conducted investigations to assess the ability of serum PSA level to predict bone scan findings (Fig. 34.4-6). In a cancer population representative of newly diagnosed patients in the United States, serum PSA level was the best predictor of bone scan results. Of 852 patients with newly detected prostate cancer, 66% had a serum PSA concentration of less than 10 ng/mL. The likelihood of a positive bone scan due to metastases was 0.6% and 2.6% for those with serum PSA concentrations between 10.1 and 15 ng/mL and 15.1 and 20 ng/mL, respectively. Use of tumor grade, local tumor stage, or a combination of these variables did not enhance the predictive power of PSA testing. Many others have confirmed these results.<sup>252,253</sup> On the basis of these results, one can omit the bone scan in patients with newly diagnosed, untreated prostate cancer who are asymptomatic and have serum PSA concentrations of less than 20 ng/mL and certainly in those with serum PSA concentrations of less than 15 ng/mL. Given that there is some risk of bone metastases in this population, it is reasonable to perform a bone scan in those patients with either very high-grade or very high-stage disease.

**FIGURE 34.4-6.** Radionuclide bone scan showing increased uptake consistent with prostate cancer metastases.

Cross-sectional imaging of the pelvis with CT or MRI in patients with prostate cancer generally is performed to exclude lymph node metastases in patients who are believed to be candidates for definitive local therapy (Fig. 34.4-7). However, the incidence of lymph node metastases is currently low (<5%), and imaging is costly and its sensitivity limited. One review of the literature encompassing 15 series and 1354 patients with an incidence of lymph node metastases of 22% revealed a sensitivity of CT and MRI of approximately 36% and a specificity of 97%.<sup>254</sup> The authors of this review suggested that only those patients with a very high risk of lymph node metastases (i.e., 45%) would benefit from cross-sectional imaging. Such patients would include those with a normal bone scan, Gleason score greater than 6, a palpable abnormality on DRE (i.e., T2 to T4 disease), and a serum PSA level of greater than 25 ng/mL.<sup>255</sup>

**FIGURE 34.4-7.** A computed tomography scan showing the presence of retroperitoneal adenopathy due to metastatic prostate cancer.

Radiolabeled monoclonal antibodies directed at PSMA have been used to stage newly diagnosed patients and identify sites of cancer recurrence after definitive therapy. Prostascint (Cytogen Corporation, Princeton, NJ) uses a murine monoclonal antibody labeled with indium 111 for the detection of lymph node and other soft tissue metastases.<sup>256,257</sup> Imaging is performed 72 to 120 hours after administration of the agent. The sensitivity, specificity, and positive predictive value of the test in one patient population with a 37% incidence of nodal metastases was 75%, 86%, and 79%, respectively. In a more recent study of 160 patients imaged before pelvic lymph node dissection, the sensitivity, specificity, and positive and negative predictive values for immunoscintigraphy were 62%, 72%, 62%, and 72%, respectively.<sup>258</sup> The authors found the test, when considered in conjunction with certain combinations of PSA level and Gleason score, was effective in predicting the risk of lymph

node metastases. The test has not gained wide popularity owing to difficulties with accurate interpretation, its cost, and the fact that similar information about risk may be gained by use of the serum PSA level, cancer grade, and cancer stage.

Whereas metastatic and regionally advanced disease are relatively uncommon at presentation, ECE and seminal vesicle invasion are not uncommon, occurring in approximately 20% to 40% and 8% of patients at presentation, respectively. Such patients are at an increased risk of recurrence with various forms of local therapy, and pretreatment knowledge of ECE would allow for more effective local therapy to be delivered (e.g., wide surgical excision, wider field, higher dose or combination radiation therapy). Whereas CT is a less reliable and efficient test for assessment of ECE or seminal vesicle invasion, as compared to other imaging modalities, both MRI using an endorectal probe and TRUS are used commonly to assess the integrity of the prostatic capsule and seminal vesicles. The performance of CT, MRI (body coil alone and endorectal coil), and TRUS in this regard is reviewed in [Table 34.4-6](#) and [Table 34.4-7](#). Given the wide range of test performance noted, other parameters of risk such as cancer grade, serum PSA level, and the number of positive biopsy samples must be taken into account when interpreting the results of either endorectal MRI or TRUS. Whereas TRUS is performed at the time of biopsy, endorectal MRI is, for the most part, used for staging only after a diagnosis has been made. Endorectal MRI may be of some value in staging intermediate-risk patients but provide little additional information in both low- and high-risk patients.

Modality	Sensitivity	Specificity	Accuracy	PPV	NPV	Ref
CT	3-75	66-88	34-67	5	6	15-23
TRUS	5-46	7-41	6-48	3-73	6-48	13,15,30
MRI	34-82	6-65	15-77	7-47	3-48	13,15,30
Endorectal MRI	15-85	4-10	6-61	6-10	4-8	30,32,33,36,35-38

CT, computed tomography; MRI, magnetic resonance imaging; PPV, positive predictive value; NPV, negative predictive value; TRUS, transrectal ultrasonography.  
Note: All values represent percentages and ranges.

Modality	Sensitivity	Specificity	Accuracy	PPV	NPV	Ref
CT	4-8	6-8	6-8	-	-	15-23
TRUS	5-75	6-10	7	5	8	15-30
MRI	3-43	6-6	7-41	3	7-73	30-38
Endorectal MRI	15-10	5-10	7-2	6-10	6-6	23,33,36,35-38

CT, computed tomography; MRI, magnetic resonance imaging; PPV, positive predictive value; NPV, negative predictive value; TRUS, transrectal ultrasonography.  
Note: All values represent percentages and ranges.

**TABLE 34.4-7.** Accuracy of Imaging for the Detection of Seminal Vesicle Invasion

The routine use of endorectal imaging is limited due to problems with interobserver variability and variable diagnostic accuracy. The development of endorectal surface coils has allowed the application of three-dimensional magnetic resonance spectroscopy (MRS) to the evaluation of prostate cancer. Significantly higher choline and lower citrate levels are observed in areas of prostate cancer as compared with either normal prostate tissue or BPH ( [Fig. 34.4-8](#)). Therefore, MRS may allow for estimation of prostate cancer volume and may improve sensitivity and specificity of cancer detection when combined with endorectal MRI. The addition of MRS to MRI recently was evaluated with respect to any improvements in cancer staging and localization. When more than 4.5 voxels per slice of prostate were involved with cancer, the risk of extracapsular invasion was 43%. If more than 6 voxels were involved, this risk rose to 75%. The impact of MRS on the accuracy of staging (detection of ECE) was most apparent when inexperienced readers were evaluating the images, suggesting that the use of such technology may be most helpful in improving the accuracy of radiologists with less experience in magnetic resonance interpretation. <sup>259,260</sup> With regard to cancer localization in patients with biopsy-proven prostate cancer, MRS in conjunction with MRI allows for improved ability to localize cancer to a sextant. <sup>261</sup> When either MRI or MRS was positive for cancer, a sensitivity of 91% was achieved. When both were positive at the same site, a specificity of 92% was achieved. Nonetheless, more experience with this technique is necessary before it can be used routinely to guide and deliver treatment.

**FIGURE 34.4-8.** **A:** Representative reception-profile corrected T2-weighted fast spin-echo axial image taken from a volume data set demonstrating a large tumor in the right midgland: low T2-weighted signal intensity ( *arrow*). **B:** T2-weighted fast spin-echo axial image with overlying point resolved spectroscopy (PRESS) selected volume (*bold white box*) and phase-encoded grid (*fine white line*) taken from a three-dimensional array of spectra. **C:** Corresponding 0.24-mL proton spectra with the major prostatic metabolites (choline-, creatine-, and citrate-labeled). Spectra in regions of cancer (left side of image) demonstrate elevated choline and reduced citrate relative to regions of healthy peripheral zone tissue. The prostate metabolite levels that are observed in different regions of zonal anatomy, benign prostatic hypertrophy, and cancer are described in detail in the text. **D:** Images can also be created from prostatic metabolite levels and overlaid on the corresponding anatomic images. The red area is where (choline + creatine) citrate ratios were greater than 3 standard deviations of healthy peripheral zone values.

#### PRETREATMENT SERUM PROSTATE-SPECIFIC ANTIGEN LEVEL, TUMOR STAGE, CANCER GRADE, AND VOLUME

Pretreatment serum PSA level is used extensively in both pretreatment risk stratification and in predicting the outcome after definitive local treatment. <sup>262,263</sup> and <sup>264</sup> The serum concentration of PSA correlates well with cancer volume and stage. However, considerable overlap exists, making use of serum PSA alone inaccurate for clinical staging in most patients. Use of serum PSA level in conjunction with cancer grade and stage adds considerable sensitivity and specificity to the prediction of lymph node status as compared to the use of PSA level alone. Investigators have published nomograms and probability curves that aid in predicting pathologic cancer stage. <sup>265,266,267</sup> and <sup>268</sup> Use of such nomograms allows a better assessment of preoperative risk and more appropriate selection of initial treatment ( [Table 34.4-8](#)). It is important to note, however, that these aid in predicting the pathologic extent of disease and not necessarily the cure rates with treatment. In addition, they do not take into account other cancer features that may be predictive. As mentioned earlier in [Prostate Biopsy and Its Impact on Risk Assessment](#), the number of positive prostate biopsies correlates with risk: Those patients in whom more than 50% of biopsy specimens prove positive or in whom two to three of three biopsy specimens on one

side are positive are more likely to have ECE.

**TABLE 34.4-8.** Prediction of Pathologic Stage Using Digital Rectal Examination, Prostate-Specific Antigen, and Tumor Grade

By the use of Gleason grade, local tumor stage, percentage of biopsy specimens involved with cancer, and serum PSA level, pretreatment risk may be assigned. [Table 34.4-9](#) is a summary of the findings from multiple analyses and can serve as a broad-based guide for pretreatment risk stratification. Future refinements in imaging and the use of molecular markers may further improve risk assessment.<sup>269,270 and 271</sup>

Risk Group	Clinic	Intermediate Local Therapy (Range)	High Local	High High	High High
Low	PSA <10 ng/mL, Gleason score ≤ 6 (range 4-6); T1, T2	4-20%	<10% positive biopsies; PSA <4 ng/mL, Gleason score ≤ 4	>10% positive biopsies	None
Intermediate	PSA 10-20 ng/mL, Gleason score 7, T2b, T3a	34-40%	<10% positive biopsies; PSA <12 ng/mL, Gleason score ≤ 4	>10% positive biopsies; Gleason score 4-7	Intermediate PSA >11 ng/mL
High	PSA >20 ng/mL, Gleason score 8-10, T3b	39-50%			Intermediate, CT, MRI of pelvis

CT, computed tomography; MRI, magnetic resonance imaging; PSA, prostate-specific antigen.  
(Data compiled from refs. 27-30, 220, 252, 263, 264, 271, 274, 322, 324, 326, 328-341.)

**TABLE 34.4-9.** Pretreatment Risk Assessment

### THE IMPACT OF RISK ASSESSMENT ON TREATMENT SELECTION

The information presented suggests that risk assessment is possible and that it provides both patients and clinicians with important information. Low-risk patients are very good candidates for definitive local therapy using standard techniques. On the basis of age, comorbidity, and the long natural history of this disease in some cases, certain patients may be candidates for surveillance alone. High-risk patients are unlikely to be cured with standard therapy and are ideal candidates for clinical trials. Combined-modality therapy may be especially important in this group of patients.<sup>272</sup> Intermediate-risk patients are candidates for modifications of standard therapy, given a significant risk of recurrence and the emerging knowledge that wide surgical excision and adjuvant radiation therapy may be useful after radical prostatectomy and that dose escalation, improved targeting, and combined-modality radiation therapy may have value over standard radiation therapy techniques in this population.<sup>273,274,275,276 and 277</sup>

### TREATMENT SELECTION FOR NONMETASTATIC (T1–T3N0M0) DISEASE

There is no consensus as to what constitutes the best form of treatment for any stage of prostatic disease. Treatment is indicated in those who are symptomatic and those who are at high risk of dying of prostate cancer or developing symptoms of the disease. Given that most patients in whom the disease is currently being detected fall into either the low- or intermediate-risk groups, immediate and aggressive treatment may not be necessary in some patients. Such patients must be informed of the potential risks and benefits of all forms of treatment as well as surveillance, which is an option for some patients. Treatment decisions should be based on cancer stage and grade as well as patient age and health. Both patient and physician bias may play a strong role in treatment selection, inasmuch as precise guidelines for treatment are not available for the majority of patients. Given the protracted and, in some cases, indolent nature of the disease, disease progression may be avoided using a variety of treatment methods. Indeed, the morbidity of different treatment regimens may guide treatment selection in some patients.

Both patients and physicians must interpret the results (morbidity and cancer control rates) of various forms of treatment with caution. Often, the morbidity of treatment is reported using physicians' estimates. However, physicians generally underestimate the impact of the disease in almost all health-related quality-of-life domains.<sup>278</sup> Given the protracted nature of prostate cancer, only a limited number of patients may die of their disease. Therefore, outcome often is assessed using end points other than cause-specific survival, the most common being PSA levels. After radical prostatectomy, the PSA level should fall to undetectable, usually within 6 weeks of surgery. A persistently detectable PSA level predicts clinical recurrence, although disease may not return for many years and may not lead to death.<sup>279</sup> After cryotherapy and radiation therapy, PSA continues to be produced in most patients. What constitutes an acceptable PSA level after either form of treatment is a matter of some debate. Whereas some argue that low (i.e., <0.5 ng/mL) nadir levels should be reached, the American Society for Therapeutic Radiology and Oncology (ASTRO) defines biochemical recurrence after radiation therapy as three consecutive rises in serum PSA level above nadir.<sup>280,281</sup> Failure cannot occur until nadir is reached. This method of defining outcome is very sensitive to the length of follow-up and the frequency of PSA testing.

### NATURAL HISTORY AND SURVEILLANCE ALONE

Certain prostate cancers may grow slowly. In addition, many patients with this disease are elderly and may have concomitant illnesses. Therefore, watchful waiting or surveillance alone may be an appropriate form of management for selected patients with prostate cancer. Contemporary series documenting the true natural history of untreated prostate cancer are limited. Many series are composed of only carefully selected patients, many of whom may have received some form of treatment, often androgen deprivation, during follow-up.

Several investigators have reported the likelihood of local and distant tumor progression in patients who were untreated or who were treated with noncurative intent (i.e., androgen deprivation) ([Table 34.4-10](#)). The risk of local progression in these series ranges from 8% to 84%, while the risk of progression to metastatic disease ranges from 6% to 74%. The results should be interpreted with caution, as most patients were older (i.e., >70 years old) and had low-grade or low-stage disease (or both). Furthermore, follow-up in these studies ranged from 4 to 14 years after diagnosis, and such differences likely account for the wide range of local and distant progression reported. Therefore, the results may underestimate the risk of disease progression in the general population of patients with prostate cancer, most notably in those who present at a younger age (i.e., <65 years). The definition of local progression in the majority of these series was based on changes in DRE, which is an imprecise measure. Two studies by Egawa et al.<sup>282</sup> and Rana et al.<sup>283</sup> have defined local progression by the development of bladder outlet obstructive symptoms necessitating surgical intervention. These were the only studies in which distant progression exceeded local progression. Finally, it must be emphasized that the use and timing of androgen deprivation therapy varied between studies.<sup>282,283,284,285,286,287,288 and 289</sup>

Study	Year	No. of Patients	Mean Follow-Up (y)	Local Tumor Progression	Metastatic Tumor Progression
Epstein et al. <sup>290</sup>	1988	107	6.2	85% of patients	25% of patients
Group <sup>291</sup>	1988	138	7	86% of patients	17% of patients
Werner and Whitmore <sup>292</sup>	1984	75	11.3-13.5	73.8% of patients, median time to progression, 28 mo	Median time to progression, 38 mo
Boer and Cook <sup>293</sup>	1981	38	6.8-12.1	N/A	65% of patients
Matheson et al. <sup>294</sup> (clinical T3)	1988	38	7.5	86% of patients	32% at 5 y, 45% at 10 y, 58% at 15 y
Matheson et al. <sup>294</sup> (clinically localized)	1987	122	6.1	N/A	38% at 5 y, 45% at 10 y
Matheson and Coakley <sup>295</sup> (age < 70)	1981	61	8.9	49% at 5 y, 75% at 10 y	6% at 5 y, 25% at 10 y
Matheson et al. <sup>295</sup> (age > 70)	1984	108	4.2	28% of patients	43% of patients
Johansson et al. <sup>296</sup>	1987	225	14	28% of untreated patients with localized disease	25% of untreated patients with localized disease
Chodak et al. <sup>297</sup>	1984	128	6.6	N/A	39% of grade 1, 45% of grade 2, 76% of grade 3 at 10 y

**TABLE 34.4-10.** Estimates of Local and Metastatic Tumor Progression in Prostate Cancer Patients Who Remain Untreated and in Those Who Are Treated with Noncurative Intent

The risk of death due to prostate cancer in these series varies. Prostate cancer caused or contributed to death in 34% to 62% of the patients who died. [290,291,292,293,294](#) and [295](#) In a study of 514 prostate cancer patients, all of whom died between 1988 and 1991 and received immediate or deferred androgen deprivation therapy only, Aus et al. [291](#) found that prostate cancer caused or contributed to death in 62% of the study population. When analyzing only those patients with clinically localized disease at diagnosis (M0), 50% still died as a result of prostate cancer. Gronberg et al. [293](#) examined 6514 similar patients, in all of whom prostate cancer was diagnosed in Northern Sweden between 1971 and 1987. Follow-up in this series ranged from 7 to 23 years after initial diagnosis. Fifty-five percent of the patients who died during this time died as a result of prostate cancer. In a series of 451 prostate cancer patients from the Connecticut Tumor Registry, Albertsen et al. [290](#) reported that prostate cancer was the underlying cause of death in 34% of those who died after a mean follow-up of 15.5 years.

Brasso et al. [295](#) found that prostate cancer caused a significant excess mortality in untreated patients, with the number of actual deaths being approximately 1.6-fold greater than the expected number of deaths in the general population. Similarly, Rana et al. [283](#) reported that actuarial survival was 17% less at 5 years and 15% less at 10 years after diagnosis for 199 prostate cancer patients who were managed conservatively, as compared to age-matched controls. Others have shown that patients with prostate cancer may lose a significant number of years of life when their disease is managed conservatively. [290,294](#) Stattin et al. [294](#) reported a life expectancy of 6.3 years in 186 prostate cancer patients who were managed with delayed androgen deprivation after transurethral prostatectomy, as compared to a 10.2-year life expectancy for age-matched controls. Finally, several investigators have reported disease-specific survival for prostate cancer patients who were untreated or treated with noncurative intent. Disease-specific survival ranged from 60% to 98% at 5 years, 34% to 92% at 10 years, and 62% to 81% at 15 years after diagnosis ([Table 34.4-11](#)). [282,283,284,285,286,287,288](#) and [289,296,297](#)

Study	Year	No. of Patients	Follow-Up (y)	Disease-Specific Survival
Group <sup>291</sup>	1988	138	7	86% at 5 y, 75% at 10 y after diagnosis
Boer and Cook <sup>293</sup>	1981	38	6.8-12.1	65-85% at 5 y (overall survival)
Johansson et al. <sup>296</sup>	1987	225	14	86% at 5 y, 85% at 10 y after diagnosis
Chodak et al. <sup>297</sup>	1984	128	6.6	87% well- or moderately differentiated, 54% poorly differentiated at 10 y after diagnosis
Rana et al. <sup>283</sup>	1984	199	4.2	70% at 5 y, 35% at 10 y after diagnosis
Werner and Whitmore <sup>292</sup>	1984	75	11.3-13.5	Median survival, 28 mo after diagnosis
Epstein et al. <sup>290</sup>	1988	107	6.2	70% at 5 y, 75% at 10 y after diagnosis
Matheson et al. <sup>294</sup> (clinically localized)	1987	122	6.1	38% at 5 y, 45% at 10 y after diagnosis
Matheson and Coakley <sup>295</sup> (age < 70)	1981	61	8.9	49% at 5 y, 75% at 10 y after diagnosis
Matheson et al. <sup>295</sup> (clinical T3)	1988	38	7.5	32% at 5 y, 45% at 10 y, 58% at 15 y after diagnosis

**TABLE 34.4-11.** Estimates of Disease-Specific Survival in Prostate Cancer Patients Who Remain Untreated and in Those Who Are Treated with Noncurative Intent

The risk of prostate cancer progression is intimately related to stage and grade of the disease at the time of diagnosis. [283,285,287,288](#) and [289,291,294,295,298](#) Patients with metastatic disease at the time of diagnosis fare significantly worse than do patients with clinically localized disease at presentation. Brasso et al. [295](#) reported that the median survival was 3.7 years for patients with clinically localized prostate cancer, 1.8 years for patients with regionally advanced disease, and only 1.1 years for patients with metastatic disease at diagnosis. In the subset of patients surviving for at least 10 years after diagnosis, prostate cancer was the underlying cause of death in 61% of patients with clinically localized disease and in 76% of patients with advanced disease at diagnosis. Johansson et al. [288](#) reported outcomes for 642 patients, most of whom were treated with immediate or delayed androgen deprivation. While the 15-year corrected survival was 81% for patients with clinically organ-confined disease (stage T0 to T2) and 57% for patients with clinical stage T3 or T4 disease at diagnosis, the 15-year corrected survival was only 6% for patients with metastases at diagnosis. In a study of 514 prostate cancer patients treated with immediate or deferred androgen deprivation, Aus et al. [291](#) reported that the median survival of patients with localized disease at diagnosis was 82 months, as compared to only 26 months for patients with metastases at diagnosis. In those with clinically localized disease, T stage correlates with outcome. The risk of local and distant cancer progression and, ultimately, death rises with T stage. The risk of metastatic progression at 10 to 15 years after diagnosis is approximately 25% to 34% for those with T3 disease, whereas it is 13% to 20% for those with stage T1 and T2 disease. [285,287,288](#) Similarly, 10- to 15-year overall and disease-specific survival is better for those with T1 and T2 disease (62% to 90%), as compared to that associated with T3 and T4 disease (57% to 70%). [288,289,298](#) It should be noted that the risk of progression from stage T1 or T2 disease to T3 disease is approximately 70% at 10 years in those managed conservatively. [285](#) Aus et al. [291](#) found that 10% of patients with clinical stage T1a disease, 47% with clinical stage T1b disease, 52% with clinical stage T2a disease, 53% with clinical stage T2b to T3 disease, and 70% with clinical stage T4 disease ultimately died of prostate cancer. [291](#)

Tumor grade may be the most important factor predicting disease progression and survival in prostate cancer patients managed conservatively. In a review of 828 prostate cancer patients obtained from six nonrandomized studies of men treated with observation and delayed androgen deprivation, Chodak et al. [297](#) reported that poorly differentiated disease was the single most important predictor of disease-specific survival. The likelihood of remaining metastasis-free 10 years after diagnosis for patients with well-, moderately, and poorly differentiated tumors was 81%, 58%, and 26%, respectively. Disease-specific survival 10 years after diagnosis was 87% for patients with well- or moderately differentiated disease and only 34% for patients with poorly differentiated disease. [297](#) Similar results with respect to disease-specific survival and prostate cancer-related death have been reported in a number of other studies ([Table 34.4-12](#)). [282,290,291,299](#) Moreover, poorly differentiated disease remains a significant predictor of prostate cancer-related death when adjusting for other factors such as tumor stage and patient age. [282,283,294,297](#) In these studies, the relative risk of prostate cancer-related death ranges from 2.6 to 3.6 for patients with moderately differentiated disease and from 6.1 to 12.9 for patients with poorly differentiated disease as compared to patients with well-differentiated prostate cancers.

Study	No. of Patients	Follow-Up (y)	Outcome	Well-Differentiated (%)	Moderately Differentiated (%)	Poorly Differentiated (%)
Johansson et al. <sup>288</sup>	642	14	Death from prostate cancer	18	38	68
Matheson et al. <sup>294</sup>	61	13.3	Death from prostate cancer at 10 y	9	28	31
Chodak et al. <sup>297</sup>	128	6.6	Disease-specific survival at 10 y	87% (well- and moderately differentiated)	N/A	34
Gronberg et al. <sup>293</sup>	6514	1-23	No. of prostate cancer deaths	68	34	72
Matheson et al. <sup>295</sup>	187	10-20	Probability of death from prostate cancer	6.7	6-12 (disease-specific survival % at 10 y)	65-76 (disease-specific survival % at 10 y)
Epstein et al. <sup>290</sup>	107	6.2	Disease-specific survival at 10 y	68	67	28
Rana et al. <sup>283</sup>	199	4.2	Risk of prostate cancer-related death	13	18	60

N/A, data not available.

**TABLE 34.4-12.** Outcome of Conservative Management of Prostate Cancer According to Histologic Tumor Grade

In one of the best-performed studies on prostate cancer natural history done to date, Albertsen et al. <sup>290,299</sup> examined the impact of tumor grade on long-term survival among prostate cancer patients who were treated with either observation or immediate or delayed androgen deprivation. In their initial study, these authors determined that tumor grade correlated with death due to prostate cancer. Nine percent of patients with well-differentiated, 28% of patients with moderately differentiated, and 51% of patients with poorly differentiated disease died as a result of their prostate cancer within 15 years of diagnosis. <sup>290</sup> These authors also compared the survival of prostate cancer patients treated conservatively with the expected survival of the general population. Age-adjusted survival for men with well-differentiated, Gleason score 2 to 4 tumors was not significantly different from that of the general population. In contrast, the maximum expected loss-of-life expectancy was 4 to 5 years for men with Gleason score 5 to 7 tumors and 6 to 8 years for men with Gleason score 8 to 10 tumors as compared to the general population. <sup>290</sup> In a subsequent study, these authors developed a competing risk analysis to estimate the probability of dying from prostate cancer in 767 men, aged 55 to 74 years, all of whom remained untreated or received immediate or delayed androgen deprivation only. <sup>299</sup> Tumor grade had the most important impact on the risk of prostate cancer–related death for these patients: 4% to 7% of men with Gleason score 2 to 4 disease, 6% to 11% of patients with Gleason score 5 disease, 18% to 30% of patients with Gleason score 6 disease, 42% to 70% of patients with Gleason score 7 disease, and 60% to 87% of patients with Gleason score 8 to 10 disease died of prostate cancer within 15 years of diagnosis. <sup>299</sup> Others have reported similar findings (see [Table 34.4-12](#)).

Watchful waiting or surveillance alone for prostate cancer is an option for all patients with the disease. However, progression is likely in many, and the risk correlates with cancer stage and grade. Patients best suited for this approach may be those who are older and have low-grade or low-stage disease and in those with significant comorbidity. In such patients, the morbidity of treatment may outweigh the risks of significant disease progression. Patients being followed up with surveillance only need to be advised that end points for intervention for those on watchful waiting regimens have not been defined.

### **RADICAL PROSTATECTOMY**

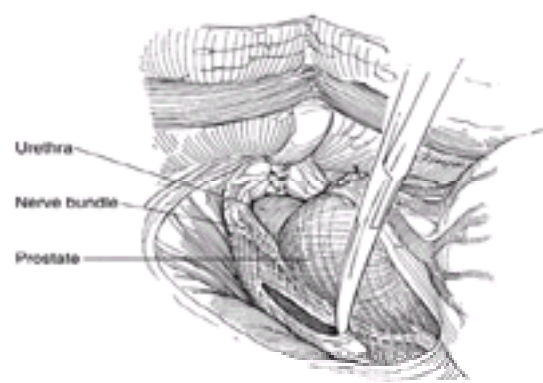

Radical prostatectomy can be performed through a lower abdominal incision (radical retropubic prostatectomy) or through a perineal incision (radical perineal prostatectomy). With the former technique, lymphadenectomy can be performed simultaneously. With radical perineal prostatectomy, lymphadenectomy can be performed through a separate incision, laparoscopically, or deleted in those at very low risk of lymph node metastases. Recently, a laparoscopic approach to radical prostatectomy has been developed. <sup>300,301</sup> Although early reports suggest that this technique is feasible and is associated with limited morbidity and acceptable positive margin and biochemical control rates, long-term follow-up in suitable patient populations is not yet available.

Contemporary series of patients with localized prostate cancers suggest that few patients harbor lymphatic disease (4% to 9%), and the risk of lymph node metastases can be quantitated as described previously in Imaging. Whereas high-risk patients benefit from lymphadenectomy, low-risk patients may forgo lymphadenectomy and be treated with definitive local therapy, whether irradiation or radical prostatectomy. <sup>302,303</sup>

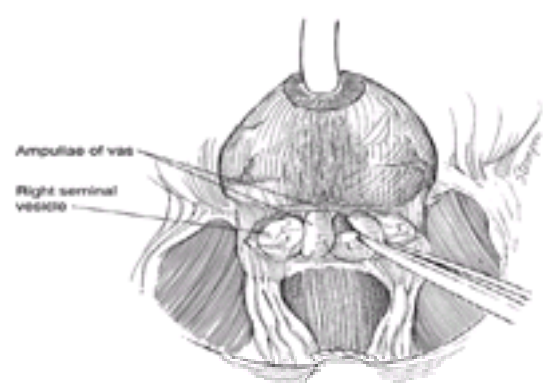

Lymphadenectomy should be considered if the Gleason score is 5 to 6 and the PSA level is at least 20 ng/mL or if the Gleason score is 7 or higher and the PSA level is at least 15 ng/mL. Patients with clinical stage C (T3) disease should also be considered as candidates for the procedure.

Radical retropubic prostatectomy is performed through a lower midline incision. The rectus abdominis muscles are separated in the midline, and the retropubic space is entered. A fixed retractor is placed. Lymphadenectomy may be performed selectively as described. Lymph node dissection has been modified over the last several years to include lymph node tissue in areas most likely to harbor disease. The limits of dissection, therefore, most often include the obturator nerve posteriorly, the common iliac artery superiorly, the circumflex iliac vein inferiorly, and the internal aspect of the external iliac vein laterally.

Exposure of the prostate when performing a radical retropubic prostatectomy is undertaken by first incising the endopelvic fascia from the area of the puboprostatic ligaments along the lateral edge of the prostate to its base ( [Fig. 34.4-9](#)). Fibers of the levator ani are separated from the apex of the prostate. The fascia and overlying dorsal vein complex generally are gathered and suture-ligated to facilitate exposure and prevent bleeding from the complex once it is cut to allow access to the urethra ( [Fig. 34.4-10](#)). The puboprostatic ligaments, which provide anterior support of the urethra, are left intact over the urethra, but any attachments to the prostate are incised. Preservation of the puboprostatic ligaments facilitates earlier and more complete return of urinary continence as compared to previous techniques, which incised these ligaments over the urethra. Care is taken during the apical dissection of the prostate simultaneously to preserve the urethra's distal continence mechanism and to excise all prostate tissue. The urethral incision should be carried posteriorly beyond the urethra to include Denonvilliers' fascia, thereby ensuring complete cancer excision.

**FIGURE 34.4-9.** Radical prostatectomy. Incision is made in the lateral prostatic fascia to allow for nerve preservation or excision, depending on clinical stage and grade of disease.

**FIGURE 34.4-10.** Radical prostatectomy, showing exposure of the seminal vesicles and ligation of the ampullae.

Penile erection is a neurovascular phenomenon, and the nerves and arterial blood supply (neurovascular bundles) crucial to potency run posterolaterally along either side of the prostate ( [Fig. 34.4-11](#)). These bundles may be spared during surgery in an effort to preserve potency. However, ECE, when it does occur, may occur in the region of the neurovascular bundles. These bundles should be preserved cautiously in those at high risk of ECE. In addition, return of potency after a nerve-sparing

radical prostatectomy is not only a function of technique but also of patient age and preoperative function. Older patients and those with poor preoperative potency may not benefit from a nerve-sparing approach. The neurovascular bundles can be located using anatomic landmarks. During nerve-sparing radical prostatectomy, the lateral prostatic fascia is incised. The neurovascular bundles run deep to this fascia at approximately the 5- and 7-o'clock positions along the posterolateral surface of the prostate. Small vascular branches to the prostate may be taken using small clips or sutures. The neurovascular bundles are at the most risk for damage at the time of urethral dissection and transection, ligation of the lateral pedicles, and dissection of the seminal vesicles. However, a nerve stimulation device may facilitate identification and preservation.<sup>304,305</sup> Electrical stimulation may result in smooth muscle relaxation of penile tissue and expansion of corporal sinusoids, resulting in increased penile blood flow, girth, and length. Either intracavernous pressure or penile circumference monitoring can note such changes. Early experience using a commercially available intraoperative, nerve-stimulating device and continuous monitoring of penile circumference during stimulation suggests that use of such a device may allow for better preservation of erectile function.

**FIGURE 34.4-11.** Typical endorectal magnetic resonance image of the prostate demonstrating the relationship of the neurovascular bundles ( arrows) to the prostate.

The lateral pedicles, branches of the prostatic and rectal arteries, are located alongside the prostate. Dissection proceeds superiorly, exposing the seminal vesicles and ampullae of the vas deferens. The ampullae are clipped or tied before being cut, and each seminal vesicle is excised in its entirety. The prostate then is separated from the bladder neck circumferentially. Once the prostate is removed, the bladder neck is closed to a smaller size, if necessary. The bladder neck is sutured to the urethral stump using interrupted suture material over a urethral catheter.

Hospitalization is limited to 2 or 3 days in most situations. The urethral catheter is removed generally between 5 and 14 days after the procedure. Approximately one-half of patients will gain almost immediate urinary control. In the remaining patients, continence will return progressively within 3 to 6 months, rarely longer. Little additional urinary control occurs beyond 12 months. Erectile function in those who have undergone a nerve-sparing approach generally takes longer to return than does urinary continence. Patients may require use of sildenafil (Viagra), vacuum devices, or intracavernous injection therapy, at least initially.

Radical prostatectomy for patients with clinically localized disease is generally well tolerated, with excellent outcomes. In a series of more than 600 men treated with prostatectomy, Trapasso et al.<sup>306</sup> reported a 10-year crude survival rate of 86% and a cause-specific survival of 94%. In an independent analysis of 3170 men treated at a different institution, Zincke et al.<sup>307</sup> reported similar 10-year crude and cause-specific survival rates of 75% and 90%, respectively. In addition, Zincke's group found that crude survival rates at 10 and 15 years after surgery were similar to those of age-matched men from the general population.<sup>307</sup> This finding suggests that carefully selected patients with clinically localized prostate cancer that is treated with prostatectomy can expect to live as long as cohorts without prostate cancer in their community.

However, clinical disease staging is far from perfect, as up to 50% of patients believed to have organ-confined prostate cancer at the time of surgery are later found to have disease beyond the prostate.<sup>262,265,307,308</sup> and <sup>309</sup> In addition, cancer recurrences are not uncommon in intermediate- to high-risk patients.<sup>59</sup> Given the protracted nature of this disease and the fact that residual and recurrent disease may respond to salvage therapy such as radiation or hormonal ablation, postoperative follow-up with sensitive serum PSA assays has become increasingly important.<sup>262,310,311,312</sup> and <sup>313</sup> Today, most clinical investigators report patient outcomes in terms of freedom from biochemical failure as well as clinical disease-free survival, in addition to crude and cause-specific survival. *Biochemical failure* is defined as either the persistence of a detectable PSA level postoperatively or the elevation of postoperative PSA to a detectable from a previously undetectable postoperative level. Total serum PSA has a half-life of 2 to 3 days, and its clearance follows first-order elimination kinetics; thus, the duration between surgery and PSA nadir generally takes several weeks and varies as a function of the patient's preoperative PSA level.<sup>314</sup> Postoperative follow-up regimens reflect PSA elimination kinetics and usually consist of symptom assessment and measurement of serum PSA every 3 months for the first year, biannually for the second year and third year, and annually thereafter. Clinical disease-free survival refers to freedom from detectable local or metastatic disease as assessed by the physician using physical examination, DRE, needle biopsy, radioisotope studies, and other traditional imaging modalities. Of note, studies from the early PSA era frequently used higher PSA cutoffs (e.g., 0.6 ng/mL). However, as the sensitivity of PSA assays improved over the last decade, most clinical investigators now use much lower cutoff points.

In the majority of cases, the first sign of disease recurrence or persistence is biochemical failure.<sup>262,279,315,316</sup> In two contemporary prostatectomy series from the Cleveland Clinic and Johns Hopkins Hospital totaling more than 2000 patients, not one patient showed signs of clinical disease in the absence of PSA failure.<sup>262,279</sup> Indeed, with the current patient follow-up regimen, nearly all recurrent clinical and metastatic disease is preceded by a rising PSA level, and only a few sporadic cases have been reported in the absence of detectable serum PSA.<sup>317</sup> After biochemical (PSA) failure, up to 68% of men will progress to detectable clinical disease at a median follow-up of 19 months. With adjuvant therapy such as irradiation or androgen deprivation at the time of PSA failure, the rate of progression to clinical disease is reportedly lower, at 21%.<sup>262</sup> Metastatic disease after PSA failure occurs in 34% of patients without adjuvant or salvage therapy, and investigators have reported a median actuarial time to metastases of 8 years from the time of PSA failure.<sup>279</sup> For those who develop metastatic disease, the median actuarial time to death was 5 years from the time of metastasis.

Several academic institutions have reported their experience in treating patients with clinically localized disease. The overall 5- and 10-year actuarial PSA progression-free rates range from 59% to 83% and 47% to 74%, respectively (Table 34.4-13).<sup>262,306,307,318,319,320,321</sup> and <sup>322</sup> The variability in outcomes likely reflects differences in patient selection, surgical technique, and definition of biochemical failure, as those with higher preoperative serum PSA levels, Gleason scores, disease stage, and positive surgical margin status tend to fare worse than counterparts with lower values or negative margins.<sup>262,322,323</sup> Reflecting the natural history of disease progression, clinical disease-free rates are higher, at 84% to 86% (5 years) and 72% to 78% (10 years).

Institution	No. of Patients	5Y (%)	10Y (%)	Outcome	Follow-Up (yr)
Washington University <sup>318</sup>	925	76	61	PSA <0.1 ng/mL	13 (median)

**TABLE 34.4-13.** Comparison of Actuarial Survival Outcomes for Patients Treated with Radical Prostatectomy

The risk of disease progression and adverse outcomes varies directly with increasing pathologic disease stage, preoperative PSA level, and prostatectomy Gleason

scores.<sup>58,262,308,322,324</sup> Whereas PSA relapse-free survival is approximately 80% to 84% for those with T2 disease, it falls to 57% to 67% for those with T3 disease. If one looks at all T stages, those patients who present with serum PSA levels of 10 ng/mL or less have PSA relapse-free survival rates of 80% to 95%, as compared to those with initial serum PSA levels of 10.1 to 20 ng/mL (48% to 75%) and those with levels in excess of 20 ng/mL (31% to 55%). Cancers with Gleason scores of 6 or less are associated with PSA relapse-free survival rates of 75% to 92%, as compared to PSA relapse-free survival rates of approximately 62% to 67% and 38% to 52% for Gleason 7 and 8 to 10 cancers, respectively. PSA relapse-free survival correlates with the risk assessment scheme outlined in [Table 34.4-9](#). At the University of California at San Francisco (UCSF), 92%, 75%, and 44% of low-, intermediate-, and high-risk patients, respectively, managed by radical prostatectomy were free of relapse at 5 years. DNA aneuploidy, seminal vesicle invasion, and positive surgical margin status have also been reported to influence survival outcomes negatively.<sup>58,273,323</sup>

### Complications

With increasing experience, the mortality and morbidity associated with radical prostatectomy has declined dramatically. Perioperative mortality in academic centers is exceedingly rare, at approximately 0.2%.<sup>307,325</sup> Intraoperative rectal injury and the need for a colostomy has decreased from 1% and 0.2%, respectively, for the period prior to 1988 to 0.6% and 0.06% for the period after. Similarly, complications such as myocardial infarction (0.1% to 0.4%), deep venous thrombosis (1.1%), pulmonary embolism (0.75%), blood transfusions (<5%), anastomotic stricture (4%), inguinal hernia (1%), and incisional hernia (0.6%) are becoming less common. In the series by Catalona et al.,<sup>325</sup> the incidence of stricture decreased with surgical experience from 6.0% for the first 1000 patients treated to 1.1% in the last 870 patients. As surgical experience continues to grow and techniques are refined, complication rates are likely to decrease further.

A more frequent surgical complication that can significantly influence patients' quality of life is incontinence, both urinary and fecal. Urinary continence is normally maintained by the bladder neck, prostatic smooth muscle, and external striated sphincter.<sup>8</sup> After surgery, the immediate postoperative incontinence rate may be as high as 80%, though more contemporary series report a much lower rate of immediate incontinence.<sup>326,327</sup> Fortunately, the majority of patients (86% to 92%) recover urinary continence within the first postoperative year with observation.<sup>326,327</sup> Some investigators have recommended pelvic floor exercises in the early postoperative period to enhance and expedite recovery of continence; however, the long-term benefits remain unclear.<sup>328,329</sup>

Depending on the patient's age, definition of incontinence, method of assessment, and surgical technique, incontinence rates at 1 year vary from 3% to 36%.<sup>307,325,327,330,331,332</sup> and <sup>333</sup> Across three institutions that included nearly 3000 patients, approximately 90% will be continent at 1 year, when continence is defined as no regular use of pads or no leakage with moderate exercise.<sup>325,326</sup> and <sup>327</sup> In a multivariate analysis of risk factors for urinary incontinence, Eastham et al.<sup>327</sup> reported that decreasing age, preservation of both neurovascular bundles, an absence of an anastomotic stricture, and use of a modified surgical technique about the striated urinary sphincter were independently associated with superior urinary outcomes. Continence appears to be equally well preserved with both the retropubic and perineal approaches.<sup>327,334</sup> Severe and persistent incontinence, defined as leakage with normal activity or the need for three or more pads per day, occurs in 1% to 6% of patients, and the use of an artificial sphincter, collagen injection therapy, or surgical sling procedure should be considered in such patients.<sup>307,327,335,336,337</sup> and <sup>338</sup>

A rare complication of surgery is fecal incontinence. Defined as the involuntary loss of liquid or solid stool, fecal incontinence may be caused by direct injury to the internal and external sphincters during perineal prostatectomy or by prolonged retraction of these segments during the procedure leading to neurologic compromise. However, the exact mechanism of injury remains elusive. In a validated patient survey, Bishoff et al.<sup>327</sup> initially evaluated 227 patients treated at two institutions and reported new-onset fecal incontinence rates of 5% and 18% for patients treated with the retropubic and perineal surgical approach, respectively. Although fecal incontinence was most often very limited, patients treated with perineal prostatectomy fared worse in terms of incontinence frequency and volume of leakage. Given the negative impact on patients' quality of life and that patients with fecal incontinence may not report their problem to health care providers, physicians must take a proactive role in assessing this complication.

Maintenance of sexual function has been a major concern for patients and physicians alike. With the advent of the nerve-sparing approach to radical retropubic prostatectomy, more than two-thirds of preoperatively potent patients treated by an experienced surgical team can anticipate return of potency without sacrificing cancer control.<sup>279,325,339,340</sup> Such rates are not reported by all investigators.<sup>341,342</sup> Return of potency after radical prostatectomy depends on many factors, including preoperative potency status, cancer stage, patient age, and whether one or both neurovascular bundles are spared. In clinical studies, *potency* usually is defined as the ability to sustain an erection sufficient for penetration and intercourse. Catalona et al.<sup>325</sup> reported recovery of potency in 68% and 47% of preoperatively potent men treated with bilateral or unilateral nerve-sparing surgery, respectively. Furthermore, younger patients reported superior outcomes. With a follow-up period of at least 18 months, 90% of men between the ages of 40 and 49 years were potent, as compared to 80%, 60%, and 47% of counterparts in their 50s, 60s, and 70s, respectively. Although not statistically significant, the authors reported a trend for better potency outcomes in men with lower preoperative PSA levels and lower disease stage. All studies suggest that the patients most likely to benefit from nerve-sparing surgery are those who are young, potent, and sexually active and have focal disease. It also appears that return of spontaneous erections after nerve-sparing surgery may be improved with early use of either sildenafil or intracavernous injection therapy.<sup>343,344</sup>

In summary, radical prostatectomy is a safe operation for properly selected patients and offers excellent cancer control. Cause-specific survival at 10 years is greater than 90%, and 70% of patients will be free of any signs of disease at 5 years. Major complications are rare, and the complication rate decreases with the surgeon's experience. With current refinements in technique, significant urinary incontinence is rare, and preservation of potency is possible in selected patients. Patients most likely to benefit from this approach are those who have long life expectancies and have either organ-confined disease or limited ECE, which can be excised completely.

### Recurrence after Radical Prostatectomy and Role of Neoadjuvant and Adjuvant Therapy

Given the cancer recurrence and secondary treatment rates after radical prostatectomy, some investigators have tested the hypothesis that these rates could be reduced by neoadjuvant androgen deprivation.<sup>345</sup> Such therapy could decrease the likelihood of positive surgical margins, leading to a decrease in local recurrence rates. Every randomized trial performed to date has shown that neoadjuvant androgen deprivation significantly decreases the rate of positive surgical margins.<sup>346,347</sup> and <sup>348</sup> The rates of positive surgical margins were decreased by approximately 40% to 60% with neoadjuvant androgen deprivation. Unfortunately, this has not translated into any improvement in clinical or biochemical control rates. In a contemporary trial reported by Klotz and other members of the Canadian Urologic Oncology Group,<sup>349</sup> 213 patients with localized prostate cancer were randomized to radical prostatectomy alone (n = 101) or 12 weeks of cyproterone acetate followed by surgery (n = 112). The probability of biochemical progression at 36 months was similar for the groups treated by surgery alone or cyproterone acetate followed by surgery: 30.1% versus 40.2% (P = .3233), respectively. This and similar trials are ongoing. Failure to demonstrate a small, but significant, benefit to neoadjuvant therapy may be due to insufficient follow-up, short duration of androgen deprivation, insufficient power of some trials to demonstrate a benefit, or inclusion in the trials of large numbers of either very low-risk or high-risk patients. Most trials used 3 months of androgen deprivation preoperatively. Some suggest that extending the length of time of neoadjuvant androgen deprivation before surgery may translate into improved outcomes, as further decreases in prostate and cancer volume and serum PSA levels occur after 3 months.<sup>350,351</sup> It is clear, however, that neoadjuvant androgen deprivation cannot substitute for careful preoperative risk assessment and meticulous surgical technique.

For those who have undergone radical prostatectomy, several models have been proposed to identify patients at very high risk for relapse. Partin et al.<sup>352</sup> developed a model from a cohort of patients from one center and validated it on a second cohort of patients from the same center. Additional independent validation was performed.<sup>353</sup> In this model, 80% of failures occur within 4 years of radical prostatectomy, with a median time to failure of 14 to 16 months. The model was defined as:  $R_w = (0.061 \times PSA_{ST}) + (0.54 \times \text{postoperative Gleason sum}) + (1.87 \times \text{specimen confined})$ . Variables were defined as follows:  $PSA_{ST} = 10 / (1 + e^{6.8704 - 0.9815 \times PSA})$ ; *specimen confined* was defined as 1 if there was capsular penetration with positive surgical margins or positive seminal vesicles and was otherwise defined as 0. Patients were considered to be at high risk for serologic relapse, as demonstrated by an  $R_w$  exceeding 5.75. From a practical standpoint, an  $R_w$  will exceed 5.75 if (1) the cancer is confined to the surgical specimen, PSA level is at least 7.3, and Gleason score is 10; (2) there is ECE with positive margins or seminal vesicle invasion, PSA level is at least 5.4, and the Gleason score is 7; or (3) there is ECE with positive margins or seminal vesicle invasion and the Gleason score exceeds 8.

A second model for patients with pathologically capsule-confined prostate cancer has been proposed by D'Amico et al.<sup>354</sup> The model was defined as:  $V_{ca} = \text{cancer-specific PSA/PSA leak into serum per cubic centimeter of cancer}$ . Variables were defined as follows: *cancer-specific PSA* = PSA (preoperative) - [0.2 × 0.33 × TRUS prostate volume]. PSA leak is a constant, as a function of Gleason sum.  $V_{ca}$  will exceed 4.0 cc in patients with pathologically capsule-confined prostate cancer if (1) Gleason score is 6 and PSA level exceeds 18, (2) Gleason score is 7 and PSA level exceeds 14, or (3) Gleason score is 8, 9, or 10. Recently, Kattan et al.<sup>355</sup> developed a preoperative nomogram for disease recurrence after radical prostatectomy. The nomogram is used by locating a patient's position on a number of

predictor variable scales. Each scale has corresponding prognostic points. The point total for all variables is summed, and this sum corresponds to the 5-year PSA progression-free survival likelihood.

From the preceding information, one can broadly identify patients who would be at high risk of relapse for whom adjuvant therapy after radical prostatectomy may be of most benefit. High-risk patients would be those having the following clinical and pathologic findings: (1) positive seminal vesicles, (2) Gleason score 6 and PSA level greater than 18, (3) Gleason score 7 and PSA level greater than 14, (4) Gleason score 8, 9, or 10 and any PSA level, and (5) those with positive surgical margins. Low-risk patients include those with a low pretreatment PSA level (i.e., <10 ng/mL), stage T1c or T2a disease, Gleason grades 1 through 3 disease, and clear surgical margins.

Optimal treatment for patients with adverse disease characteristics, as well as the timing of such treatment, remains controversial. Standard second treatment options after radical prostatectomy include radiation therapy with or without androgen deprivation or androgen deprivation alone. Adjuvant treatment, if given, can be tailored to the risk of relapse as well as to the pattern of suspected relapse (local vs. distant). Distant relapse may be more likely in those with high-grade disease, lymph node metastasis, and very high pretreatment PSA levels, as well as in those patients whose serum PSA level fails to fall to undetectable levels immediately after surgery. Patients at high risk of distant relapse are ideal candidates for experimental adjuvant systemic therapy, whereas those at risk of local relapse are candidates for radiation delivered to the prostatic bed.

The impact of positive surgical margins on outcome is a matter of controversy. Despite careful case selection before radical prostatectomy, between 14% and 41% of patients have tumor extending to the surgical margin on final pathologic analysis, with 33% to 62% of these patients failing radical prostatectomy based on the presence of a detectable serum PSA level.<sup>356,357,358 and 359</sup>

Radiation therapy may be given after surgery (adjuvant radiation), on the basis of adverse disease characteristics such as positive surgical margins, or after a documented disease recurrence (therapeutic radiation), on the basis of either biopsy-proven recurrence or biochemical failure alone. Proponents of adjuvant radiation argue that treatment is more effective when the local tumor burden is minimal and that series to date show that patients who undergo adjuvant radiation have been shown to achieve and maintain an undetectable serum PSA level in 77% to 94% of such cases.<sup>360,361,362 and 363</sup> However, despite improved local tumor control, no survival advantage has been demonstrated with adjuvant radiation. Studies have shown that between 42% and 70% of patients with positive surgical margins will maintain undetectable serum PSA levels without adjuvant therapy (Table 34.4-14).<sup>364,365,366,367 and 368</sup> Pathologic factors such as the location, extent, and number of positive margins may have an impact on the likelihood of disease recurrence in this setting.<sup>368</sup>

**TABLE 34.4-14.** Likelihood of Maintaining an Undetectable Serum Prostate-Specific Antigen in Patients with a Positive Surgical Margin

To date, no published studies have compared immediate versus delayed treatment in a prospective randomized fashion. Although the Southwest Oncology Group has instituted a randomized trial examining this question, the results of this study are not yet available. A decision to give adjuvant radiation is based on (1) the likelihood of cancer recurrence with adjuvant radiation, (2) the likelihood of cancer recurrence with surveillance alone, (3) the efficacy of radiation when given for biochemical recurrence (efficacy of therapeutic radiation), and (4) the morbidity of radiation. Grossfeld et al.<sup>369</sup> at UCSF created and tested a decision analysis model to help determine the preferred management of a positive surgical margin after radical prostatectomy. The model suggested that immediate radiation may be the preferred course of management for patients with a positive surgical margin and a high likelihood of recurrent local (rather than distant) disease. Such patients included those with low- to intermediate-grade disease (Gleason score <8), multiple positive margins, and no evidence of seminal vesicle invasion. For patients with no evidence of seminal vesicle invasion and all tumor grades, the model gave an equal value to surveillance and immediate adjuvant radiation. Surveillance was still recommended for patients with a preoperative PSA level of less than 15 ng/mL and for those with a single positive margin. However, the authors stressed that their model, which was based on literature- and institution-based estimates of the efficacy of adjuvant and delayed radiation, may be useful to physicians and patients who can apply individualized probability estimates and utility values for determining their preferred course of management postoperatively. Further research is needed to confirm these results and to determine whether adjuvant radiation therapy is appropriate for patients with other adverse disease characteristics such as established ECE.

## RADIATION THERAPY

### Curative Potential of Radiation Therapy

Radiation therapy was introduced as a curative modality for localized prostate cancer in the 1950s, largely due to the work of Malcolm Bagshaw<sup>409,410</sup> of Stanford University. Using emerging techniques of megavoltage radiation therapy, it became possible to deliver tumoricidal dose levels to prostate tumors without excessive damage to the skin and the normal tissues surrounding the prostate.<sup>409,410</sup> This approach continues to represent the basic tenet of curative radiation therapy in prostate cancer, although systems of treatment planning and delivery have since advanced to improve precision and decrease toxicity. The ability of radiation to cure localized prostate cancer has thus improved consistently over the past three decades.<sup>410,411,412,413,414 and 415</sup>

Failure of radiation therapy to control localized prostate cancer results most frequently from resistance of tumor clonogens to the dose levels used and from failure to cover the entire target volume with the prescribed tumor dose. Before CT became available for treatment planning, tumor target volumes were assumed from planar radiographic images and frequently were inaccurate.<sup>416</sup> To compensate for target volume uncertainties, treatment volumes were classically increased to include a wide safety margin, thus including substantial portions of bladder and rectum in the high-dose region. Because of the high sensitivity of pelvic organs to radiation, the ability to deliver prostate doses exceeding 70 Gy with conventional megavoltage techniques was seriously compromised.<sup>417,418 and 419</sup> Whereas clinical data have indicated a need for higher doses to achieve maximal local tumor control,<sup>420</sup> conventional radiation therapy techniques have, in many cases, fallen short of the levels required to eradicate the tumor.<sup>421</sup> Further, while CT-assisted treatment planning has significantly improved the anatomic definitions of the tumor target,<sup>422,423</sup> wide safety margins have remained a common practice to compensate for uncertainties in patient positioning and organ motion. Finally, because computers available for treatment planning were, until recently, slow and limited in performance, calculations of dose distributions were restricted to a limited number of planes within the target volume, and the dose to the rest of the tumor was assumed based on reasonable, albeit imprecise, projections. Hence, the problem of geographic misses and tumor underdosage have continued to contribute to a high frequency of local tumor failure.

Advances in computer technology have enabled the implementation of three-dimensional conformal radiation therapy (3D-CRT) as an approach to overcome some of these problems.<sup>415,421</sup> Three-dimensional treatment planning is based on the ability to define each pixel anatomically within the entire 3D space of irradiated tissues and to calculate precisely the dose delivered at each point. It uses advanced imaging technology for tumor and normal organ segmentation, new algorithms for dose calculations, and computer-aided optimization to generate treatment plans that conform the prescribed dose to the tumor while maximally excluding the adjacent normal organs. The ability to exclude the normal tissues from the volume receiving high-dose irradiation has permitted significant increases in tumor dose without a concomitant increase in normal tissue toxicity.<sup>415</sup> The improved precision also decreased the risks of anatomic tumor misses and underdosage, further improving the potential for local tumor cure. Indeed, a recent outcome assessment involving the use of postirradiation biopsies provided conclusive evidence for the effects of 3D-CRT and dose escalation on the local cure of prostate cancer, thus defining new standards for curative radiation therapy in this disease.<sup>415</sup>

### Effect of Dose on Local Tumor Control

Several studies have addressed the relationship between radiation dose and local control in prostate cancer. <sup>415,424,425,426,427,428</sup> and <sup>429</sup> The biologic effects of radiation on tumor and normal tissues result in dose-response patterns that translate into sigmoid-shaped curves when plotted graphically. <sup>430,431</sup> Because human tumors consist of heterogeneous clonogen populations with regard to radiation sensitivity, <sup>432</sup> it was suggested that tumor control curves would be relatively shallow, representing population averages for clones of different radiosensitivities. <sup>433,434</sup> The available clinical data mostly confirm this hypothesis, reporting tumor control curves with  $g_{50}$  values of approximately 2. <sup>435,436,437,438,439,440</sup> and <sup>441</sup> The validity of this model to prostate cancer was confirmed recently at the Memorial Sloan-Kettering Cancer Center (MSKCC) in a postirradiation biopsy study of 150 patients who did not receive neoadjuvant androgen deprivation therapy. <sup>415,442</sup> The diagnostic accuracy of posttreatment biopsies depends, among other factors, on the time interval from completion of treatment to biopsy. <sup>443,444,445</sup> and <sup>446</sup> For example, Scardino and Wheeler <sup>443</sup> reported that 32% of patients with a positive biopsy at 12 months after radiation therapy had a negative pathologic specimen at 24 months. As recommended by the ASTRO consensus statement, <sup>447</sup> biopsies were performed in the MSKCC study at 2.5 years or longer after 3D-CRT. The tumor dose was increased gradually in consecutive groups of patients, from 64.8 Gy to 81.0 Gy by increments of 5.4 Gy. Figure 34.4-12 shows that the rate of negative biopsies increased linearly from 48% in patients receiving 64.8 Gy to 94% after 81 Gy. The calculated  $g_{50}$  value for this set of data is 2.22. There was a concomitant increase in PSA relapse-free survival in patients receiving the high-dose range, providing further evidence for a significant effect of dose escalation on the cure of human prostate cancer.

FIGURE 34.4-12. Tumor control curve, showing effect of radiation dose on the rate of negative prostate biopsies.

### Serum Prostate-Specific Antigen as a Surrogate for Defining Tumor Control after Radiation Therapy

After pelvic irradiation, serum PSA level generally declines over 1 to 2 years, but usually it is not reduced to undetectable levels, as 70% of patients receiving radiation therapy for rectal and other nonprostatic tumors have PSA levels of less than 1.0 ng/mL for extended periods after irradiation. <sup>448</sup> On the basis of these data, it was suggested that cure of localized prostate cancer with radiation would be associated with maintained PSA profiles of less than 1.0 ng/mL. <sup>449,450</sup> It also was suggested that an increased serum PSA level from such postirradiation nadir values can serve as an indicator of disease relapse. Reviewing the emerging data in the field, the ASTRO consensus statement <sup>451</sup> has established a definition for PSA relapse as three consecutive rising PSA values from an established nadir value. The date of failure was defined as the midpoint between the last postirradiation nadir value and the first of the three consecutive increases. This guideline did not stipulate a specific nadir value that is associated with a complete response. However, multiple studies employing multivariate analyses have indicated that a PSA nadir of less than 1 ng/mL represents an independent variable in predicting long-term PSA relapse-free survival. <sup>450,452,453</sup> For example, Kavadi et al. <sup>450</sup> reported that the 5-year PSA relapse-free survival for patients who achieved nadir levels of less than 1.0 ng/mL was 17%, as compared to 70% for patients with posttreatment nadir levels exceeding 1.0 ng/mL. In this study, nadir levels of 50.5 ng/mL did not provide for improved prediction of outcome. The Eastern Virginia Medical School, <sup>453</sup> however, reported 5-year PSA relapse-free survival of 91% and 72% in patients with postirradiation nadir levels of less than 0.5 ng/mL and 0.5 to 1.0 ng/mL, respectively ( $P = .06$ ).

Shipley et al. <sup>454</sup> defined the long-term pattern of PSA response in an outcome study of a multiinstitutional pooled cohort of 1765 patients with T1 to T2 prostate cancer, treated with advanced external-beam techniques to doses ranging from 63 to 79 Gy (median dose, 69.4 Gy). Nadir posttreatment PSA values of  $\leq 1.0$  ng/mL were recorded in 80% of the patients, and only 12.8% had values in excess of 2.0 ng/mL. The overall 5-year PSA relapse-free survival was 65.8%, and of the 448 patients followed for more than 5 years, only 5% relapsed from the fifth to the eighth year. Though this study provided evidence that the majority of PSA relapses occur within the first 5 years after radiation therapy, it did not provide evidence that PSA relapse connotes anatomic relapse and that a nonrising profile correlates with lack of tumor relapse. The MSKCC posttherapy biopsy study <sup>415,442</sup> did, however, address this issue. Of patients undergoing biopsy at more than 2.5 years after treatment, 50 of 51 (98%) with a posttreatment PSA nadir of not more than 1.0 ng/mL and a nonrising PSA profile had negative biopsies, as compared with only 21 of 42 (50%) of those with a similar nadir but with a rising PSA profile ( $P < .001$ ). Of patients with a PSA nadir of more than 1.0 ng/mL, 7 of 10 (70%) of those with a nonrising PSA profile and 21 of 47 (45%) with a rising PSA profile had negative biopsy specimens ( $P = .2$ ). Taken together, these data strongly suggest that in early-stage patients in whom PSA levels of not more than 1.0 ng/mL are nadir, a maintained PSA relapse-free profile serves to indicate a 95% likelihood of permanent tumor control after radiation therapy.

### Definition of Target Volume

Carcinoma of the prostate is frequently multifocal, involving more than one lobe of the gland. <sup>455</sup> Therefore, the clinical target volume (CTV) for irradiation consists of the total prostatic gland, including the seminal vesicles, as visualized on CT. Capsular involvement with or without periprostatic invasion has been demonstrated in 15% to 66% of radical prostatectomy specimens from patients with stage T1 or T2 disease. <sup>456,457</sup> and <sup>458</sup> Hence, the prostatic capsule and the immediate periprostatic tissues are incorporated in the CTV. The planning target volume (PTV) encompasses the CTV and an additional 1.0-cm margin of tissue to compensate for patient setup uncertainties and organ motion. <sup>459,460</sup>

The inclusion of pelvic lymph nodes in the CTV has been an issue of continued controversy. Lymph node metastases are common in prostate cancer, and their frequency correlates with stage, tumor volume, and histologic grade. <sup>461,462</sup> and <sup>463</sup> The major lymph node-bearing areas that drain the prostate include the external iliac, hypogastric, presacral, and internal pudendal nodes. These chains of nodes can be encompassed by treatment fields that involve a major portion of the pelvis. <sup>464</sup> Several old retrospective studies have suggested that pelvic irradiation in addition to limited prostatic fields improves disease-free survival and results in fewer pelvic failures in T2 or T3 patients. <sup>465,466</sup> and <sup>467</sup> Most studies were conducted in the pre-PSA era and without staging laparotomies, leaving open questions regarding the extent of lymph node involvement and their response to therapy. However, Seaward et al. <sup>467</sup> described treatment results in 201 patients considered to be at high risk for lymph node involvement based on combined pretreatment profiles of PSA levels and Gleason scores. The risk of positive nodes ( $N+ = 31\%$ ) was calculated using the equation  $[N+ = 2/3(\text{PSA}) + (\text{GS} - 6) \times 10]$ , as suggested by Roach et al. <sup>468</sup> Freedom from PSA failure was significantly improved in 117 patients who received whole pelvis irradiation, as compared to 84 patients whose treatment was limited to the prostate only (median PSA relapse-free survival of 34.3 months vs. 21.0 months;  $P = .0001$ ). Prospective randomized studies in patients undergoing staging laparotomy, carried out by the Stanford group, <sup>469,470</sup> suggested that prophylactic lymph node irradiation may be of benefit only in patients with T1 and T2 disease. However, multiple other studies failed to demonstrate a benefit of prophylactic whole pelvis irradiation. <sup>471,472,473,474,475</sup> and <sup>476</sup> The Radiation Therapy Oncology Group study (RTOG 77-06), which randomized 449 patients with T1b or T2N0M0 tumors to receive either prostatic or prostatic plus whole pelvis irradiation after bipedal lymphography or staging laparotomy, <sup>475,476</sup> reported no significant differences in local control and survival (median follow-up of 12 years). The actuarial rates of local relapse at 12 years were 27% for prostate irradiation alone and 22% for prostate plus pelvic irradiation ( $P = .2$ ), and the actuarial survival rates were 43% and 38%, respectively ( $P = .4$ ). Based on these observations, it is generally accepted that elective pelvic irradiation is unlikely to affect the outcome of treatment, and pelvic lymph nodes generally are not included in the CTV for treatment planning.

### Simulation and Treatment Planning

**CONVENTIONAL (TWO-DIMENSIONAL) EXTERNAL-BEAM RADIATION THERAPY.** Treatment is most frequently planned in the supine position at 100 cm source-axis distance, and immobilization devices are increasingly used to reduce patient motion during treatment. Localization skin marks are placed on the patient that correspond to a standardized treatment isocenter, a midline point near the center of the prostate located 1 cm inferior and 6 cm posterior to the upper border of the symphysis pubis. Simulation radiographs are obtained in the treatment position from the level of L5-S1 to 1.0 cm caudal to the ischial tuberosities. The target volume and the surrounding normal organs are drawn on orthogonal planar radiographs produced on conventional simulators or on digitally reconstructed radiographs generated from CT images obtained by CT simulators. To assist in defining the PTV, it is customary to use urinary bladder and rectal catheters and contrast media. A No. 16 Foley catheter is introduced into the bladder, and the balloon is inflated with 5 mL of 90% Hypaque solution. The balloon is pressed against the bladder trigone with light pressure, and the catheter is taped to the thigh. In addition, 30 mL of low-density Hypaque (30%) is introduced into the bladder. A second Foley catheter is placed in the rectum and the balloon is inflated with air and pressed against the internal sphincter of the rectum to indicate the location of the anus. Low-density Hypaque (30%) is also placed in the rectum to outline the rectal wall.

The superior border of the prostatic field usually is located approximately 2 cm above the Foley balloon and includes nearly 30% of the bladder detected by the contrast media (Fig. 34.4-13A and Fig. 34.4-13B). The inferior border is located short of the internal anal sphincter. The anterior margin is at the posterior cortex of the pubic bone, and the posterior border extends 6 to 10 mm posterior to the anterior rectal wall, sparing the posterior rectal wall. The right and left lateral margins are usually marked at 3.5 to 4.0 cm from the isocenter (see Fig. 34.4-13A and Fig. 34.4-13B). When there is an indication to treat the pelvic nodes, the inferior border usually is extended to the ischial tuberosities and the superior border to the top surface of L5 (see Fig. 34.4-13C and Fig. 34.4-13D). The lateral borders are placed approximately 1 cm lateral to the widest diameter of the pelvic inlet, but the superior and inferior corners are trimmed to protect as much bone marrow as possible. The anterior border of the lateral field extends to the anterior aspect of the pubic symphysis, while the posterior margin is established at the midlumen of the rectum inferiorly and at the midsacral bone superiorly (see Fig. 34.4-13C and Fig. 34.4-13D). The patient receives tattoo marks at the anterior and two lateral triangulation points in a single transverse plane, corresponding to the isocenter of the treatment field.

**FIGURE 34.4-13.** Simulation radiographs of a case planned for treatment with four-field conventional technique. **A:** Anteroposterior localization film of the prostate planning target volume (PTV) and the planned rectangular treatment field. Contrast material (Hypaque) has been placed in the urinary bladder and the rectum, and the balloons of the Foley catheters placed in the bladder and rectum. The setup point (SP) is marked on the patient's skin. The center point for the treatment field is designated (R). **B:** Lateral localization of the prostate PTV and the prostatic field **(C)** and **(D)**. Pelvic fields designed in this patient to treat the pelvic lymph nodes electively. (From ref. 464, with permission.)

Treatment plans typically consist of an isocentric four-field box, designed to include the prostate, seminal vesicles, and periprostatic tissues. The cross sections of the beams may be shaped with Cerrobend blocks to protect, surrounding normal tissues, as the situation permits. The daily PTV dose is 1.8 to 2.0 Gy, delivered five times per week with all fields treated at each session, to a total dose of 65 to 70 Gy in 7 to 8 weeks. When the pelvic nodes are treated, radiation is planned first to the entire pelvic field to a dose of 45 to 50 Gy in 5 weeks. The prostate PTV then is boosted to a dose of 20 Gy, raising the dose to the primary prostatic tumor to a total of 65 to 70 Gy. To improve the tolerance of treatment, a "sandwich" technique has been proposed in which the delivery to the large pelvic field is split and the small boost field is delivered in between.<sup>477</sup> This technique permits a rest period and a partial recovery of the bowel and bladder from the toxic effects of the initial pelvic field irradiation.

**THREE-DIMENSIONAL CONFORMAL RADIATION THERAPY.** Although 3D treatment-planning systems vary in detail, all are based on common principles. The simulation consists of a combination of conventional and CT-assisted procedures. Conventional simulators can be used to determine the positioning of the patient, to define a provisional isocenter, and to produce reference localization skin marks. CT images are used to segment the prostate and normal organs and to generate high-resolution 3D reconstructions. The CT data are also used in calculations of dose distribution, as modern dose calculation formalisms are based on electron density ratios of the anatomic structures included in the treatment fields.<sup>421</sup> Several algorithms are in use for 3D dose calculations, but the more advanced methods, such as the pencil-beam convolution algorithm with pixel-by-pixel inhomogeneity corrections,<sup>421</sup> are required for maximal accuracy.

Treatment is planned in the supine or prone position<sup>478</sup> within individually fabricated immobilization casts to ensure reproducible positioning during repeated treatment sessions.<sup>479</sup> Because prostatic displacement during a course of radiation therapy was shown to be affected by rectal and bladder volumes,<sup>480</sup> some studies have recommended that the simulation and each treatment session be carried out with the patient's bladder and rectum emptied, to reduce daily variations in prostate location and geometry. The tumor target and the critical normal structures are segmented on every CT slice where they appear. The PTV extends from 1.0 cm caudal to the apex of the prostate to 1.0 cm cephalad to the superior tips of the seminal vesicles and encompasses the prostate with a 1.0-cm margin, except posteriorly at the interface with the rectum, where some investigators have suggested the use of a 0.6-cm margin to reduce the risk of rectal toxicity.<sup>479</sup> The target volume and the normal organs then are reconstructed by the computer in 3D and are displayed with the beam's-eye view technique.<sup>481</sup> The most commonly used beam arrangement consists of six coplanar fields (two lateral opposed fields and two pair of oblique fields) shaped to conform the PTV.<sup>482</sup> Dose calculations then are performed and the adequacy of target coverage by the prescription dose is evaluated on displays of isodose or color-wash distributions ( Fig. 34.4-14) and by dose-volume histograms.<sup>483</sup>

The target dose is either prescribed to the median International Commission on Radiation Units and Measurement (ICRU<sub>50</sub>) reference point<sup>484</sup> or to the maximum isodose surface distribution that completely encompasses the PTV.<sup>482</sup> Some investigators have suggested that the rectal wall dose be restricted to no more than 30% of the prescription dose, the bladder wall dose to 50%, and the bowel dose (when bowel happens to be included in the PTV) to 65%, to decrease the risk of toxicity.<sup>485</sup>

When radiation cannot be administered without exceeding these limits, a 3-month course of neoadjuvant androgen deprivation has been suggested to decrease the target volume. Significant reductions in PTV and, consequently, in normal tissue volumes carried to the prescription dose have been observed in nearly 90% of patients treated with this approach.<sup>485</sup> Beam apertures are automatically shaped by the treatment planning computer, applying continuously varying apertures with a margin of 0.5 cm around the outline of the tumor target, to account for beam penumbra. Cerrobend blocks or multileaf collimators then are used to shape the planned treatment fields. To assure that treatment is delivered as planned, automated on-line electronic portal imaging has also become available recently. In the future, portal imaging may also provide on-line automated corrections of patient setup errors during the treatment session through computer-driven feedback mechanisms.

**FIGURE 34.4-14.** Color wash displays of the dose distribution of a six-field coplanar prostate three-dimensional conformal radiation therapy plan with 15-MV x-rays. The planned treatment consists of one pair of lateral and two pairs of oblique fields. The dose distribution is shown on **(A)** axial, **(B)** sagittal, and **(C)** coronal

computed tomography reconstructions of the prostate and surrounding normal tissue at the mid-plan of planning target volume (PTV). The boundaries of the PTV are shown in yellow dots. The red region represents the prescription isodose distribution, and the yellow region corresponds to approximately 70% to 80%, green to 45% to 70%, and blue to 45% or less of the prescription dose.

**INTENSITY-MODULATED RADIATION THERAPY.** For details of simulation and treatment planning using intensity-modulated radiation therapy (IMRT), see [Chapter 29.4](#).

### Tolerance of Treatment and Late Complications

Doses of 70 Gy or less, when delivered with conventional (two-dimensional) external-beam irradiation, are fairly well tolerated. However, grade 2 [RTOG/European Organization for Research and Treatment of Cancer (EORTC) scoring scheme; [Table 34.4-15](#)] or higher acute rectal morbidity or urinary symptoms requiring medication (or both) occur in approximately 60% of patients.<sup>486</sup> Symptoms typically appear during the third week of treatment and resolve within days to weeks after its completion. Acute intestinal symptoms, especially those associated with whole pelvis irradiation, are most commonly relieved with diet manipulations. Otherwise, medications such as diphenoxylate hydrochloride (Lomotil) are appropriate to relieve symptoms. Internal and external hemorrhoids may become inflamed during a course of therapy. These symptoms often are best treated with sitz baths and cortisone suppositories. Acute urinary symptoms are treated with phenazopyridine hydrochloride (Pyridium), nonsteroidal antiinflammatory agents, or  $\alpha$ -adrenergic blockers such as terazosin. Zelefsky et al.<sup>487</sup> recently reported that  $\alpha$ -adrenergic blockers were significantly more effective than nonsteroidal antiinflammatory agents, resulting in significant resolution of urinary symptoms in 66% and moderate improvement in 22%; in only 12% was minimal relief to no improvement observed. In contrast, among patients treated with ibuprofen, only 16% experienced significant symptom relief, 28% exhibited moderate improvement, and 56% demonstrated minimal to no response.

Grade	Rectal	Bladder
0	No toxicity	No toxicity
1	Increased frequency or change in quality of bowel habits not requiring medication, normal discomfort not requiring analgesia	Frequency of voiding or nocturia/low frequency that does not limit activity, urgency, bladder spasms requiring analgesia
2	Diarrhea requiring antiperistaltic drugs (e.g., diphenoxylate [Lomotil]) or other drugs not necessitating systemic pain relief or additional pain-requiring analgesia	Frequency of voiding or nocturia/low frequency that does not limit activity, urgency, bladder spasms requiring analgesia
3	Diarrhea requiring parenteral antiperistaltic or fluid electrolyte replacement, or systemic pain relief or additional pain-requiring analgesia	Frequency with urgency and nocturia/low or moderate frequency, urinary pain, or bladder spasms requiring systemic analgesia, or urinary tract infection with or without fever
4	Nausea or colonic obstruction, fecal or perforation, gastrointestinal bleeding, requiring transfusion, abdominal pain or necrosis requiring high-dose analgesics or bowel resection	Frequency requiring transfusion or analgesia, urinary tract infection or the presence of obstruction or necrosis
Grade 0	No toxicity	No toxicity
1	Mild dysuria with increasing void frequency (more than 8 times daily) slight hematuria or bleeding	High frequency of voiding, moderate hematuria, or urinary tract infection
2	Moderate dysuria and void frequency (more than 8 times daily) moderate hematuria or moderate bleeding	Moderate frequency of voiding, moderate hematuria, or urinary tract infection
3	Obstruction or bleeding requiring surgery	Severe frequency with dysuria, severe hematuria, or urinary tract infection with moderate hematuria, obstruction or bladder spasm requiring surgery
4	Necrosis, perforation, fecal	Necrosis, obstruction, bladder spasm, or urinary tract infection requiring surgery

**TABLE 34.4-15.** Radiation Therapy Oncology Group–European Organization for Research and Treatment of Cancer Scoring Scheme for Acute and Late Rectal and Bladder Morbidity

Late complications develop within 3 to 6 months after completion of radiation therapy. Zelefsky et al.<sup>415</sup> reported that the median time to onset of grade 2 or worse late rectal toxicity was 12 months, with a range of 3 to 39 months. Similarly, Teshima et al.<sup>488</sup> from the Fox Chase Cancer Center reported median times to occurrence of grade 2 and 3 rectal toxicities at 13 and 18 months, respectively. The incidence of late complications in patients receiving conventional radiation therapy doses of 70 Gy is low. An analysis of 1020 patients treated in two large RTOG trials demonstrated an incidence of chronic urinary sequelae (i.e., cystitis, hematuria, urethral stricture, or bladder contracture) requiring hospitalization in 7.3% of cases, but the incidence of urinary complications requiring major surgical interventions was only 0.5%.<sup>489</sup> More than one-half of chronic urinary complications were urethral strictures, occurring mostly in patients who had undergone a previous transurethral radical prostatectomy. The incidence of chronic intestinal sequelae (chronic diarrhea, proctitis, rectal or anal stricture, rectal bleeding, or ulcer) requiring hospitalization for diagnosis and minor intervention was 3.3%, with only 0.6% of patients experiencing bowel obstruction or perforation. Fatal complications were extremely uncommon (0.2%).

The risk of late complications increases when radiation doses exceed 70 Gy. Leibel et al.<sup>490</sup> reported 6.9% grade 3 to 4 complications in 174 prostate cancer patients treated with doses exceeding 70 Gy, as compared with 3.5% after treatment with less than 70 Gy. Sandler et al.<sup>491</sup> reported that the actuarial incidence of grade 3 to 4 rectal toxicity for patients who received doses in excess of 68 Gy was 9% at 3 years, as compared to 2% for those who received lower doses. Schultheiss et al.<sup>492</sup> reported late toxicity in 712 patients treated with conventional or conformal radiation techniques. The risk of late toxicity strongly correlated with the central axis dose. The 5-year incidence of grade 2 or 3 late rectal toxicity was 27%, 35%, 43% for central axis doses of 71 to 74 Gy, 74 to 77 Gy, and 77 Gy or more, respectively ( $P < .001$ ).

Rectal complications have also been correlated with the volume of anterior rectal wall receiving a given dose (the so-called volume effect). Benk et al.,<sup>493</sup> from the Massachusetts General Hospital, reported dose-volume patterns and their relationship with rectal bleeding in patients treated with 50.4 Gy whole pelvis photon-beam radiation therapy followed by 25.2 cobalt-gray equivalents (CGE) delivered via a 160-MeV perineal proton beam boost. A logistic regression analysis revealed ten dose-volume combinations that were more likely associated with late rectal bleeding, ranging from 60 CGE delivered to 70% of the anterior rectal wall to 75 CGE involving 30% of the rectal wall. When portions of the anterior rectal wall were exposed to 75 CGE, the actuarial incidence of bleeding at 40 months was 61% when 40% or more of the wall received this dose, as compared with 19% when less than 40% of the wall was exposed ( $P = .0036$ ). Lee et al.<sup>494</sup> reported that among patients receiving PTV doses of less than 76 Gy, the use of a rectal block significantly reduced the incidence of grade 2 to 3 rectal toxicity, from 22% without a block to 7% with a block ( $P = .003$ ). These data indicated the need to spare the rectal wall maximally when protocols of high-dose therapy are implemented, to improve the local outcome in prostate cancer.

3D-CRT has been developed, in part, to address this issue. The ability of the 3D approach to reduce rectal and bladder toxicities has been demonstrated in several studies. The Fox Chase Cancer Center<sup>495</sup> reported acute grade 2 gastrointestinal or genitourinary morbidity with 3D-CRT in 84 of 247 patients (34%), as compared with 93 of 162 patients (57%) treated with conventional radiation therapy techniques ( $P < .001$ ). Dearnaley et al.<sup>496</sup> randomized patients to receive a dose of 64 Gy with conformal or conventional techniques. The late grade 2 rectal toxicity was 5% for 3D-CRT patients, as compared with 15% for the conventional plan ( $P = .01$ ). Leibel et al.<sup>442</sup> have recently updated the MSKCC series of 1100 patients treated with 3D-CRT. In consecutive groups of patients, the tumor dose was gradually increased from 64.8 Gy to 86.4 Gy by increments of 5.4 Gy. The rate of grade 3 rectal bleeding requiring one or more transfusions or one or more laser cauterization procedures was 1%, and the rate of grade 3 urethral stricture was 1%. All strictures occurred in patients who previously underwent transurethral prostate resections. The 5-year actuarial risk of grade 2 rectal bleeding for patients receiving 64.8 to 70.2 Gy was 6%, as compared to 17% for those treated with 75.6 to 81 Gy ( $P < .001$ ).

The rising rate of grade 2 rectal bleeding with increasing 3D-CRT dose<sup>442</sup> indicated that dose escalation would require improved 3D-CRT techniques to decrease the volume of exposed rectal wall and decrease the risk of rectal toxicity. IMRT provides this option. A recent study from MSKCC compared 20 patients in whom concomitant 3D-CRT and IMRT were planned.<sup>497</sup> Only 9%  $\pm$  3% of the rectal wall would have received 75 Gy with the IMRT plan, as compared with 14%  $\pm$  3% with a routine six-field 3D-CRT plan ( $P < .01$ ). There was also a significant improvement of the percentage PTV receiving the prescription dose (81 Gy) with IMRT. These data indicated that IMRT significantly improves the conformality of the radiation treatment in prostate cancer. To validate the expected decrease in toxicity, the incidence of rectal bleeding was recorded in 61 patients treated to 81 Gy with routine six-field 3D-CRT and was compared with the rates in 171 patients treated to the same dose with IMRT. [Figure 34.4-15](#) shows that the 2-year actuarial risk of grade 2 to 3 rectal bleeding was 2% for IMRT and 10% for conventional 3D-CRT ( $P < .001$ ). Only one patient in each treatment group developed grade 3 rectal bleeding.

**FIGURE 34.4-15.** Radiation toxicity. Actuarial risk of grade 2–3 rectal bleeding in 232 patients treated with conventional three-dimensional conformal radiation therapy (3D-CRT) or intensity-modulated radiation therapy (IMRT).

Sexual function is preserved in 73% to 82% within the first 12 to 15 months after irradiation,<sup>498,499</sup> but erectile potency diminishes with advancing time, with only 30% to 61% of patients maintaining their potency at 5 years or longer after irradiation.<sup>500</sup> The etiology of erectile dysfunction after radiation therapy appears to be related to vascular disruption caused by treatment as opposed to radiation damage to the nerve bundles.<sup>501</sup> Doppler blood flow studies of the corporal vasculature in patients with erectile dysfunction after radiation therapy suggested that arteriogenic rather than cavernosal or neurogenic dysfunction underlie this toxicity.<sup>501</sup> Patients who develop impotence after radiation therapy can be effectively treated with intracavernosal prostaglandin injection therapy.<sup>502</sup> Preliminary observations with sildenafil in these patients demonstrated a 74% response rate.<sup>503</sup> Improved responses to the medication were noted among patients with normal erectile function prior to radiation therapy, as compared to those with declining pretreatment function.<sup>503</sup>

### Results of Treatment

Before the PSA era, the outcome of radiation therapy was assessed by DRE, radiography, and isotope scans. Although outcome assessment by this method is somewhat imprecise, especially with regards to local control, it nonetheless appeared that the long-term results of radiation therapy in T1 and T2 disease were similar to those observed with radical prostatectomy.<sup>411,412,455,456,457</sup> and <sup>458,477</sup> Using a hazard function over successive 5-year intervals, Coleman et al.<sup>504</sup> reported that with the exception of very small tumors, there was a similar constant risk of relapse for surgery and radiation therapy throughout a follow-up period of 20 years. Stage for stage, the survival outcome was similar for the surgical and radiation series. Hanks<sup>411,505</sup> reported a 14% 10-year cause-specific mortality in 104 lymphadenectomy-staged patients with stages T1b to T2N0 disease treated in the RTOG trial 77-06. Eighty-seven percent of the patients were clinically free of local recurrences, 79% were free of distant metastases, and 67% were free of any failure. The survival rate was nearly identical to the expected survival in a life table for an age-matched control population throughout the 10 years of observation (63% observed vs. 59% expected at 10 years).<sup>411,505</sup> It has been frequently stated that although the results of radiation and radical surgery are comparable up to 10 years, at longer follow-up periods there may be a selective, rapid decrement in survival and disease-free survival for irradiated patients. Table 34.4-16 summarizes published long-term results with conventional external-beam irradiation, indicating outcome data for irradiated patients at 15 years that are similar to published data for radical prostatectomy.<sup>412,505,506</sup> and <sup>507,507a,507b</sup>

Author	Stage	No. of Patients	Survival (%)			Local Relapse-Free Survival (%)		
			5Y	10Y	15Y	5Y	10Y	15Y
Bagshaw <sup>411</sup>	T1	335	85	65	40	90	85	90
	T2	242	85	55	35	80	70	65

**TABLE 34.4-16.** Results of Conventional External-Beam Radiation Therapy in Stage T1 through T3 Carcinoma of the Prostate

With the introduction of PSA level as a surrogate for defining tumor control after definitive therapy, it became evident that more failures can be documented after definitive therapy than had previously been appreciated. For example, Zietman et al.<sup>508</sup> reported clinical relapse-free survival of 65% at 10 years in 504 T1 or T2 patients, as compared with freedom from PSA relapse in only 40% of patients. Other studies have confirmed that PSA relapse precedes evidence of anatomic relapse, frequently by more than 2 years.<sup>509,510</sup> The study by Zietman et al.<sup>508</sup> also reported that of the 60% of patients who exhibited a PSA relapse, local progression by 10 years was found in only 13%. These data suggest that most of the rise in PSA level originates from distant metastases. However, Zagars et al.<sup>511</sup> reported that in 80% of PSA relapsing patients, the rise in PSA was associated with a local failure only. The latter study also reported that the rate of PSA relapse in stage T1 or T2a patients was 26% at 5 years, suggesting that radiation therapy cure may occur substantially less frequently than had previously been assumed.

This issue was addressed further by Kupelian et al.,<sup>512</sup> who reviewed 298 stage T1 or T2 patients treated with radical prostatectomy and 253 treated with radiation therapy. The 5-year PSA relapse-free survival rates for radiation versus surgery were 43% and 57%, respectively. Multivariate analysis of time to failure showed that pretreatment PSA level and biopsy Gleason scores were independent predictors of PSA relapse. Based on these parameters, a low risk (pretreatment PSA of  $\leq 10.0$  ng/mL and Gleason score  $\leq 6$ ) and high risk (PSA  $> 10.0$  ng/mL or Gleason score  $\geq 7$ ) were defined. For low-risk patients, the 5-year PSA relapse-free survival rates for radiation versus surgery were 81% and 80%, while for the high-risk group the rates were 26% versus 37%, respectively. Zagars<sup>510</sup> reported 94% 6-year PSA relapse-free survival in T1 or T2 patients with a PSA level of 4 ng/mL or less and a Gleason score of 2 to 6, 70% for patients with a PSA level of 4 ng/mL or less and a Gleason score of 7 to 10, or a PSA level of 4 to 10 ng/mL and a Gleason score of 2 to 7, and 60% for patients with a PSA level exceeding 4 and a Gleason score of 8 or more.

Shibley et al.<sup>454</sup> further defined the prognostic subgroups for PSA outcome in T1 and T2 patients treated with radiation therapy. This study entailed a multiinstitutional pooled cohort of 1765 patients treated with advanced external-beam techniques to doses ranging from 63 to 79 Gy (median dose, 69.4 Gy). The overall 5-year PSA relapse-free survival was 65.8%. Recursive partitioning analysis of initial PSA, palpation stage, and Gleason score yielded four prognostic groups. Patients with a PSA level of less than 9.2 ng/mL had a 5-year PSA relapse-free survival rate of 81%, whereas for patients with PSA levels between 9.2 and 19.7 ng/mL, it was 69%; for those whose PSA level was at least 19.7 ng/mL and who had a Gleason score of 2 to 6, it was 47%, and for patients with a PSA level of 19.7 ng/mL or more and a Gleason score of 7 to 10, the rate was 29%.

The validity of patient stratification by pretreatment variables as an approach to predict the outcome of treatment has been confirmed by multiple groups and has become standard in the field. Using proportional hazard regression analysis, most studies have identified pretreatment PSA, palpation stage, the Gleason score, and the dose as independent variables that affect long-term outcome. Different combinations of these prognostic variables have been suggested to generate risk groups for PSA relapse. Figure 34.4-16 shows the outcome data generated from the MSKCC 3D-CRT dose escalation database.<sup>415,442</sup> The tumor dose was gradually increased by increments of 5.4 Gy from 64.8 Gy to 86.4 Gy. A dose of 64.8 Gy was given to 96 patients, 70.2 Gy to 268 patients, 75.6 Gy to 446 patients, 81.0 Gy to 250 patients, and 86.4 Gy to 40 patients. The 5-year actuarial PSA relapse-free survival for patients with favorable prognostic indicators (stage T1 or T2, pretreatment PSA level  $\leq 10.0$  ng/mL, and Gleason score  $\leq 6$ ) receiving 64.8 to 70.2 Gy was reported as 80%, compared to 91% for those receiving at least 75.6 Gy ( $P = .03$ ). The corresponding rates for patients with intermediate prognosis (one of the prognostic indicators having a higher value) were 47% versus 70% ( $P = .004$ ) and, for the group with unfavorable prognosis (two or more of the prognostic indicators having higher values), were 27% versus 47% ( $P = .04$ ). Androgen deprivation did not improve PSA relapse-free survival in any of the risk groups. This study defines the critical role of dose in affecting the long-term cure of prostate cancer with radiation.

Combined with the results of posttreatment biopsies obtained in patients followed for 2.5 years (see Fig. 34.4-12), these data suggest that at least 81 Gy may be required for a maximal probability of cure. The data also demonstrate that a significant proportion of patients with unfavorable prognostic indicators may still have disease that is confined to the prostate and therefore is potentially curable with radiation alone.

**FIGURE 34.4-16.** Risk of treatment failure after three-dimensional conformal radiation therapy. (Data from refs. 415, 442.)

Investigators from the Fox Chase Cancer Center<sup>513</sup> have reported a direct relationship between radiation dose and 5-year PSA relapse-free survival in patients treated to doses ranging from 66 to 79 Gy. The study matched by stage and grade 357 patients treated with at least 74 Gy 3D-CRT and 357 patients treated with less than 74 Gy with either conventional or conformal techniques. The 5-year PSA relapse-free survival rates were 71% and 56% for the high- and low-dose groups, respectively ( $P = .003$ ). There was also a dose effect on 5-year freedom from distant metastases (97% vs. 88%;  $P = .0004$ ), cause-specific survival (99% vs. 94%;  $P = .007$ ), and overall survival (88% vs. 79%;  $P = .01$ ). Roach et al.<sup>514</sup> reported an advantage for using higher doses of 3D-CRT in patients with poorly differentiated histologies. Among 50 patients with pretreatment PSA levels of less than 20 ng/mL, the PSA relapse-free survival at 3 years was 83% for patients treated with more than 71 Gy and 0% for those treated to lower doses ( $P = .03$ ).

Zagars et al.<sup>515</sup> also observed a dose effect on the outcome in a retrospective analysis of 94 patients with localized prostate cancer treated with high-dose 3D-CRT (74 to 78 Gy) and 844 patients treated with conventional-dose irradiation (60 to 70 Gy). For analysis, patients were divided into three groups reflecting low (<67 Gy), intermediate (67 to 77 Gy), and high (>77 Gy) treatment dose. The 3-year PSA relapse-free survival rates were 61%, 74%, and 96%, for the low-, intermediate-, and high-dose groups, respectively ( $P < .01$ ). When patients were stratified by the pretreatment PSA level, clinical stage (T1 or T2 vs. T3 or T4), or Gleason score (≤6 vs. 7 to 10), statistically improved PSA outcome was observed in all subgroups except for those with pretreatment PSA levels of less than 4.0 ng/mL. To further prove the impact of dose on the outcome, these investigators randomized 304 patients to receive either 70 Gy using a four-field conventional technique or the same treatment plus a six-field conformal boost to a total dose of 78 Gy.<sup>516</sup> The overall 4-year PSA relapse-free survival was 72% for the 70-Gy patients and 77% for the 78-Gy patients ( $P = .21$ ). A significant difference was nonetheless observed in patients with a pretreatment PSA level exceeding 10 ng/mL (47% for the 70-Gy and 68% for the 78-Gy patients;  $P < .01$ ), with the most striking effect observed in T1 and T2 patients in this subgroup (55% for the 70-Gy and 93% for the 78-Gy patients;  $P = .003$ ). The difference in the PSA outcome for patients with a pretreatment PSA level of less than 10 ng/mL was not significant. Further follow-up will be required to assess the impact of dose on the latter group of patients.

#### ANDROGEN ABLATION PLUS RADIATION THERAPY

The discovery that both normal and tumor prostate cells are sensitive to androgen ablation has led to its use as either neoadjuvant or adjuvant treatment in combination with radiation therapy. The rationale for this neoadjuvant approach is to debulk large prostate glands prior to irradiation and possibly to sensitize the tumor to the lethal effect of radiation, whereas adjuvant therapy is designed to eradicate residual disease, remaining either locally or at remote sites, after radiation therapy. Several groups have demonstrated the effectiveness of neoadjuvant androgen deprivation in decreasing the size of the prostate prior to radiation therapy, thus improving the ability to deliver maximal radiation doses without exceeding normal tissue tolerance.<sup>517,518 and 519</sup> For example, Zelefsky et al.<sup>519</sup> demonstrated that 3 months of leuprolide acetate and flutamide (Eulexin) reduced the prostate PTV by a mean of 25% (range, 3% to 52%). Further, two posttreatment biopsy series demonstrated improved local control when neoadjuvant androgen ablation was used, suggesting either an additive effect or a sensitizing effect induced by androgen deprivation. Zelefsky et al.<sup>415</sup> reported a 10% incidence of positive biopsies (3 of 31) in patients pretreated for 3 months with androgen deprivation, as compared with 46% (48 of 105) in those patients who received radiation therapy alone ( $P < .001$ ). The relative distribution of the prognostic risk groups and the prescribed dose did not differ significantly between the two groups. Laverdiere et al.<sup>520</sup> reported preliminary results of a randomized trial of stage T2 and T3 prostate cancer patients who underwent biopsy at 24 months after radiation therapy. Patients treated for 3 months with neoadjuvant androgen deprivation followed by 64 Gy of radiation therapy had a 28% incidence of tumor-positive biopsy specimens, as compared to a 65% incidence in those patients receiving radiation alone. However, androgen deprivation given for 3 months before and 6 months after 64-Gy radiation therapy was associated with only a 5% rate of positive biopsies, consistent with an additive rather than a radiation-sensitizing effect.

The clinical value of the neoadjuvant approach was tested in RTOG trial 86-10.<sup>521</sup> Patients with large T2, T3, and T4 prostate tumors were randomized to either receive 2 months of leuprolide and Eulexin before and during radiation therapy or radiation without androgen ablation. The cumulative incidence of local progression at 5 years was 46% for patients undergoing androgen ablation and 71% for patients receiving radiation alone ( $P < .001$ ). Progression-free survival rates, including the ability to maintain normal PSA levels, were 36% and 15%, respectively ( $P < .001$ ). There was, however, no difference in survival. The use of neoadjuvant androgen ablation in patients with locally confined disease (stage T1 to T2a) and a good prognosis currently is being tested by RTOG trial 94-08. Patients are stratified by pretreatment PSA level and Gleason score. It should be emphasized, however, that the use of androgen ablation is associated with significant side effects, such as hot flashes, loss of libido, impotence, decrease in muscle tone, and anemia, which can significantly impair the quality of life of treated patients.

Use of the adjuvant approach has been tested in two prospectively randomized studies. RTOG trial 85-31<sup>522</sup> involved 977 T3 or T4 patients treated with whole pelvis irradiation to 45 Gy plus a prostate boost to 20 to 25 Gy. Patients were randomized to receive adjuvant goserelin initiated during the last week of radiation and continued indefinitely until relapse or initiated on evidence of postirradiation relapse. Actuarial local relapse-free survival at 5 years was 84% for the adjuvant arm and 71% for the radiation-alone arm ( $P < .0001$ ). The corresponding rates for freedom from distant metastases and disease-free survival were 83% versus 70% ( $P < .001$ ) and 60% versus 44% ( $P < .0001$ ). The actuarial 5-year PSA relapse-free survival was 53% for the adjuvant group versus 20% for the radiation-alone group ( $P < .0001$ ). There was, however, no difference in the overall 5-year survival (75% vs. 71%;  $P = .52$ ). In contrast, EORTC trial 22863 did show a survival advantage for patients who received adjuvant androgen ablation.<sup>523</sup> In this study, 415 patients with locally advanced prostate cancer were randomly assigned to receive radiation therapy alone (50 Gy to the pelvis plus a 20-Gy prostatic boost) or radiation therapy plus goserelin initiated before radiation therapy and continued after irradiation until relapse. The actuarial 5-year disease-free survival (clinical) was 85% in the combined-treatment group and 48% for the radiation therapy group ( $P < .001$ ). The local recurrence-free survival was 97% versus 77% ( $P < .001$ ), PSA relapse-free survival was 81% versus 43% ( $P < .001$ ), and metastasis-free survival was 98% versus 56% ( $P < .001$ ), respectively. The overall survival at 5 years was 79% for the adjuvant group versus 62% for the radiation alone group ( $P = .001$ ). The validity of the latter observation has been questioned, because the survival level for the radiation-alone group (62%) appears significantly lower than published rates in similar patients.<sup>524</sup> Hence, while addition of adjuvant androgen ablation to definitive radiation therapy has been associated with a highly significant improvement in local control and freedom from disease progression, its impact on survival remains an open question.

#### INTERSTITIAL THERAPY

The basic paradigm of interstitial brachytherapy is based on the principle that deposition of radiation energy in tissues decreases exponentially as a square function of the distance from the radiation source. Thus, while tumor tissue infiltrated with radioactive sources would receive maximal doses of radiation, there will be a rapid falloff of the dose in surrounding normal tissues. Over the years, a range of isotopes (e.g., <sup>226</sup>Ra, <sup>198</sup>Au, <sup>125</sup>I, <sup>192</sup>Ir, <sup>103</sup>Pd) have been tested, and the techniques have evolved from free-hand implantation to ultrasonography- and CT-guided template systems.<sup>525,526,527,528 and 529</sup> Retropubic implantation of the prostate with <sup>125</sup>I sources was the technique of choice until a decade ago.<sup>525,527,529</sup> Long-term follow-up, however, indicated that local failure was significantly increased within nearly all stages as compared with external-beam-treated patients.<sup>529,530 and 531</sup> The causes for local failure in these patients are not fully known, but difficulties in achieving a

geometrically acceptable distribution of seeds and a homogeneous dose distribution within the prostate have been regarded as major factors affecting this outcome.

More recently, new approaches of percutaneous transperineal implantation have been developed. These systems use sophisticated diagnostic localization procedures for source placement and new methods of dosimetry and computer-aided optimization of treatment planning that improve the ability to produce homogeneous dose distribution within the target volume.<sup>526,527,532,533</sup> The most popular approach has been the TRUS-guided implantation of <sup>125</sup>I or <sup>103</sup>Pd sources with or without supplemental external-beam irradiation.<sup>527,532,533</sup> Treatment planning is based on CT or TRUS, with images obtained at 5-mm intervals. Isodose distributions are provided at each 5-mm increment throughout the treatment volume to determine the precise localization of seed placement and the source strength required to achieve a dose of 160 Gy with <sup>125</sup>I or <sup>115</sup>Gy with <sup>103</sup>Pd. Implantation is performed while the patient lies in a dorsal lithotomy position and is under spinal anesthesia. A needle guidance template is attached to an ultrasound apparatus and is placed against the perineum. Needles containing the radioactive sources are inserted through the template under TRUS guidance with supplemental fluoroscopy. Compliance of source placement with the pretreatment plan is determined by direct visualization on biplanar ultrasonography. After implantation, 5-mm-thick CT images of the prostate are obtained, and isodose contours are calculated to evaluate the dose that will actually be delivered to the prostate and the surrounding normal tissues. Wallner et al.<sup>526,534</sup> has recently described a method for 3D CT-based pretreatment planning and an implantation technique using individualized template devices that permit more precise source placement within the target volume.

The technologic improvements in transperineal ultrasound-based or CT-planned permanent seed implantation have enhanced the ability of this modality to target high radiation doses to the prostate more precisely than in the past. Concomitantly, treatment results have improved significantly, especially in patients with favorable-risk disease. Three- to 5-year PSA relapse-free survival rates have ranged between 76% and 96%.<sup>535,536,537</sup> and <sup>538</sup> A recent study by Blasko et al.<sup>535</sup> reported the results in 138 T1c to T2 patients with Gleason scores of 6 or less. PSA decreased gradually to levels of less than 1.0 ng/mL over the first 4 years after implantation in 97%, and the actuarial PSA relapse-free survival at 5 years was 93%. Priestly and Beyer<sup>536</sup> reported a rate of 94% PSA relapse-free survival at 5 years for T1 patients, 70% for T2a and T2b patients, and 34% for T1c patients. In contrast, Storey et al.<sup>537</sup> failed to demonstrate effects of stage and Gleason score on the PSA outcome in 206 patients. Freedom from PSA failure correlated, however, with pretreatment PSA levels. Actuarial 5-year freedom from failure was 76% in patients with a pretreatment PSA level of not more than 10 ng/mL, 51% for patients with values of in excess of 10 ng/mL, and 84% for patients with a PSA level of less than 4 ng/mL. Stock et al.<sup>538</sup> demonstrated a dose response for <sup>125</sup>I prostate implants. Using TG43 guidelines, dose-volume histograms were calculated. The dose delivered to the gland was defined as the D90 (dose delivered to 90% of prostate tissue as defined by CT). Patients receiving a D90 dose of less than 140 Gy had a 4-year relapse-free survival of 68%, as compared with 92% for those receiving a D90 dose of at least 140 Gy ( $P = .02$ ). Two-year posttreatment biopsies were negative in 70% (33 of 47) of patients with a D90 of less than 140 Gy, as compared with a rate of 83% (24 of 29) in patients with a D90 of at least 140 Gy ( $P = .2$ ).

In the absence of a randomized trial comparing 3D-CRT and permanent interstitial implantation for early-stage prostatic cancer, it has become a challenge to select the most appropriate treatment for a given patient. Zelefsky et al.<sup>539</sup> recently addressed this issue. Their study compared patients with favorable-risk prostate cancer treated with either 3D-CRT ( $n = 137$ ) or transperineal <sup>125</sup>I implantations ( $n = 145$ ). The 3D-CRT dose range was 64.8 to 81.0 Gy, and the implant dose range was 110 to 257 Gy (median, 150 Gy). The 5-year PSA relapse-free survival rates for the 3D-CRT and the implant groups were 88% and 82%, respectively ( $P = .09$ ). Protracted grade 2 urinary symptoms persisting for 12 to 70 months were observed in 45 (31%) of the implant patients. In contrast, the 5-year actuarial likelihood of late grade 2 urinary toxicity for the 3D-CRT group was only 8%. The 5-year actuarial likelihood of developing a urethral stricture (grade 3 urinary toxicity) for the 3D-CRT and implant groups was 2% and 12%, respectively ( $P < .0002$ ). The 5-year actuarial probabilities of rectal toxicity were not significantly different. The 5-year likelihood of posttreatment erectile dysfunction among patients who were potent prior to treatment was 43% for the 3D-CRT and 53% for the implant group ( $P = .52$ ). These data demonstrated that 3D-CRT and transperineal <sup>125</sup>I implantation are each associated with an excellent PSA outcome, but issues of quality of life associated with treatment toxicities may serve as guidelines for therapy selection in the individual patient.

## CRYOTHERAPY

Loening et al.,<sup>540</sup> at the University of Iowa, first popularized cryosurgical ablation of prostate cancer in 1969. In their technique, the posterior surface of the prostate, seminal vesicles, and bladder base were exposed through a perineal incision. A cryoprobe then was inserted first into the perivesical fascia and later into the ampullae, seminal vesicles, and entire prostate. The technique was monitored by visual and tactile inspection only. Such therapy resulted in coagulative necrosis of epithelial elements and replacement with fibrous stroma. Outcomes (survival and recurrence) were related to stage and grade. Approximately 41% of patients eventually had evidence of persistent or recurrent disease. At that time, the technique compared favorably with other treatment modalities with respect to survival. However, morbidity was significant and included urethral sloughing of tissue, urethrorectal or urethrocutaneous fistula development, bladder neck obstruction, and urinary incontinence. Porter et al.<sup>541</sup> updated the outcomes of 51 men who underwent cryosurgery alone using this early technique for the management of prostate cancer between 1973 to 1977. Cancer recurrence was documented in 78.4% of the men, and 47.1% died of prostate cancer. Local recurrence was documented in at least 67% of those undergoing the procedure. Kaplan-Meier analyses demonstrated median progression-free and overall survival times of 34 and 75 months, respectively.

Despite this early experience, there has been a resurgence of interest in cryosurgery as a less invasive form of treatment for localized prostate cancer. This interest stems from technical innovations including improved percutaneous techniques, expertise in TRUS, improved cryotechnology, and a better understanding of cryobiology.

Freezing of the prostate is carried out using a multiprobe cryosurgical device.<sup>542</sup> The two parameters that correlate with the likelihood of cell destruction are the cooling rate during freezing and the lowest temperature achieved.<sup>543</sup> Damage may occur due to chemical injury or intracellular ice formation. Cellular destruction occurs as a result of freezing of the extracellular compartment and withdrawal of water from the cells occurring at  $-15^{\circ}\text{C}$ , intracellular ice formation occurring at  $-20^{\circ}\text{C}$  to  $-40^{\circ}\text{C}$ , thawing (which results in recrystallization), and tissue thrombosis.<sup>544</sup> Cell death requires temperatures lower than  $-20^{\circ}\text{C}$ . However, temperatures as low as  $-40^{\circ}\text{C}$  may be necessary to ensure complete freezing of the intracellular compartment. This fact has important clinical implications to the urologist performing cryosurgery, as the hyperchoic edge of the ice ball visualized is  $0^{\circ}$  to  $-2^{\circ}\text{C}$ , and temperatures as low as  $-20^{\circ}$  to  $-40^{\circ}\text{C}$  are inside this edge. Therefore, one must extend the ice ball well beyond the edge of the prostate to ensure adequate tissue ablation. Rapid freezing allows for minimal loss of intracellular water and, therefore, the maximal chance of intracellular ice formation. Passive warming, which occurs slowly (over 15 to 20 minutes) after the cryoprobes are allowed to thaw, results in formation of larger ice crystals, a process called *recrystallization*, and this process further destroys tissues. After one episode of freezing, the cells are very vulnerable to additional cycles, and a second freezing cycle will allow for destruction of surviving cells. The destructive process may be facilitated by thrombosis of small vessels and the resulting tissue anoxia.

The ice balls generated by current methods are elliptic in shape, with the maximal radius at the tip. The radius is directly proportional to the rate of flow of liquid nitrogen. At high flow rates, the gradient from the outer edge—which, as mentioned, is at  $0^{\circ}\text{C}$ —to the zone at  $20^{\circ}\text{C}$  is narrow, approximately 2 mm. At low flow rates, this gradient is widened. The ice ball is approximately 4 cm long. Therefore, it is frequently necessary to pull the cryoprobes back toward the apex of the prostate after the initial freezing at the base, to ensure complete destruction of the gland.

Patients, after induction of regional or general anesthesia, are placed in the lithotomy position. A urethral warming device is placed to preserve the urethra and avoid sloughing of tissue postoperatively. This device circulates heated water. An ultrasound transducer is inserted into the rectum, and volume measurements are made of the prostate and cancer or cancers. Using a needle guide, an 18-gauge, hollow-core needle is inserted into the prostate under TRUS guidance. Once in position, a 0.038 J-tipped guidewire is advanced through the needle to the proximal extent of the prostatic capsule. Cannulas and dilators are passed over the wires to facilitate placement of five or more cryoprobes. Generally, two probes are placed anteromedially, two posterolaterally, and one posteriorly. Liquid nitrogen is circulated through these needles, and the resulting freezing zones, or ice balls, can be monitored by ultrasonography. The anterior probes are activated first and allowed to extend posteriorly and laterally. Once these have reached the desired position, thawing is begun, and the posterior probes are activated. Most often, two freeze-thaw cycles are performed, certainly in the area of cancer. In addition, if the ice ball does not adequately extend to the apex of the prostate, the cryoprobes are pulled backward into the apex, and additional freezing is carried out. In areas of ECE, greater propagation of the freeze zone is permitted laterally. If necessary, an additional probe may be placed in any area of gross ECE.

Androgen deprivation before cryosurgery should be considered in patients with large glands or extensive local disease, as such therapy serves to shrink the prostate and cancer, allows for even distribution of the cryoprobes, eliminates steep temperature gradients between the probes, reduces bulky extracapsular disease, and may allow for widening of the periprostatic space and better protection of surrounding structures.

Patients who undergo cryosurgery alone rarely require hospitalization, and the procedure usually is performed on a “come and go” basis. A urethral catheter is left in place for 3 weeks, as such a period of urethral catheterization appears to be associated with a lower likelihood of postoperative tissue sloughing and urinary retention as compared to use of a suprapubic tube alone or shorter periods of urethral catheterization. Patients are followed with serial PSA measurements and assessment of

symptom scores. TRUS-guided biopsies of the prostate should be considered in most patients at 6 to 12 months after the procedure, certainly in those who fail to reach PSA nadirs of less than 0.4 ng/mL or in those whose serum PSA falls to a low level initially but rises later.

The efficacy of various forms of treatment for prostate cancer can be assessed by analyzing several end points. Commonly, patients who have been treated with cryotherapy have undergone repeat prostatic biopsy 6 to 12 months after the procedure. The positive biopsy rate after cryoablation ranged between 7.7% and 25%. These results must be analyzed cautiously as not all patients treated underwent biopsy, some patients received neoadjuvant androgen deprivation (which could have affected biopsy data), and false-negative biopsy results are not uncommon, certainly in those with limited disease before treatment. Not surprisingly, there is a relationship between clinical stage and the likelihood of a positive posttreatment biopsy after cryotherapy. The likelihood of a positive biopsy is approximately 9% for those with clinical stage T1 or T2 disease and at least 21% for those with T3 disease.<sup>545,546</sup> Interestingly, benign epithelium, often very focal, has been seen in up to 71% of patients after cryotherapy. The significance of benign epithelium is unknown, and such findings may represent areas of the prostate not frozen to low temperatures, perhaps, in the area of the urethral warmer.

It must be recognized that certain areas of the prostate or seminal vesicles are more likely to be sites of treatment failure. It appears that recurrence is more common in cancers located at the apex (9.5%) and seminal vesicles (43.8%), in contrast to those located in the midgland (4.1%) and base (0%).<sup>547</sup> Similarly, Bahn et al.<sup>548</sup> noted that the apex and, to some extent, the seminal vesicles were more likely to harbor residual disease as compared to the rest of the prostate.

Serum PSA level after definitive treatment such as radical prostatectomy or radiation therapy has been shown to be an important determinant of eventual outcome. What constitutes an acceptable PSA level after cryotherapy has not been well evaluated. Radiation or cryotherapy does not result in complete destruction of all prostate tissue. Detectable levels of PSA may be due to either malignant or benign epithelial elements. Therefore, a low but stable PSA after cryotherapy may not be associated with disease progression. A similar situation has been noted for patients who undergo radiation therapy. This issue was addressed recently at UCSF by Shinohara et al.,<sup>549</sup> who correlated the rates of biochemical and biopsy failure with the PSA nadir after cryosurgical treatment of prostate cancer in 132 patients who underwent 145 cryosurgical ablation procedures. Follow-up included PSA testing at 3, 6, and 12 months and every 6 months thereafter. Biopsies were performed at 6 months, and biochemical failure was defined as a PSA nadir of at least 0.5 ng/mL or subsequent PSA elevation of at least 0.2 ng/mL. Biochemical and biopsy failures were correlated with PSA nadir values after cryosurgery (<0.1 ng/mL, 0.1 to 0.4 ng/mL, 0.5 to 1.5 ng/mL, and >1.5 ng/mL). Biochemical failure (subsequent rise in PSA of 0.2 ng/mL or more) was lowest in those who achieved PSA nadirs of less than 0.1 ng/mL (21%) but was common in those with higher nadir values. Biopsy failure was lowest in those with nadirs of less than 0.1 ng/mL (1.5%) and in those with nadirs of not more than 0.4 ng/mL (10%). In contrast, 55% of the patients with nadir values of 0.5 ng/mL or more had biopsy failure. Both biochemical and biopsy failure tended to occur within the first 12 months after treatment (i.e., 96% and 88% of the biochemical and biopsy failures, respectively). Based on this single study, a PSA nadir of not more than 0.4 ng/mL should be achieved after cryotherapy. Higher values are associated with a significant risk of continued PSA elevation and a high likelihood of residual disease detected on prostatic biopsy.

Greene et al.<sup>550</sup> similarly showed that a serum PSA level in excess of 0.5 ng/mL was highly predictive of biopsy and biochemical failure after cryotherapy. Long<sup>551</sup> recently analyzed a very well-characterized series of 145 patients. The crude rates of maintaining either a negative biopsy or a serum PSA level of less than 0.3 ng/mL at 6 and 24 months after the procedure were 87% and 73%, respectively. However, the overall actuarial rate at 42 months of maintaining a serum PSA level of less than 0.3 ng/mL was 59%.

Koppie et al.<sup>552</sup> recently reported intermediate-term results of cryotherapy in 176 patients who underwent 207 cryosurgical procedures for clinically localized (stages T1 through T4) prostate cancer using a multiprobe cryosurgical device. The patient population was composed of men who generally had intermediate- or high-risk disease (T3 or T4 disease in 61%). Actuarial biochemical recurrence-free survival rates at 1 year and 3 years after treatment for those patients undergoing primary cryosurgery (excluding repeat procedures and patients who failed previous radiation or radical prostatectomy) were 62% and 49%, respectively. PSA nadir ( $P = .001$ ) and pretreatment serum PSA level ( $P = .008$ ) were significantly associated with outcome after cryosurgery. Outcome correlated with pretreatment risk status. Actuarial biochemical recurrence-free survival 1 year and 3 years after cryosurgery was 82% and 69% for low-risk patients and 58% and 45% for intermediate- to high-risk patients, respectively ( $P = .048$ ). Neoadjuvant androgen deprivation was not shown to improve outcome significantly after cryosurgery. Prostate biopsy was performed after 167 procedures and proved to be positive in 64 (38%) such cases.

Impotence is the most common complication of cryotherapy, occurring in more than 80% of the men who are potent before cryotherapy and who undergo complete (bilateral) treatment of the prostate. Impotence is a product of damage to the neurovascular bundles during the freezing process. Clearly, some patients who are impotent just after the procedure will regain erectile function with time. However, this number appears to be limited, and most men who become impotent after the procedure require long-term treatment for this condition.

Sloughing of tissue occurs in approximately 3% to 10% of patients. The likelihood of either urinary retention due to necrotic tissue obstruction or stricture formation is related to the type of urethral warmer used. Sloughing of urethral tissue, urinary retention, incontinence, and stricture disease are much less common in those patients treated with effective, commercially available urethral warming devices.<sup>553</sup> In addition, leaving the urethral catheter in place for a prolonged period rather than relying on suprapubic urinary drainage will further decrease the likelihood of this complication. Sosa et al.,<sup>553</sup> in a multicenter review, reported the following incidence of early complications: urinary retention for longer than 1 month, 6.8%; pain, 9.4%; infections, 13.4%; and fistula formation, 1.4%. Complications are much more common in those who undergo cryoablation for management of local disease recurrence after radiation therapy. In this patient population, urinary incontinence is common, occurring in 42% of patients, and is usually moderate to severe in nature.<sup>554</sup> Resolution of incontinence will occur in approximately one-half of these patients within 1 year of treatment. Therefore, early and aggressive treatment of incontinence should be delayed until it is ascertained that resolution will not occur.

Options for treatment of incontinence, should it persist, are limited. Collagen injection should be delayed 12 to 15 months after the procedure to allow for healing. Although complete resolution of incontinence is unlikely, significant improvement may be noted in some patients after collagen injection. The use of an artificial sphincter is an option, but additional endoscopic procedures may be necessary, and revision is likely in some patients.

## MANAGEMENT OF LOCAL FAILURE AFTER SURGERY, RADIATION THERAPY, AND CRYOTHERAPY

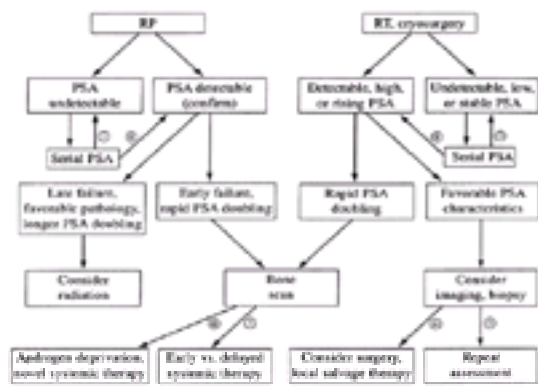

A significant number of men who undergo standard local treatment for prostate cancer will experience biochemical recurrence, which may herald the development of clinical recurrence in some. A recent analysis of patients enrolled in a disease registry of prostate cancer patients demonstrated that 22% of patients who received initial treatment with radical prostatectomy, radiation therapy, or cryotherapy required a second form of prostate cancer treatment within 3 years of initial therapy.<sup>555</sup> Similar results have been reported by others.<sup>556</sup>

Serial PSA measurements provide the most reliable method of detecting recurrence, as tumor progression rarely occurs in the absence of PSA elevation. Distinguishing between local recurrence and distant failure is crucial to subsequent treatment decisions. Physical examination of the prostate or surgical bed by DRE is neither sensitive nor specific for the detection of local recurrence after any form of local therapy. PSA kinetics, in conjunction with pretreatment pathologic stage and grade, may provide the best means of identifying the location of tumor recurrence. Patients with low-grade or low-stage disease and PSA levels of less than 10 ng/mL at the time of initial therapy are most at risk for local recurrence, whereas those with seminal vesicle invasion, high-grade cancers (Gleason score >7), positive lymph nodes, or initial serum PSA levels exceeding 20 ng/mL are more likely to experience failure distantly. A PSA velocity of less than 0.75 ng/mL/y was observed in 94% of patients with local recurrence after radical prostatectomy.<sup>557</sup> Conversely, more than 50% of men with metastatic disease had a PSA velocity greater than 0.75 ng/mL/y. Clearly, a PSA doubling time of less than 6 months suggests distant disease.<sup>306</sup>

Patients with detectable or increasing PSA levels after either surgery or radiation therapy, respectively, may be candidates for local imaging complemented by TRUS-guided biopsy. After surgery, anastomotic biopsy may be positive for local recurrence in 40% to 50% of patients with detectable levels of PSA.<sup>558</sup> However, anastomotic biopsy generally is not necessary after radical prostatectomy, as treatment decisions can be made on the basis of PSA kinetics alone. Indications for TRUS-guided biopsy after either radiation or other forms of focal therapy such as cryotherapy are not clear. Most would agree that such biopsies should be considered in those patients treated with radiation therapy or cryotherapy who show serial elevations in serum PSA level after reaching a PSA nadir. Nadir levels of PSA usually are reached within 8 to 18 months after external-beam irradiation, longer with brachytherapy, and within 3 months after cryotherapy. Both endorectal MRI complemented by spectroscopy and monoclonal antibody imaging may complement the use of PSA kinetics to define the site of recurrence after local therapy.<sup>559</sup> However, CT, MRI, and bone scans rarely are required in the early evaluation of asymptomatic patients with biochemical failure after radical prostatectomy, radiation therapy, and cryoablation (Fig. 34.4-17). In the absence of symptoms, the probability of a positive bone scan due to metastatic disease is less than 5% until the serum PSA level exceeds 40 ng/mL.<sup>560,561</sup> Radioimmunosintigraphy using an antibody to PSMA has been used to identify the site of recurrence in those patients who experience biochemical failure after radical prostatectomy. The sensitivity and specificity for the detection of recurrence is highly variable, ranging between 44% and 90% and 36% and 86%, respectively.<sup>562</sup> In most patients, this procedure may add little prognostic information over that gained by analysis of posttreatment PSA

kinetics and pretreatment cancer grade, stage, and serum PSA level.

**FIGURE 34.4-17.** Algorithm for evaluation of those with biochemical failure after radical prostatectomy (RP), radiation therapy (RT), or cryotherapy for presumed localized prostate cancer. PSA, prostate-specific antigen.

Treatment options after radical prostatectomy include surveillance alone, systemic therapy, or radiation to the prostatic bed. In general, 30% to 65% of men who undergo therapeutic, or salvage, radiation therapy after radical prostatectomy will develop and maintain undetectable PSA levels ( [Table 34.4-17](#)). Schild et al.<sup>563</sup> reported an overall 50% disease-free survival at 3 years; however, 78% of those patients with a pre-radiation therapy PSA level of less than 1.0 ng/mL were disease-free, whereas only 18% of men with a PSA level greater than 1.0 ng/mL remained disease-free. Others have reported similar findings, suggesting that therapeutic radiation after surgery should be applied early. Patients most likely to benefit from salvage radiation after prostatectomy include those with low- to moderate-grade tumors with an undetectable postoperative PSA that rises after more than 1 year. The exact timing of radiation therapy has yet to be determined, although a pre-radiation therapy PSA cutoff of 2.0 ng/mL currently appears reasonable. Such therapy is usually well tolerated, although transient changes in bowel and bladder function may occur. In a study of 294 men who underwent radiation therapy after surgery, no significant long-term impact of postoperative radiation was seen on either urinary continence or erectile dysfunction.<sup>564,565</sup> Although both brachytherapy and cryotherapy have been used to manage local recurrences after radical prostatectomy, the experience with these modalities is very limited.

Author	No. of Patients	Undetectable PSA (%) Favorable Response	Follow-Up after RT

**TABLE 34.4-17.** Probability of an Undetectable Prostate-Specific Antigen Level after Therapeutic Radiation for a Detectable Prostate-Specific Antigen Level after Prostatectomy

Androgen deprivation is the most common form of secondary treatment (88%) after radiation therapy.<sup>566</sup> Such therapy generally is considered palliative rather than curative.

Curative forms of secondary treatment should be considered in properly selected patients. Salvage radical prostatectomy is one option. Cause-specific survival after this procedure ranges from 70% to 90% and 30% to 50% at 8 to 10 years, respectively. In a series from Tefilli et al.,<sup>564</sup> all patients with organ-confined disease were disease-free at 34 months. Amling et al.<sup>569</sup> reported a 10-year disease-free survival of 43% in 108 patients, similar to the results from Rogers et al.<sup>567</sup> and Moul et al.<sup>568</sup> DNA ploidy, preoperative serum PSA level, and Gleason score were significant predictors of outcome postoperatively. Those patients most likely to benefit from salvage surgery include those with favorable disease characteristics before radiation therapy and those with PSA kinetics after radiation therapy consistent with local rather than distant recurrence. Complications of salvage prostatectomy are more common than after primary prostatectomy. Urinary incontinence is seen in 20% to 60% of patients, bladder neck contracture occurs in approximately 20%, and impotence is virtually universal. Rectal injury occurs in fewer than 10% of patients and rarely necessitates fecal diversion. Contemporary series report better outcomes due to improved patient selection, earlier identification of failure, and improved surgical technique.

The largest series of patients treated with cryoablation for local recurrence after primary radiation therapy was reported by Greene and Pisters et al.<sup>550,570</sup> from the M. D. Anderson Cancer Center. Negative sextant biopsies were noted in 77% of patients 6 months after cryoablation. However, only 45 of 150 patients (30%) had a persistently undetectable PSA level with a mean follow-up of 13.5 months. Incontinence was common, and up to 50% of such patients may require transurethral resection for urinary retention and obstructive voiding symptoms. Impotence occurred in at least 80% of men. An effective urethra warming device was determined to be essential to minimize tissue sloughing. Complications such as urethrorectal fistula, abscess formation, and urethral stricture were rare. Additional radiation is an option also.

Grado et al.<sup>571</sup> followed 49 patients treated with brachytherapy after biopsy-proven primary radiation therapy failure. Actuarial biochemical-free survival was 34% at 5 years and was associated with a post-salvage PSA nadir of less than 0.5 ng/mL. Local disease control was 98%; only a single patient demonstrated local, clinical failure. These results are encouraging, especially given the treatment population. The median age was 73.3 years, and 71% had locally advanced disease at initial presentation. Ninety percent of the cancers were moderately to poorly differentiated on prebrachytherapy biopsies. Complications were similar to those seen in patients undergoing primary brachytherapy.

For those patients whose cancers recur after cryotherapy, the choice of secondary treatment is not well defined. Repeat freezing has been reported, as has salvage prostatectomy. In the subset of patients at UCSF who underwent multiple cryotherapy procedures, 67% had no cancer on subsequent biopsies but only 33% achieved long-term, favorable PSA values.<sup>552</sup> Radical prostatectomy is an option, but morbidity may be significant. Radiation treatment can be used after cryoablation and, unlike cryotherapy after radiation, salvage radiation therapy after cryotherapy appears to be associated with minimal morbidity.

New forms of salvage therapy are being developed and refined. Both high-intensity focused ultrasonography and radiofrequency interstitial ablation are being studied and appear to have promise in local control of prostate cancer.<sup>572,573</sup> These methods induce coagulative necrosis of tissue. In preliminary studies, primary high-intensity focused ultrasonography achieved short-term, local control in 60% to 80% of patients. Radiofrequency ablation was able to produce predictable lesions in prostates prior to radical prostatectomy. The long-term efficacy and morbidity of these new forms of focal therapy require further study.

Finally, many patients in whom local therapy fails, as evidenced by rising PSA levels, may not develop clinical evidence of disease.<sup>279</sup> Therefore, observation alone is an option in low-risk, asymptomatic patients in whom primary therapy fails. In such patients, the morbidity and cost of secondary therapy must be carefully considered and compared to the risk of clinical progression of disease.

## TREATMENT SELECTION FOR ADVANCED DISEASE: METASTATIC AND LOCAL REGIONAL DISEASE

The spectrum of advanced prostate cancer has changed considerably over the last 10 years since the introduction and widespread use of PSA screening. Prostate cancer is diagnosed in fewer patients at a time when their disease is overtly metastatic. Most cancers are detected earlier, frequently at an asymptomatic stage. Nonetheless, a large number of patients still die of prostate cancer despite earlier detection, which reflects the existence of occult metastatic disease.<sup>1</sup> A redefinition of advanced disease in the current era would seem appropriate, given these changes. Advanced disease might include patients who, at time of diagnosis, have poor-risk features but no overt metastases. One might include two other subsets of patients as having advanced disease: patients who demonstrate cancer progression after either local therapy or androgen ablation therapy, as evidenced solely by a rise in the serum PSA level. With improvements in our understanding of risk stratification, the traditional stage-based therapy may become obsolete, replaced by multifactor stratification schemes and biologically based therapies. However, until the paradigm has changed, we must discuss treatment based on stage or modality.

### ANDROGEN DEPRIVATION

#### Overview

Androgen deprivation remains the mainstay of therapy for patients with advanced prostate cancer. Because androgen may play a role as both a survival factor and a growth factor for prostatic carcinoma cells, interference with the androgen-signaling pathway will generate clinically meaningful remissions in the majority of patients. These remissions are manifest by a reduction in symptoms related to disease, if they exist, and a reduction in the serum PSA level. A decline in serum PSA level reflects, in part, a decrease in the cellular production of PSA, as the PSA gene promoter is, in part, androgen-regulated<sup>574</sup>; thus, withdrawal of androgen will reduce the production of PSA protein. In addition, the reduction in serum PSA level may reflect the consequence of metabolic changes in the cell or a reduction in the prostate cancer cell mass, presumably through induction of cell death pathways. It is likely that the remission sustained by the vast majority of patients reflects a composite of all of these phenomena, although conceivably one or another mechanism may dominate in any one individual.

The majority of circulating androgen is produced by the testicles in the form of testosterone, and the remainder is produced by the adrenal glands, which synthesize the so-called adrenal androgens. These adrenal androgens may contribute up to 40% of the androgen detected within the prostate.<sup>575</sup> Androgen deprivation is achieved through surgical (orchiectomy) or chemical (gonadotropin-releasing hormone analogues) castration. Estrogens and progestational agents, which are less frequently used, will also reduce androgen levels through nuclear receptor-mediated activity. Antiandrogens (androgen receptor antagonists) or agents that interfere with the adrenal production of androgens, such as ketoconazole or aminoglutethimide, also are used.

Most of the data that currently exists regarding the comparative efficacy of androgen ablation strategies and the overall management of patients with advanced disease have been acquired through studies involving patients with radiographic evidence of metastatic disease (M+). How applicable the results of these studies are to patients with earlier stages of advanced prostate cancer is uncertain. Nonetheless, in the M+ population, response durations to androgen deprivation average 12 to 18 months.<sup>576</sup> Even in this far-advanced group of patients, heterogeneity exists, as evidenced by the fact that a minority of patients will demonstrate no biochemical or clinical disease progression 5 years after initiating therapy. An increase in serum PSA level remains the earliest indicator of relapse, although a small subset of patients (<5%) will experience relapse even in the absence of serum PSA progression. Optimal therapy for patients with earlier disease (i.e., locally advanced patients or those who experience relapse after local therapy) remains undefined. Significant side effects exist as a result of treatment with androgen deprivation therapy, and the cost of therapy can be significant as well. Thus, the choice and timing of treatment depends on several factors, including the stage of disease, whether symptoms are present, the rate of disease progression, patient preference, and a full knowledge of the toxicity profiles of the drugs used.

#### Timing of Androgen Deprivation Therapy

Although it is assumed that androgen deprivation therapy is life-prolonging, this has never been formally proven. Nonetheless, it is likely that androgen deprivation therapy delays the onset of radiographic progression or symptoms in an otherwise asymptomatic man, presumably by reducing the overall tumor cell mass. Whether the earlier initiation of androgen deprivation therapy increases survival duration has long been debated. In theory, it seems reasonable that the earlier the initiation of androgen deprivation therapy, the better the outcome. This would follow from the assumption that, as tumors evolve and acquire more genetic change, the proportion of hormone-refractory cells in the tumor increases.

Three studies now offer evidence that supports the earlier initiation of androgen deprivation therapy. In a study conducted by Bolla et al.,<sup>577</sup> 415 men with locally advanced or high-grade prostate cancer were randomized to receive either external-beam radiation therapy alone or external-beam radiation therapy plus 3 years of androgen deprivation therapy. Cyproterone acetate (a steroidal antiandrogen) and goserelin administration were begun at the time of radiation. The cyproterone acetate was continued for a duration of 1 month, whereas the goserelin was continued for 3 years. Patients were followed for a median duration of 3 years. The actuarial 5-year survival for the radiation-alone group was 62% [95% confidence interval (CI), 52% to 72%] and for the radiation-plus-goserelin group was 79% (95% CI, 72% to 86%) ( $P = .001$ ). The survival benefit observed in the combination-therapy arm suggested a benefit to the earlier institution of androgen deprivation therapy. This study has been criticized for the relatively brief duration of follow-up (median, 3 years) at the time of publication and for the long duration of androgen deprivation therapy.<sup>578</sup>

Another study, conducted by the British Medical Research Council (MRC),<sup>579</sup> enrolled and randomized 938 men with locally advanced or metastatic prostate cancer to receive either early androgen deprivation therapy (orchiectomy or LHRH analogue) or delayed androgen deprivation therapy. In this study, disease progression (defined as a conversion from M0 to M+ or, alternatively, local progression requiring treatment) occurred more frequently and earlier in the delayed treatment arm ( $P < .001$ ). In addition, deaths attributable to prostate cancer occurred more frequently in the delayed-therapy arm (257 vs. 203;  $P = .001$ ). This study has been criticized because of the potential bias created by differing follow-up schedules between arms, resulting in some of the men never actually receiving androgen deprivation therapy in the delayed androgen deprivation therapy arm.<sup>578</sup>

The third study that supports earlier intervention is a study by Messing et al.,<sup>580</sup> in which 98 men who had undergone a radical prostatectomy and were found to have pathologically documented metastatic disease to lymph nodes were randomized to receive either early androgen deprivation therapy (LHRH analogue or orchiectomy plus an antiandrogen) or deferred therapy. A dramatic and statistically significant difference in survival duration in favor of the early androgen deprivation therapy arm was found. After a median of 7.1 years, 7 of 47 men in the immediate therapy arm, as compared to 18 of 51 men in the delayed therapy arm, had died ( $P = .02$ ). Three men died of prostate cancer in the immediate therapy arm, as compared to 16 men in the delayed therapy arm ( $P < .01$ ). At the time of the last follow-up, 36 men in the immediate treatment arm versus 9 in the delayed treatment arm were alive without evidence of detectable serum PSA or clinical evidence of disease ( $P < .001$ ).

Although these three studies suggest that early androgen deprivation therapy may confer a survival advantage over delayed therapy, these studies do not define the optimal timing of androgen deprivation therapy for patients in the modern era. Little justification can be made for withholding androgen deprivation therapy when radiographic evidence of metastatic disease is present. However, for patients earlier in their disease course (i.e., patients who have undergone definitive local therapy but who are at high risk of relapse or patients with rising serum PSA levels after local therapy), the appropriate timing of treatment remains to be defined. Given the heterogeneity in the biologic behavior of tumors in the patient population with rising serum PSA levels after local therapy, several factors should be considered during decision making regarding timing. These factors include those that predict the rapidity of onset of clinical symptoms such as PSA velocity, tumor grade, and the time since local therapy was implemented.<sup>581</sup> In addition, patient factors that potentially affect quality of life should be taken into account. These include patient anxiety, on the one hand, and the short-term and long-term impact of androgen deprivation, on the other.

#### Prognostic Factors

Most of the studies that have analyzed predictive and prognostic factors of response and survival in patients undergoing androgen deprivation therapy have done so in patients with radiographic evidence of metastatic disease (M+). In such studies, factors that reflect more extensive disease are associated with a poorer prognosis.<sup>582,583,584,585,586</sup> and <sup>587</sup> Two such factors are performance status and the presence or absence of symptoms. More quantifiable parameters include the number of bone metastases, the presence of appendicular bone disease in addition to axial bone disease, and higher serum alkaline phosphatase levels. Serum PSA levels are not consistently a predictor of response duration or survival. This apparent paradox may reflect the high variability in PSA production between tumors at the cellular level. In addition, the fact that less well differentiated tumors produce less PSA may mute a direct relationship.<sup>588</sup> As a posttreatment dynamic factor, some studies indicate that normalization of serum PSA level may be associated with a better outcome.<sup>583,589,590</sup> However, Eisenberger et al.<sup>591</sup> found in a randomized study of more than 1300 men with metastatic prostate cancer in which orchiectomy was compared to orchiectomy plus flutamide that, although the serum PSA level

normalized (PSA <4) more frequently in men receiving the combination treatment, no difference in survival between the two arms was seen. Patients with visceral metastases<sup>582,583</sup> and patients with lower serum testosterone levels<sup>587</sup> prior to treatment appear to have a poorer outcome. To date, no molecular markers that predict response and response duration to androgen deprivation therapy have been identified.

### **Monotherapy**

**ORCHIECTOMY.** Surgical castration (orchiectomy) remains the standard for patients who will require permanent androgen deprivation therapy. It has the advantages of convenience and cost (as compared to other modalities) and abrogates compliance issues. In addition, clinical response is rapid after the procedure is performed. In patients with symptomatic metastatic disease, significant improvement in symptoms can be achieved within 24 to 48 hours after orchiectomy. Many patients will choose alternative treatments because of the psychological impact of surgical castration or the desire to be treated with androgen deprivation in an intermittent fashion.

**LUTEINIZING HORMONE-RELEASING HORMONE ANALOGUES.** Peptide analogues of LHRH, which possess partial agonistic or antagonistic effects, have been used extensively in the treatment of prostate cancer. The commercially approved agents goserelin and leuprolide are partial agonists. These agents will initially cause a transient increase in luteinizing hormone (LH) and follicle-stimulating hormone production, followed by a decline. Consequently, serum testosterone levels decrease within weeks of initial administration. In patients with radiographic evidence of metastases, there is concern that this "flare" in serum LH and testosterone levels within the first couple of weeks after therapy is initiated may worsen existing disease.<sup>592,593</sup> Thus, these agents are commonly used in conjunction with an antiandrogen such as flutamide, nilutamide, or bicalutamide, which blocks ligand binding to the androgen receptor. In one trial, flutamide was shown to abrogate the clinical effects of the serum LH and testosterone flare.<sup>594</sup>

The LHRH analogues are as effective as other modalities in the treatment of patients with advanced prostate cancer. Randomized studies have demonstrated the equal efficacy of LHRH analogues to orchiectomy<sup>595</sup> and to diethylstilbestrol (DES).<sup>596</sup> Depot formulations have been developed that permit monthly or, alternatively, every-3- and -4-month administration. Depot formulations allowing yearly dosing will soon become available. Pure LHRH antagonists have been developed and are currently in clinical trials. Their niche may be in the treatment of patients with symptomatic metastatic disease who are initiating androgen ablative therapy. Because an LH flare should not occur with these agents, their use may obviate the need for concomitant use of an antiandrogen.

**ESTROGENS.** Estrogens such as DES inhibit LHRH production by the hypothalamus and LH production by the pituitary and, thus, reduce serum levels of testosterone. Whether the entire salutary effect of estrogens is a result of their ability to lower testosterone, which is well established, or a result of other independent mechanisms remains unknown. The presence of estrogen receptors in prostate epithelium suggests that there may be a direct effect.<sup>597</sup> Estrogen therapy was the first exogenous therapy for prostate cancer. In the first Veterans Administration Cooperative Urological Research Group study (VACURG I), patients were randomized to one of four arms: DES, 5 mg alone; orchiectomy alone; DES, 5 mg, plus orchiectomy; or DES, 5 mg, plus placebo.<sup>598</sup> Although the overall survival of patients randomized to DES was the same as for those randomized to orchiectomy, the cancer-specific mortality was lower in the DES-treated group. In this study, the possible therapeutic benefit of DES, 5 mg/d, was offset by an increase in cardiovascular mortality. In VACURG II, patients were randomized to different doses of DES (0.2 mg, 1 mg, and 5 mg) or placebo.<sup>598</sup> The survival of men treated with 1 mg and 5 mg was equivalent, but there was greater toxicity with 5 mg. In another study, men were randomized to leuprolide, 1 mg/d, or to DES, 3 mg/d. Equal efficacy was seen, although the cardiovascular complication rate was higher with DES, 3 mg/d, as compared to leuprolide. Although DES, 1 mg/d, appears to be effective in patients with advanced disease, a significant proportion of men do not achieve castration levels of serum testosterone.<sup>599</sup> In practice, estrogens are used infrequently because of their side effects and their lack of availability, although there is a resurgence of interest in agents that target the estrogen receptor.

**ANTIANDROGENS.** The antiandrogens are competitive inhibitors of testosterone at the androgen receptor. Two classes of antiandrogens are in clinical use, the first of which is the steroidal antiandrogens, which include cyproterone acetate (Androcur) and megestrol acetate (Megace). The second group is nonsteroidal antiandrogens, which include flutamide (Eulexin), bicalutamide (Casodex), and nilutamide (Anadron). The steroidal antiandrogens have broader activity than their nonsteroidal counterparts. In addition to their effect on the androgen receptor, they possess progestational and glucocorticoid activity. The steroidal antiandrogens suppress testosterone through their feedback effects at the pituitary and hypothalamus. As monotherapy, neither cyproterone acetate nor megestrol acetate is capable of suppressing serum androgen levels completely or indefinitely and, as a result, these agents rarely are used as monotherapy.

In contrast, nonsteroidal antiandrogens act principally through the androgen receptor. Through these agents' stimulation of the hypothalamus, serum testosterone levels may increase or remain unchanged as compared to pretherapy levels. The nonsteroidal antiandrogens have been used in three clinical settings: first, as part of combined androgen blockade (in conjunction with surgical or chemical castration); second, as salvage monotherapy in patients who were previously treated with androgen deprivation therapy; and third, as initial therapy without surgical or chemical castration. When used in this last setting, they have the potential advantage of allowing potency to be maintained as serum levels of testosterone are maintained. Small clinical trials<sup>600</sup> have been conducted that demonstrated both their efficacy (as determined by their ability to lower serum PSA levels) as sole agents and in conjunction with 5 $\alpha$ -reductase inhibitors<sup>601</sup> (which inhibit conversion of testosterone to the more potent form, DHT) and their ability to preserve potency in a proportion of men. However, in two randomized studies, nonsteroidal antiandrogens were found not to be as effective as castration. In one study of 92 patients with M+ prostate cancer, flutamide (250 mg t.i.d.) was compared to DES (1 mg t.i.d.).<sup>602</sup> A significant difference in survival was observed in favor of DES. Median survivals were 43.2 and 28.5 months, respectively ( $P = .04$ ). In another study, orchiectomy was compared to 50 mg/d of bicalutamide.<sup>603</sup> In this study, survival duration was superior with orchiectomy. It should be noted that, in retrospect, this dose of bicalutamide was suboptimal. Another study in which patients were randomized to goserelin plus flutamide or to bicalutamide, 150 mg/d, was conducted.<sup>604</sup> Progression-free and overall survival were equivalent in both arms. In two other studies that were combined for publication, bicalutamide, 150 mg/d, was equivalent to orchiectomy or goserelin for M0 patients but proved inferior for M+ patients.<sup>605</sup> Antiandrogens should therefore not be used as monotherapy in patients with M+ disease. Their use as monotherapy in patients with earlier disease may be equivalent to castration; however, longer follow-up is needed.

**COMPARISON OF MONOTHERAPEUTIC AGENTS.** Numerous trials have compared the efficacy of the various monotherapeutic agents. The most comprehensive analysis of these studies was performed by the Technology Evaluation Center, an evidence-based practice center for the Agency of Health Care Policy and Research.<sup>606</sup> The conclusions, based on a metaanalysis of ten trials that included 1908 patients, were that no difference in survival existed between patients treated with LHRH agonists or patients treated with orchiectomy or DES and no difference in survival existed between patients treated with the different LHRH agonists.

### **Combined Androgen Blockade**

The role of adrenal androgens in supporting prostate cancer cell growth is uncertain. The adrenal androgens are relatively weak as compared to testosterone. The concept of combined androgen blockade (CAB) was developed by Labrie et al.<sup>607</sup> in an effort to try to suppress testicular androgen production and block adrenal androgens to afford a better androgen deprivation strategy. In the mid-1980s, Labrie et al.<sup>607</sup> demonstrated dramatic responses of patients with metastatic prostate cancer to a combination of chemical or surgical castration and an antiandrogen. In 1989, Crawford et al.<sup>608</sup> published the results of a National Cancer Institute-sponsored intergroup trial (INT-0036) in which 603 men with M+ prostate cancer were randomized to either leuprolide, 1 mg/d SC, or to leuprolide plus flutamide, 250 mg PO t.i.d. CAB resulted in a significant improvement to disease progression over time and a significant difference in median survival in favor of CAB (median survival, 28.3 months vs. 35.6 months;  $P = .035$ ), as compared to leuprolide alone.

Two other studies demonstrated an improvement in survival associated with CAB. In the EORTC trial, 326 men were randomized to either goserelin, 3.6 mg SC for 4 weeks plus flutamide 250 mg PO t.i.d., or orchiectomy.<sup>609</sup> An improvement in median survival was again observed with CAB (34.4 months vs. 27.1 months;  $P = .02$ ). In the other study, 457 men were randomized to orchiectomy or to orchiectomy plus nilutamide.<sup>610</sup> An improvement in survival was again observed (37.1 months vs. 29.8 months;  $P = .04$ ) in favor of CAB.

Most randomized studies to date, however, have not shown an advantage of CAB, although some of these studies have been criticized for being too small, having inadequate follow-up, or for using steroidal antiandrogens. The largest study to date (INT-105) was a study of 1387 men with M+ prostate cancer in which orchiectomy was compared to orchiectomy plus flutamide.<sup>591</sup> Interestingly, although there was a difference in the frequency with which patients achieved a serum PSA level of less than 4.0 ng/mL [74% (95% CI, 69.4 to 78.2) vs. 61.5% (95% CI, 56.4 to 66.4);  $P < .001$ ], there was no difference in overall survival between the two groups.

A metaanalysis was performed by the Prostate Cancer Trialists' Collaborative Group,<sup>611</sup> which sought to reconcile all the studies of CAB. Overall, no benefit was observed for CAB. Criticisms of this particular metaanalysis included the validity of combining studies in which steroidal and nonsteroidal antiandrogens were used and the inclusion of trials that used LHRH analogues but did not use short-term antiandrogen therapy to block the flare. In a second metaanalysis, which excluded studies published only as abstracts, those that did not present data on survival, and those that used short-term antiandrogens, a benefit was seen for CAB (RR, 0.78;

95% CI, 0.67 to 0.90).<sup>612</sup> In a third metaanalysis, no benefits were seen at 2 years, although a modest benefit was observed at 5 years (hazard ratio, 0.861; 95% CI, 0.78 to 0.95).<sup>613</sup> In summary, if a benefit exists for CAB in patients with M+ disease, it is extremely modest.

One caveat in drawing conclusions from these studies is that the majority of patients who were randomized were patients with M+ disease. Far fewer M0 patients were included. Thus, while it is reasonable to conclude that the benefits of CAB in patients with M+ prostate cancer is minimal, at best, for patients with earlier disease, it is less clear. In current practice, antiandrogens should be used at least for a short duration (1 to 2 months) when an LHRH analogue is used in patients with M+ disease. In M+ patients, antiandrogens are of uncertain value when an orchiectomy is performed. However, for patients with earlier forms of disease, given the paucity of relevant data, CAB is a reasonable option. Furthermore, it is important to note that the binding affinity of the currently used antiandrogens for the androgen receptor is relatively low. As more potent or more specific antiandrogens are developed, these issues may need to be readdressed.

**PERIPHERAL ANDROGEN BLOCKADE.** The efficacy of antiandrogens as monotherapy may be less than that of chemical or surgical castration. Nonetheless, this therapy has the potential appeal of sparing sexual function and reducing other treatment-related side effects, including hot flashes. The strategy of combining an antiandrogen with a 5 $\alpha$ -reductase inhibitor (which reduces the conversion of testosterone to DHT) has also been explored. In one study, the addition of a 5 $\alpha$ -reductase inhibitor (finasteride) added further antiandrogenic effect to that which already was achieved by an antiandrogen alone, as measured by a further reduction in serum PSA level after the achievement of a nadir with flutamide.<sup>601</sup> Other studies have demonstrated PSA responses and the maintenance of potency in men treated with the combination.<sup>600,614</sup> In one randomized phase II study, there was no difference in the percentage of decrease in serum PSA level when finasteride plus flutamide was compared to goserelin plus flutamide or to goserelin plus finasteride.<sup>615</sup> This approach, although appealing, should still be regarded as experimental. Larger studies have not yet been completed, nor have phase III randomized studies yet been performed that compare this strategy to standard therapies, with survival as an end point.

**INTERMITTENT HORMONAL THERAPY.** The scientific basis for intermittent hormonal therapy is that hormonally dependent clones of prostate cancer cells may potentially prevent the growth of hormonally independent cells through the elaboration of growth inhibitory factors. Alternatively, the reintroduction of androgen after androgen withdrawal may result in the generation of differentiated tumor cells.<sup>616</sup> It might be advantageous, therefore, to allow the reintroduction of androgen after androgen withdrawal to delay the emergence of an androgen-independent phenotype. This has been substantiated in some tumor models (Shionogi and LNCaP)<sup>617,618</sup> but not others (Dunning).<sup>619</sup> Practically speaking, this treatment involves continuing androgen ablation until adequate testosterone suppression is achieved and then maintaining suppression for some time. This is followed by the discontinuance of therapy and then readministration of therapy at an arbitrary point determined by serum PSA progression. A number of pilot studies testing the feasibility of this approach have been performed.<sup>616,620,621</sup> In general, these studies have suggested that the quality of life of patients treated with this approach may be better and that patients can be maintained off of androgen deprivation therapy for significant periods. Although this approach has wide appeal, it still should be regarded as investigational. A large, randomized intergroup study is now under way comparing continuous hormonal therapy to intermittent hormonal therapy.

**SIDE EFFECTS OF THERAPY.** Although there is a growing appreciation of the breadth and significance of side effects of androgen ablation, comprehensive prospective studies are lacking and, therefore, the frequency of side effects is difficult to quantify. The most frequently described side effects of testosterone suppression are loss of libido, decreased sexual performance, and hot flashes.<sup>613</sup> It appears that the majority of patients are so affected. More subtle, nonquantifiable effects include fatigue and mood changes.<sup>613</sup> The fatigue that results is probably multifactorial. Decreases in serum testosterone level result in a reduction of muscle and red cell mass. In addition, psychological effects, which result in fatigue, may be operable. Other observable side effects are decreased body hair, peripheral edema, and gynecomastia.<sup>613</sup> Peripheral edema appears to be more common with LHRH analogues, whereas gynecomastia is more frequent and more severely associated with estrogens, with antiandrogen monotherapy, or with combined antiandrogen and 5 $\alpha$ -reductase inhibitor use. The observed incidence of cardiovascular events, including thromboembolic events, is relatively low with all agents and may well be the anticipated rate in the generally elderly population having an underlying malignancy.<sup>613</sup> The exception to this is estrogens, which reproducibly are associated with higher rates of thromboembolic and cardiovascular events,<sup>613</sup> although this effect may depend on dose and route of administration. Although the incidence of osteopenia and vitamin D deficiency in middle-aged and elderly men has been underappreciated, androgen ablative therapy is likely associated with further bone loss,<sup>622,623</sup> and <sup>624</sup> which may result in the greater potential for osteoporotic fractures. Whether bisphosphonates or other agents will prevent these side effects or whether selective androgen receptor modulators will decrease the degree of bone loss is under investigation.

### **Recurrent Disease after Primary Androgen Ablative Therapy**

After androgen ablation, the serum PSA level almost always decreases and achieves a nadir value. This nadir is maintained for a variable period, reflecting (presumably) the inherent composition of the tumor with regard to sensitivity to androgen ablation and the growth kinetics of the remaining androgen-independent cell population. The earliest manifestation of relapse, in most circumstances, is a rise in serum PSA level. Although some patients will manifest a clinical relapse without a rise in their serum PSA level, this is unusual and may be more frequently associated with prostate cancers that exhibit neuroendocrine differentiation. It is important to note that although the serum PSA level in general correlates with tumor cell mass in all stages of disease, this relationship is altered after androgen deprivation therapy. Serum PSA levels generally are lower per tumor cell volume as compared to pretherapy levels. The velocity of serum PSA increase at the time of relapse after androgen therapy may or may not parallel the serum PSA velocity prior to androgen deprivation therapy, presumably reflecting the kinetics of the tumor in these two different stages. In general, however, the serum PSA increase that is seen after androgen ablative therapy predates the onset of radiographic and clinical evidence of disease progression by months, if not years. The PSA velocity in this setting is predictive of survival.

The mechanism by which prostate cancer cells grow independent of androgen is uncertain. Whether this represents clonal evolution of cells acquiring an androgen-independent phenotype through mutations or epigenetic phenomena or through the growth of a preexistent cell type, such as a stem cell, the growth of which was always androgen-independent is uncertain. Nonetheless, the designations assigned to this stage of disease, including *androgen-independent*, *androgen-refractory*, *hormone-independent*, and *hormone-refractory*, have been used often and interchangeably. Until better genetic stratification of tumors in this stage of disease occurs, there is little value in separating out by name these different categories.

### **SECONDARY HORMONAL THERAPY**

Prostate cancer epithelial cells maintain their ability to grow in response to the administration of androgens even after primary androgen deprivation therapy stops working. Two trials in which androgen was readministered to patients demonstrated more rapid disease progression.<sup>625,626</sup> Two studies have compared the outcomes of patients in a retrospective fashion if primary androgen deprivation was maintained. In one study, discontinuance of androgen deprivation after failure was an independent predictor of survival,<sup>627</sup> while it failed to be a factor in another study.<sup>628</sup> It is current practice to maintain androgen deprivation (castrate levels of testosterone) even after primary androgen withdrawal stops working. Tumor progression after primary androgen ablation is poorly understood mechanistically and is likely multifactorial. A small subset of patients who experience relapse actually have noncastrate levels of testosterone. Therefore, it is reasonable to check serum testosterone levels at this point and to recommend surgical castration if castrate levels have not been achieved. It had not been until the advent and use of PSA testing that there was some appreciation of the utility of secondary hormonal manipulations after primary androgen deprivation therapy had failed. The implication of serum PSA decline with secondary therapy has not been studied but, in general, for the sake of consistency, a 50% decline in serum PSA level in this setting has been considered a benchmark for response.

### **Antiandrogen Withdrawal Responses**

One of the most interesting observations made in the last decade was the recognition that the withdrawal of antiandrogen therapy (while maintaining testosterone suppression) may be associated with biochemical (PSA) and, in some cases, symptomatic and objective responses.<sup>629</sup> Such responses were described initially in the context of withdrawal of flutamide<sup>630,631</sup> and <sup>632</sup> but have since been described on withdrawal of bicalutamide<sup>633,634</sup> and nilutamide.<sup>635,636</sup> Withdrawal responses occur in approximately 25% of patients (range, 15% to 50%). The likelihood of response may correlate with the duration of exposure to the antiandrogen. Other factors such as the type of initial therapy used, whether the antiandrogen was used as part of CAB or was added at the time of disease progression, and other clinical variables have not proven to be predictive of an antiandrogen withdrawal response. Antiandrogen responses generally are observed within a few weeks after withdrawal of the antiandrogen. Responses that occur after withdrawal of bicalutamide may occur later (i.e., up to 8 weeks), perhaps because of this agent's longer serum half-life.<sup>633</sup> The typical duration of antiandrogen withdrawal response is 3 to 4 months, although withdrawal responses may last several years. The mechanism of antiandrogen withdrawal has not yet been defined; however, it is likely that at least one mechanism is the emergence of prostate cancer cells with mutated androgen receptors that respond to an antiandrogen as an agonist rather than an antagonist.<sup>637,638,639,640</sup> and <sup>641</sup> In fact, when studies have been performed looking for mutated androgen receptors, they are almost exclusively detected in the context of treatment with CAB. Because of the potential benefit of discontinuance of the antiandrogen and the fact that this maneuver is nontoxic and usually is required for enrollment into most clinical trials, it is very reasonable to initiate antiandrogen withdrawal as the first

approach for patients whose disease is progressing while they are being treated with antiandrogen therapy. Whether subsequent reintroduction of the same antiandrogen is useful has not been studied.

As mentioned, secondary hormonal maneuvers will elicit responses in patients whose tumors are progressing while they are on primary androgen ablative therapy. The mechanism of these responses probably is multifactorial and likely includes (1) a further reduction in testosterone in those patients who have not achieved a complete reduction of testosterone, (2) blockade of the effect of residual serum androgens through binding of the androgen receptor, (3) reduction in adrenal androgen production, and (4) binding of agents to other nuclear receptors, such as the estrogen receptor, in the prostate cancer cell.

### **Antiandrogens**

Although the nonsteroidal antiandrogens bind the androgen receptor, it is interesting that non-cross-resistance exists between these agents. Scher et al. <sup>642</sup> treated 51 patients who had tumor progression after primary androgen ablative therapy with bicalutamide (200 mg/d). Twelve (24%) patients responded. More frequent responses (in 10 of 26 patients, or 38%) were seen in patients previously treated with flutamide. In another study, Joyce et al. <sup>643</sup> treated 31 patients with bicalutamide, 150 mg/d. Seven patients responded, six of whom had received prior flutamide. Interestingly, the two most impressive responses were those patients who had experienced a flutamide withdrawal response. Responses to nilutamide after flutamide have also been noted. <sup>644</sup> However, no reports of flutamide activity after bicalutamide treatment have been published.

### **Adrenal Androgen Inhibitors**

The rationale behind using adrenal androgen inhibitors is that approximately 5% to 10% of circulating androgen is derived from the adrenal gland and that a higher proportion of androgen within prostate cancer cells may be of adrenal origin. The two most commonly used agents in this setting are aminoglutethimide and ketoconazole, both of which have frequently been used in conjunction with corticosteroids. Therefore, it is difficult to ascertain the true activity of aminoglutethimide and ketoconazole as single agents, as corticosteroids have activity in this disease. Ketoconazole, which inhibits cytochrome P-450 and suppresses both testicular and adrenal androgen production, has significant activity. In one study of men treated with ketoconazole (1200 mg/d) plus hydrocortisone, 30 of 48 patients experienced a decline in serum PSA of greater than 50%. <sup>645</sup> The median duration of response was 3.5 months. Ketoconazole is active at lower doses (i.e., 200 mg t.i.d.) and less toxic, though the comparative efficacy of low versus higher doses has not been studied. The need to combine ketoconazole with a corticosteroid particularly at the lower dose is uncertain. Because ketoconazole requires an acidic stomach pH for optimal absorption, patients are instructed not to take antacids, H<sub>2</sub> blockers, or proton pump inhibitors. The drug should be ingested between meals. Ketoconazole causes nausea and vomiting in 15% of patients, which necessitates discontinuance in some cases. In addition, liver function test abnormalities are seen and, therefore, liver function should be monitored.

### **Glucocorticoids**

Glucocorticoids also have significant activity in prostate cancer. Kelly et al. <sup>646</sup> treated 30 men with hormone-refractory prostate cancer with hydrocortisone, 40 mg/d, and observed a response rate of 20%. Tannock et al. <sup>647</sup> compared prednisone, 10 mg/d, to prednisone plus mitoxantrone. Twenty-two percent of patients treated with glucocorticoids alone responded. This was also seen in a CALGB study comparing hydrocortisone, 40 mg/d, to hydrocortisone plus mitoxantrone. <sup>648</sup> Twenty-two percent of patients responded (PSA decline) to hydrocortisone alone. In another study, 16% of 230 patients receiving hydrocortisone responded, as assessed by declines in serum PSA level. <sup>649</sup>

Megestrol acetate has very modest activity in prostate cancer. Dawson et al. <sup>650</sup> found that, in a randomized study of 160 mg versus 640 mg of megestrol acetate, 12% of patients responded (PSA decline). Because megestrol acetate, which is more commonly used to treat anorexia or hot flashes, may cause a clinical flare in disease, patients in whom this agent is used should be monitored closely.

### **Estrogens**

DES has activity as secondary therapy in patients with hormone-refractory prostate cancer. In one study, 9 of 21 (43%) patients responded by PSA criteria. <sup>651</sup> Interestingly, PC-SPES, a nutritional supplement consisting of eight different herbs, clearly has activity in prostate cancer. DiPaola et al. <sup>652</sup> demonstrated that this concoction had estrogenic activity *in vitro* and serum PSA-lowering activity in men with prostate cancer. It was associated with estrogen-like side effects, including gynecomastia. Interestingly, however, Kameda et al. <sup>653</sup> treated with PC-SPES 34 patients with androgen-independent prostate cancer; all patients had rising serum PSA levels after androgen deprivation and had undergone antiandrogen withdrawal. Fifty-three percent of the patients had a greater than 50% decline in PSA level. Whether the activity of PC-SPES in patients with hormone-refractory prostate cancer is strictly through its estrogenic properties or is modulated by other mechanisms remains to be determined.

## **MEASURING RESPONSE**

One of the most difficult issues in assessing the potential benefits of different forms of therapy in hormone-refractory prostate cancer is the difficulty in measuring response. Few patients have measurable disease, as most patients have osteoblastic bone metastases in which changes are difficult to quantify. Many studies have suggested that a decline in serum PSA level is of biologic importance and clinical significance. Myers et al. <sup>654</sup> demonstrated that a decline in PSA of 50% or greater was associated with prolonged survival in patients treated with suramin. Similarly, an analysis of 110 patients treated at MSKCC with a variety of agents demonstrated that a 50% or greater decline in PSA level was associated with a 21-month median survival, as compared to an 8-month median survival in those without such declines. <sup>655</sup> In the CALGB study comparing hydrocortisone to hydrocortisone plus mitoxantrone, patients who achieved a greater than 50% decline in PSA level survived longer than those who did not. <sup>648</sup> A 75% decrease in PSA level was not associated with better survival than was a 50% decline. In this study, minor (<50%) declines in PSA level were not associated with altered survival.

These studies formed the foundation for the consensus report of the PSA working group in assessing clinical trials in hormone-refractory prostate cancer. <sup>656</sup> The benchmark was set at a minimum 50% decline in PSA level. Although this is a useful benchmark, it is important to note that some potentially effective agents may not decrease PSA. It also is important to note that some agents have direct effects on PSA production such that it may be difficult to assess their activity through serum PSA changes alone.

## **PROGNOSTIC FACTORS**

The main utility of prognostic factors in patients with advanced cancers is that they help to stratify patients into groups entering into clinical trials. In addition, use of prognostic factors may give some insight into predictive factors for response. Although many studies have addressed this issue, few have been useful. In a recent review, <sup>657</sup> nine studies contained sufficient numbers of patients to perform multivariate analysis. <sup>658,659,660,661,662,663,664</sup> and <sup>665</sup> The most reproducibly important factors that emerged were performance status and hemoglobin level. Other factors of importance appeared to be serum levels of lactate dehydrogenase, alkaline phosphatase, and acid phosphatase.

## **CHEMOTHERAPY**

The traditional view of cytotoxic chemotherapy for prostate cancer is that it had little or no impact on the natural history of the disease. In 1985, Eisenberger et al. <sup>666</sup> reviewed 17 randomized clinical trials that involved 1464 patients. The complete and partial response rate in these trials was 4.5%. In a review of 26 chemotherapy trials performed between 1987 and 1991, the overall response rate was 8.7%. <sup>667</sup> Over the last 5 to 10 years, however, increasing evidence of clinical efficacy of chemotherapy in prostate cancer has emerged. Nonetheless, no trial to date has demonstrated a survival benefit for patients treated with chemotherapy for prostate cancer. The perception of increased efficacy of chemotherapy is the result of several factors. Increased use of the serum PSA level in monitoring activity in clinical trials has suggested that some of the older drugs that previously were believed to be inactive are, in fact, active in this disease. Patients are being placed on clinical trials at an earlier stage because of the recognition that elevations in serum PSA level precede clinical relapse. Furthermore, newer drug combinations have been developed that have greater activity and, finally, better supportive measures, including antiemetics and growth factor support, have allowed clinicians to treat a relatively elderly population in a safer fashion.

Two recently published phase III trials demonstrated the utility of mitoxantrone plus a corticosteroid in hormone-refractory prostate cancer. The first study compared

prednisone (10 mg/d) to prednisone (10 mg/d) plus mitoxantrone (12 mg IV every 3 weeks).<sup>647</sup> One hundred and sixty-one patients with hormone-refractory prostate cancer and pain requiring analgesics were entered into the trial. The primary end point in this trial was a significant impact on pain as measured by a drop of 2 points on a 6-point pain scale. Twenty-three (29%) of 80 patients who received mitoxantrone plus prednisone, as compared to 10 (12%) of 81 patients who received prednisone alone, achieved this palliative response ( $P = .01$ ). In addition, the duration of the palliation was longer for those patients who received mitoxantrone plus prednisone (median duration, 43 weeks vs. 18 weeks;  $P < .0001$ ). In another study, hydrocortisone given as a split dose of 30 mg in the morning and 10 mg in the evening was compared to hydrocortisone plus mitoxantrone, 14 mg/m<sup>2</sup> given every 3 weeks.<sup>648</sup> Two hundred and forty-two patients with metastatic hormone-refractory prostate cancer were randomized in this trial. The primary end point for this study was an improvement in survival with mitoxantrone plus hydrocortisone as compared to hydrocortisone alone. No difference in survival was observed (12.6 months vs. 12.3 months). More patients responded (as measured by a greater than 50% decline in PSA level) with mitoxantrone plus hydrocortisone than with hydrocortisone alone (38% vs. 22%;  $P = .008$ ). Pain responses were more frequent in the combination arm. These two studies led to U.S. Food and Drug Administration approval of mitoxantrone for the treatment of hormone-refractory prostate cancer.

### **Estramustine-Based Chemotherapy**

Estramustine is a conjugate of estrogen mustard and estradiol. Originally synthesized to permit the selective delivery of an alkylating agent into an estrogen receptor-positive cancer cell, more recent studies have shown that estramustine possesses little alkylating activity and may work by inhibiting mitosis through binding microtubular proteins in the nuclear matrix. Estramustine preferentially enters cells that possess the estramustine-binding protein, a protein in high concentration in prostatic epithelial cells. As a single agent, estramustine has modest activity. Its activity is related in part to its estrogenic properties but, in addition, perhaps to its microtubular inhibitory properties. Eighteen phase II trials involving 634 patients with hormone-refractory disease demonstrated an objective response rate to estramustine of 19%.<sup>668</sup>

When it was realized that estramustine had microtubular inhibitory properties, *in vitro* studies were performed that demonstrated synergy of this drug with other agents involved in microtubular assembly. Three trials were conducted involving estramustine and vinblastine.<sup>669,670 and 671</sup> The doses chosen in these studies generally were estramustine, 10 mg/kg/d, along with weekly vinblastine, 4 mg/m<sup>2</sup>. Of 92 patients entered into these three phase II studies, PSA responses were observed in 44 of 88 patients (50%), and objective responses were seen in 6 of 25 patients (24%) with measurable disease. The value of adding estramustine to vinblastine was questioned in a randomized study in which 201 patients with hormone-refractory prostate cancer were randomized to either vinblastine alone, 4 mg/m<sup>2</sup>/wk, or vinblastine plus estramustine, 600 mg/m<sup>2</sup>/d.<sup>672</sup> Although there was a difference in median survival between the two groups—11.9 months for the combination versus 9.2 months for vinblastine alone—this did not reach statistical significance ( $P = .08$ ). Patients who were treated with the combination had a longer progression-free survival (3.7 months vs. 2.2 months;  $P < .001$ ). PSA responses were more frequent in the combination arm (25.2% vs. 3.2%;  $P < .0001$ ). Interestingly, more frequent gastrointestinal toxicity but less frequent granulocytopenia was seen in the estramustine arm. This study supported the concept that estramustine added activity to vinblastine.

Other estramustine combinations have been investigated. The combination of estramustine and etoposide also showed *in vitro* synergy. Four trials have been conducted with this combination, enrolling a total of 205 patients.<sup>664,673,674 and 675</sup> PSA responses were seen in 106 of 190 patients (56%), and measurable responses were noted in 40 of 82 patients (49%). Estramustine has been combined with vinorelbine in three trials.<sup>676,677 and 678</sup> One of seven patients with measurable disease responded, and 21 of 47 patients (45%) had a PSA response. Another strategy has been to combine estramustine with the taxanes. Interestingly, one small study of 23 patients with hormone-refractory prostate cancer examined the activity of taxol given as a 24-hour constant infusion at a dose of 135 to 170 mg/m<sup>2</sup>.<sup>679</sup> In that study, one patient had a partial response, but no patient had a decline in serum PSA level of greater than 50%. In the one published study in which estramustine was combined with paclitaxel, 4 of 9 patients (44%) had a measurable response, and 17 of 32 (53%) had a PSA response.<sup>680</sup> In a parallel strategy, docetaxel was combined with estramustine. Picus and Schultz<sup>681</sup> demonstrated that docetaxel, when given alone, was active in prostate cancer. In this study, 16 of 35 patients (46%) responded to docetaxel (75 mg/m<sup>2</sup>) given every 3 weeks. Petrylak et al.<sup>682</sup> treated 34 patients with estramustine, 280 mg t.i.d., plus docetaxel, 40 to 80 mg/m<sup>2</sup> every 21 days. Twenty of 34 patients (59%) had more than a 50% decline in PSA level. Kreis et al.<sup>683</sup> observed that 14 of 17 patients (82%) treated with estramustine, 14 mg/kg, and docetaxel, 40 to 80 mg/m<sup>2</sup>, responded. The dose-limiting toxicity was grade IV leukopenia and grade III fatigue and diarrhea. CALGB completed a phase II study of estramustine and docetaxel in 40 patients with hormone-refractory prostate cancer.<sup>684</sup> Eleven of nineteen men (58%) who were evaluable for response had a PSA response. Because of the significant activity seen with estramustine plus docetaxel, a comparative study is now under way comparing docetaxel plus estramustine to mitoxantrone plus prednisone.

Three-drug regimens have emerged, including estramustine, etoposide, and paclitaxel. In a study of 40 patients, 10 of 22 patients (45%) with measurable disease responded, and 26 of 40 patients (65%) had a PSA response.<sup>683</sup> In another study, estramustine, etoposide, and vinorelbine were used.<sup>685</sup> Two of three patients with measurable disease responded, and 14 of 25 patients (56%) had a PSA response. Kelly et al.<sup>686</sup> treated 56 patients with a combination of carboplatin (AUC 6), taxol (60 to 100 mg/m<sup>2</sup>/wk), and estramustine (10 mg/m<sup>2</sup> in three divided doses). A 50% PSA decline was seen in 63% of patients (95% CI, 50% to 76%). Unfortunately, the incidence of deep venous thrombosis reported in this study was 25%.

Clearly, these three-drug combinations are active. Some questions still remain about estramustine-based regimens. First and foremost, are they active enough to prolong survival? Second, what is the contribution of estramustine to these combinations and what is the optimal dosing of estramustine? What are the optimal doses and schedules of the taxanes, and what are the comparative values of three-drug versus two-drug combinations? Finally, what are the details of their activity in early disease?

### **Other Agents**

A number of other drugs are active in patients with hormone-refractory prostate cancer, including cyclophosphamide. Raghaven et al.<sup>687</sup> treated 30 patients with hormone-refractory prostate cancer with oral cyclophosphamide at a dose 100 mg/m<sup>2</sup> for 14 days. Eighteen (60%) had significant improvement in symptoms, whereas 6 (20%) had objective responses.

Doxorubicin has been used in the context of hormone-refractory prostate cancer as well. No study has looked at a single-agent doxorubicin regimen in the post-PSA era. However, this drug has been combined with other agents. A popular regimen was the combination of 5-fluorouracil, doxorubicin, and mitomycin C. In one trial, 48% of 62 patients (i.e., 30 patients) responded.<sup>688</sup> However, in two larger, multicenter studies, response rates were much lower.<sup>689,690</sup> Another combination that has been tried is doxorubicin and cyclophosphamide. In one study, 5 of 15 patients (33%) with measurable disease had a response, and 46% of patients enrolled had a greater than 50% decline in PSA levels.<sup>691</sup>

A regimen popularized at the M. D. Anderson Cancer Center has been a combination of doxorubicin and ketoconazole. In one study, 39 patients were treated with weekly doxorubicin (20 mg/m<sup>2</sup>) and daily ketoconazole (1200 mg/d).<sup>692</sup> A PSA decline of greater than 50% was seen in 21 of 38 patients (55%). Seven of twelve patients had a measurable partial response. This regimen has been used as an alternating regimen with estramustine and vinblastine. In one study at the M. D. Anderson Cancer Center of 46 patients with hormone-refractory prostate cancer, 31 patients (67%) had a greater than 50% decline in PSA level, and 12 of 16 patients (75%) had a measurable response.<sup>693</sup>

## **PALLIATION**

### **Bisphosphonates**

Prostate cancer has a strong propensity to spread to bone. Osteoblastic metastases are seen most commonly, principally in the axial structures (pelvis, vertebral bodies) but also in the appendicular structures (long bones, ribs, etc.). This propensity has been a subject of research for many years. One explanation was that tumor cells gained access to vertebral and pelvic bones by retrograde flow through Batson's plexus of paravertebral veins. Other explanations include a similarity between the growth factor requirements that support prostate cancer cell growth and osteoblast growth. Some such factors include osteopontin, osteonectin, insulin-like growth factor (IGF), fibroblast growth factor, transforming growth factor- $\beta$ , and endothelin-1 (ET-1).<sup>694</sup> Although prostate cancer is primarily an osteoblastic disease, as evidenced by the preponderance of sclerotic bone lesions, it is not uncommon to see mixed blastic and lytic disease. The extent of bone turnover of metastatic bone sites, as measured by a variety of parameters, is high. Bone resorption is mediated through various factors via osteoclastic activity. The value of bisphosphonates in reducing biochemical and clinical parameters of prostate cancer-mediated bone disease is uncertain. Several large, multiinstitutional, randomized trials have now been completed that should clarify these issues. Bisphosphonates have also been used in the context of preventing osteoporosis in patients undergoing androgen

deprivation therapy. The value in this setting also remains uncertain, although randomized studies should answer this question.

### **Radiopharmaceuticals**

Radiopharmaceuticals in use are of two general types. The first type are bone-seeking radioisotopes. Strontium 89 is the only approved agent of this type. In a randomized study, strontium 89 was shown to be superior to placebo with respect to bone pain palliation.<sup>695</sup> Pain relief usually occurs within a few weeks after treatment, although 15% of patients will experience a flare in pain within the first 2 weeks. Strontium 89 requires redosing every 3 months. It is generally well tolerated, although progressive bone marrow suppression may occur with repeat dosing. The mechanism of its activity is uncertain, but it is rare to see pain relief coupled with a decline in serum PSA level.

Two trials have been completed that test the value of adding strontium 89 at the time of radiation therapy for symptomatic bone pain relief. In one study, 305 patients with symptomatic bone pain were randomized, after receiving radiation therapy, to receive strontium 89 or hemibody radiation.<sup>696</sup> Twelve weeks after treatment, there was no difference in the degree of improvement in bone pain. However, fewer patients developed new painful areas when strontium 89 was used (47% vs. 65%;  $P < .01$ ). In another trial, patients who had undergone palliative radiation therapy to a bone lesion were randomized to either strontium 89 therapy or no further therapy.<sup>697</sup> There was no difference in overall survival. However, analgesic consumption was reduced when strontium 89 was used. Fewer patients had new painful lesions, and the interval before additional radiation therapy was needed was longer for those receiving strontium 89.

The second general type of radiopharmaceutical in clinical use is a radioisotope coupled to a bisphosphonate. For these agents, homing to bone is based on the ability of bisphosphonate to adhere to the surface of bone. The currently approved agent in this class is samarium 153 EDTMP (ethylenediaminetetramethylene phosphonate) which, in addition to emitting short-range- $\beta$ -particles, is a  $\gamma$ -particle emitter as well. Because of this, imaging is possible.

## **FUTURE THERAPIES: NOVEL TARGETS**

### **GROWTH FACTOR AND GROWTH FACTOR RECEPTORS AS TARGETS**

Some of the most promising targets for cancer therapy are growth factors and growth factor (tyrosine kinase) receptors. Some of the relevant pathways include such growth factor and receptor pathways as epidermal growth factor (EGF), transforming growth factor- $\beta$ , IGF-1 and IGF-2, and platelet-derived growth factor (PDGF). For several reasons, these growth factors and their tyrosine kinase receptors can be viewed as potential targets in prostate cancer. First, epidemiologic studies suggest that growth factor levels may be involved in either the development or progression of prostate cancer (e.g., IGF-1).<sup>698</sup> Second, some of these growth factors or receptors are dysregulated in different stages of prostate cancer.<sup>699,700</sup> Third, therapeutics such as small molecules and antibodies have been developed against these targets. Finally, there is evidence that targeting these pathways will be effective in cancer therapy. Specifically, an inhibitor of the Ab1 tyrosine kinase used for the treatment of chronic myelogenous leukemia has been shown to be effective. Furthermore, Herceptin, an antibody directed against Her-2/neu, is an effective therapeutic agent when coupled with chemotherapy in the treatment of breast cancer.<sup>701</sup>

A number of growth factors and receptors are potential targets in prostate cancer, as altered expression of growth factor or receptor can be demonstrated particularly in the context of hormone-refractory prostate cancer. Her-2/neu overexpression can be demonstrated in prostate cancers.<sup>702,703</sup> and <sup>704</sup> Overexpression of Her-2/neu may be a mechanism of androgen-independent growth, perhaps through activation of the androgen receptor pathway.<sup>705</sup> Clinical trials involving Herceptin alone and coupled with chemotherapeutic agents currently are under way. The EGF family of receptors is present in normal and malignant prostate epithelium.<sup>706</sup> EGF receptors, when activated by EGF or TGF- $\alpha$ , can stimulate prostate epithelial cell growth. Mechanistically, this may occur through activation of the androgen receptor pathway, suppression of p27, or activation of mitogen-activated protein (MAP) kinase. The EGF pathway is potentially a good target for prostate cancer. Antibodies directed against the receptor (C225), as well as small-molecule inhibitors, have been developed and are in clinical trials.

PDGF has been shown to regulate prostate epithelial stromal interactions in a paracrine fashion.<sup>707</sup> The receptor may be overexpressed in metastatic, hormone-refractory disease.<sup>708</sup> Small-molecule inhibitors have been developed, but clinical trials have not yet been reported.

Nerve growth factor (NGF) is highly concentrated in the prostate.<sup>709</sup> NGF and a related family of peptides, the neurotrophins, influence proliferation, differentiation, and survival of epithelial cells through activation of trk receptors. Trk receptors are expressed in most malignant prostate epithelial tumors.<sup>710</sup> Trk receptor antagonists have been developed and are in clinical trials.

IGF-1 levels may be related to prostate cancer development and progression. *In vitro*, IGF-1 is mitogenic to prostate cancer cell lines.<sup>711</sup> Although the development of specific IGF-1 receptor inhibitors is in progress, none are in clinical testing. Somatostatin analogues have been used because of their ability to lower serum IGF-1 levels. Thus far, no activity has been noted.

ET-1, a potent vasoconstrictor and mitogen for malignant epithelial cells, is overexpressed in the prostatic epithelium.<sup>712</sup> Receptors for ET-1 are expressed in the stroma (ET-B) and epithelium (ET-A). ET-1 plasma levels are higher in patients with advanced disease as compared to those with localized disease or normal controls.<sup>713</sup> An ET-A receptor antagonist, ABT-627, has recently undergone clinical testing and has shown promising results with respect to pain control and disease stabilization.

### **SIGNAL TRANSDUCTION PATHWAYS**

The downstream target pathways of the cell surface growth factor receptors are the MAP kinase, phosphoinositide 3 (PI3) kinase, and phospholipase C pathways. The MAP kinase cascade involves a series of serine threonine and tyrosine kinases that are activated by cell surface signals. EGF, NGF, PDGF, and Her-2/neu all activate MAP kinases and, thus, this pathway may be a relevant target. Currently, inhibitors of MAP kinase are being developed.

The PI3-kinase pathway also is activated by cell surface receptors and may turn out to be a highly relevant pathway in prostate cancer. PTEN, a dual-specificity phosphatase, has been demonstrated to have tumor suppressor activity.<sup>714</sup> In the case of prostate cancer, PTEN is frequently mutated.<sup>715</sup> In addition, PTEN expression appears to correlate with tumor aggressiveness.<sup>716</sup> PTEN normally dephosphorylates lipid substrates of PI3-kinase, including Akt. It appears that Akt is up-regulated in PTEN-mutated cells. Akt, in turn, has the capability of activating several pathways that control proliferation and cell survival. Components of this pathway are, therefore, potentially critical targets in the treatment of prostate cancer. Inhibitors of PI3-kinase and Akt are in development, though they are not yet in clinical trials.

### **DIFFERENTIATION THERAPY**

Differentiation therapy refers to a form of treatment that causes cancer cells to differentiate into a less malignant phenotype or to undergo programmed cell death. This has been demonstrated to be an effective modality for the treatment of promyelocytic leukemia. Several agents are currently in clinical trials in prostate cancer, including phenylacetate and phenylbutyrate and several nuclear receptor agonists, including vitamin D analogues, retinoic acid analogues, and peroxisome proliferator-activated receptor gamma (PPAR $\gamma$ ) analogues.

Phenylacetate and phenylbutyrate cause growth arrest and differentiation of prostate cancer cells in culture.<sup>717</sup> These agents have a range of effects including histone acetylation, inhibition of isoprenylation, glutamine depletion, alterations in lipid metabolism, and DNA methylation. Both agents have shown activity in early clinical trials in prostate cancer patients.

The retinoids are compounds that bind to two classes of nuclear receptors, the retinoic acid receptors and the retinoid X receptors. The retinoids cause differentiation of epithelial cells. *In vitro*, the activity of different retinoids is variable, ranging from growth inhibition to growth stimulation. Thus far, clinical trials with retinoids in prostate have been disappointing. The drug liarazole, which has a range of activities including inhibition of retinoid acid metabolism, has shown activity in prostate cancer.<sup>718</sup> In one phase III study comparing liarazole to cyproterone acetate, 20% of patients with hormone-refractory prostate cancer responded to liarazole.<sup>719</sup>

Interest in vitamin D and its analogues is based on epidemiologic data linking low levels of vitamin D and vitamin D receptor polymorphisms to prostate cancer

risk,<sup>720,721</sup> as well as *in vitro* data demonstrating a growth-inhibitory effect of these compounds. Noncalcemic vitamin D analogues are now in clinical trials.

PPAR $\gamma$ , a receptor involved in fat cell differentiation, is also present in epithelial cells.<sup>722</sup> Agonists of PPAR $\gamma$  have a growth-inhibitory effect on prostatic cancer cells *in vitro*.<sup>723</sup> Promising results have been achieved with troglitazone in very early studies.

## ANTIMETASTATIC THERAPY

The process of metastasis is complex and involves multiple steps. A fundamental step in this process is degradation of the extracellular matrix, which involves enzymes known as *matrix metalloproteinase*. One agent, Marimastat, a selective but non-specific matrix metalloprotease inhibitor, has been tested in patients with prostate cancer.<sup>724</sup> The drug is well tolerated and now is the subject of a prospective, randomized, controlled trial.

## IMMUNOTHERAPY

Several immunotherapeutic approaches are currently being investigated in patients with prostate cancer. One such regimen is a coupled antibody approach, in which antibodies are directed against tumor-specific antigens coupled to a toxin or radioisotope. Currently in clinical trials is an antibody directed against PSMA coupled to an  $\alpha$ -particle emitter. Another approach is vaccination with antigens enriched on tumor cells, such as specific complex carbohydrate moieties. Still another approach involves mucin 1 (MUC1), an epithelial mucin glycoprotein vaccination with an adjuvant. Incorporating the PSA gene into a herpesvirus vector is another immunotherapeutic modality. A novel approach employs dendritic cells (antigen-presenting cells) loaded with a specific tumor antigen such as PSA, PSMA, or acid phosphatase. The loaded dendritic cells are infused into the patient in an effort to stimulate an immune response. Several clinical trials of this nature are in progress.

One can also augment the production of specific cytokines that stimulate the immune system. One popular approach has been the use of granulocyte-megakaryocyte colony-stimulating factor administered exogenously or delivered in autologous or allogeneic prostate cancer cells. Clinical trials incorporating these different approaches are currently being conducted.

## ANGIOGENIC APPROACHES

Angiogenesis is a complex, multistep process that is fundamental to tumor growth and metastasis. This process appears to be important in the growth and progression of localized prostate cancer, as evidenced by a correlation between microvessel density and prognosis in this disease. Whether angiogenesis is important in the establishment of bone metastasis in prostate cancer is uncertain. One of the important mediators of angiogenesis is vascular endothelial growth factor (VEGF). A number of strategies have been developed and directed at VEGF, including VEGF antibodies and small-molecule inhibitors of the VEGF receptors (Flk and KDR). These agents are in clinical trials currently.

A number of additional agents with *in vitro* antiangiogenic properties have been developed (TNP-470, endostatin, etc.) and also are in clinical trials.

#### INTRODUCTION

Primary cancer of the urethra and penis is uncommon. The rarity of tumors involving the penis and urethra has contributed to the lack of a standardized approach in the management of patients with these neoplasms.

Squamous cell carcinoma is the most common cancer in the penis and urethra. The patterns of spread, treatment approaches, and prognosis are related to the extent of disease and the region of the urethra or penis involved by the tumor. Carcinoma of the penis often remains localized for prolonged periods. When metastasis occurs, it follows a stepwise pattern; first, to the inguinal (groin) lymph nodes and, second, to the pelvic lymph nodes. Distant dissemination occurs later. A favorable natural history permits cure of most localized penile cancers and of many with inguinal metastases. Urethral carcinoma in both males and females tends to invade locally and metastasize to regional lymph nodes early in its evolution. Most of these tumors are far advanced locally when diagnosed. This feature accounts for the relative poor prognosis of urethral cancer despite aggressive management.<sup>1</sup>

#### CARCINOMA OF THE MALE URETHRA

Carcinoma of the male urethra is extremely rare. Approximately 600 cases have been reported. Urethral carcinoma has been reported in boys as young as 13 years of age and in men in their 90s, although most patients are older than 50 years of age. Significant etiologic factors have not been identified, but chronic inflammation appears to play a role in the initiation of disease, because many patients have prior sexually transmitted disease, urethritis, or urethral stricture. The incidence of urethral stricture in men with carcinoma of the urethra ranges from 24% to 76%. The most frequent site of stricture and malignancy is the bulbomembranous urethra. No racial predisposition has been noted.

#### SYMPTOMS

The lesion is often insidious at onset with symptoms attributed to benign urethral disease with stricture rather than to malignancy. Men often present with a palpable urethral mass or obstructive symptoms. On occasion, pain associated with urethral fistula or periurethral abscess may herald the presence of a male urethral cancer. Urethral stricture or bleeding in a man without a history of trauma or venereal disease should suggest the possibility of urethral carcinoma. Because of the nonspecific nature of the symptoms, diagnosis is often delayed.<sup>2</sup> The most common presenting symptoms are listed in [Table 34.5-1](#). Most reflect local involvements by the lesion.

Symptoms*	Number of Patients (%)
Palpable urethral mass	34 (72)
Obstructive symptoms (with or without retention)	32 (65)
Pain	12 (26)
Urethral fistula or periurethral abscess	10 (21)
Hematuria	10 (21)
Palpable inguinal mass	9 (19)

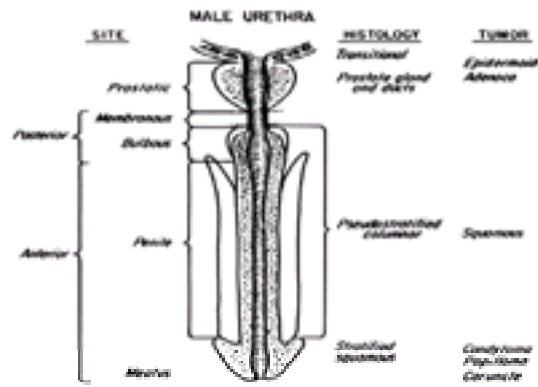

\*Presenting symptoms of 47 patients.

TABLE 34.5-1. Cancer of the Urethra and Penis

#### PATHOLOGY

Tumors of the male urethra can be categorized according to histology of the cells lining the anatomic region of origin ( [Fig. 34.5-1](#)). The epithelium of the prostatic urethra gives rise to transitional cell carcinoma that is histologically and clinically distinct from adenocarcinoma commonly associated with the prostatic glands, but that is identical to the bladder urothelium. Tumors originating in the area of the trigone or bladder neck with direct extension into the prostatic urethra may be mistakenly diagnosed as primary urethral carcinoma unless careful examination and biopsy excludes the vesical neck as the site of origin. Male urethral carcinoma occurs in the bulbomembranous urethra in 60%, penile urethra in 30%, and prostatic urethra in 10%. Histologically, 80% of male urethral cancers are squamous cell carcinoma, 15% are transitional cell carcinoma, and approximately 5% are adenocarcinoma and undifferentiated tumors.<sup>1</sup>

**FIGURE 34.5-1.** Anatomy and pathology of male urethral carcinoma.

Male urethral carcinoma spreads by direct extension to adjacent structures and usually involves the vascular spaces of the corpus spongiosum and the periurethral tissues. Carcinoma of the bulbomembranous urethra extends to the urogenital diaphragm, prostate, perineum, and scrotal skin. Hematogenous spread is uncommon except in advanced disease. Metastasis occurs by lymphatic embolization to regional lymph nodes. The lymphatics from the anterior urethra drain into the superficial and deep inguinal lymph nodes and occasionally to the external iliac lymph nodes. The lymphatics from the posterior urethra drain into the external iliac, obturator, and hypogastric nodes. Tumors of the anterior urethra usually metastasize to the inguinal nodes, and tumors of the posterior urethra most commonly spread to the pelvic nodes, although exceptions occur. Palpable inguinal lymph nodes occur in approximately 20% of cases and almost always represent metastatic disease.<sup>3</sup>

### EVALUATION AND STAGING

The diagnosis is made by transurethral biopsy. The extent of local involvement is determined by careful inspection and palpation of the external genitalia and perineum at the time of cystourethroscopy and by bimanual examination with the patient under anesthesia. Needle biopsy is occasionally helpful in determining local extent of neoplasm. Cytologic studies of voided urine may be helpful for diagnosing some patients. Computed tomography (CT) or magnetic resonance imaging (MRI) may help to evaluate the pelvic and paraaortic nodes. Local soft tissue and bone extension are best evaluated by an MRI scan.

The tumor, node, and metastasis (TNM) staging system is commonly used to assess carcinoma of the urethra<sup>4</sup> (Table 34.5-2). The TNM staging classification is based on depth of invasion of the primary tumor, the presence or absence of regional lymph node involvement, and distant metastasis.

PRIMARY TUMOR (MALE AND FEMALE)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Noninvasive papillary, prostatic, or squamous carcinoma
Tis	Carcinoma in situ
T1	Tumor involves subepithelial connective tissue
T2	Tumor involves the corpus spongiosum or the prostate or the periurethral muscle
T3	Tumor involves the corpus cavernosum or beyond the penile urethra, or the anterior vagina or bladder neck
T4	Tumor involves other adjacent organs
REGIONAL LYMPH NODES	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node, 0 cm or less in greatest dimension
N2	Metastasis in a single lymph node, more than 0 cm but not more than 5 cm in greatest dimension; or multiple lymph nodes, none more than 5 cm in greatest dimension
N3	Metastasis in a lymph node more than 5 cm in greatest dimension
DISTANT METASTASIS	
Mx	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

(From ref. 4, with permission.)

**TABLE 34.5-2.** Tumor (T), Node (N), Metastasis (M) Classification of Carcinoma of the Urethra

### TREATMENT

Surgical excision is the primary therapy for carcinoma of the male urethra. The extent of surgery depends on the location and stage of the tumor. In general, anterior urethral carcinoma is more amenable to surgical control and has a better prognosis than posterior urethral carcinoma. Although some instances of tumor control by irradiation have been reported, in general, radiation has been reserved for patients with early-stage lesions of the anterior urethra who refuse surgery. Radiation therapy has the advantage of preserving the penis but may result in urethral stricture and chronic edema and does not prevent new tumor occurrences in the retained urethra. Combination chemotherapy has achieved encouraging results in patients with metastatic urothelial cancer and is now being integrated more frequently with irradiation and definitive surgery in patients with locally advanced urethral carcinomas.<sup>5</sup>

### SURGERY

Table 34.5-3 shows 5-year survival rates in cancer of the male urethra according to stage, site, and surgical treatment.<sup>6,7,8,9 and 10</sup>

Stage	Site	Treatment	Patients	Survivors (%)
Superficial	Anterior or posterior	Transurethral resection or fulguration	82	81 (98)
Invasive	Fossa navicularis	Partial penectomy	12	11 (92)
	Penile	Partial or total penectomy	86	33 (38)
	Bulbomembranous	Extended excision*	83	28 (34)
	Prostatic	Cystoprostatectomy	14	4 (29)

\*En bloc excision of the penis, scrotum, prostate, and bladder with resection of the inferior pubic ramus.

**TABLE 34.5-3.** Five-Year Survival Rate in Cancer of the Male Urethra

### Carcinoma of the Distal Urethra

Carcinoma of the penile urethra may be treated by transurethral resection (TUR), local excision, partial amputation, or radical amputation with or without emasculation. For a superficial papillary or an *in situ* tumor, TUR and fulguration is sufficient. For a tumor infiltrating the corpus and localized to the distal half of the penis, a partial amputation with a 2-cm margin proximal to the visible or palpable tumor is the accepted treatment. If the infiltrating tumor is located in the proximal penile urethra or involves the entire urethra, radical amputation is necessary. This procedure may involve emasculation if the scrotal skin or genitalia are involved. Ilioinguinal groin node dissection is indicated only if the inguinal nodes are palpable. There is no evidence of benefit from prophylactic groin dissection. Carcinoma involving the distal or penile urethra generally enjoys a more favorable prognosis than cancers involving the entire or more proximal regions of the urethra.

## **Carcinoma of the Bulbomembranous Urethra**

Transurethral or segmental resection may be adequate for treatment of early superficial tumors involving the bulbomembranous urethra, but such cases are rare. Most patients present with an infiltrating bulky tumor with invasion of surrounding structures. Approximately one-third of these patients are locally understaged and later prove to have pelvic or groin metastasis. The overall survival of patients in this group is poor despite a distinctly radical surgical approach, but radical excision offers the best opportunity for long-term disease control and the lowest incidence of local recurrence. Postoperative morbidity is high. Despite the dismal prognosis, experience suggests that when local control of the tumor can be achieved, overall long-term results are favorable. Such tumors tend to be locally extensive and are apt to recur locally with inadequate local treatment. Metastasis appears to be a late event, which has led to aggressive combined therapy approaches in patients with bulky posterior urethral carcinoma.

### **Treatment Results for Carcinoma of the Bulbomembranous and Anterior Urethra**

Surgery alone gives suboptimal results in the management of male urethral carcinoma. In the Dinney et al. series,<sup>11</sup> two of five patients with tumors of the anterior urethra and none of the four patients with tumors of the bulbomembranous urethra were alive after being treated by surgery alone. In the Dalbagni et al. series,<sup>12</sup> 7 of 18 patients (38%) with tumors of the anterior urethra are disease-free, and 4 of 28 patients (14%) with tumors of the bulbar urethra are disease-free.

Radiation therapy alone was ineffective, as summarized by Zeidman et al.<sup>13</sup> Patients who receive radiation therapy followed by salvage surgery seem to fare worse than if surgery was performed in integrated fashion. A combination of preoperative irradiation (20 to 60 cGy) followed by surgical excision of the inferior pubic rami with partial symphysiectomy, anterior perineum, urogenital diaphragm, and genitalia, *en bloc* with the pelvic organs and lymph nodes, may improve local control and survival.<sup>14</sup> Results suggest that approximately one-third of patients undergoing such extended excision of locally advanced neoplasms can be salvaged.

The integration of chemotherapy used as systemic therapy, and radiosensitization followed by surgery, can be successful in both the bulbomembranous and prostatic urethra. Anecdotal reports document successful treatment using M-VAC [methotrexate, vinblastine, Adriamycin (doxorubicin), and cisplatin] for transitional cell tumors and 5-fluorouracil (FU) plus either mitomycin-C or cisplatin for squamous cell carcinoma.<sup>5,14,15,16,17,18</sup> and <sup>19</sup> Three reports substantiate the use of mitomycin-C plus FU chemotherapy integrated with radiation therapy and surgery for squamous cell carcinoma. Baskin and Turzan<sup>16</sup> reported the first case of penile-preserving surgery for carcinoma of the male urethra with combined FU plus mitomycin-C and radiotherapy followed by distal urethrectomy. Licht et al.<sup>17</sup> reported one complete response among two patients treated with similar chemotherapy and radiation for a squamous cell carcinoma of the urethra with lymph node metastasis. Oberfield<sup>18</sup> reported genital preservation in two patients with an invasive squamous cell carcinoma of the bulbar urethra with this chemotherapy regimen plus radiation. In the series by Gheiler et al.,<sup>19</sup> four patients with high-stage tumors were treated with neoadjuvant chemotherapy and radiation before surgery, two of whom were rendered disease-free. Success using cisplatin and FU has been reported in both squamous cell carcinoma<sup>14</sup> and adenocarcinoma.<sup>20</sup>

### **Primary Carcinoma of the Prostatic Urethra**

Primary carcinoma arising from the prostatic urethra is rare. Tumors may be transitional or adenocarcinoma, and the diagnosis is based on a solitary tumor in the prostatic urethra without associated coexisting or preexisting urothelial tumors within the bladder and the bladder neck. There are no characteristic symptoms of this lesion. Patients generally present with hematuria or obstructive urinary symptoms. Prostatic induration on rectal examination represents advanced disease. The serum prostate-specific antigen and acid phosphatase values are normal. Diagnosis depends on transurethral biopsy of the prostate.

Superficial lesions of the prostatic urethra are managed successfully by transurethral resection in the majority of patients. However, such tumors are uncommon. In most instances, the tumor involves the bulk of the prostate with variable extension to the bulbomembranous urethra or to the bladder neck and trigone. In this situation, cystoprostatectomy and urethrectomy is the treatment of choice. In limited experience, the overall 5-year survival rate of patients treated with radical surgery, with or without preoperative irradiation, is poor. Combined modality therapy offers a prospect for improved results. For example, a total of 11 patients with advanced tumors of the prostate, prostatic urethra, or bulbomembranous urethra received neoadjuvant chemotherapy (i.e., M-VAC). Of ten evaluable patients, four (40%) were downstaged to complete clinical remission, including three of five with transitional cell tumors of the prostate and prostatic urethra.<sup>5</sup> In selected responding patients, conservative transurethral resection or prostatectomy rather than pelvic exenteration can be entertained. Most patients, however, are best treated with a combination of aggressive surgery, irradiation, and chemotherapy, although the optimal strategy using these modalities is not established.<sup>14,15</sup>

## **RADIATION THERAPY**

Radiation therapy alone and postoperative radiation are rarely implemented in the management of men with urethral carcinoma. The most common approach has been external-beam radiotherapy, using various techniques to deliver 50 to 60 cGy in 5 to 9 weeks. The long-term results of radiotherapy have been mixed, with the best results reported for patients with distal lesions, for whom the outcome is similar to that reported with surgery.<sup>21</sup>

## **CARCINOMA OF THE FEMALE URETHRA**

Carcinoma of the urethra is unusual among genitourinary tract neoplasms in that it occurs more often in women than in men. Tumors present most commonly in postmenopausal and older women, with 75% of patients older than 50 years of age. The disease is more prevalent among whites than other races.

### **ETIOLOGY**

The cause of urethral carcinoma in women has not been established with certainty, although a causal relationship is reported with chronic irritation, urinary tract infection, and malignancy. Proliferative lesions, such as caruncles, papillomas, adenomas, and polyps, have been associated with subsequent malignancy. Leukoplakia of the urethra is considered a premalignant lesion and is treated with wide local excision.

### **SYMPTOMS**

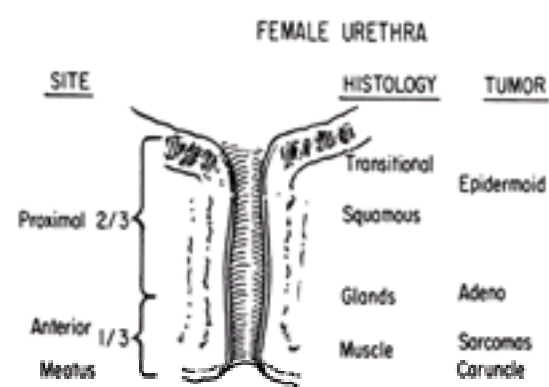

Most patients present with urinary frequency, hesitancy, obstruction, and a palpable urethral mass. Tumors may present as a papillary growth within the urethra and may later become a soft fungating mass that bleeds easily. Ulcerative lesions may produce a foul-smelling discharge. The lesion may be detected first as a submucosal mass in the anterior wall of the vagina. Spread from the primary lesion is by local extension and infiltration with subsequent involvement of the bladder neck, vagina, or vulva. It may be difficult on initial physical examination to differentiate malignant tumors of the urethra from those of the vulva or vagina.

Lymphatics of the anterior urethra and labia drain to the superficial and then deep inguinal nodes, whereas the posterior urethra drains to the external iliac, hypogastric, and obturator lymph nodes. These boundaries are not distinct, and anatomic crossovers are possible. Clinically palpable inguinal nodes are found in one-third of patients, but histologic confirmation of malignancy is made in more than 90% of this group.<sup>22,23</sup> Pelvic node involvement occurs in 20%, and an additional 15% of patients develop metastatic nodal disease during follow-up. Metastasis outside the pelvis at the time of initial presentation is uncommon.

### **PATHOLOGY**

Stratified squamous epithelium lines the distal two-thirds of the female urethra, and transitional epithelium lines the proximal one-third ( Fig. 34.5-2). The submucosa of the urethra contains numerous periurethral glands. Tumor histology is a reflection of the site, with squamous cell carcinoma being the predominant tumor type and usually presenting in the proximal two-thirds of the urethra. In general, carcinomas of the anterior urethra are low grade and less extensive. Carcinomas of the proximal or entire urethra are of higher grade and locally advanced. Squamous cell carcinoma accounts for approximately 60%; transitional cell carcinoma, 20%; adenocarcinoma, 10%; undifferentiated tumors and sarcomas, 5%; and melanoma, 2%. Histologic characteristics do not appear to significantly affect the prognosis, and different histologic types are often treated in a similar fashion.

**FIGURE 34.5-2.** Anatomy and pathology of female urethral carcinoma.

## EVALUATION AND STAGING

A pelvic examination under anesthesia combined with urethroscopy, cystoscopy, and biopsies is performed. Cytologic evaluation of the urine may be of value. Radiographic evaluation consists of a chest x-ray and CT scan of the abdomen and pelvis. A barium enema and bone scan should be obtained in symptomatic patients.

There has been no universally accepted staging system for female urethral carcinoma. The TNM staging system has been adapted to female urethral cancer (see [Table 34.5-2](#)), but the practical fact is that staging, treatment, and prognosis are simplified by dividing tumors into anterior and low-stage versus posterior or entire urethra and advanced stage.

## TREATMENT

The most significant prognostic factor for local control and survival is the anatomic location and extent of the tumor. Treatment is based primarily on the tumor stage at the time of presentation. [Table 34.5-4](#)<sup>8,24</sup> shows 5-year survival rates in female urethral cancer of both early and advanced stage after treatment.

Stage	Treatment	Patients	Survivors (%)
Early	Radiotherapy	140	94 (67)
	Surgery	24	20 (83)
	Radiotherapy plus surgery	5	4 (80)
Advanced	Radiotherapy	157	34 (34)
	Radiotherapy plus surgery	39	21 (54)

(Adapted from refs. 8 and 24, with permission.)

**TABLE 34.5-4.** Five-Year Survival Rate in Female Urethral Cancer

Most urethral cancers in women are locally advanced when detected and involve the proximal one-third or entire urethra. Such lesions clearly do worse than localized, low-grade, anterior urethral lesions. Poor prognosis attributed to urethral cancers in women is because of the advanced stage (high tumor volume), adjacent organ involvement, inability to obtain a clear surgical margin (because of soft tissue infiltration), nodal disease, morbidity of extensive treatment, and inadequate systemic therapy for metastatic tumor. Single-modality therapy often fails for advanced cases and is successful only in selected cases.

## SURGERY

Local excision is often sufficient in selected patients with carcinoma of the distal urethra. For example, meatal tumors, if diagnosed early, are associated with an excellent 5-year survival rate. Such tumors are superficial and well localized. The incidence of lymph node metastasis with distal urethral carcinoma is low. Local excision controls the primary tumor, and urinary continence is maintained.

For tumors involving the proximal urethra or extending beyond the urethra into the adjacent structures, more aggressive treatment is required. When surgery is considered, extensive resection is necessary, including total urethrectomy, cystectomy with pelvic lymph node dissection, and removal of most (if not all) of the vagina. Extended excision to include resection of adjacent pubic symphysis and urogenital diaphragm similar to that for proximal male urethral cancer has resulted in local control of a few cases of far advanced urethral carcinoma. Even extensive surgery, however, often fails because of soft tissue infiltration by the tumor beyond the confines of the bladder neck, urethra, and vagina. Local recurrence after surgery alone is common. Anterior exenteration alone led to 10% to 17% 5-year survival and a local recurrence rate of 67%.<sup>25</sup> Garden et al.<sup>26</sup> reported 41% and 31% 5- and 10-year actuarial survival rates, respectively, with a 5-year local control rate of 64% with radiation therapy. Dalbagni et al.<sup>27</sup> reported an overall 5-year survival rate of 32%—that is, the rates were 78% for low-stage and 22% for high-stage tumors, 54% for tumors of the anterior urethra, and 25% and 18% for tumors of the posterior and whole urethra, respectively. No difference was found in survival between women treated with radiation or surgery.<sup>27</sup>

In cases of palpable inguinal nodes, inguinal lymphadenectomy has been advocated. Inguinal lymph node dissection is usually not performed in the absence of palpable disease in the groin.<sup>28,29</sup>

## RADIATION THERAPY

Irradiation alone, as with surgical excision, may control small lesions in the distal urethra. Radiation of these small lesions can be accomplished with brachytherapy without additional external-beam irradiation.<sup>30</sup> Interstitial or intracavitary irradiation delivering a 50 to 65 Gy tumor dose has been demonstrated to be sufficient to control small distal urethral lesions.

Tumors of the proximal urethra, bladder neck invasion, or involvement of the entire urethra require combined external irradiation and brachytherapy. External irradiation is delivered to the primary tumor site and regional lymph node. The groin should receive prophylactic irradiation to 50 Gy if there is no palpable adenopathy. In the presence of palpable inguinal lymph nodes, bolus is added to the groin and the total dose is increased from 60 to 65 Gy. The pelvis is treated to 50 Gy by the combined whole pelvis and split field technique. The pelvic side wall can be boosted to 60 Gy in the presence of lymphadenopathy as detected by CT scan. The primary tumor site is boosted with brachytherapy (one or two implants using iridium 192) to bring the total tumor dose from 70 to 80 Gy, depending on tumor size. Complications from irradiation include bowel obstruction, fistula formation, urethral stricture, and incontinence. Radiation therapy alone controls only approximately one-third of cases of advanced disease, and severe complications occur in 15% to 40% of patients.<sup>31,32,33 and 34</sup>

## COMBINED MODALITY THERAPY

Although the number of cases of advanced female urethral carcinoma is small, it is obvious that either extensive surgery alone or high-dose irradiation alone produces an unacceptably high morbidity rate and low tumor control rate. This fact has led to combined treatment strategies with chemotherapy, radiation therapy,

and surgery in women with advanced urethral cancer. M-VAC chemotherapy and irradiation followed by surgery have been used in patients with transitional cell carcinoma, and those with squamous cell carcinoma have received combined mitomycin-C and 5-fluorouracil and irradiation followed by surgery. <sup>3,35,36</sup> and <sup>37</sup> Long-term results from combined modality therapy are unavailable.

## CANCER OF THE PENIS

Carcinoma of the penis represents 2% of urogenital cancers. Although rare in North America, tumors of the penis account for 10% to 12% of all malignancies in males among populations in which circumcision is not a common practice. <sup>38</sup>

Penile cancer is the most common genitourinary cancer in Paraguay, representing 45% to 76% of all genitourinary malignancies. <sup>39</sup> In Uganda, where circumcision is usually not performed, penile cancer is the most commonly diagnosed cancer in males. <sup>40</sup> Although malignant penile lesions have been found in young men, most patients are older than 50 years.

### ETIOLOGY

Most penile cancers occur in uncircumcised men, suggesting an irritative effect of smegma combined with poor hygiene. Carcinoma is rare among men who were circumcised in the neonatal period, but circumcision performed at puberty or in adulthood does not have the same protective potential as circumcision at birth. <sup>41,42</sup> Although the annual age-adjusted incidence of carcinoma of the penis for males in the United States is only 1 per 100,000, the lifetime risk of penile cancer developing in uncircumcised males may be as high as 1 in 600. <sup>42</sup> Smegma, the product of bacterial action on desquamated epithelial cells is carcinogenic in animal systems, although the specific component responsible for malignant degeneration in human males has not been identified.

Conflicting reports support and deny the association of penile carcinoma with cervical carcinoma in sexual partners or with herpetic infection. No compelling data support the assertion that penile cancer is a sexually transmitted disease. <sup>43</sup> No persistent etiologic relation has been documented between carcinoma of the penis and the venereal diseases of syphilis, granuloma inguinale, or chancroid. Evidence that human papillomavirus (HPV) may be causative is scanty, although HPV transfection alters human epithelial cell differentiation *in vitro* and has not been ruled out as a potential cause of some cases of penile cancer. <sup>44</sup>

### SYMPTOMS

The most common presenting manifestation of penile cancer is a mass or persistent sore or ulcer of the glans, foreskin, or shaft of the penis. Most penile carcinomas are painless, and there may be significant ulceration and bleeding. Less commonly, the initial symptoms are related to inguinal lymphadenopathy. <sup>45</sup>

It has been estimated that more than one-half of patients delay more than 1 year in seeking treatment after the appearance of the lesion, although such delays are uncommon in the United States. Any delay in the recognition, diagnosis, and therapy of penile carcinoma significantly worsens its prognosis. <sup>45</sup>

### PATHOLOGY

Penile carcinoma is most often squamous cell in origin, although malignant melanoma, basal cell carcinoma, Bowen's disease (carcinoma *in situ*), mesenchymal tumors (including Kaposi's sarcoma), metastatic lesions, and leukemic or lymphomatous infiltrates may involve the penis. Several premalignant lesions have been identified (Table 34.5-5).

Lesion	Characteristics	Treatment
Leukoplakia	White plaque	Local excision
Dyskeratosis of Queen	Red, red, white lesion; cellular dyskeratosis with multiple mitoses; identical to carcinoma in situ of skin; 15% to 20% may develop areas of squamous cell carcinoma; may be partial	Local excision; topical 5-fluorouracil; radiotherapy
Bowen's disease	Red plaque	Local excision
Microinvasive carcinoma	Small, asymptomatic lesion; no ulceration; nests often involved	Local excision; topical therapy (?)
Invasive carcinoma	Large, verrucous lesion; histologically invasive; may undergo squamous degeneration	Local excision with negative margins; topical therapy; radiation therapy; or limited chemotherapy

TABLE 34.5-5. Premalignant Lesions of the Penis

### STAGING

The initial diagnosis is made by incisional or excisional biopsy. Physical examination determines the extent of local invasion and the status of the inguinal lymph nodes that are essential to proper staging. A CT or MRI scan to evaluate the pelvic and abdominal lymph nodes may also be helpful. The TNM classification (Table 34.5-6) is used to determine the stage of the primary tumor and to quantify nodal metastasis. Nodal status is the most significant prognostic variable predicting survival. <sup>46</sup> The incidence of groin metastasis (palpable or not) increases with T category of the primary lesion. Nodal disease occurs in 20% of T1 tumors and in 47% to 66% of T2–4 penile cancers. <sup>47</sup>

Stage	Description
Ta	Noninvasive verrucous cancer
T1	Tumor less than 2 cm, superficial or exophytic
T2	Tumor greater than 2 cm but less than 5 cm, or tumor invades subepithelial connective tissue
T3	Tumor greater than 5 cm, or tumor invades corpus spongiosum or cavernosum, or urethra
T4	Tumor invades other adjacent structures
N0	No regional lymph node metastasis
N1	Movable, unilateral inguinal lymph node involvement
N2	Movable, bilateral inguinal lymph node involvement
N3	Fixed inguinal lymph node or pelvic node involvement
M0	No evidence of distant metastasis
M1	Evidence of distant metastasis

TABLE 34.5-6. Tumor (T), Node (N), Metastasis (M) Classification of Penile Cancer

### TREATMENT

Treatment depends on the local extent of the primary neoplasm and the status of the regional lymph nodes. Wide excision or partial penectomy with or without inguinal lymph node dissection is the most commonly accepted treatment for small and well localized tumors. <sup>48,49</sup> Radiotherapy may be effective for some patients with noninvasive small lesions and may avoid the functional sacrifice associated with penectomy. <sup>50</sup> Radiation may be associated with necrosis or urethral stenosis, resulting in a nonfunctioning penis. Several investigations have demonstrated that local relapses after radiotherapy can be salvaged by a partial or total amputation of

the penis without apparently affecting the prognosis, although this approach remains controversial. <sup>51</sup>

Paramount to treatment planning is a consideration of the lymphatic drainage of the penis ( Fig. 34.5-3). The skin of the penis and the lymphatics of the prepuce drain primarily into the superficial inguinal nodes. Bilateral drainage occurs as a result of the freely anastomosing system and crossover at the base of the penis. The glans is drained by the superficial inguinal nodes, but along with those of the corpora, the lymphatics of the glans penis empty into the deep inguinal and iliac nodes. The superficial nodes are located in the deep portion of Camper's fascia above the deep fascia of the thigh, the fascia lata. The superficial lymphatics drain into the deep inguinal lymphatics surrounding the femoral vessels and then to the external iliac, common iliac, and paraaortic lymphatic channels. Tumor invasion of the corpora cavernosa or the posterior urethra may lead to deep pelvic lymphatic metastasis to internal iliac and obturator nodes.

**FIGURE 34.5-3.** Lymphatic drainage of the penis.

## SURGERY

Surgery aims to control the primary neoplasm and is involved in the evaluation and therapy of nodal disease. Bilateral pelvic and inguinal node dissection is indicated, where possible, for any positive groin metastasis detected at the time of or within 6 months of treatment of the penile tumor. This is because lymphatic crossover at the base of the penis accounts for at least 60% contralateral groin metastasis, even in the face of unilateral palpable inguinal nodes. <sup>50,52</sup> Delayed (6 months or more) appearance of unilateral groin metastasis requires only ipsilateral ilioinguinal node dissection.

### *Treatment of Primary Lesion*

Surgical therapy involves removal of the lesion with adequate margins to minimize the risk of local recurrence. Small tumors that are limited to the prepuce are treated by circumcision alone. Lesions that on physical examination involve only the skin may be controlled by wide excisional biopsy. Partial or total penectomy is indicated for lesions that because of their size, invasiveness, or location on the shaft are not amenable to more conservative treatment. Partial penectomy includes a 2-cm margin of normal shaft proximal to the primary tumor. For extensive lesions approaching the base of the penis, total penectomy is accomplished with excision of both corpora and creation of a perineal urethrostomy. Local recurrence after a properly planned and executed partial or total penectomy is rare. <sup>52,53 and 54</sup>

### *Management of Regional Lymph Nodes*

Several factors determine the role of regional lymphadenectomy in patients with penile cancer. First, 50% of patients with squamous cell penile cancer have palpable inguinal lymph nodes at diagnosis. In one-half of these cases, inguinal adenopathy represents benign inflammatory changes associated with ulcerated or infected penile lesions. Clinical assessment of the lymph nodes should be delayed until after a 4- to 6-week course of antibiotic therapy. Persistent adenopathy after 6 weeks warrants biopsy and therapy. Second, approximately 20% of patients with no palpable adenopathy have occult lymphatic metastases. Third, lymph node dissection can be curative for the majority of patients with isolated tumor-bearing inguinal nodes.

Overall, 50% of patients with positive inguinal nodes can be rendered disease-free by surgical resection. <sup>53</sup> The volume of lymph node disease and its location appear to be important predictors of success. In one study of 119 patients, unilateral inguinal node involvement had a median 5-year survival rate of 56%, compared with 9% of patients with bilateral inguinal node metastases, extranodal disease, or iliac node involvement. <sup>54,55</sup> Cure is unlikely by surgical means if the pelvic lymph nodes are involved.

The primary controversy in the surgical management of penile cancer concerns the role of lymph node dissection if there is no clinically identifiable inguinal disease. The overall incidence of false-negative nodes in T1 and T2 disease is approximately 20%, but late nodal extension to the groin after adequate excision of the primary occurs in only 5% to 11% of patients. Routine lymph node dissection is therefore difficult to justify for low-stage primary disease. In patients with advanced (T3, T4) invasive primary tumors, the likelihood of nodal metastases increases, and in some series, two-thirds of patients with clinically negative nodes have histologically confirmed metastasis on lymph node dissection. <sup>56</sup> The significant morbidity that may accompany groin dissection and the lack of controlled prospective studies to document the benefit of early "prophylactic" versus late "therapeutic" groin dissection has led many surgeons and centers to delay lymphadenectomy until clinical evidence of lymph node involvement exists.

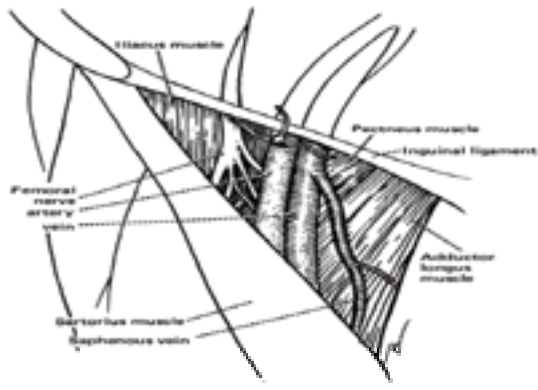

Ekstrom and Edsmyr <sup>52</sup> identified a 50% disease control rate among patients who had node dissection delayed until adenopathy was evident. Frew and colleagues <sup>57</sup> could identify no cancer deaths among patients in whom lymph node excision was deferred until clinical node disease was found. Beggs and Spratt <sup>58</sup> reported no significant adverse effect on survival in patients with delayed groin dissection. However, others have reported a significant decrease in 5-year survival rates in patients with therapeutic rather than prophylactic groin dissection and have suggested that delayed surgery is inappropriate. <sup>59</sup> One study showed that 62% of patients survived 5 years if the lymph node dissection was done concomitantly with the primary therapy of the penile lesion, as opposed to an 8% survival rate among those who underwent lymphadenectomy when it became obvious that the nodes were pathologically involved. <sup>47</sup> Most patients who benefited from groin dissection had locally advanced penile cancers. The current recommendation is that, among patients with low-stage (T1, T2) penile cancer and palpably negative groins, expectant management is reasonable in that delayed inguinal lymph node dissection for clinically positive nodes does not seem to compromise long-term survival when compared with patients who never develop inguinal lymphadenopathy. <sup>60</sup> However, for locally advanced (T3, T4) tumors, a "prophylactic" bilateral lymph node dissection may result in improved survival among patients with clinically undetected inguinal metastasis. <sup>56</sup>

Cabanas <sup>61</sup> described a technique of "sentinel node" biopsy followed by formal node dissection if metastatic disease is found. In Cabanas' series, inguinal-femoral-iliac node involvement was not demonstrated without a positive sentinel node biopsy. However, Perinetti and colleagues <sup>62</sup> have reported patients with negative sentinel node biopsies who later developed unresectable bilateral groin disease. A modified or extended sentinel lymph node dissection also has been advocated to cure those patients with limited inguinal disease and to reduce the morbidity of a formal radical ilioinguinal lymphadenectomy. However, Pettaway <sup>63</sup> reported that, among 14 patients who underwent a negative modified superficial inguinal dissection, 5 relapsed with incurable groin metastasis from 3 to 21 months later. Thus, radical ilioinguinal lymphadenectomy is the procedure of choice if groin dissection is indicated.

The operation is performed essentially as described by Whitmore and Vaghaiwala. <sup>64</sup> Bilateral pelvic lymph node dissection is performed. The dissection limits are defined by the genitofemoral nerve laterally, the bladder medially, the bifurcation of the common iliac artery superiorly, and the fascia covering the obturator internus and levator ani muscles inferiorly. Cloquet's node is removed from the femoral canal.

The inguinal incision is planned to provide adequate margins surrounding lymph nodes containing obvious tumor and simultaneously to remove the area of skin at greatest risk of devitalization and necrosis. An elliptical incision is made over the inguinal ligament from the anterosuperior iliac spine to the pubic tubercle. The borders of the ellipse parallel the inguinal ligament and extend 4 to 6 cm in vertical diameter at the widest point. Because penile cancers appear to involve the inguinal lymph nodes by tumor embolization rather than through permeation of lymphatic channels, wide thin skin flaps and a thorough dissection, skeletonizing the femoral vessels as is required for malignant melanoma, are not required. The nodes in the superficial and deep inguinal areas are completely removed from the

inguinal ligament to the apex of the femoral triangle in the groin ( Fig. 34.5-4). With this technique, the incidence of postoperative wound necrosis is markedly reduced.

**FIGURE 34.5-4.** Anatomic limits of groin dissection.

### Radiation Therapy

The main advantage for radiation therapy in penile tumors is that it provides an option of functional preservation of the penis. However, for radiation to represent an alternative to surgery, it must yield comparable local control rates with minimal toxic effects. Several series report initial rates of local control in 80% to 90% of patients treated with radiotherapy, but 10% to 20% eventually relapse and require surgical salvage.<sup>65,66 and 67</sup> Furthermore, inadequate control of the primary tumor risks interval metastasis and a reduced cure rate.

Radiation techniques have included interstitial implantation of radium needles,<sup>192</sup>Ir sources, or external-beam radiotherapy. The use of brachytherapy has been limited to small tumors. Results from a series of 50 patients implanted with <sup>192</sup>Ir wires showed that the tumor was controlled in 95% of the patients with noninfiltrating tumors of 4 cm or less, with the penis conserved in 80% without major impairments of function.<sup>68</sup> When external-beam radiotherapy is used, treatment is usually delivered with a custom-made plastic or wax mold to ensure a uniform dose distribution and to overcome the skin-sparing effects of supervoltage beams. Circumcision is usually recommended before radiotherapy to minimize radiation morbidity associated with cellulitis of the prepuce and the adjacent structures. The whole shaft of the penis is treated to 40 Gy in 20 fractions in 4 weeks, and the primary lesion is boosted to a total dose of 60 Gy. Superficial small lesions can be treated with localized fields using superficial x-rays or electron beams carried to a similar dose.

External-beam radiotherapy of low-stage tumors usually produces 70% to 80% local success rates. Local failures appear in 20% of patients, but some can be salvaged with surgery. If prophylactic or therapeutic lymph node dissection cannot be performed, external-beam radiotherapy to the inguinal and pelvic lymph nodes carried to 50 Gy may provide palliation for some patients.<sup>69,70</sup>

The Royal Marsden Hospital has recently updated their experience with treating 101 patients with radiation for carcinoma of the penis. This group reported an 30% local recurrence rate in patients treated with at least 60Gy of external-beam radiation therapy. However, local control was eventually achieved in 71 of 74 patients with stage I disease, which included retreatment with salvage surgery in 17 patients who had local recurrence following radiation. Unfortunately, very little quality of life information has been published following treatment of penile cancer. However, a recent study from the Norwegian Radium Hospital reports clear results of sexual performance using a formal prospective analysis. This study found that the overall sexual function was preserved or only slightly diminished in 10 of the 12 irradiated patients. However, the analysis also showed that the overall sexual function was normal in only one of five men following wide local excision and in only two of nine men after partial penectomy.

### CHEMOTHERAPY

Chemotherapy for urethral and penile carcinoma varies with the histology of the lesion. For patients with pure transitional tumors, cisplatin-combination regimens have shown efficacy. The results with chemotherapy for squamous cell tumors of the penis vary according to the extent of disease, with higher rates of response for locoregional (inguinal) than metastatic (pelvic and beyond) disease. Antitumor activity has been demonstrated with single-agent bleomycin, methotrexate, and cisplatin.<sup>71,72</sup> Partial responses occur in up to one-third of patients, but complete remissions are rare.

Large trials evaluating the role of multiagent chemotherapy in advanced carcinoma of the penis are uncommon. However, cisplatin-based regimens predominate the recent literature. Early trials evaluated the cisplatin/cyclophosphamide/bleomycin combination,<sup>73,74</sup> with clinical responses seen in 4 of 13 patients; cisplatin was given by either the peripheral or the intraarterial route. The cisplatin/bleomycin/methotrexate regimen has been the most extensively studied.<sup>75,76 and 77</sup> The M. D. Anderson Cancer Center experience was first reported by Dexeus and colleagues.<sup>75</sup> Sella et al.<sup>76</sup> subsequently reported on 26 assessable patients with squamous cell carcinoma of the genitourinary tract, 20 of whom had penile cancer. The complete and partial response proportions were 15% and 50%, respectively; results were not characterized by the site of the primary tumor. Haas et al.<sup>77</sup> reporting for the Southwest Oncology Group, evaluated this three-drug regimen in 40 patients with locally advanced or unresectable disease, none of whom had prior chemotherapy. Complete response was seen in 12.5% and a major response in 32.5% of patients. The median duration of response was 16 weeks, and the median survival was 28 weeks. Toxicity was substantial, including five treatment-related deaths.

Other reports showed activity of cisplatin and 5-fluorouracil, a combination that has been extensively evaluated in head and neck tumors. Hussein and colleagues<sup>78</sup> treated six men with recurrent or unresectable squamous cell carcinoma of the penis. Overall, one complete response and five partial responses were documented, including two patients with unresectable disease who were rendered disease-free by surgery. Fisher and coworkers<sup>79</sup> treated five patients with biopsy-proven unresectable disease and reported major responses in four patients, including two men who were pathologically free of disease at surgery. Shamma et al.<sup>80</sup> treated eight patients, two of whom responded.

Most regimens studied in penile cancer use older agents. More recent studies have identified new, active agents in squamous cell carcinoma of the cervix and head and neck, including ifosfamide, paclitaxel, docetaxel, gemcitabine, and vinorelbine (Navelbine). Single and multiagent regimens that include these new drugs are active in squamous cell carcinoma of other origins; they have not been pursued as yet in penile cancer. In summary, chemotherapy is sufficiently active in penile cancer to consider its inclusion in multimodality therapy for patients with bulky or fixed inguinal metastases.

### INTRODUCTION

Cancers of the testis make up a morphologically and clinically diverse group of neoplasms ( [Table 35-1](#)). The overwhelming majority are primary in the testis, and most of these are germ cell tumors (GCTs). The management of each neoplasm is dependent on the histology and influenced by the anatomy of the testis and its lymphatic and vascular drainage. GCT is a highly curable disease requiring proper management at all stages.

A. Germ cell tumors (demonstrating one or more of the following characteristics)
1. Seminoma
a. Classic (typical) seminoma
b. Anaplastic seminoma
c. Spermatocytic seminoma
2. Embryonal carcinoma
3. Teratoma
a. Mature
b. Immature
c. Mature or immature teratoma with malignant transformation
4. Choriocarcinoma
5. Mixed germ cell tumor (embryonal stem tumor; embryonal adenosarcoma; or other germ cell tumor)
B. Non-germ cell (gonadal stromal) tumors
1. Leydig cell tumor
2. Sertoli cell tumor
3. Gonadoblastoma cell tumor (adult and juvenile types)
C. Both germ cell and gonadal stromal elements
1. Gonadoblastoma
D. Adrenal and gonadocytular tumors
1. Mesothelioma
2. Soft tissue myxoid (e.g., sarcoma)
3. Adenoid (e.g., adenocarcinoma) of the rete testis
E. Miscellaneous mesenchyma
1. Cystic
2. Epithelial
3. Fibrous
F. Metastatic neoplasms

TABLE 35-1. Histologic Classification of Testicular Neoplasms

### BACKGROUND: INCIDENCE

GCTs are the most common solid tumor in men between the ages of 20 and 35 years. There are three modal peaks: infancy, ages 25 to 40, and approximately age 60. A solid testicular mass in a man aged 50 or greater is usually a lymphoma. The incidence of GCTs appears to be increasing. An estimated 7000 new cases (6900 testis) and 300 deaths caused by germ cell tumors of all primary sites will be reported in the United States in 2000.<sup>1</sup> The incidence of testis cancer varies significantly according to geographic area. The reported incidence is highest in Scandinavia, Switzerland, Germany, and New Zealand; intermediate in the United States and Great Britain; and lowest in Africa and Asia. The rising risk of testicular GCT incidence is associated with a birth cohort effect in both the United States and Europe.<sup>2,3</sup>

## EPIDEMIOLOGY

GCTs are seen principally in young whites, and rarely in African Americans. The published ratio between white and African American patients is approximately 4:1 to 5:1, although it was closer to a 40:1 ratio in the U.S. military.<sup>4</sup> In African Americans, GCT behaves similarly to that of the general population.<sup>5</sup> Familial clustering has been observed, particularly among siblings.<sup>6</sup>

The cause of GCT is unknown. Random genetic events occurring during the early stages of meiosis seem to be responsible for the malignant transformation of germ cells (see [Biology](#), later in this chapter). A few congenital developmental defects predispose to the disease.

## CRYPTORCHIDISM

The risk of GCT occurring in the cryptorchid testis is several times the risk in normally descended testes. Between 5% and 20% of patients with a history of cryptorchidism develop a tumor in the *normally* descended testis.<sup>7</sup> An abdominal cryptorchid testis is more likely to develop GCT than an inguinal cryptorchid testis.<sup>7</sup> The protective effect of orchiopexy is difficult to quantify, but most data suggest a reduced likelihood of GCT if orchiopexy is performed before puberty. If the testis is inguinal, hormonally functioning, and easily examined, surveillance is recommended. If the testis is not amenable to orchiopexy or cannot be adequately examined, orchiectomy is recommended.

## DIETHYLSTILBESTROL

Exogenous administration of estrogens to pregnant mice causes testicular maldescent and dysgenesis in offspring. Cryptorchidism and dysgenesis have also been reported in the male children of women exposed to diethylstilbestrol or oral contraceptives. Despite anecdotes associating diethylstilbestrol exposure with the development of GCT, epidemiologic studies have failed to identify such an association.<sup>8</sup>

## KLINEFELTER'S SYNDROME

Klinefelter's syndrome is characterized by testicular atrophy, absence of spermatogenesis, a eunuchoid habitus, and gynecomastia. It is diagnosed by a 47,XXY karyotype. Klinefelter's syndrome patients have an increased incidence of mediastinal GCT.

## OTHERS

A history of trauma is frequently noted by patients with testicular cancer; however, no evidence supports a direct causal relationship. Rather, the trauma usually prompts examination. Viral orchitis, usually secondary to mumps, may result in testicular atrophy. However, epidemiologic studies have failed to identify viral infection as a cause. More recently, testicular cancer has been reported in men infected with the human immunodeficiency virus. However, too few data support a higher incidence in individuals infected with human immunodeficiency virus, and the results of treatment are similar.<sup>9,10</sup> Reports implicating vasectomy as a cause of GCT have not been confirmed in cohort analysis.<sup>11</sup>

## INITIAL PRESENTATION AND MANAGEMENT

### SYMPTOMS AND SIGNS

The pathognomonic presentation of a primary testicular tumor is a painless testicular mass that may range in size from a few millimeters to several centimeters. However, the painless testicular mass occurs in only a minority of patients. The majority present with more diffuse testicular pain, swelling, hardness, or some combination of these findings. Since infectious epididymitis or orchitis, or a combination of the two, is more common, a trial of antibiotic therapy is often required in questionable cases. Acute testicular pain, simulating testicular torsion, occurs less frequently and may represent intratumoral hemorrhage. If the testicular discomfort does not abate or findings do not revert to normal within 2 to 4 weeks, a testicular ultrasound is indicated. On ultrasound, the typical testicular tumor is intratesticular and may produce one or more discrete hypoechoic masses. A pattern of multiple, diffuse calcifications in the testis has been associated with GCT.<sup>12</sup> Higher stage at presentation has been associated with delay in diagnosis,<sup>13</sup> and the experience of the treatment unit with the management of GCT appears to influence survival.<sup>14,15</sup> and <sup>16</sup>

### DIAGNOSIS

A radical inguinal orchiectomy, using an inguinal incision with early high ligation of the spermatic cord at the deep inguinal ring, minimizes local tumor recurrence and aberrant lymphatic spread and is the only acceptable therapeutic and diagnostic procedure. The vasal and vascular components are doubly clamped and divided separately; their respective stumps are pushed into the retroperitoneal space to facilitate removal of the gonadal vessels at the time of retroperitoneal lymph node dissection (RPLND). The testicle and spermatic cord are removed *en bloc*, avoiding any spillage, and meticulous hemostasis is achieved. A transscrotal orchiectomy is contraindicated, because it permits the development of alternate lymphatic drainage pathways to the inguinal and pelvic lymph nodes and leaves intact the spermatic cord from the external to the internal ring. In the rare situation in which the diagnosis of a testicular tumor is in question, then an inguinal incision is required for an open biopsy. The testis can then be examined *in situ* in a sterile field and an appropriate biopsy taken with minimal risk of scrotal or inguinal contamination. Regardless of the preoperative diagnosis, all potential, primary testicular malignancies should be managed through an inguinal approach.

Extragenital GCTs account for fewer than 10% of GCT. The mediastinum and retroperitoneum are the most common primary sites. Pineal tumors, occurring most frequently in children, are usually GCT. Because of their unique access to the meninges, the metastatic pattern of pineal GCT includes intradural sites along the neuraxis and is infrequently systemic. The management of pineal GCT is discussed in [Chapter 43](#). In extremely rare circumstances, primary GCTs have been found in unusual sites such as the sacrum, thyroid, paranasal sinuses, and soft tissues of the head and neck.<sup>17,18</sup> In patients with extragenital presentations of GCT, a testicular ultrasound is required. The management of extragenital and testicular GCT is the same, and primary site is an independent factor in staging and risk classification.

## HISTOLOGY

GCT is classified into two major subgroups: seminoma and nonseminoma. Three classifications are summarized in [Table 35-2](#). The Mostofi adaptation of the Dixon/Moore classification<sup>19</sup> was largely adopted by the World Health Organization and is the classification most commonly used in North America and Europe.<sup>20</sup> The British Tumor Panel's modification of the classification developed by Pugh is widely used in Great Britain and Australia.<sup>21</sup>

Dixon and Moore <sup>19</sup>	World Health Organization <sup>20</sup>	British Tumor Panel <sup>21</sup>
Seminoma	Seminoma Typical (classical) Anaplastic	Seminoma
Embryonal carcinoma	Embryonal carcinoma	Malignant teratoma, undifferentiated
Teratoma	Teratoma Mature Immature With malignant differentiation	Malignant teratoma, differentiated
Choriocarcinoma	Choriocarcinoma	Malignant teratoma, trophoblastic
Yolk sac tumor (endodermal sinus tumor)	Yolk sac tumor	Yolk sac tumor
Teratocarcinoma (teratoma + embryonal carcinoma + other elements)	Mixed germ cell tumors (specify components)	Malignant teratoma, intermediate

TABLE 35-2. Comparison of Three Classifications of Germ Cell Tumors

## CARCINOMA *IN SITU*

Carcinoma *in situ* (CIS)<sup>22</sup> (intratubular germ cell neoplasia) precedes invasive testicular GCT in virtually all cases of typical and anaplastic seminoma and all nonseminomatous histologies in the adult. CIS is frequently present in retroperitoneal presentations and is rarely, if ever, present in mediastinal presentations.<sup>23</sup> It has not been described in spermatocytic seminoma and rarely in tumors arising in prepubertal patients.<sup>24,25</sup> Cytologically, CIS preceding seminoma and nonseminoma is identical. The median time for progression of CIS to invasive disease is 5 years.<sup>26,27</sup> In the general population, the incidence of CIS is low,<sup>28</sup> whereas in men with impaired fertility, the incidence is approximately 0.5%.<sup>29,30</sup> The incidence of CIS is 2% to 5% in both cryptorchid testes and the contralateral testis in patients with a documented prior testicular GCT.<sup>31,32</sup>

## SEMINOMA

Seminoma accounts for approximately 50% of all GCT and most frequently appears in the fourth decade of life. The typical or classic form consists of sheets of large cells with abundant cytoplasm and round, hyperchromatic nuclei with prominent nucleoli. A lymphocytic infiltrate, granulomatous reaction with giant cells, or both, are frequently present. Trophoblastic giant cells capable of producing human chorionic gonadotropin (HCG) are present in 15% to 20% of tumors. The presence of syncytiotrophoblastic giant cells in an otherwise pure seminoma does *not* influence prognosis or treatment. *Anaplastic* seminoma is an older term used when three or more mitotic figures are seen per high-power field, and it has no clinical or prognostic importance. Stage for stage, anaplastic seminoma is similar in response and prognosis to classical seminoma.<sup>33</sup>

An *atypical* form of seminoma has been described with unusual immunohistochemical features. Although the cells cytologically resemble classical seminoma, lymphocytic infiltrate and granulomatous reaction are absent, necrosis is more common, and the nuclear to cytoplasmic ratio is higher. These tumors must be distinguished morphologically from solid variants of embryonal carcinoma and yolk sac tumor. Atypical seminoma frequently shows cytoplasmic expression of low-molecular-weight keratin or the type 1 precursor to the blood group antigens, whereas typical seminoma stains negative.<sup>34</sup> Electron microscopic studies have shown that the individual tumor cells acquire cytoplasmic cytokeratin intermediate filaments, suggesting epithelial differentiation. There has been no specific association of atypical seminoma with an adverse prognosis, and its management is currently the same as any other seminoma.

Spermatocytic seminoma is a rare histologic variant seen almost exclusively in men above the age of 45. The relationship of spermatocytic seminoma to other GCTs is not clear, since it is not associated with CIS or bilaterality, does not express placental alkaline phosphatase (PLAP) (see [Immunohistochemical Markers](#), later in this chapter), and has not been shown to have the same genetic abnormalities as other GCTs. Metastatic potential is minimal.

## NONSEMINOMATOUS GERM CELL TUMORS

Nonseminomatous histology makes up approximately 50% of all GCTs and most frequently presents in the third decade of life. Most tumors are mixed, consisting of two or more cell types. Seminoma may be a component, but the definition of a pure seminoma *excludes* the presence of any nonseminomatous cell type. The presence of any nonseminomatous cell type (other than syncytiotrophoblasts) imparts the prognosis and management principles of a nonseminomatous tumor.

### Embryonal Carcinoma

Embryonal carcinoma is the most undifferentiated somatic cell type. Individual cells are epithelioid in appearance and may be arranged in glandular or tubular nests and cords or as solid sheets of cells. Tumor necrosis and hemorrhage are frequently observed.

### Choriocarcinoma

Choriocarcinoma, by definition, consists of both cytotrophoblasts and syncytiotrophoblasts. If cytotrophoblasts are not present, then the diagnosis of choriocarcinoma cannot be made. Pure choriocarcinoma is an extremely rare presentation usually associated with widespread hematogenous metastases and high levels of HCG. Hemorrhage into the primary tumor is frequent and is an occasional severe complication when it spontaneously occurs at a metastatic site.<sup>35</sup> Elements of choriocarcinoma are frequently found in mixed tumors but appear to have no prognostic importance.<sup>36</sup> Syncytiotrophoblastic giant cells can be seen as a component of any GCT (including pure seminoma). They impart no prognostic value by themselves.

### Yolk Sac Tumor

Yolk sac tumor (endodermal sinus tumor) is often confused with a glandular form of embryonal carcinoma. This tumor mimics the yolk sac of the embryo and produces  $\alpha$ -fetoprotein (AFP). The cells may have a papillary, glandular, microcystic, or solid appearance and may be associated with Schiller-Duval bodies, which are perivascular arrangements of epithelial cells with an intervening extracellular space. Rarely, *embryoid bodies* resembling the early embryo can be seen. Yolk sac histology is infrequently the only histologic subtype in adult GCT except in the mediastinum where pure yolk sac tumors account for a minority of primary tumors.

### Teratoma

Teratoma is composed of somatic cell types from two or more germ layers (ectoderm, mesoderm, or endoderm) and is derived from a totipotential, malignant precursor cell (embryonal carcinoma or yolk sac tumor). *Mature teratoma* consists of adult-type differentiated elements such as cartilage, glandular epithelium, nerve tissue, or other differentiated cell types. *Immature teratoma* generally refers to a tumor with partial somatic differentiation, similar to that seen in a fetus. Both mature and immature teratomas are histologically benign. *Teratoma with malignant transformation* refers to a form of teratoma in which one of its components, either immature or mature, develops aggressive growth and histologically resembles another malignancy. These usually take the form of sarcomas (most frequently embryonal rhabdomyosarcoma), and, less frequently, carcinomas (e.g., enteric-type adenocarcinoma), neuroectodermal tumors, or combinations of these.<sup>37</sup> Acute nonlymphocytic leukemias have arisen in the context of mediastinal nonseminomatous GCT, but not from other primary sites.<sup>38</sup> In a review of 41 cases of pure mature or immature teratoma of the testis, 26 (63%) displayed retroperitoneal or systemic metastases, with or without increased levels of serum tumor markers.<sup>39</sup> Therefore, a primary testicular tumor in a postpubertal boy or man that displays only histologically mature or immature teratoma must be considered to be a fully malignant GCT, and management should proceed as if malignant components are present.

## BIOLOGY

Adult human male GCTs make up a unique system for the study of the mechanism of transformation of a totipotential germ cell in lineage differentiation. The pluripotentiality of the tumor cells manifests as histologic differentiation into germ cell–like undifferentiated (seminoma), primitive zygotic (embryonal carcinoma), embryonal-like somatically differentiated (teratoma), and extraembryonically differentiated (choriocarcinoma and yolk sac tumor) phenotypes. Until fairly recently, the molecular mechanisms of germ cell transformation, GCT differentiation, or GCT chemotherapy sensitivity and resistance were poorly understood. More recent studies of GCTs have suggested that (1) overexpression of cyclin D2 is an early, possibly oncogenic, event in germ cell tumorigenesis; (2) differentiation in GCTs may be governed by several possibly interacting pathways such as loss of regulators of germ cell totipotentiality and of embryonic development, and genomic imprinting; and (3) chemotherapy sensitivity and resistance may be rooted in part in a p53-dependent apoptotic pathway.

### Mechanism of Germ Cell Transformation

Genetic analysis of male GCTs has yielded important data relevant to the mechanism of germ cell transformation.<sup>40</sup> Virtually 100% of tumors show increased copy number of 12p, as one or more copies of *i*(12p) or as tandem duplications of 12p, *in situ* or transposed elsewhere in the genome (Fig. 35-1).<sup>40</sup> This chromosomal marker has been observed as early as CIS, suggesting that it is among the earliest, if not the earliest, genetic change associated with the origin of these tumors.<sup>40</sup> A candidate gene, *CCND2*, mapped to 12p13, has been identified as the possible driver gene on 12p whose deregulated expression may lead to GCT development.<sup>41</sup> It is abundantly expressed in CIS as well as in many lineages of GCTs.<sup>41</sup> Cyclin D2 is one of the D-type cyclins that, along with the cyclin-dependent kinases *cdk4*, *cdk6*, or both, regulates the phosphorylation of pRB and controls the G<sub>1</sub>/S cell-cycle checkpoint.<sup>42</sup> Disruption of this checkpoint through amplification or

overexpression of D-type cyclins is known to be one of the important pathways in human tumor development.<sup>42</sup>

**FIGURE 35-1. A:** Karyotype of a male germ cell tumor cell line with hyperdiploid chromosome number containing three copies (\*\*\*) of i(12p) chromosomes. Arrows indicate abnormal chromosomes. M1 through M6 are unidentified marker chromosomes. **B:** Abnormalities of 12p in male germ cell tumor showing three normal chromosomes 12 and an i(12p). **C:** Tandem duplication of 12p in i(12p) negative tumor. Abnormally banded marker chromosome (left) revealed chromosome 12 material by chromosome 12 painting probe (middle) and 12p painting probe identified the region of amplification to be 12p (right).

The precursor of all GCTs is considered to be CIS; however, the stage of germ cell development at which transformation occurs is not known. Two models of origin of CIS cells have been proposed. One model proposed by Skakkebaek and colleagues<sup>43,44</sup> suggested that fetal gonocytes that have escaped normal development into spermatogonia may undergo abnormal cell division mediated by a kit receptor/stem cell factor (kit ligand) paracrine loop, leading to uncontrolled proliferation of gonocytes. Such gonocytes have been postulated to be susceptible to subsequent invasive growth through the mediation of postnatal and pubertal gonadotrophin stimulation. This hypothesis is based on a consideration of immunophenotypic markers expressed by gonocytes and CIS cells, types of abnormal germ cells seen in developmental disorders that predispose to GCTs, and epidemiology of GCT incidence.<sup>43</sup> A second model proposed by Chaganti and colleagues takes into account four established genetic properties of GCTs, namely, increased 12p copy number, expression of cyclin D2 in CIS, consistent near triploid-tetraploid chromosome numbers, and abundant expression of wild-type p53.<sup>45</sup> According to this model, aberrant chromatid exchange events during meiotic crossing over may lead to increased 12p copy number and overexpression of cyclin D2. In a cell containing unrepaired DNA breaks (recombination-associated), overexpressing cyclin D2 may block a p53-dependent apoptotic response and lead to reinitiation of cell-cycle and genomic instability.<sup>45</sup> A role for cyclin D2 in the development of GCTs has also been suggested by Sicinski et al.<sup>46</sup> through studies of mice homozygously inactivated (mutant) for the *CCND2* gene, and expression of *CCND2* mRNA in ovarian granulosa cell tumors and testicular GCT cell lines. In germ cells that have reentered cell cycle following cyclin D2 activation, downstream events such as loss of tumor suppressor genes (TSGs) brought about by genomic instability may lead to neoplastic progression. Extensive molecular genetic analysis has identified genomic, functional (expression), or both kinds of loss of several known TSGs such as *RB1*, *DCC*, and *NME*, and genomic loss at several previously recognized as well as novel chromosomal sites.<sup>40,47</sup>

### Embryonal-Like Differentiation in Germ Cell Tumors

Male GCTs display, albeit in a spatially and temporally abnormal manner, patterns of differentiation that mimic stages normally undergone by the developing zygote. Among GCTs, seminoma can be viewed as transformed germ cells that have retained the inhibitory mechanism for zygotic-like differentiation, a feature of germ cells before fertilization. The *in vivo* expression patterns of kit receptor and stem cell factor in GCTs are consistent with such a view. Thus, the kit receptor, which normally is expressed by spermatogonia and primary spermatocytes,<sup>48</sup> is expressed mainly by CIS and seminoma.<sup>49</sup> On the other hand, nonseminoma appear to down-regulate kit and up-regulate stem cell factor, consistent with their loss of germ cell phenotype and acquisition of somatic fates.<sup>49</sup> The key developmental difference between seminoma and nonseminoma appears to be the loss of ability to retain germ cell-like totipotentiality by the former.

A great deal of effort has been directed toward understanding the mechanistic basis of decisions that determine the nature and regulation of proliferation and differentiation signals in the developing zygote.<sup>50,51</sup> In this context, GCTs and derived embryonal carcinoma cell lines provide a unique opportunity to study embryonal versus extraembryonal pathways of differentiation, as well as development of somatic lineage. Analysis of genome-wide allelic loss in GCTs showed an overall higher loss in the highly differentiated teratomas compared with the less differentiated embryonal carcinomas.<sup>52</sup> These studies identified chromosomal sites that may harbor effector genes such as transcription factors whose loss may prompt either induction of differentiation or lineage decision.

The ability of GCTs to undergo an embryonal-like developmental program without the contribution of a maternal complement has obvious implications to genomic imprinting. Parental imprints are erased in normal germ cells before meiosis, and new imprinting patterns are laid down during gametogenesis and again during embryogenesis.<sup>53,54</sup> Therefore, the target cell for transformation proposed in our model, the meiotic spermatocyte, would be imprint-erased, which is consistent with observations of biallelic expression in GCTs of *IGF2* and *H19* genes which normally show monoallelic expression in postfertilization somatic tissues.<sup>55,56</sup> A possible mechanism by which embryonal and extraembryonal types of major differentiation paths are initiated in imprint-erased transformed germ cells may be differential methylation of critical chromosomal regions.

### Chemotherapy Resistance of Germ Cell Tumors

Molecular genetic studies of GCTs that are clinically resistant to cisplatin-based chemotherapy have identified a subset that harbors *TP53* gene mutations,<sup>57</sup> a molecular alteration not normally associated with GCTs.<sup>58,59</sup> Evaluation of the cellular response to cisplatin in one GCT-derived cell line with a *TP53* gene mutation indicated a relative resistance to cisplatin, in contrast to the extreme sensitivity of another GCT-derived cell line with wild-type *TP53*.<sup>57</sup> Presumably, the cisplatin resistance of this subset of GCTs is rooted in their inability to mount an apoptotic response after drug exposure because of an inactivating *TP53* gene mutation. On the whole, these tumors display higher than normal levels of wild-type p53,<sup>60,61</sup> with somewhat lower levels in mature teratomas.<sup>62</sup> Thus, somatic differentiation associated with a decline in p53 levels may make up a cellular setting for the operation of selective pressure for *TP53* gene mutation.

A cohort of cisplatin-resistant GCTs has been analyzed for the presence of amplified DNA sequences,<sup>63</sup> a genetic abnormality often associated with tumor progression and resistance to therapy. In this study, comparative genomic hybridization was performed on a panel of GCTs consisting of 17 resistant and 17 sensitive tumors.<sup>63</sup> High-level amplification of eight chromosomal regions (other than 12p) was detected in five resistant tumors, but in none of the sensitive group.<sup>63</sup> Once the identity and function of the amplified genes are determined, they may become relevant to the understanding of chemotherapy resistance of GCTs and other tumor types.

Male GCTs offer a system in which the cellular factors portending exquisite sensitivity to chemotherapy can be studied. Some studies have described a reduced ability of GCT cell lines to repair DNA lesions induced by cisplatin.<sup>64,65</sup> Although the precise biochemical link between the induction of physical damage in DNA and the cellular response to it is unclear, in general, cells treated with DNA-damaging agents respond either by induction of a delay in the cell cycle at the G<sub>1</sub> to S phase boundary, or by the induction of apoptosis, both of which are thought to be mediated by p53.<sup>66</sup> It has also been suggested that the rapid apoptotic response of GCTs on exposure to chemotherapeutic agents may be caused by a high ratio of the proapoptotic bax protein to the antiapoptotic bcl-2 protein, favoring apoptosis.<sup>67</sup> This has been substantiated in a limited number of GCT cell lines and needs to be further investigated at the *in vivo* level.<sup>67</sup> However, other *in vitro* studies have suggested that bcl-x<sub>L</sub>, a bcl-2-related antiapoptotic protein, may act as the regulator of DNA damage-induced cell death in GCTs, rather than bcl-2.<sup>68</sup> In these studies, exogenous overexpression of bcl-2 in a GCT cell line resulted in sensitization of the cell line to DNA damage-induced cell death. Associated with this sensitization was a decreased endogenous expression of bcl-x<sub>L</sub> with little or no change in the level of bax expression. A much attenuated apoptotic response to cisplatin has been observed in somatically differentiated GCT cell lines, reflecting the relative resistance of teratoma elements of GCT specimens.<sup>69</sup> The elucidation of the molecular mechanisms whereby the unique apoptotic response to chemotherapeutic agents is achieved in GCTs will contribute to the understanding of how such a response is achieved, as well as show how resistance may be circumvented in GCTs and other tumor types.

## IMMUNOHISTOCHEMICAL MARKERS

Seminoma do not display differentiation *in vitro* or *in vivo* and do not express markers of somatic differentiation such as low-molecular-weight keratins, vimentin, or blood group antigens.<sup>34,70</sup> However, essentially all seminoma express PLAP and kit receptor CD117.<sup>49,71,72</sup> Embryonal carcinoma and yolk sac tumor do display some somatic differentiation. Surface expression of low-molecular-weight keratins (e.g., AE-1, CAM 5.2) and the type 1 precursor substance of the blood group antigens is invariable.<sup>34,70</sup> Most embryonal carcinoma, but not seminoma, also express the CD30 antigen, originally described as a marker of Hodgkin's disease and anaplastic large cell lymphoma.<sup>73,74</sup> and <sup>75</sup> Vimentin expression is limited to mesenchymal components of mature teratoma and interstitial and other support cells. In tumors of uncertain histogenesis, immunohistochemical studies that include PLAP, kit receptor, and low-molecular-weight keratins may be useful in establishing a diagnosis. It should be remembered that cytokeratins are expressed by all epithelial tumors, and PLAP immunoreactivity is present in a small subset of epithelial neoplasms, especially (but not limited to) those of Müllerian origin.

## STAGING

A comprehensive evaluation is necessary to define the extent of disease and to determine the appropriate treatment, and should include pathologic examination of the primary tumor, physical examination, determination of serum concentrations of AFP and HCG, and radiographic studies.

### Anatomic Considerations

The initial route of metastasis is lymphatic drainage to retroperitoneal lymph nodes ( Fig. 35-2). From the testes, several lymphatic vessels emerge from the mediastinum testis and accompany the gonadal vessels in the spermatic cord. Where the spermatic vessels cross ventral to the ureter, some of these lymphatics diverge medially and drain into the retroperitoneal lymph node chain, whereas others follow the spermatic vessels to their origin. Lymph nodes located lateral or anterior to the inferior vena cava are called paracaval or precaval nodes, respectively. Interaortocaval nodes are those nodes between the inferior vena cava and the aorta. Nodes anterior or lateral to the aorta are preaortic or paraaortic nodes, respectively. The primary *landing zone* for a right testicular tumor lies in the interaortocaval nodes immediately below the renal vessels, and the ipsilateral distribution includes the paracaval, preaortic, and right common iliac. The primary landing zone for a left testicular tumor lies in the true paraaortic nodes just below the left renal vessels, and the ipsilateral distribution for the left testis includes the paraaortic, preaortic, and left common iliac nodes. Metastatic nodal disease in more caudal areas such as the common iliac, external iliac, or inguinal lymph nodes is usually secondary to large volume of disease with retrograde spread. If the patient has undergone a herniorrhaphy, vasectomy, or other transscrotal procedure unrelated to the tumor, additional attention should be paid to pelvic and inguinal lymph nodes.

FIGURE 35-2. Retroperitoneal lymph nodes.

Contralateral retroperitoneal metastasis is represented by involvement of nodes usually associated with a tumor from the opposite side. For example, paraaortic lymphadenopathy in the presence of a right-sided primary tumor is considered contralateral. Contralateral spread is more common with right-sided tumors, rare with left-sided primaries, and usually in the setting of large-volume disease.

Retroperitoneal lymphatics continue cephalad and empty into the cisterna chyli via the right and left lumbar trunks. Lymphatic involvement above the retroperitoneal nodes results in involvement of the retrocrural nodes. Supradiaphragmatic spread occurs via the thoracic duct, leading to posterior mediastinal and left supraclavicular lymph node involvement. The anterior mediastinum is not part of this usual nodal hierarchy.

## TUMOR IMAGING

Plain chest radiography and computed tomography (CT) are the most important radiologic investigations in determining extent of disease and treatment. The role of magnetic resonance imaging (MRI) is limited.

### Computed Tomography

CT is the most effective radiographic technique for identifying metastatic involvement both above and below the diaphragm. Well-circumscribed pulmonary lesions less than 5 mm may be detected, and although these may represent metastases, many lesions in this size range represent benign processes, and their clinical importance depends on clinical stage. In seminoma, such lesions are usually benign.

CT scan of the abdomen is the best technique for identifying retroperitoneal lymphadenopathy and has replaced intravenous pyelography and lymphangiography. The abdominal CT scan is normal in 70% of newly diagnosed seminoma and at least one-third of newly diagnosed nonseminoma. Because GCTs may grow rapidly, treatment decisions should be made within 4 weeks of the last abdominal CT scan. Lymph nodes in the primary landing zones measuring 10 to 20 mm are involved by GCT approximately 70% of the time and those measuring 4 to 10 mm are involved 50% of the time.<sup>76,77,78</sup> and <sup>79</sup> The duodenum and proximal jejunum must be adequately opacified by oral contrast. In evaluation of the postchemotherapy mass, the CT scan is unable to distinguish between residual malignant tumor, teratoma, and necrosis or fibrosis; a *normal* postchemotherapy CT scan does not preclude the presence of disease.

### Magnetic Resonance Imaging

Like CT scanning, MRI can identify enlarged lymph nodes. Although MRI occasionally provides valuable preoperative information regarding vascular anatomy and the patency of the great vessels in patients with bulky retroperitoneal disease following chemotherapy, it adds little in the management of most patients with GCT. Both MRI and CT are equally unable to detect viable GCT after chemotherapy.

### Lymphangiography

Historically, lymphangiography was used to determine the extent of retroperitoneal involvement in both seminoma and nonseminoma. In most patients, CT scanning has replaced it. The role of lymphangiography is limited to patients with stage I seminoma. In patients with seminoma, lymphangiography may reduce normal tissue irradiation by permitting more precise ports and identifying where a *boost* of radiation may be needed for abnormal nodes seen on lymphangiography but not evident on CT scan.

### Positron Emission Tomography

Studies have compared positron emission tomography (PET) with CT for the evaluation of patients with newly diagnosed disease or residual disease after

chemotherapy. Although early studies suggest that PET may be more sensitive than CT, disease less than 0.5 cm was not detected.<sup>80</sup> In patients with residual disease, PET has not been consistently able to identify residual viable malignant GCT and does not detect teratoma.<sup>81,82</sup> and<sup>83</sup> Therefore, insufficient data exist to recommend PET as part of staging or in the evaluation of residual disease after chemotherapy.

## SERUM TUMOR MARKERS

### a-Fetoprotein

AFP is a 70,000 molecular-weight glycoprotein produced in the liver, gastrointestinal tract, and fetal yolk sac, and its secretion in GCT is restricted to nonseminomatous histology, usually embryonal cell carcinoma or endodermal sinus tumor. AFP is detected by radioimmunoassay and reported in nanograms per milliliter. The normal adult concentration is usually less than 15 ng/mL. The serum half-life is 5 to 7 days. In patients with pure seminoma, elevated serum concentrations of AFP reflect an undetected nonseminomatous element. An increased serum AFP concentration is present in 10% to 20% of clinical stage I, 20% to 40% of low-burden clinical stage II, and 40% to 60% of high-burden disease. Because of stage migration, the frequency and degree of increased AFP concentrations in patients with advanced tumors has declined.<sup>84</sup>

### Human Chorionic Gonadotropin

HCG is a glycoprotein composed of two subunits and is produced by syncytiotrophoblasts. The a subunit is identical to that of luteinizing hormone, follicle-stimulating hormone, and thyroid-stimulating hormone. The b subunits of HCG, luteinizing hormone, follicle-stimulating hormone, and thyroid-stimulating hormone are homologous but have distinct amino acid sequences.<sup>85</sup> Elevated serum concentrations can be found in patients with pure seminoma as well as those with nonseminomatous GCT. Most vendors have adopted the World Health Organization Third International Standard (code number 75/537) resulting in some uniformity in the radioimmunoassays to detect the HCG b subunit. The serum half-life is 18 to 36 hours.

Approximately 10% to 20% of clinical stage I, 20% to 30% of low-volume clinical stage II, and 40% of patients with advanced nonseminomatous GCT present with elevated serum concentrations of HCG; the frequency and degree to which the HCG is elevated has decreased over time.<sup>84</sup> Approximately 15% to 25% of patients with advanced pure seminoma have increased serum concentrations of HCG.<sup>86</sup> False elevations of HCG secondary to either cross-reactivity of the antibody with luteinizing hormone, treatment-induced hypogonadism, or pituitary production of HCG have been reported.<sup>87,88</sup> and<sup>89</sup>

### Lactate Dehydrogenase

The serum level of lactate dehydrogenase (LDH) has independent prognostic significance in patients with advanced GCT and should be determined in all patients. Increases in the serum concentration are a reflection of tumor burden, growth rate, and cellular proliferation. LDH comprises multiple isoenzymes, but, in practice, the combined LDH value for all isoenzymes is used for clinical decision making. Comparison of one laboratory with another is possible by using ratios of the detected level to the upper limit of normal for the individual assay.<sup>90</sup> Increased serum LDH concentrations are observed in approximately 60% of nonseminomatous GCT patients with advanced disease and in 80% of patients with advanced seminoma.<sup>86,91</sup>

## STAGING CLASSIFICATIONS

Revised tumor, nodes, and metastases (TNM) and stage groupings of the American Joint Committee on Cancer and the Union Internationale Centre le Cancre were adopted in 1997 (Table 35-3A and Table 35-3B).<sup>92</sup> For the first time, an S category for the serum concentrations of AFP, HCG, and LDH was incorporated because of its independent prognostic significance. Broadly, stage I disease is confined to the testis, stage II disease is restricted to the retroperitoneum, and stage III disease represents involvement of supradiaphragmatic or other nodal sites, or visceral disease. Levels of AFP, HCG, and LDH determine overall stage.

TABLE 35-3A. TNM Staging of Testis Tumors: American Joint Committee on Cancer<sup>92</sup>

	Lactate Dehydrogenase	Human Chorionic Gonadotropin (IU/mL)	a-Fetoprotein (ng/mL)
<b>SERUM TUMOR MARKERS (S)</b>			
S1	<1.5 × UL*	<5000	<1000

TABLE 35-3B. TNM Staging of Testis Tumors: American Joint Committee on Cancer<sup>92</sup>

### Factors Affecting Staging of the Primary Tumor (T Stage)

The T stage of the primary lesion (not size), histology, and serum tumor marker concentrations predict the likelihood of retroperitoneal disease. For nonseminomatous GCT, the presence of either lymphatic or vascular invasion or both has been associated with a higher likelihood of retroperitoneal metastases (approximately 50%) and is now included in the definition of T2. invasion through the tunica albuginea into tunica vaginalis (also T2), spermatic cord (T3), or scrotum (T4) is an additional adverse feature.

Reproducible prognostic factors predicting retroperitoneal disease in seminoma have not been identified. A Princess Margaret Hospital study of seminoma patients treated with radiation therapy identified anaplastic histology, invasion of the tunica, and invasion of the epididymis as prognostic for relapse.<sup>93</sup> However, other studies have failed to confirm these findings.<sup>94,95</sup> Similarly, the presence of increased serum concentrations of HCG are not consistently associated with a poor prognosis.<sup>86,96,97</sup>

## Factors Affecting Staging of Regional (Retroperitoneal) Nodes (N Stage)

Metastatic disease to retroperitoneal lymph nodes is considered to be stage II disease. The classification of retroperitoneal lymph node involvement is based either on pathologic evaluation after RPLND or clinical evidence of retroperitoneal lymph node involvement (see [Table 35-3A](#) and [Table 35-3B](#)).

**PATHOLOGIC STAGING.** The number and size of retroperitoneal lymph nodes found at RPLND have prognostic importance.<sup>98,99,100,101</sup> and <sup>102</sup> Most retrospective studies report a less than or equal to 35% incidence of recurrent disease when fewer than six nodes are involved with tumor, and the largest node is less than 2 cm, and no extranodal tumor extension is evident. More extensive tumor involvement is generally associated with a recurrence rate of greater than or equal to 50%. Once lymph node involvement is demonstrated, the histology of the primary tumor, and the presence or absence of vascular invasion in the primary tumor do not appear to add prognostic value.

**CLINICAL STAGING.** The transverse diameter of the largest lymph node has been used to subcategorize stage II disease (see [Table 35-3A](#) and [Table 35-3B](#)). For seminoma, the size of retroperitoneal adenopathy usually dictates the treatment modality. Relapse proportions after definitive radiation therapy for seminoma increase progressively from approximately 15% for nodes less than 5 cm to approximately 40% to 60% for nodes greater than 5 cm.<sup>93,103</sup> In nonseminoma, treatment decisions are based on retroperitoneal lymph node size, location of the adenopathy, and the presence and degree of increase in serum tumor marker concentrations.

## Prognostic Factors in Advanced Disease

Because 70% to 80% of patients with advanced GCT are cured with modern cisplatin-based chemotherapy, it has become necessary to stratify patients according to the likelihood of cure. Although survival is the best reflection of cure, complete response is often used as a surrogate for cure, since few patients relapse after being rendered free of disease. Histology, metastatic site, primary site, and serum tumor marker concentrations are independent prognostic variables and have been shown to predict the likelihood of cure. Patients who are more likely to be cured (good-risk or good-prognosis subgroup) constitute the majority of GCT patients with advanced disease and should be treated with regimens that have maximum efficacy with minimal toxicity. In contrast, patients who are unlikely to be cured (poor risk or poor prognosis) constitute the minority of patients. For them, more effective therapy is needed; toxicity is an important but secondary issue.

Between 1980 and 1997, several classification algorithms were used to assign good- and poor-risk status based on the extent of disease, specific sites of disease, pretreatment serum tumor marker concentrations, or all these factors. The Memorial Sloan-Kettering Cancer Center (MSKCC)<sup>104</sup> and Indiana University<sup>105</sup> allocation criteria were the most frequently used criteria in the United States and Medical Research Council and European Organization for the Research and Treatment of Cancer (EORTC)<sup>106</sup> criteria in Europe ([Table 35-4](#)). A comparison of these four risk criteria in advanced nonseminomatous GCT demonstrated marked differences and revealed that the allocation to either good- or poor-risk categories was in agreement in only 56% of patients.<sup>107</sup> Substantial numbers of patients assigned good-risk status by stringent criteria were classified as poor risk by those that were less stringent. The proportion cured in the poor-risk group increases with less stringent algorithms.<sup>107</sup>

	Memorial Sloan-Kettering <sup>104</sup>	Indiana University <sup>105</sup>	European Organization for the Research and Treatment of Cancer <sup>106</sup>	International <sup>108</sup>
Primary site	Yes	No	No	Mediastinal
AFP	No	No	>100 IU/L	>1000 ng/mL
Human chorionic gonadotropin	Continuous	No	>100 IU/L	>1000 mIU/mL
Lactate dehydrogenase	Continuous	No	No	>10 × normal <sup>a</sup>
Metastatic sites	No	Bone, liver, brain	Bone, liver	Bone, liver, brain

<sup>a</sup>Normal defined as the upper limit of normal for the specific assay.

**TABLE 35-4.** Comparison of Four Poor-Risk Classification Algorithms

The International Germ Cell Cancer Collaborative Group (IGCCCG), representing GCT clinical trialists from Europe, North America, and Australia, analyzed data from over 5000 patients treated with platinum-based chemotherapy in order to develop a common classification system. The IGCCCG found that the independent prognostic factors for progression-free survival for patients with nonseminomatous GCT included pretreatment levels of LDH, HCG, and AFP; site of the primary tumor (i.e., mediastinal vs. testis or retroperitoneal); and the presence of nonpulmonary visceral metastases (such as bone, brain, or liver metastases).<sup>108</sup> Nonpulmonary visceral metastasis was the only significant prognostic factor in seminoma patients. Investigators agreed on three strata of good-, intermediate-, and poor-prognosis patients with nonseminomatous GCT; no poor-risk stratum could be defined in seminoma ([Table 35-5](#)). The marker cutoff values were incorporated into the revised TNM classification.<sup>92</sup> Hence, the IGCCCG grouping should be used in future clinical trials and in treatment decision making for patients requiring initial chemotherapy for advanced disease.

	Seminoma	Nonseminoma
Good risk	Any HCG Any LDH Nonpulmonary visceral metastases absent Any primary site	AFP < 10,000 ng/mL HCG < 1000 mIU/mL LDH < 1.5 × upper limit of normal Nonpulmonary visceral metastases absent Mediastinal or retroperitoneal primary tumor
Intermediate risk	Nonpulmonary visceral metastases present Any HCG Any LDH Any primary site	AFP 10,000–50,000 ng/mL HCG 1000–10,000 mIU/mL LDH 1.5–10.0 × upper limit of normal Nonpulmonary visceral metastases absent Mediastinal or retroperitoneal primary site
Poor risk	—	Mediastinal primary site Nonpulmonary visceral metastases present (e.g., bone, liver, brain) AFP ≥ 10,000 ng/mL HCG ≥ 10,000 mIU/mL LDH ≥ 10 × upper limit of normal

AFP,  $\alpha$ -fetoprotein; HCG, human chorionic gonadotropin; LDH, lactate dehydrogenase.

**TABLE 35-5.** Germ Cell Tumor Risk Classification: International Consensus<sup>108</sup>

## MANAGEMENT OF CLINICAL STAGE I DISEASE

### SEMINOMA

#### Radiation Therapy

Radiation therapy remains the treatment of choice for patients with clinical stage I seminoma. The ipsilateral hemiscrotum does not require therapy unless gross tumor spillage has taken place. A randomized trial shows that a simple paraaortic portal excluding the ipsilateral iliac and pelvic nodes is as effective as the dog-leg portal in overall survival. Although more pelvic relapses may be seen, the toxicity appears less ([Fig. 35-3A](#)).<sup>109</sup> This more restricted portal may be considered a standard of care. Conventional fractionation for clinical stage I disease is 150 to 180 cGy/d for five sessions per week using high-energy linear accelerator beams to a total dose of 2500 to 3000 cGy. Elective, prophylactic radiation therapy to the mediastinum is contraindicated.<sup>110</sup> The contralateral testis should be shielded during treatment. Proper shielding results in an exposure less than 1% of the total dose. For left-sided primary testicular tumors, the left renal hilum must be encompassed. Treatment of pelvic lymph nodes is sometimes required for T4 primary tumors or for scrotal violations with tumor spillage. An involved spermatic cord margin at the internal ring

may also require field extension. The relapse rate within the irradiated portal after adequate radiation therapy is negligible. The systemic relapse rate, usually presenting as a supraclavicular mass, averages 4% to 5% ([Table 35-6](#)), and the death rate is under 2%.<sup>95,109,110,111,112,113 and 114</sup>

**FIGURE 35-3.** **A:** Para-aortic portal for clinical stage I seminoma. **B:** Contoured anterior and posterior radiation treatment fields for men with clinical stage IIA or IIB left testicular cancer. The diagonally shaded area is an individually made, 8-cm-thick Cerrobend block.

Stage	Patients	Relapse Sites (%)		
		Relapse (%)	Med/SCLN	Other ± Med/SCLN
Stage I <sup>95,109-114</sup>	1854	81 (4)	33 (41)	48 (59)
Stage IIA/B or nonpalpable <sup>110,112,113,116</sup>	206	14 (7)	3 (21)	11 (79)
Stage IIC or palpable <sup>110,112,113,117</sup>	90	43 (48)	12 (28)	31 (72)

SCLN, supraclavicular lymph node.

**TABLE 35-6.** Treatment of Seminoma with Radiation Therapy: Outcome and Relapse Patterns

### Observation

Although the dose of radiation therapy is low and the cure rate exceptionally high, long-term sequelae include the potential for an increased incidence of gastrointestinal neoplasms (see [Treatment Sequelae](#), later in this chapter).<sup>115,116</sup> As a consequence, surveillance has been studied as the only management after orchiectomy, to be followed by chemotherapy at relapse ([Table 35-7](#)).<sup>93,117</sup> The relapse rate is approximately 15%, but the median time to relapse is approximately 12 months, longer than that observed for nonseminomatous GCT. Moreover, relapses have occurred at intervals more than 5 years from diagnosis.<sup>93</sup> In addition, over 5 years of follow-up, surveillance is also approximately 30% less expensive.<sup>118</sup> Therefore, in the United States, observation for clinical stage I seminoma is not considered routine.

	Relapse	Patients	Relapse (%)	Median Time to Relapse (mo; range)	Def. of Recurrence (%)	Median Follow-Up (y)
Seminoma	95	121	11 (9)	11 (6-46)	4 (8)	31 mo
	117	202	3 (15)	12 (5-41)	1 (5)	15/30/75 annual/1/2 progression-free rate

**TABLE 35-7.** Observation in the Management of Clinical Stage I Germ Cell Tumors

### NONSEMINOMATOUS GERM CELL TUMORS

Nonseminomatous GCT is thought to be radioresistant, although one randomized trial reported no retroperitoneal relapse after radiation therapy.<sup>119</sup> However, radiation therapy plays no role in its initial management, since chemotherapy for subsequent relapse might be compromised and the systemic relapse rate is higher than for seminoma.<sup>119</sup> If a patient has clinical stage I disease at the conclusion of initial staging, the choice of management options depends on specific histologic features and the status of serum tumor marker concentrations.

### Retroperitoneal Lymph Node Dissection

Because of predictable lymphatic metastatic spread, the conventional approach to patients with clinical stage I nonseminomatous GCT has been the modified, bilateral RPLND ([Fig. 35-4A](#)). Adequate exposure for RPLND can be achieved through either a thoracoabdominal or transabdominal approach. The standard bilateral infrahilar RPLND template, which remains the standard against which therapeutic alternatives are judged, includes the precaval, paracaval, interaortocaval, preaortic, paraaortic, and common iliac lymph nodes bilaterally.

**FIGURE 35-4.** **A:** Standard modified bilateral retroperitoneal lymph node dissection. **B:** Modified nerve-avoiding template for right testicular tumors. **C:** Modified

nerve-avoiding template for left testicular tumors. L., left; R., right; v., vein.

Despite refinement of radiologic imaging, 15% to 40% of patients are clinically understaged. Retroperitoneal metastases are found in approximately 30% of patients judged preoperatively to be clinical stage I. Retroperitoneal relapse occurs in approximately 20% to 25% of patients on clinical stage I surveillance protocols. [120,121,122](#) and [123](#)

Infield recurrence is rare after a properly performed RPLND, which is a curative procedure, and surgical mortality is less than 1%. Major complications are unusual but can include pancreatitis, renal vascular or ureteral injuries, chylous ascites, aortic wall necrosis, bowel obstruction, pulmonary emboli, hemorrhage, and wound dehiscence. Minor complications include lymphocele, atelectasis, wound infection, and prolonged ileus. [124,125](#)

In the past, most patients undergoing bilateral RPLND experienced retrograde ejaculation and subsequent infertility. An improved understanding of the neuroanatomy of seminal emission and ejaculation, the pattern of retroperitoneal metastasis for right- and left-sided tumors, and surgical mapping studies [126,127](#) led to modification of infrahilar surgical boundaries and techniques.

**NEUROANATOMY.** Antegrade ejaculation requires coordination of three separate events: (1) closure of the bladder neck, (2) seminal emission, and (3) ejaculation. The sympathetic fibers that mediate seminal emission emanate primarily from the T-12 to L-3 thoracolumbar spinal cord. In the midretroperitoneum, after leaving the sympathetic trunk, the fibers converge toward midline and form the hypogastric plexus near the aortic bifurcation. From the hypogastric plexus, sympathetic fibers travel via pelvic nerves to innervate the vas deferens, seminal vesicles, prostate, and bladder neck. Ejaculation is mediated by combined autonomic and somatic innervation originating at the sacral and lumbar spinal cord levels. Sympathetic stimulation tightens the bladder neck, while pudendal somatic innervation from S-2 to S-4 causes relaxation of the external urethral sphincter and rhythmic contraction of bulbourethral and perineal muscles. Preservation of ejaculatory capacity requires preservation of paravertebral sympathetic ganglia and their fibers, which converge at the superior hypogastric plexus around the aortic bifurcation. Sympathetic chains and postganglionic sympathetic fibers can be prospectively identified, meticulously dissected, and preserved.

**NERVE-SPARING RETROPERITONEAL LYMPH NODE DISSECTION.** Nerve-sparing RPLND may be of two types: nerve-dissecting or nerve-avoiding. Despite pathologic stage II disease in patients selected for this procedure, recurrences in the retroperitoneum are rare. [128,129](#) and [130](#) Modified, nerve-avoiding RPLND templates were designed to avoid the hypogastric plexus and contralateral sympathetic fibers responsible for ejaculation in clinical stage I or IIA disease ( [Figs. 35-4B](#) and [C](#)). These template dissections do not attempt to identify specific nerve fibers. Rather, their design minimizes trauma to the hypogastric plexus by limiting the contralateral dissection to the level above the takeoff of inferior mesenteric artery. This method avoids transection of the contralateral nerves and results in preservation of ejaculation rates in approximately 50% to 80% of patients. [128,131,132](#) These rates are higher for a right-sided, nerve-avoiding template dissection compared with modified, left-sided dissection.

Preservation of ejaculation appears to be more successful when nerves are prospectively identified and spared, compared with modified template dissection, although duration of operation is usually longer for the former. With nerve dissection, approximately 95% of patients are left with normal ejaculatory status postoperatively. Regardless of technique, retrograde ejaculation is a potential risk with any RPLND; therefore, preoperative sperm banking is recommended.  $\alpha$ -Adrenergic drugs such as ephedrine, pseudoephedrine, and imipramine occasionally promote antegrade ejaculation in a subset patients who are anejaculatory following RPLND. [133](#) The low number of reported such cases suggests substantial case selection, and many patients do not respond to  $\alpha$ -adrenergic stimulation. Transrectal electroejaculation provides an option for patients who fail sympathomimetic agents. [134](#)

Several investigators have reported that laparoscopic retroperitoneal lymph node dissection (LRPLND) for clinical stage I nonseminomatous testicular cancer is technically feasible. [135](#) After a lengthy learning curve, postoperative morbidity, operative blood loss and length of hospital stay may be significantly less compared with open surgery. [136](#) However, several important points must be emphasized. First, surgical templates are limited to the ipsilateral side with omission of interaortocaval dissection for left-sided tumors. [136](#) Second, therapeutic efficacy is difficult to assess, since all patients with retroperitoneal disease, regardless of tumor volume, were treated with postoperative chemotherapy, including two patients with microscopic metastases who received three cycles of cisplatin, etoposide, bleomycin (BEP). [136,137](#) Finally, available follow-up is short. Late relapses are potentially catastrophic with inadequate control of the retroperitoneum. [138,139](#) In patients with clinical stage I disease experiencing a late relapse (greater than 2 years after initial treatment), the retroperitoneum was the most common site of recurrence. [138](#) Furthermore, 11 of 12 patients with low-volume retroperitoneal disease, and three with high-volume disease had received adjuvant cisplatin-based chemotherapy. [138](#) Therefore, LRPLND is not routine and should only be considered by those who are experts.

### **Observation**

The driving forces for observation studies in clinical stage I patients were the infertility resulting from RPLND (due to retrograde ejaculation), the frequent absence of therapeutic benefit (i.e., orchiectomy was a curative procedure or systemic disease occurred in the absence of retroperitoneal disease), and the ability of cisplatin-based chemotherapy to cure systemic disease. Approximately 25% of patients with T1N0M0 disease and normal serum tumor markers relapse during surveillance (see [Table 35-7](#)). [121,122](#) and [123,140,141](#) A higher likelihood of retroperitoneal, systemic, or both kinds of relapse is associated with T2 to T4 tumors (T2 now includes lymphatic or vascular invasion). Some studies suggest that a high percentage of embryonal carcinoma also predicts a higher likelihood of relapse. [141,142](#) However, the correlation between lymphatic and vascular invasion and the presence of embryonal carcinoma is high, and general agreement on histologic criteria for relapse *independent* of vascular or lymphatic invasion does not exist. The retroperitoneum is the site of relapse in approximately two-thirds of patients, the lungs or markers alone in approximately one-third, and other visceral sites much less frequently. With observation, there is a slightly higher likelihood that both chemotherapy and modified bilateral RPLND ( *not* nerve-sparing) will be needed in order to achieve the same cure rate.

Patients with clinical stage I nonseminomatous GCT with a T1 tumor and serum tumor markers that are normal or declining at half-life should be offered both surgical and observation options. If RPLND is chosen, it should be of the nerve-sparing type, thereby preserving ejaculatory capacity in the majority of patients. Frequent CT scans of the abdomen are unnecessary once an RPLND has been performed. If surveillance is chosen, then a possibly unnecessary RPLND is avoided, limiting therapy to orchiectomy alone in at least 70% of the patients (i.e., those who never relapse). Patient compliance cannot be overemphasized. A physical examination, chest radiography, and determinations of AFP and HCG levels are required at monthly intervals in the first year, every other month in the second year, quarterly in the third year, and less frequently thereafter. An abdominal CT scan is required quarterly in the first year, every 4 months in the second year, and every 6 months beginning in the third year. Visits and evaluations should be annual in the fifth year and beyond. In both situations, relapses are extremely uncommon after two years and have only rarely been observed after 5 years.

### **Chemotherapy**

There are limited data regarding chemotherapy as initial treatment of clinical stage I disease when the risk of retroperitoneal disease is high. In three reports of patients receiving two cycles of cisplatin-based chemotherapy, fewer than 5% relapsed and approximately 1% died of GCT. [143,144](#) and [145](#) Although this approach avoids RPLND and the duration of therapy is brief, these patients are exposed to the transient (e.g., myelosuppression), permanent (e.g., neuropathy), and delayed (e.g., Raynaud's phenomenon, acute leukemia) toxicities of chemotherapy.

Rarely, patients with *clinical stage I disease* are found to have persistently elevated serum concentrations of AFP, HCG, or both after orchiectomy. If these markers increase or plateau at an elevated level after a period of observation, metastatic disease is present. This group of patients should receive initial systemic chemotherapy, since the disease is often not limited to the retroperitoneum. [146,147](#) An RPLND should be done only if clinical studies at the conclusion of therapy demonstrate new disease.

## **MANAGEMENT OF CLINICAL STAGE II (Low Tumor Burden)**

### **SEMINOMA**

Low-tumor-burden stage II seminoma includes all patients with retroperitoneal metastases measuring less than 5 cm in maximum transverse diameter (clinical stages

IIA and IIB; see [Table 35-6](#)).<sup>110,112,113,148</sup> Radiation therapy is the treatment of choice for most patients with these stages of disease. A dog-leg radiation portal is used. Fractionation is the same as that of patients with clinical stage I disease, except that a boost of approximately 500 to 750 rads is administered to involved lymph nodes (see [Fig. 35-3B](#)). Relapses occur in from 5% to 15%, and death from seminoma is rare. Prophylactic mediastinal radiation therapy is not indicated, since relapses solely in the anterior or posterior mediastinum are infrequent (see [Table 35-6](#)). The combination of supradiaphragmatic and infradiaphragmatic radiation therapy results in chemotherapy intolerance, a high rate of treatment-related mortality due to chemotherapy, and a greater than expected death rate from disease due to the inability to administer adequate doses of chemotherapy.<sup>149</sup>

There are exceptions to the need for radiation therapy for clinical stage I and nonbulky clinical stage II seminoma. (1) A *horseshoe kidney* is a contraindication to retroperitoneal radiation therapy due to the high likelihood of radiation-induced renal failure. Observation is preferred in clinical stage I, and primary chemotherapy is the treatment of choice for clinical stage II. (2) Patients who develop a *second metachronous testicular GCT* and who have undergone a prior RPLND or received radiation therapy should be observed frequently if clinical stage I disease is present and undergo primary chemotherapy in the unlikely event that the disease is confined to residual retroperitoneal lymph nodes. (3) *Inflammatory bowel disease* may also be a contraindication to radiation therapy. A discussion with an experienced radiation oncologist is indicated under such circumstances. If the decision is not to administer radiation therapy, then the management policies noted previously for patients with a *horseshoe kidney* should be followed.

### NONSEMINOMATOUS GERM CELL TUMORS

Low-tumor-burden clinical stage II nonseminomatous GCT encompasses disease ipsilateral to the primary tumor, at or below the renal hilum, not associated with tumor-related back pain, and limited to the primary landing zone. The presence of supra hilar or retrocrural lymphadenopathy, bilateral retroperitoneal nodal metastases, back pain, or contralateral lymph nodes (even if the ipsilateral lymph nodes do not appear to be involved) generally implies unresectable disease (e.g., tumor-associated back pain) or a higher likelihood of metastatic disease (supra hilar and retrocrural adenopathy), and initial chemotherapy is preferred. Ipsilateral solitary lymph nodes less than 3 cm are best handled by RPLND. Lymph nodes between 3 to 5 cm, even if solitary, may be associated with more extensive disease than can be detected on abdominal CT scan.

#### Retroperitoneal Lymph Node Dissection

The standard approach to patients with clinical stage IIA and some IIB tumors has been RPLND. The priority is to perform a definitive therapeutic operation, following which there is a minimum likelihood of infield recurrence. Margins of resection should not be compromised in an attempt to maintain ejaculatory function. Nerve-sparing dissection may be possible, depending on the location and volume of disease.

An important exception to this approach may be patients with clinical stage IIA or IIB and elevated serum tumor markers. Investigators at MSKCC reported that elevated serum tumor markers pre-RPLND were the most significant predictor for (1) relapse in patients with low-volume (pN1) retroperitoneal disease who did not receive adjuvant chemotherapy, and (2) for persistent nonseminomatous GCT (usually persistent marker elevation) despite complete resection of high-volume (pN2, pN3) retroperitoneal disease.<sup>150</sup> Elevated serum tumor markers usually reflect systemic disease, and these patients should be considered for primary cisplatin-based chemotherapy. However, for patients with apparent low-volume disease and normal markers, RPLND is often therapeutic and cost effective.<sup>151</sup>

#### Adjuvant Chemotherapy

Surveillance is a treatment choice for compliant patients with fewer than six involved nodes and none greater than 2 cm ([Table 35-8](#)).<sup>98,101,102,152,153</sup> Surveillance requires close monitoring, and chemotherapy is reserved for patients who relapse. Patient compliance, psychological factors, age, or other issues may make adjuvant chemotherapy the preferred choice in rare patients. Three or four cycles of cisplatin-based therapy are required at relapse according to disease status at that time.

Reference	Tumor Size	Patients	Relapse (%)
98	Metastatic involvement only	6	1 (17)
101	<4 nodes; no node >2 cm; no extranodal extension	39	3 (8)
102	<4 nodes; no node >2 cm; no extranodal extension	47	11 (24)
152	Solitary node <2 cm; <4 nodes no node >2 cm; no extranodal extension	49	1 (2)
153	<4 nodes; no node >2 cm; no extranodal extension	30	11 (37)
Total		171	34 (20)

\*Excluded patients treated with chemotherapy with and without additional agents, but did not include cisplatin.

**TABLE 35-8.** Pathologic Stage II Nonseminomatous Germ Cell Tumors: Surveillance for Minimal Nodal Involvement at Retroperitoneal Lymph Node Dissection

Adjuvant chemotherapy remains a strong consideration in patients when greater than or equal to six nodes are involved, any node is greater than 2 cm, or there is extranodal extension. In the late 1970s, treatment programs based on cisplatin, vinblastine, and bleomycin were given as adjuvant therapy following RPLND, and nearly 100% of patients survived relapse free.<sup>98,154</sup> Considerable treatment-related morbidity was associated with these regimens, prompting efforts to reduce toxicity. Two cycles of cisplatin-based chemotherapy are nearly always effective in preventing relapse ([Table 35-9](#)).<sup>99,102,154,155</sup> and <sup>156</sup> A randomized trial showed that observation with standard treatment at relapse and two cycles of adjuvant chemotherapy had equivalent survival.<sup>102</sup> Etoposide has replaced vinblastine in adjuvant regimens. A more recent study showed that etoposide plus cisplatin alone is adequate, and that bleomycin is unnecessary as part of adjuvant therapy.<sup>156</sup>

Reference	Stage <sup>a</sup>	Regimen	Cycle	Patients (N, %)	Patients Alive and Relapse Free (%)	Median Follow-Up
98	IIA, IIB	VEB	2	26 (98)	18	31

156	IIA, IIB	EP	2	39 (98)	38	31

EP, etoposide + cisplatin; VE, vinorelbine + etoposide; VEB, vinorelbine + etoposide + bleomycin; VEB, vinorelbine + etoposide + bleomycin; VEB, vinorelbine + etoposide + bleomycin + cisplatin; PEB, cisplatin + etoposide + bleomycin; VEB, vinorelbine + etoposide + bleomycin; VEB, vinorelbine + etoposide + bleomycin + cisplatin.

<sup>a</sup>For certain pathologic staging is used for these trials with groupings.

The patients who relapsed on adjuvant therapy are never treated adjuvant chemotherapy.

**TABLE 35-9.** Cisplatin -Containing Adjuvant Chemotherapy Trials

### IDENTIFICATION OF RELAPSE

Careful periodic follow-up after locoregional therapy is required after radiation therapy for clinical stage I, IIA, and IIB seminoma during observation for clinical stage I nonseminomatous GCT, and after RPLND without adjuvant chemotherapy. After radiation therapy, a chest radiograph, determination of serum concentrations of AFP and HCG, and a physical examination should be performed every 6 weeks to 3 months in the first year, every 3 to 4 months in the second year, and less frequently thereafter. An abdominal CT scan should be done at the conclusion of radiation therapy. Following RPLND, a chest radiograph, determinations of serum concentrations of AFP and HCG, and a physical examination are required every 1 to 2 months in the first year, every 2 to 3 months in the second, and less frequently

in the third year and beyond, with annual visits to detect late relapse and second primary tumors after the fifth year. Provided that follow-up has been adequate, virtually all of these patients relapse with low-volume disease and are cured with chemotherapy.

## MANAGEMENT OF STAGE II AND STAGE III DISEASE (HIGH TUMOR BURDEN)

High-burden disease includes all patients with extensive or bulky retroperitoneal, supradiaphragmatic nodal or visceral metastases, including patients with stage IIC seminoma. This last group has a high relapse rate with radiation therapy alone (see [Table 35-6](#)).<sup>110,111,148,157</sup> Cisplatin-based chemotherapy cures 70% to 80% of those patients. Early clinical trials developed effective regimens such as cisplatin, vinblastine, and bleomycin<sup>158</sup> and cisplatin, vinblastine, bleomycin, dactinomycin, and cyclophosphamide,<sup>91</sup> eliminated maintenance therapy,<sup>159</sup> and replaced vinblastine with etoposide.<sup>158</sup> Adjunctive surgery was shown to be essential to achieving a disease-free state. Although the majority of patients was cured, significant adverse events were observed, including treatment mortality, myelosuppression, pulmonary fibrosis, Raynaud's phenomenon, coronary artery disease, nephrotoxicity, and intestinal ileus.<sup>158,160,161</sup> Good- and poor-risk allocation algorithms were developed and clinical trials performed to address issues represented by different risks of treatment failure. The commonly used standard treatment regimens are summarized in [Table 35-10](#).

<b>A. Previously untreated, good risk</b>	
1.	Etoposide, 100 mg/m <sup>2</sup> IV daily × 5 days Cisplatin, 20 mg/m <sup>2</sup> IV daily × 5 days Four cycles administered at 21-day intervals
2.	Etoposide, 100 mg/m <sup>2</sup> IV daily × 5 days Cisplatin, 20 mg/m <sup>2</sup> IV daily × 5 days Bleomycin, 30 U IV weekly on days 2, 9, and 16 Three cycles administered at 21-day intervals
<b>B. Previously untreated, poor risk</b>	
	Etoposide, 100 mg/m <sup>2</sup> IV daily × 5 days Cisplatin, 20 mg/m <sup>2</sup> IV daily × 5 days Bleomycin, 30 U IV weekly on days 2, 9, and 16 Four cycles administered at 21-day intervals
<b>C. Previously treated, first-line salvage therapy</b>	
	Ifosfamide, 1.2 g/m <sup>2</sup> IV daily × 5 days Mesna, 400 mg/m <sup>2</sup> IV every 8 hours × 5 days Cisplatin, 20 mg/m <sup>2</sup> IV daily × 5 days plus either Vinorelbine, 0.11 mg/kg IV days 1 and 2 or Etoposide, 75 mg/m <sup>2</sup> IV daily × 5 days

**TABLE 35-10.** Commonly Used Chemotherapy Regimens for Metastatic Germ Cell Tumors

## GOOD-PROGNOSIS GERM CELL TUMOR

Good-risk patients are those with a high likelihood of cure. All good-risk allocation criteria identify patients with a high probability of complete response. Response proportions range from 88% to 95% with favorable survival distributions.<sup>107</sup> Since the advent of good-risk stratification, trials have focused on eliminating bleomycin from treatment regimens, reducing the number of cycles of therapy, and substituting carboplatin for cisplatin ([Table 35-11](#)).<sup>162,163,164,165,166,167</sup> and <sup>168</sup>

Regimen	Good-Risk Criteria	Regimen (Cycles)	Complete Response (%)	Durable Response (%)	Conclusion
162	Indiana	BEP (3)	87	92	Regimen equivalent
		BEP (4)	88	92	
163	MARCC	VABEP (4)	86	88	Regimen equivalent
		EP (4)	85	85	
164	EORTC	BEP (3)	85	85	BEP superior; survival later
		EP (4)	87	85	
165	Indiana	BEP (3)	84	88	EP (3) inferior
		EP (4)	86	88	
166	MARCC	CEP (4)	80	81	CE inferior
		EP (4)	88	78	
167	MRC/EORTC	CEB (3)	87	77	CEB inferior
		BEP (3)	84	85	
168	GTEG	BEP (3)	82	—	Regimen equivalent
		EP (4)	81	—	

B, Bleomycin; C, carboplatin; E, etoposide; MARCC, Memorial Sloan-Kettering Cancer Center; MRC, Medical Research Council; MRC/EORTC, Memorial Sloan-Kettering Cancer Center/EORTC; CEP, carboplatin, etoposide, and bleomycin; VABEP, vinorelbine, etoposide, and bleomycin; VABEP + cyclophosphamide.

Response defined as follows: 1, cure; 2, partial.

**TABLE 35-11.** Randomized Trials in Good-Prognosis Germ Cell Tumors

A randomized trial performed by Indiana University examined the duration of therapy<sup>162</sup> in 184 patients who received either four cycles of BEP administered over 12 weeks or three cycles administered over 9 weeks. Bleomycin was discontinued for any clinically evident pulmonary toxicity. A disease-free status was achieved by 98% of patients receiving three cycles, and 92% survived, compared with a 97% disease-free status and 92% survival among patients treated with four cycles.

Three randomized clinical trials have evaluated the elimination of bleomycin from regimens containing etoposide and cisplatin. Etoposide and cisplatin (EP) for four cycles was compared with a five-drug, bleomycin-containing regimen (cisplatin, vinblastine, bleomycin, dactinomycin, and cyclophosphamide) in 164 evaluable patients and was found to be therapeutically equivalent.<sup>163</sup> A subsequent analysis evaluated late relapse in patients receiving EP, and none were observed with a median follow-up of 5 years.<sup>169</sup> A randomized trial of cisplatin and etoposide with (BEP) and without bleomycin (EP) was performed by the EORTC in 395 patients. The dose of etoposide in this study was 360 mg/m<sup>2</sup> per cycle, with the dose modifications for thrombocytopenia in contrast to 500 mg/m<sup>2</sup> per cycle without dose attenuations in American trials. The bleomycin arm was more toxic, including Raynaud's phenomenon in 8% of patients and two patients who died of pulmonary toxicity. Complete response was lower in EP patients (87% vs. 95%,  $P = .0075$ ), but no differences were observed in relapses, time to progression, or survival with over 7 years of follow-up.<sup>164</sup> It can be concluded from this study that bleomycin cannot be deleted from good-risk therapy when European doses of etoposide are used.

A French trial directly compared three cycles of BEP to four cycles of EP in 250 patients. This trial used standard doses of bleomycin (30 U/week days 1, 8, and 15 of each cycle) and an etoposide dose of 100 mg/m<sup>2</sup> on days 1 through 5 (total 500 mg/m<sup>2</sup>/cycle) in both arms of the trial.<sup>168</sup> The criteria for good risk were those developed by the Institute Gustave Roussy; 97% of patients were good-risk by the IGCCCG criteria. With a median follow-up of 24 months, the survival was similar in both arms [97% for BEP (three cycles) vs. 96% for EP (four cycles)]. Finally, three cycles of BEP were compared with three cycles of EP in 166 patients.<sup>165</sup> The number of patients with persistent or progressive carcinoma, relapse or viable cancer at postchemotherapy surgery was the end point. An interim analysis revealed an increased number of adverse events in the two-drug arm, resulting in early termination of the study.

Two randomized trials have evaluated the substitution of carboplatin for cisplatin. In a multiinstitutional trial of 265 patients, four cycles of carboplatin plus etoposide were compared with four cycles of EP.<sup>166</sup> Although the proportions of complete response did not differ significantly, patients receiving carboplatin plus etoposide had an inferior event-free (incomplete response or relapse) ( $P = .02$ ) and relapse-free ( $P = .005$ ) survival, and significantly worse myelosuppression requiring platelet transfusions and hospitalization for granulocytopenic fever. In subset analysis, carboplatin plus etoposide was inferior to EP in both seminoma and nonseminoma patients. The Medical Research Council and EORTC conducted a confirmatory, randomized trial comparing carboplatin, etoposide, and bleomycin with BEP in 598 patients. Bleomycin was administered at 30 U once every 3 weeks. Complete response was greater in patients allocated to BEP (94% vs. 87%,  $P = .009$ ). Survival was inferior in carboplatin, etoposide, and bleomycin ( $P = .003$ ), with BEP patients experiencing a 3-year survival of 97% compared with 90% for carboplatin, etoposide, and bleomycin patients. Conventional dose carboplatin therapy is inferior to cisplatin therapy in GCT patients.

Although good-risk studies differ in eligibility criteria, an efficacy threshold has been reached. Cisplatin-based therapy (greater than or equal to 100 mg/m<sup>2</sup>/cycle) is required; there is no role for carboplatin-based therapy. Four cycles of EP and three cycles of BEP using a 500 mg/m<sup>2</sup> cumulative dose of etoposide per course are therapeutically equivalent in randomized comparison.<sup>168</sup>

## POOR- (AND INTERMEDIATE-) RISK GERM CELL TUMOR

Between 20% and 30% of patients with advanced GCT fail to achieve durable, complete response to first-line, cisplatin-containing chemotherapy. In general, clinical trials for the poor-risk subgroup attempt to improve efficacy by evaluating regimens that have been effective in salvage therapy, substituting a new agent for an existing one or incorporating a dose-intensive regimen. Numerous studies have evaluated the importance of increased serum tumor marker concentrations, number of metastatic sites, size of specific tumor site, site of metastasis (e.g., liver), site of primary tumor (extragonadal or gonadal), and histology<sup>104,105</sup> in an attempt to identify poor-risk patients. Unlike good-risk criteria, the choice of poor-risk selection algorithm is critical. If the criteria are insufficiently stringent, then a proportion of good-risk patients will be treated and unnecessarily exposed to the enhanced toxicity of intensive therapy. In addition, the response proportion will be inflated, making therapy appear more effective than is warranted. The lack of uniform predictive criteria was addressed by the IGCCCG criteria.<sup>108</sup> Durable complete responses occur in 75% and 40% of intermediate- and poor-risk patients, respectively. Because the optimal chemotherapy regimen has not been determined, clinical trials designed to cure an increased proportion of patients remain a priority, and such patients should be treated on clinical trials.

### Conventional Dose Therapy

The results of randomized studies conducted in poor-risk patients are shown in [Table 35-12](#).<sup>106,158,170 and 173</sup> A randomized trial comparing BEP to cisplatin, vinblastine, and bleomycin showed that etoposide-containing therapy was superior to vinblastine-based therapy in the subset of poor-risk patients (Indiana advanced disease class).<sup>158</sup> One randomized trial suggested that a regimen with cisplatin, 200 mg/m<sup>2</sup>, etoposide, vinblastine, and bleomycin was superior to cisplatin, 100 mg/m<sup>2</sup>, vinblastine, and bleomycin.<sup>170</sup> A subsequent randomized trial showed that BEP, 200 mg/m<sup>2</sup>, had equal efficacy but greater toxicity than standard BEP.<sup>171</sup>; the apparently improved efficacy of cisplatin, 200 mg/m<sup>2</sup>, etoposide, vinblastine, and bleomycin was attributable to etoposide. The role of ifosfamide was tested in a randomized trial; there was no therapeutic benefit of ifosfamide, cisplatin, and etoposide over BEP, and toxicity with ifosfamide, cisplatin, and etoposide was more severe.<sup>174</sup> These results paralleled the absence of survival benefits among consecutive phase II trials of conventional dose, cisplatin-based therapy conducted at MSKCC.<sup>91,175</sup> Therefore, in poor-risk patients, four cycles of BEP remain the standard regimen with which investigational regimens should be compared. Likewise, in intermediate-risk patients by IGCCCG criteria, four cycles of BEP is considered standard therapy.

Reference	Critera	Treatment	No. of Patients	% Complete Response	% Durable	Benefit Over Standard Arm
106	IGCCCG	BEV	102	75	35	Yes
158	Indiana	BEV	102	75	35	Yes

**TABLE 35-12.** Results of Randomized Trials in Patients with Poor-Risk Germ Cell Tumors

### High-Dose Therapy

The success of high-dose, carboplatin-containing chemotherapy in the treatment of patients with refractory disease led to its incorporation into initial therapy. Stringent selection criteria and rapid hematopoietic reconstitution are required to minimize treatment-related morbidity and mortality.

Two pilot studies clarify high-dose therapy requirements in this setting. In these studies conducted at MSKCC, 58 poor-risk patients were first identified based on clinical presentation, and further selected to receive high-dose therapy based on the clearance of AFP, HCG, or both from serum during standard induction therapy. If the half-life was prolonged, treatment was changed to two-drug, high-dose therapy (etoposide plus carboplatin).<sup>176,177</sup> Hematopoietic reconstitution was rapid, only one treatment-related death was observed, and an improved survival trend was observed when this approach was compared with historic poor-risk experience with conventional dose, cisplatin-combination therapy.<sup>176,177</sup>

One randomized trial of dose-intensified therapy failed to show a therapeutic benefit.<sup>178</sup> Greater treatment-related morbidity and mortality and lower survival were observed in the high-dose therapy arm. However, the trial was flawed because of a lower dose intensity of cisplatin and a lower total dose of cisplatin in the high-dose arm. Since cisplatin, 200 mg/m<sup>2</sup>, is not superior to cisplatin 100 mg/m<sup>2</sup>,<sup>171</sup> the choice of cisplatin over carboplatin did not permit an adequate dose escalation to overcome resistance.

An ongoing national randomized trial is comparing four cycles of BEP to two cycles of BEP followed by two cycles of three-drug, high-dose therapy in poor- and intermediate-risk patients, and patients should participate if possible.

## MANAGEMENT OF RESIDUAL DISEASE

Adjunctive surgical resection of residual disease after chemotherapy is an integral part of the comprehensive management of all patients with advanced GCT.<sup>179,180</sup> In general, surgical exploration is indicated when serum tumor marker concentrations have normalized and residual radiographic abnormalities are present. Increased serum concentrations of AFP and HCG after chemotherapy are often characterized by unresectable, viable GCT, and salvage chemotherapy is usually recommended for these patients.<sup>179</sup> Necrotic debris and fibrosis, teratoma, and viable carcinoma can be found at any resected site. Since the relapse rate of patients with necrosis and fibrosis or mature or immature teratoma is 5% to 10% following complete resection of residual disease at all sites, no further therapy is required.<sup>181,182,183 and 184</sup> If viable GCT is present at any site but all disease is completely resected, 30% to 50% of patients relapse following two additional cycles of therapy. Survival is poor among those who do not receive additional chemotherapy.<sup>183,185</sup>

### Retroperitoneum

**NONSEMINOMATOUS GERM CELL TUMORS.** In the retroperitoneum, necrosis and fibrotic debris make up 45% to 50% of pathologic findings, teratoma another 35%, and viable GCT the remaining 15% to 20% ([Table 35-13](#)).<sup>181,183,184,186,187,188 and 189</sup> A bilateral RPLND is required, and retrograde ejaculation is the principal long-term consequence.

Reference	No. of Patients	Necrosis	Teratoma	Carcinoma
181	122	57	48	17
183	80	35	35	12
184	78	51	22	5
186	73	25	32	16
189	556	250	236	70
Total	909	418 (46%)	371 (41%)	120 (13%)

**TABLE 35-13.** Pathologic Findings in the Retroperitoneum after Chemotherapy in Patients with Advanced Germ Cell Tumors

There is general agreement over the need to resect all sites of measurable residual disease. Since nearly 50% of resected residual retroperitoneal tumors have only necrosis and fibrosis, many studies have attempted to predict their presence. Among 80 patients with sequential CT scans before and after chemotherapy at Indiana University, neither viable GCT nor teratoma was found among 15 patients if no teratoma was present in the primary tumor and the retroperitoneal tumor volume (not diameter) by CT scan had decreased by less than or equal to 90%.<sup>183</sup> Conversely, teratoma in the primary tumor predicts the presence of teratoma or viable GCT in the postchemotherapy resection despite reduction in the original tumor mass.<sup>181,183,184</sup>

Other data suggest that RPLND may be needed regardless of postchemotherapy size. The definition of a normal CT scan has not been consistent. Lymph node diameters of less than or equal to 10 mm,<sup>190</sup> less than or equal to 15 mm,<sup>191</sup> and less than or equal to 20 mm<sup>192</sup> have been reported to represent normal CT scans after chemotherapy. Fossa et al. reported that 12 of 37 (30%) patients with normal postchemotherapy serum tumor marker concentrations and CT scan (all nodes less than or equal to 10 mm) had teratoma, and one patient had viable GCT.<sup>191</sup> Toner et al. reported that 8 of 39 (21%) patients with residual masses less than 1.5 cm had viable residual malignancy or teratoma.<sup>181</sup> CT criteria alone are not sufficiently reliable to distinguish viable tumor or teratoma from necrosis. PET scanning has been studied as a technique to detect necrosis and fibrosis, but teratoma was not reliably predicted.<sup>81,82</sup>

The decision to recommend postchemotherapy surgery depends on the frequency of viable carcinoma, the biologic potential of teratoma, and the morbidity of RPLND. If viable carcinoma is present, it is partially drug-resistant and will progress. The cure rate of relapsed disease to ifosfamide-based therapy is approximately 25%.<sup>193,194</sup> and <sup>195</sup> If viable disease is completely resected and two additional cycles of cisplatin-based therapy are administered, the cure rate is 50% to 70%.<sup>181,185</sup> Teratoma may be found in metastatic sites despite its absence in the primary tumor. Toner et al. reported that among 75 patients without teratoma in the primary tumor who underwent resection of a residual mass, 25 (33%) had teratoma at a metastatic site.<sup>181</sup> Mature teratoma may grow rapidly (*growing teratoma syndrome*),<sup>196,197</sup> become unresectable, or cause vascular or ureteral obstruction.<sup>198</sup> Malignant transformation of teratoma (i.e., the development of non-germ cell malignant elements such as sarcoma or carcinoma) is present in a minority of resected retroperitoneal teratoma.<sup>37,199</sup> These are clonal in origin with the original GCT and do not represent second primary cancers.<sup>200,201</sup> and <sup>202</sup> Surgery is the only therapy (except for leukemia) for this subset of tumors that would otherwise recur and fail to respond to additional chemotherapy. Late local recurrence (defined as greater than 2 years after therapy) of both teratoma and viable GCT is more common when teratoma is present at a metastatic site,<sup>139,203,204</sup> underscoring the need for initial complete surgical resection. Late recurrences of malignant GCT are often chemotherapy resistant, and chance of survival is poor.<sup>203,204,205,206,207</sup>

The complication rate of RPLND following chemotherapy is higher than that of primary RPLND.<sup>124,208</sup> Large-volume residual disease, postchemotherapy desmoplastic reaction, prior exposure to bleomycin, and more extensive retroperitoneal dissection increase the technical demands of the procedure. Careful monitoring of intraoperative and postoperative oxygen concentration (particularly in patients who have received bleomycin), meticulous fluid management with strict replacement criteria, and an emphasis on colloid rather than crystalloid have reduced pulmonary toxicity and nearly eliminated perioperative death from acute respiratory distress syndrome.<sup>179</sup>

Ejaculatory dysfunction and sterility are common sequelae of the standard, modified bilateral RPLND, particularly after primary chemotherapy.<sup>124</sup> Nerve-avoiding RPLND templates are not acceptable alternatives for residual disease after chemotherapy, since there is a higher risk of disease in sites outside the limits of the nerve-avoiding template in patients with a prior high-volume disease.<sup>209</sup> However, in selected patients without severe postchemotherapy desmoplastic changes, it is occasionally technically possible to identify individual sympathetic nerves. Wahle et al. reported that among 296 patients who underwent postchemotherapy RPLND, a select subset of 40 (13.5%) patients underwent nerve-dissecting RPLND after chemotherapy.<sup>210</sup> The majority of these 40 patients had relatively low-volume unilateral adenopathy before induction chemotherapy. With a minimum of 1-year follow-up, 34 of 38 (89%) patients reported normal ejaculation; nine patients reported ten pregnancies. There were no infield recurrences.<sup>210</sup> The best oncologic approach in patients requiring postchemotherapy RPLND remains a bilateral dissection with a nerve-sparing approach limited to a minority of patients.

In summary, all residual retroperitoneal disease should be resected. The need for postchemotherapy RPLND is controversial when the postchemotherapy CT scan, usually of the retroperitoneum, is interpreted as normal. Multivariate analyses show that approximately 20% of patients predicted to have necrosis (fibrosis) have either teratoma or viable GCT.<sup>181,211</sup> No single criterion or combination of criteria predict a negative pathology with sufficient accuracy to eliminate the risk of residual teratoma or viable GCT and obviate postchemotherapy RPLND. The risks of residual teratoma must be weighed against the growth and metastatic potential of viable GCT and the morbidity of the procedure.

**SEMINOMA.** The approach to the patient with pure seminoma and a postchemotherapy residual mass is controversial. Two important features distinguish seminoma from nonseminomatous tumors. First, teratoma in the residual mass is rare. Second, a complete RPLND following chemotherapy is often not technically feasible, secondary to the severe desmoplastic reaction and obliteration of tissue planes.<sup>212</sup> Consequently, perioperative morbidity has been reported to be higher for seminoma than for nonseminomatous GCT.<sup>213,214</sup>

A number of studies evaluated this issue in seminoma patients.<sup>149,212,213,214,215,216</sup> and <sup>217</sup> Loehrer et al. reported that among 62 patients, 13 underwent attempted surgical excision of residual disease and three (23%) had residual malignancy.<sup>149</sup> The size of residual mass was not considered predictive. Fossa et al. reported 39 patients, 15 of whom received prior radiation therapy.<sup>214</sup> Twelve patients underwent exploration for residual disease; three (25%) had viable seminoma. One postoperative death due to pulmonary toxicity was observed. In a cohort of 45 patients, the size of residual mass was highly correlated with the site of the initial tumor but was not associated with the risk of recurrence.<sup>212</sup> These data support the notion that the majority of patients with persistent radiographic abnormalities do not have residual malignant disease.

The experience at MSKCC differed. Bilateral RPLND was not usually possible or attempted; surgery was often limited to resection of the residual mass or multiple biopsies of the residual radiographic abnormality. In an initial cohort of 104 patients, 8 of 30 (27% of patients with a residual mass greater than 3 cm) relapsed or had residual seminoma.<sup>217</sup> No postoperative deaths occurred. Conversely, among 74 tumors measuring less than 3 cm in diameter, no viable tumor was identified, and only two patients (3%) relapsed at the site of residual disease. Neither of these had undergone operation. Fewer tumors greater than 3 cm were present among patients treated after 1987 compared with those treated before 1987. Those investigators concluded that resection or biopsy of the residual masses greater than or equal to 3 cm was preferable to observation. If viable seminoma was documented, additional therapy was required.<sup>217</sup>

In summary, residual masses less than 3 cm should be observed. Controversy exists regarding the minority of patients with a residual mass measuring greater than or equal to 3 cm. Radiation therapy to the area of residual disease is feasible, but approximately 75% of patients would receive it unnecessarily and it did not appear to reduce the likelihood of recurrence.<sup>212</sup> Careful observation is an alternative, but relapse with subsequent ifosfamide-based salvage chemotherapy has a low cure rate (see [Prognostic Factors: Salvage Chemotherapy](#), later in this chapter). Surgical resection that can identify residual disease and direct immediate therapy has low morbidity given modern techniques and perioperative care.<sup>217</sup> All factors (e.g., size, site, patient age) must be considered in making this therapeutic decision.

### **Lung and Mediastinal Resections**

Resection of residual disease at sites other than the retroperitoneum is less controversial. There is a higher likelihood of teratoma, viable cancer at nonretroperitoneal sites, or both, with the highest likelihood seen in the mediastinum, probably because residual disease in the mediastinum is usually associated with a mediastinal primary tumor.<sup>181</sup> Size of the pretreatment and the postchemotherapy pulmonary nodule does not correlate with final histology. Different histologies may also be present in each lung. Therefore, residual intrathoracic disease should always be resected.<sup>218,219</sup>

### **Other Procedures**

A small percentage of patients requires operation at multiple sites, usually the retroperitoneum and lung and (less frequently) the neck.<sup>220</sup> Histology at different sites is not predictable based on histology at one site. When the histologic specimen from the retroperitoneum is compared with that from a second site, the histologies are

dissimilar in approximately 35% of cases.<sup>182,218,219</sup> When the lung and retroperitoneum are simultaneously involved, multiple, separate procedures may be required, but simultaneous bilateral thoracic and retroperitoneal resections are possible.<sup>221</sup> If a primary testis tumor is present and an orchiectomy is not performed *before* chemotherapy, then it should be performed *after* chemotherapy, as that testis may harbor viable residual disease.<sup>222,223</sup> Studies confirm that all sites of residual disease should generally be resected regardless of histologic findings at the initial procedure.

## MANAGEMENT OF RELAPSE AFTER CHEMOTHERAPY

Twenty percent to 30% of patients with advanced GCT relapse or fail to achieve a complete response to conventional cisplatin-based chemotherapy. Effective (and curative) second- and third-line salvage offer further treatment options.

### CONVENTIONAL DOSE SALVAGE THERAPY

After the single-agent activity of ifosfamide was identified,<sup>224,225</sup> it was combined with cisplatin and etoposide or cisplatin and vinblastine in patients whose disease was resistant to two prior regimens (Table 35-14).<sup>193,194</sup> and <sup>195,226,227</sup> and <sup>228</sup> In this heavily pretreated group, between 25% and 35% of patients achieved a complete response, and 15% to 27% remained in durable complete remission.<sup>226,229</sup> Nephrotoxicity and severe neutropenia were extremely common. Results suggesting an improved complete response rate when paclitaxel is substituted for vinblastine await completion of ongoing phase II studies.<sup>230</sup>

Reference	Regimen	No. of Prior Regimens	Evaluate	Complete Response (%)	Durable Complete Response (%)

TABLE 35-14. Ifosfamide -Based Salvage Regimens for Relapsed and Refractory Germ Cell Tumors

### HIGH-DOSE THERAPY

The chemosensitivity of GCT, the dose-response phenomena for individual drugs, the rare occurrence of bone marrow metastasis, and a young patient population permit consideration of high-dose therapy. More recent studies have included carboplatin and etoposide with or without an oxazaphosphorine (cyclophosphamide or ifosfamide) and show that a proportion of patients can be cured. In three relatively large series conducted in patients with refractory, progressive GCT, 15% to 21% of patients remained alive and disease-free with long-term follow-up (Table 35-15).<sup>231,232,233,234</sup> While these series demonstrate the curative potential of high-dose therapy, the majority of patients with cisplatin-refractory GCT die of disease, and new drugs and strategies are still needed. Studies incorporating paclitaxel are ongoing.

Reference	Regimen <sup>1</sup>	Regimen <sup>2</sup>	Regimen <sup>3</sup>	Regimen <sup>4</sup>
231	4	4	3	6

Best complete response	31	15	4	11
Best durable, disease-free	15	11	1	11
Median follow-up of survivors (mo)	124	15	3	16

TABLE 35-15. High-Dose Carboplatin-Containing Chemotherapy in Patients with Refractory, Progressive Germ Cell Tumor

The major toxicities of dose-intensive therapy are hematologic and infectious, with most studies reporting a 10% to 12% treatment-related death rate.<sup>235</sup> Hematopoietic growth factor support decreases the duration of neutropenia and hospitalization.<sup>236</sup> Peripheral blood-derived stem cells have largely replaced the use of autologous bone marrow, and a randomized trial showed that peripheral blood-derived stem cells result not only in rapid neutrophil reconstitution but also faster platelet engraftment.<sup>237</sup>

### PROGNOSTIC FACTORS: SALVAGE CHEMOTHERAPY

Despite an occasional cure, the majority of patients receiving salvage chemotherapy fail to achieve a durable complete response and are subsequently considered for high-dose chemotherapy. Prognostic factors can be used to predict which patients are most likely to benefit from conventional dose salvage therapy. Patients with a testis primary site *and* a prior complete response have a better prognosis, and conventional dose cisplatin salvage therapy (vinblastine, ifosfamide, and cisplatin) is reasonable in these patients.<sup>238</sup> Patients with an incomplete response to initial therapy or a relapsing extragonadal nonseminomatous GCT have a less than 10% 3-year survival response to conventional dose, cisplatin-containing salvage therapy.<sup>238</sup> In these circumstances, a dose-intensive program, a novel treatment strategy, or a new agent should be considered. The contribution of serum tumor marker concentrations to prognosis in this group of patients has not been established.

Prognostic factors can also be used to identify patients most likely to benefit from salvage high-dose, stem cell-supported, carboplatin-containing chemotherapy. Patients with primary mediastinal GCT refractory to initial and salvage chemotherapy, patients with *absolute refractory* disease (rising markers or radiographic evidence of progressive disease within 4 weeks of cisplatin therapy), and patients with high HCG levels rarely achieve a complete response.<sup>233,239</sup> These patients should be considered for phase II studies. All other patients are candidates for a high-dose approach.

### NEW AGENTS

A number of single-agent trials have been conducted against refractory GCT.<sup>240,241,242,243,244</sup> and <sup>245</sup> Of note, ifosfamide, paclitaxel, and oral etoposide and gemcitabine have demonstrated antitumor activity.<sup>239,245,246</sup> and <sup>247</sup> Because paclitaxel is synergistic with cisplatin and oxazaphosphorines *in vitro*, it is being studied in dose-intensive therapy with peripheral blood-derived, stem cell support, and in conventional dose therapy with ifosfamide plus cisplatin. Oral etoposide plays a palliative role in refractory GCT.

### ROLE OF SURGERY

histologic findings of resected masses following second-line or salvage chemotherapy differ from those observed following primary therapy. Viable tumor occurs in

approximately 50% of specimens, teratoma in 40%, and necrosis in only 10%.<sup>185</sup> Additional standard-dose chemotherapy adds no benefit to patients with viable nonseminomatous GCT in the resected specimen after *salvage* chemotherapy, as opposed to clear benefit with two additional cycles following complete resection of nonseminomatous GCT after primary chemotherapy.

In general, surgery should be avoided in patients in whom serum tumor marker concentrations remain elevated. While this general rule holds true, surgery has curative potential in a highly select group of patients with increased marker levels, even after salvage chemotherapy. In a study at Indiana University, 38 of 48 (79%) such patients were rendered grossly free of disease, 29 (60%) normalized markers, and ten (21%) had no evidence of disease with a median follow-up of 46 months.<sup>248</sup> Eastham et al. observed that 6 of 16 (31%) patients undergoing resection of residual disease in the face of elevated serum tumor markers were cured.<sup>249</sup> Five of these six patients had retroperitoneal disease only. Finally, Wood et al. examined 15 patients refractory to cisplatin-based therapy who underwent surgical resection of a solitary site of residual disease despite elevated markers at MSKCC.<sup>250</sup> Seven patients (47%) remained free of disease. These are all highly selected patients. At MSKCC, only 4% of patients with refractory disease were surgical candidates when markers were elevated after salvage chemotherapy. Only a small subset of patients with chemotherapy-resistant disease can be cured with surgery. Patients with a solitary retroperitoneal mass and increased AFP seemed to be the best candidates. Technically difficult, this surgery should be performed at a tertiary center.

## TREATMENT SEQUELAE

### CHEMOTHERAPY

Acute and subacute chemotherapy toxicity frequently occurs but is generally controllable. Control of nausea and vomiting is extremely important in order to maintain adequate hydration. Concurrent administration of a 5-HT<sub>3</sub> antagonist with dexamethasone is superior to a 5-HT<sub>3</sub> antagonist alone.<sup>251</sup> Since cisplatin induces delayed emesis, administration of oral metoclopramide and a benzodiazepine plus dexamethasone for 2 to 4 days after therapy is sometimes necessary. While these antiemetic regimens now permit the administration of 5-day, low-dose, cisplatin-based programs in the office or other outpatient settings, an occasional patient develops severe nausea and vomiting and should be hospitalized in order to protect renal function.

Nephrotoxicity from cisplatin occurs to some extent in all patients and is cumulative. Due to the effect of cisplatin on proximal tubules, progressive reduction in glomerular filtration and cumulative hypomagnesemia may result, associated with an increase in serum creatinine from pretreatment baseline,<sup>252,253</sup> particularly after ifosfamide-based salvage chemotherapy.<sup>229</sup> Nephrotoxicity may be severe in patients receiving high-dose chemotherapy in the salvage setting but does not appear to influence response rate or hematologic recovery.<sup>254</sup> Reports of an increased frequency of diastolic hypertension and cardiac events have appeared,<sup>255</sup> and longer follow-up is needed to establish this association with greater certainty. There are also reports of increased mean cholesterol levels, increased low-density and decreased high-density lipoprotein levels, and increased weight years after chemotherapy for GCT.<sup>256,257</sup>

Myelosuppression frequently occurs.<sup>158,163,166,193,195</sup> Anemia occurs in virtually all patients, but infrequently results in the need for red blood cell transfusions in those previously untreated. Grade 4 thrombocytopenia (platelet count less than 50,000) is distinctly uncommon with primary cisplatin-based therapy, but frequent during salvage chemotherapy. Neutropenic fever occurs in approximately 10% to 15% of patients receiving EP, is more common with the addition of bleomycin, and occurs in more than 50% of patients receiving salvage chemotherapy. Hematopoietic growth factors are recommended prophylactically following neutropenic fever but do not improve survival when given.<sup>258</sup> Severe anemia, neutropenia and neutropenic fever, and thrombocytopenia often accompany ifosfamide-based salvage therapy; hematopoietic growth factor support should be used prophylactically from the beginning of salvage therapy.

Peripheral neuropathy occurs in a majority of patients receiving vinblastine.<sup>259,260</sup> Replacing vinblastine with etoposide decreased the frequency of neuropathy, although cisplatin still causes symptomatic neuropathy in a minority of patients. Auditory toxicity from cisplatin is often associated with reduced high-tone hearing and, less frequently, tinnitus, but patients rarely require hearing aids.

Pulmonary toxicity from bleomycin is rare but can be fatal. In one randomized trial, it resulted in approximately one-half of the treatment-induced deaths.<sup>158</sup> In good-risk patients, a reduction in the number of bleomycin doses from 12 to 9 resulted in no bleomycin-related, treatment-related deaths.<sup>162</sup> Pulmonary function tests (vital capacity and diffusion capacity of carbon monoxide) have been used to dictate changes in bleomycin administration.<sup>91,163</sup> However, the diffusion capacity of carbon monoxide may not predict clinically significant bleomycin-induced lung damage.<sup>261</sup>

Vascular toxicity, most prominently as Raynaud's phenomenon, occurs in a minority (less than 10%) of patients receiving bleomycin administered by weekly bolus. It occurs in the absence of cisplatin (albeit less frequently).<sup>158,160,260</sup> The substitution of etoposide for vinblastine did not reduce the incidence of Raynaud's phenomenon.<sup>158</sup> Erectile dysfunction may be associated with Raynaud's phenomenon as a sign of microvascular angiopathy.<sup>262</sup> Other vascular events include pulmonary emboli,<sup>91</sup> angina and myocardial infarction.<sup>161,260</sup> Coronary artery disease resulting from mediastinal radiation therapy is well recognized and emphasizes the need to avoid mediastinal radiation therapy in the management of patients with seminoma.

Infertility is an important consideration. A minority of patients is infertile at diagnosis. Reduced spermatogenesis and higher follicle-stimulating hormone levels compared with healthy men are frequent in newly diagnosed patients.<sup>263</sup> A similar impairment of testicular function occurs in men with CIS (intratubular germ cell neoplasia).<sup>264</sup> However, paternity in patients on surveillance for clinical stage I disease did not seem to be reduced.<sup>265</sup> A standard, modified bilateral RPLND causes retrograde ejaculation in nearly all patients. Nerve-dissecting and nerve-avoiding RPLND reduce, but do not eliminate, that risk. Chemotherapy may affect the germinal epithelium directly, and Leydig cell insufficiency is frequent.<sup>266,267</sup> After chemotherapy, persistent oligospermia and abnormal forms and motility have been reported,<sup>268</sup> but conception may occur despite oligospermia.

Second malignancies are rare. Metachronous GCT appearing in the contralateral testis occurs in approximately 2% to 3% of all patients.<sup>269</sup> After the second orchiectomy, replacement testosterone is required to maintain normal serum testosterone levels, secondary sexual characteristics, and sexual function. Etoposide causes secondary leukemia characterized by translocations involving chromosome 11q in fewer than 0.5% of patients receiving a total dose less than 2000 mg/m<sup>2</sup>.<sup>270,271</sup> and as many as 6% of patients receiving total etoposide doses of greater than 3000 mg/m<sup>2</sup>.<sup>272</sup> However, reports showed acute leukemia in 0.8% to 1.3% of patients receiving median cumulative etoposide doses greater than 2400 mg/m<sup>2</sup>.<sup>273</sup> The latent period is short, averaging 2 to 4 years.

The incidence of gastrointestinal malignancies increased after radiation therapy or radiation therapy plus chemotherapy.<sup>115,116</sup> The relative risk increases with time and is greatest after 10 years.<sup>115</sup> Stomach cancer is the most prevalent gastrointestinal tumor. An excess of soft tissue sarcoma has also been observed.<sup>115,274</sup> The latent interval is long, and radiation therapy was implicated in the majority.<sup>116,274</sup> These second malignancies do not outweigh the enormous benefits of treatment intervention. Along with the risk of recurrence, these second primary neoplasms emphasize the need for long-term follow-up of treated patients.

Sarcoidosis appears more frequently in GCT patients.<sup>275</sup> Strictly speaking, it is not a sequela of therapy. It occurs both before and after GCT diagnosis. Paratracheal adenopathy or pulmonary nodules without retroperitoneal adenopathy or elevated serum tumor marker levels, particularly in patients with seminoma, suggest the possible presence of sarcoidosis and should lead to biopsy.

### MIDLINE TUMORS OF UNCERTAIN HISTOGENESIS

A subset of patients with poorly differentiated carcinoma of unknown histogenesis and uncertain primary site achieve complete response and long-term survival following treatment with cisplatin-combination therapy.<sup>276,277</sup> In a series of 220 patients, 26% of patients achieved a complete response; the 10-year actuarial survival was 16%.<sup>277</sup> Because of cisplatin sensitivity, predominant midline tumor distribution, and occurrence in relatively young patients, the presence of unrecognized extragonadal GCT was suggested despite the absence of increased serum concentration of AFP, HCG, or both in most cases.<sup>276,277</sup> Since i(12p) is a specific chromosomal marker characterizing GCT,<sup>200</sup> genetic analysis was undertaken. i(12p) and chromosome 12 aneuploidy were identified by conventional or molecular cytogenetic analysis or Southern blot analysis for 12p copy number, permitting a diagnosis of GCT in approximately 30% of such tumors.<sup>278</sup> A significantly greater complete plus partial response proportion to cisplatin-based therapy and longer survival were associated with the presence of a GCT genetic marker.<sup>278</sup> Genetic analyses also identified other tumors such as primitive neuroectodermal tumors, lymphoma, desmoplastic small cell tumor, melanoma, and clear cell sarcoma, indicating that this group of midline tumors has a heterogeneous histogenesis. Therefore, genetic analysis using conventional and molecular techniques has both

diagnostic and prognostic value.

## OTHER TESTICULAR TUMORS

### LEYDIG CELL TUMORS

Leydig cell (interstitial cell) tumors account for approximately 2% of testicular tumors. <sup>279,280</sup> Approximately 75% appear in adults who present with a palpable mass or testicular swelling indistinguishable from GCT. A minority has gynecomastia or decreased libido. The remaining 25% of cases present in children, sometimes with signs of sexual pseudoprecocity such as pubic hair, voice change, or enlarged genitalia. <sup>279</sup> A testicular mass associated with virilization in a prepubertal patient is a Leydig cell tumor until proven otherwise. There is no association between Leydig cell tumors and cryptorchidism. These tumors consist of tightly packed polygonal cells with eosinophilic granular cytoplasm and round nuclei with prominent nucleoli. Characteristic intracytoplasmic inclusion bodies (Rinke crystals) are seen in approximately 25% to 40% of cases. <sup>280</sup> A radical inguinal orchiectomy is required, and clinical staging includes a chest radiography, CT scan of the abdomen and pelvis, and studies for urinary and serum steroids.

Most Leydig cell tumors are benign. Malignant potential is difficult to predict. Vascular invasion, cellular atypia, tumor necrosis, infiltrative margins, increased mitotic rate, tumor size less than 5 cm and older age at presentation have been reported to be predictive of malignant potential. <sup>280,281</sup> and <sup>282</sup> Metastases are the only reliable criteria of malignancy. The most frequent sites of metastatic spread are the regional lymph nodes followed by lung, liver, and bone. RPLND is reasonable in selected cases with adverse features. <sup>282</sup> Metastatic Leydig cell tumors are radioresistant and chemoresistant. For metastatic disease, particularly that which secretes steroids, ortho-para-DDD, a potent inhibitor of steroidogenesis, has produced responses, but cure is not possible. <sup>283</sup>

### SERTOLI CELL TUMORS

Sertoli cell tumors (SCT) account for fewer than 1% of primary testicular neoplasms. They are subclassified into classic, large cell calcifying (LCCSCT), and sclerosing. <sup>284,285</sup> SCT present as a painless, enlarging mass requiring a radical inguinal orchiectomy. LCCSCT are noted for multifocality, familial tendency, and bilaterality. An association has been reported between LCCSCT, pituitary adenoma, adrenocortical hyperplasia, cardiac myxoma, and pigmented skin and mucosal lesions. <sup>286</sup> Precocious puberty is commonly noted in boys with LCCSCT, whereas feminization occurs in approximately 25% of classical SCT but is rare in LCCSCT. <sup>284</sup> A testicular mass associated with feminization in a prepubertal patient is a classic SCT until proven otherwise.

Most SCT are benign and require RPLND only if accompanied by retroperitoneal adenopathy. Metastases are the only reliable indicator of malignancy, occurring in fewer than 10% of cases. <sup>279</sup> The most common sites for metastatic spread are retroperitoneal lymph nodes, mediastinal nodes, lungs, liver, and bone. Sclerosing SCT and LCCSCT have minimal metastatic potential. Radiation therapy and chemotherapy are ineffective.

### GRANULOSA CELL TUMORS

Granulosa cell tumors histologically resemble adult-type granulosa cell tumors of the ovary. Gynecomastia and increased estrogen secretion are common. These tumors are extremely rare; their metastatic potential appears limited. Radical orchiectomy is required.

Juvenile granulosa cell tumors are the most common gonadal stromal neoplasms in early childhood, and the morphology may be confused with a yolk sac tumor. These patients usually present with maldescended testes, ambiguous genitalia, and an abnormal karyotype.

### GONADOBLASTOMA

Gonadoblastoma are composed of sex cord elements admixed with germ cells. Often bilateral, they occur in men with chromosome abnormalities and those with dysgenetic gonads. Metastases from the GCT element may occur.

### MESOTHELIOMA

Mesothelioma of the tunica vaginalis may invade the testis and frequently extend to the internal ring. Surgical intervention requires radical orchiectomy and complete excision of the spermatic cord and hemiscrotum. Retroperitoneal or inguinal metastases may occur if the testis is invaded or if vascular invasion is present. Aggressive surgery is the only useful therapy.

### SARCOMAS

#### ADENOCARCINOMA OF THE RETE TESTIS

This highly malignant neoplasm arises from the collecting system of the testis. <sup>2,279</sup> Located posteriorly, it often invades adjacent structures such as the cord and epididymis. Over one-half of patients present with metastatic disease. Survival rates are poor, with 30% to 50% dying within 1 year. These tumors generally do not respond to either radiation therapy or chemotherapy. <sup>279</sup> Following radical orchiectomy, RPLND may be curative in some patients with minimal retroperitoneal involvement.

### EPIDERMOID CYST

Epidermoid cysts of the testis usually present between the second and fourth decades. <sup>288</sup> They are usually asymptomatic and discovered incidentally. These tumors are round, firm, and sharply demarcated on gross examination. Microscopically, the cyst is lined with stratified squamous epithelium. The adjacent testicular parenchyma is benign, and no CIS is present. The histogenesis of these tumors is uncertain. The clinical behavior of these tumors is uniformly benign; consequently, patients require no further therapy following resection. Testicular ultrasound may be diagnostic, in which case enucleation of the mass is sufficient treatment. Nevertheless, thorough histologic sampling must be performed to rule out a mature teratoma.

### LYMPHOMA

Lymphoma is the most common secondary tumor of the testicle and the most frequent testicular neoplasm in men older than age 50. <sup>279,280</sup> Approximately 40% of patients report systemic symptoms such as fatigue, weight loss, and fever. Painless testicular enlargement is common, whereas bilateral involvement occurs in approximately one-third of patients. <sup>289</sup> Radical orchiectomy establishes the diagnosis and cures a small subset of patients. However, most cases are associated with systemic disease. Central nervous system as well as bone marrow diseases are common. Survival is generally poor. Management of lymphoma is discussed in [Chapter 45](#).

#### **Metastatic Carcinoma**

Metastatic carcinoma to the testicle is rare and usually associated with diffuse systemic disease. <sup>279</sup> Bilateral involvement is noted in 15% of cases. The most common primary sites include prostate, lung, melanoma, and kidney. Treatment may include radical orchiectomy with further therapy dictated by the primary tumor.

#### ENDOMETRIAL CANCER

Although endometrial cancer, the most common gynecologic cancer, carries the best prognosis, it is important to differentiate between the classic endometrioid tumors, which tend to be estrogen-dependent and well differentiated, from other less common high-risk uterine malignancies, such as uterine papillary serous carcinomas (UPSC), clear cell carcinomas, mixed Müllerian tumors, or sarcomas, which appear to have a different biology.

#### MICROSATELLITE INSTABILITY

The replication error (RER+) phenotype is characteristic of cancers arising in hereditary nonpolyposis colorectal cancer (HNPCC) kindreds (a familial cancer syndrome with a high incidence of colon, endometrial, and gastric cancers, and a lower incidence of ovarian and pancreatic cancers), and also is found in approximately 20% to 25% of sporadic endometrial cancers. Microsatellite instability appears to occur at the same frequency in the acknowledged precursor of endometrial cancer, complex atypical hyperplasia, as it does in the sporadic endometrial cancer cases.<sup>1</sup> The RER+ phenotype per se does not appear to correlate with clinicopathologic features of the tumors or clinical outcome; thus, the hereditary form of endometrial cancer alone does not appear to portend a worse prognosis than the sporadic form. Mutation of the transforming growth factor- $\beta$  (TGF- $\beta$ ) type II receptor gene is common in RER+ colon and gastric cancers but uncommon in RER+ endometrial cancers, even those arising in HNPCC kindreds.<sup>2</sup> This suggests that the genesis of RER+ tumors, even within the same familial cancer syndrome, is not the same. Although inactivation of both alleles of either hMSH2 and hMLH1 (DNA mismatch repair genes) appears to underlie microsatellite instability in tumors of HNPCC kindreds, similar to the findings in sporadic colon cancers, sporadic endometrial cancers have not been associated with mutations of any of the known human mismatch repair genes.<sup>3</sup> Instead, hypermethylation of the hMLH1 promoter region (which is linked to attenuation of MLH1 expression in sporadic RER+ colorectal carcinomas) was observed in 71% of sporadic RER+ endometrial cancer cases.<sup>3</sup> In contrast, 25% of uterine sarcomas, an entity not recognized to be part of a familial cancer syndrome, exhibit microsatellite instability that may be related to a mutation in the hMSH2 gene.<sup>4</sup> Microsatellite instability does not appear to be a feature of the UPSC or clear cell carcinomas.<sup>5</sup>

#### LOSS OF HETEROZYGOSITY STUDIES AND TUMOR SUPPRESSOR GENES

Unlike most other cancers studied to date, regions of sustained allelic loss in most chromosomes characterize endometrial cancer. Regions of chromosomal abnormality commonly found in this disease are listed in [Table 36.1-1](#). Chromosome 17p is frequently involved, which contains the p53 gene known to confer a poor prognosis in endometrial cancers when mutated, and which plays an important role in the transition to carcinoma from atypical hyperplasia. Other frequently involved regions include 3p, 10q, and 18q. The PTEN tumor suppressor gene is contained on chromosome 10q; mutations of this gene occur in complex atypical hyperplasia, as well as in one-third of endometrial cancers,<sup>1</sup> but it is not a common feature of UPSC.<sup>6</sup> Unexpectedly, in endometrial cancers, this finding mutation of PTEN tumor suppressor gene is associated with lack of overexpression of p53, as well as with early stage and improved clinical outcome.<sup>6</sup> Chromosome 18q contains the DCC gene, a putative tumor suppressor gene frequently mutated in colon cancers. Chromosome 18 was found to be capable of suppressing tumorigenicity of endometrial cancer cells in nude mice by the procedure of microcell fusion, with DCC expression elevated in most of the suppressed hybrids.<sup>7</sup>

TABLE 36.1-1. Common Regions of Chromosomal Abnormalities

#### ONCOGENES

K-ras activating point mutations in codons 12 and 13 have been implicated in the development of atypical endometrial hyperplasias and endometrioid carcinomas in Asian women, as well as in colon cancers. Studies of endometrial cancers arising in women in the United States, however, show the prevalence of such mutations to be significantly lower.<sup>8</sup> Notable was the almost complete absence of K-ras mutations in UPSC when compared to the usual endometrioid tumors.<sup>8</sup> In contrast, mutation-dependent and -independent inactivation of p53 is observed in the large majority of UPSC cases.<sup>9</sup>

Overexpression of HER-2/*neu* has been associated with advanced-stage, deep myometrial invasion, and poor survival in endometrial cancers in several studies. Gene amplification did not underlie all cases of HER-2/*neu* overexpression, although both gene amplification and overexpression were each associated with poor

outcome.<sup>10</sup> When multivariate analysis was used to determine whether HER-2/ *neu* was an independent prognostic factor in endometrial cancers when taking into account other molecular features such as DNA ploidy, epidermal growth factor receptor (EGFR), or p53 status, HER-2/ *neu* did not achieve significance.<sup>11</sup> Both c-myc gene amplification and c-fms<sup>12</sup> overexpression also have been associated with advanced-stage and high-grade endometrial cancers.

## HORMONE-RELATED MOLECULAR ABNORMALITIES

Estrogen acts as a tumor promoter for the classic endometrioid cancers, with the well- and moderately differentiated tumors containing significant levels of estrogen or progesterone receptors or both. Aromatase cytochrome P-450 is part of the complex responsible for conversion of C19 steroids to estrogen; its increased expression in endometrial cancers but not in normal endometria suggest a role in promotion of neoplastic proliferation.<sup>13</sup> Two different functional isoforms of both the estrogen and progesterone receptors have been described that may account for some of the tissue-specific differences in the effects of hormones and their antagonists on the breast as compared with the endometrium.

Tamoxifen, an estrogen receptor antagonist/agonist, has been associated with an increased risk of development of endometrial cancers. Although studies using murine models have been generally reassuring in regards to the safety of the selective estrogen receptor modulator, raloxifene, on the endometrium, clinical studies to date have been plagued by short follow-up. The molecular mechanisms for the antiestrogenic actions of raloxifene relate to a specific molecular perturbation at aspartate 351 of the ligand-binding domain of the estrogen receptor, on its binding to raloxifene.<sup>14</sup>

## MOLECULES INVOLVED IN ADHESION AND INVASION

Integrin (cell adhesion molecules) expression inversely correlates with grade in endometrial cancers, with the loss of the  $\beta_1$  integrin associated with lymph node metastases.<sup>15</sup> Variant forms of CD44 (a molecule important for cell adhesion and migration) are less frequently expressed in endometrial cancers than in normal endometria, and its absence was significantly associated with an increased propensity for lymph-vascular space invasion.<sup>16</sup> These data suggest that CD44 may play an important role in the function of the normal endometria, where it is strongly expressed near the basement membrane, and its loss may be related to invasion and metastasis.

## OVARIAN CANCER

Most of the breakthroughs in understanding the molecular basis for ovarian cancer have been in the area of hereditary epithelial ovarian cancer syndromes, which affect 5% to 10% of ovarian cancer patients. Much work is still needed to understand the biology underlying sporadic ovarian cancers, which invariably present as advanced-stage disease and have a poor long-term outcome.

### CLONALITY

In the search for the precursors of invasive epithelial ovarian cancer, molecular studies have been performed on normal ovaries; on benign, borderline, and invasive cancers; and on cancers with adjacent benign-appearing cysts. Such studies have been greatly aided by the ability to culture normal, immortalized, and transformed ovarian surface epithelial cells, as well as transformed cells originating from benign ovarian neoplasms. Evidence for a unifocal origin for these cancers appears to predominate, with bilateral ovarian cancers and metastases sharing common molecular features. Studies of microsatellite instability (which occurs in 17% of cases but appears not to be related to family history<sup>17</sup>) and studies of X chromosome inactivation support the clonal origin of these cancers. This is contrasted to the multifocal origin proposed for a proportion (25%) of the papillary serous carcinomas of the peritoneum; these tumors of multifocal origin are associated with germline BRCA1 (breast cancer gene) mutations.<sup>18</sup> Interestingly, loss of heterozygosity studies, and K-ras and p53 mutation analyses, do not demonstrate shared findings between borderline or benign neoplasms and invasive cancers, suggesting that these entities are not the precursors of invasive epithelial ovarian cancers. For instance, frequent loss of heterozygosity of a portion of Xq on the inactive X chromosome was seen in borderline tumors, but not in low-grade invasive ovarian cancers.<sup>19</sup> Notably, p53 mutations, which are absent in solitary borderline and benign neoplasms, are present along with allelic loss of chromosome 11p in benign-appearing cysts adjacent to the invasive cancers.<sup>20</sup> Similarly, common genetic alterations (such as loss of heterozygosity involving the same allele) were observed in endometrioid and clear cell ovarian carcinomas and adjacent endometriosis.<sup>21</sup>

### BRCA1 AND BRCA2 GENES

Unlike most epithelia, division of normal ovarian surface epithelial cells gives rise to two daughter cells with equal growth potential.<sup>22</sup> This provides a mechanism for the involvement of tumor suppressor genes in the development of ovarian cancer, in that repeated division of these cells can unmask such recessive mutations. In addition to being a tumor suppressor gene, BRCA1 may function as a transcription factor, as well as conferring protection against DNA damage. The latter mechanism also has been proposed as a function of BRCA2. Mutations of BRCA1 (unlike BRCA2) can account for the large majority of the familial cases of breast-ovarian cancer syndrome and site-specific ovarian cancers.<sup>23</sup> Among breast-ovarian cancer families, there is significant evidence for heterogeneity of risk among BRCA1-mutation carriers. Assuming two BRCA1 alleles exist, one allele would confer a lifetime breast cancer risk of 62% and an ovarian cancer risk of 11%, whereas the other allele confers a 39% breast cancer risk and a 42% ovarian cancer risk by age 60 years, with the first allele representing 71% of the mutations.<sup>24</sup> BRCA1 mutations specifically localized to the 5' region may increase the risk for ovarian cancer in these patients.<sup>25</sup> BRCA2 mutations confer susceptibility to ovarian cancer with a significantly lower penetrance than for BRCA1. Compared to population-control cases, familial ovarian cancer in general, including disease associated with BRCA1 or BRCA2 mutations, are more frequently associated with advanced stage and, hence, a poorer clinical outcome.<sup>26</sup> Stage for stage, however, BRCA1 mutations do not appear to result in a survival difference. Serous tumors appear to be a hallmark of BRCA1 mutation-associated ovarian cancers, and germline BRCA1 mutations have been reported to occur in papillary serous carcinomas of the peritoneum with a frequency comparable to that in epithelial ovarian cancers.<sup>27</sup> However, no morphologic changes can differentiate normal ovaries removed prophylactically from carriers of a BRCA1 or BRCA2 mutation from ovaries removed from noncarriers; thus, identification of a premalignant lesion remains elusive.<sup>28</sup>

In sporadic ovarian cancer, which represents 95% of ovarian cancer cases, few mutations of BRCA1 or BRCA2 were detected, whereas frequent allelic losses that included the BRCA1 region of chromosome 17q were demonstrated (see [Table 36.1-1](#) for regions of chromosomal abnormality commonly associated with ovarian cancer).<sup>29</sup> These and other data suggest the involvement of additional tumor suppressor genes in the etiology of most of the sporadic ovarian cancers, including one or two that possibly are localized distal to the BRCA1 gene. An intriguing finding is the fact that, present in the germline of patients with sporadic ovarian cancer, is a Taq1 restriction fragment length polymorphism in an intron within the sequences encoding the hormone-binding domain of the progesterone receptor gene.<sup>30</sup> This finding may be associated with coding region mutations of the gene and may contribute to tumorigenesis.

### OTHER TUMOR SUPPRESSOR GENES

Functional wild-type p53 has been shown to be required for sensitivity to a variety of chemotherapeutic drugs and radiation, playing a crucial role in the execution of the common end pathway of apoptosis. p53 mutation of one allele predisposes the cell to the loss of wild-type p53 function, which has been shown in ovarian cancer cells to lead to the development of platinum resistance *in vitro*.<sup>31</sup> In ovarian cancers, p53 mutations, which are seen in 50% of advanced cases,<sup>32</sup> are associated with high grade and poor survival, but not with clinical chemoresistance. p53 mutations appear to arise before the onset of ovarian cancer metastasis, but are not present in the germline of patients with familial ovarian cancer phenotypes.<sup>33</sup> p53 has been explored as a target for gene therapy in ovarian cancer by several groups. Similarly, other proapoptotic genes, such as the BAX gene, have been the focus of gene therapy efforts at ovarian selective tumor expression.<sup>34</sup>

Other putative tumor suppressor genes in ovarian cancer include GPC3 (whose promoter is hypermethylated leading to gene silencing), Noey2 (ARH1, an imprinted tumor suppressor gene), OVCA1, and DOC-2, among others. The widespread loss of heterozygosity found in invasive ovarian cancers indicates that there may be several other tumor suppressor genes inactivated during tumorigenesis. The search for such genes (and likewise oncogenes) in ovarian cancer has been greatly facilitated by the advent of technologies such as complementary DNA microarray,<sup>35</sup> comparative genomic hybridization, differential display, and serial analysis of gene expression.

### ONCOGENES AND GROWTH FACTORS

Cytokines which may act via autocrine or paracrine routes on ovarian cancer cells include EGF, TGF- $\beta$ , tumor necrosis factor, interleukin-6 (IL-6), lysophosphatidic acid (LPA), heregulin, vascular endothelial growth factor (VEGF), and the macrophage colony-stimulating factor (CSF-1). Ovarian cancer cells have been shown to

contain receptors for these cytokines and thus are capable of responding by phenotypic change, including growth stimulation or inhibition depending on the stimuli. Coexpression of CSF-1 and the protooncogene *c-fms* (which encodes for the CSF-1 receptor) in ovarian cancer metastases portends a poor outcome.<sup>36</sup> Other oncogenes activated in ovarian cancer include K-ras (mutated in 40% of mucinous tumors), HER-2/ *neu* (which does not appear to be related to poor prognosis in ovarian cancer, unlike breast cancer), *c-myc*, PIK3CA [the catalytic subunit of phosphatidylinositol 3-kinase (PI3-kinase)], and AKT-2 (which is activated by several mitogenic growth factors and serves as a downstream effector of PI3-kinase). Of interest, BRCA1- or BRCA2-linked ovarian cancers do not appear to develop through mutations of K-ras or amplification of HER-2/ *neu*, *c-myc*, or AKT-2.<sup>37</sup> Both tyrosine kinase growth factor receptors and protein tyrosine phosphatases (PTP) may also play an important role: overexpression of PTP1B in ovarian cancers has been correlated with the expression of the tyrosine kinase receptors EGFR, HER-2/ *neu*, and *c-fms*.<sup>38</sup>

## DRUG RESISTANCE

The phenomenon of platinum resistance remains the most germane for ovarian cancer patients, although with the inclusion of paclitaxel in first-line therapy, acquired classic multidrug resistance (*mdr*) is also a relevant mechanism. The first relationship between genomic aberrations in ovarian cancer (gains at specific loci on chromosomes 1q and 13q) and platinum resistance has been described.<sup>39</sup>

Augmented DNA repair at several levels appears to contribute significantly to platinum resistance. In ovarian cancers, elevated levels of ERCC-1 and XPAC, rate-limiting DNA repair genes, are found in clinically platinum-resistant tumors. However, because overexpression of ERCC-1 *in vitro* leads to increased platinum sensitivity, the relative role of the different DNA repair genes in this process remains unclear. Elevated intracellular levels of glutathione, which lead to increased intracellular detoxification of platinum, generally correlate with *in vitro* platinum resistance and have been reported to confer poor survival.<sup>40</sup> In platinum-resistant ovarian cancer cells, an elevated level of  $\gamma$ -glutamylcysteine synthetase, an enzyme that contributes to biosynthesis of glutathione, is associated with increased *c-jun* expression.<sup>41</sup> On the other hand, glutathione S-transferase (GST) levels do not consistently correlate with platinum resistance *in vitro* or *in vivo*. In ovarian cancer, two GST null genotypes have been found to be associated with lack of responsiveness to platinum or other alkylating agents and with poor survival, which is thought to be due to the contribution of the GST null phenotype to loss of p53 function.<sup>42</sup>

Other interactions between cytokines or oncogenes and modulation of platinum activity have been reported in ovarian cancer. IL-6 has been shown to block apoptosis induced by platinum in ovarian cancer cells.<sup>43</sup> The addition of antibody to HER-2/ *neu* enhances chemosensitization of platinum in ovarian cancer cells.<sup>44</sup> Similarly, antisense down-regulation of *c-raf* or *c-myc* has been used to sensitize activity of platinum in several tumors. Anti-*fas* antibody-mediated apoptosis is enhanced by low-dose platinum in resistant ovarian cancers.<sup>45</sup>

On the other hand, overexpression of BAX is associated with chemosensitivity to platinum and paclitaxel, as well as to an improved disease-free survival rate in ovarian cancer.<sup>46</sup> p53 mutations result in the loss of ability of p53 to transactivate BAX in platinum-resistant ovarian cancer cells.<sup>47</sup> IL-1 $\alpha$ , through inhibition of DNA repair, also sensitizes the activity of platinum in ovarian cancer cells<sup>48</sup>; and tumor necrosis factor, an apoptosis inducer, can ameliorate platinum resistance in ovarian cancer cells. Transfection of the cytokeratin 18 gene, which encodes an intermediate filament protein into platinum-resistant ovarian cancer cells, leads to a marked increase in platinum sensitivity.<sup>49</sup>

The prevalence of MDR-1 overexpression in ovarian cancer appears to depend on the sensitivity of the methodology used. There is agreement, however, that acquired *mdr* is clinically relevant for these patients. Mutated p53 can contribute to classic *mdr* because it can transcriptionally activate the MDR-1 promoter, a phenomenon that is repressed by wild-type p53. Proteins associated with the *mdr* phenotype and expressed in MDR-1–negative cancers are MRP (MDR-associated protein involved in glutathione conjugate transport) and LRP (lung resistance protein). LRP appears to correlate with clinical chemoresistance (remarkably, both to agents associated with classic *mdr*, as well as to the class of platinum/alkylating agents) among ovarian cancer patients.<sup>50</sup>

Aside from *mdr*, the other major mechanism of paclitaxel resistance involves stimulation of expression of the  $\beta$ -tubulin genes in the resistant ovarian cancers.<sup>51</sup> Antisense down-regulation of  $\beta$ -tubulin sensitizes these cells to paclitaxel.

## MOLECULES INVOLVED IN ADHESION, MOTILITY, INVASION, ANGIOGENESIS, AND METASTASIS

The cell adhesion molecules CD44 and E-cadherin both are expressed when ovarian cancer cells are attached to peritoneal mesothelium, but such expression is lost when the cells are found in ascites fluid.<sup>52</sup> The  $\beta_1$  integrin is also found to be an important mediator of ovarian cancer cell adhesion to peritoneal cells.<sup>53</sup> Urokinase-type plasminogen activator is the primary plasminogen activator found in ovarian cancer tissues and, along with the matrix metalloproteinases (in particular, MMP-2 and -9), are important to the biology of invasion and metastasis of ovarian cancer. Inhibitors of urokinase<sup>54</sup> have been shown to block invasive capacity of ovarian cancer cells, whereas a synthetic matrix metalloproteinase inhibitor decreases tumor burden (an effect that is even more pronounced in the presence of platinum<sup>55</sup>) in mice bearing human ovarian cancer xenografts. Urokinase has been shown to be inducible by CSF-1, a cytokine important to *in vivo* metastasis in ovarian cancer,<sup>56</sup> with CSF-1–induced invasion being mediated by urokinase activity,<sup>54</sup> and CSF-1–induced motility being mediated by PAI-1 activity. Urokinase-stimulated invasion is also induced by LPA, which also enhances drug resistance.<sup>57</sup> VEGF, a critical mediator of tumor angiogenesis, is expressed in abundant amounts in ascites and in the malignant ovary.<sup>58</sup> It is notable that molecules important to these related biologic phenotypes, such as E-cadherin and nm23 (associated with absence of lymph node metastasis), also may have putative tumor suppressor function, based on loss of heterozygosity studies or sequence analysis.

## CERVICAL AND VULVAR CANCER

The study of the role of viruses in the carcinogenesis of lower genital tract malignancies (thought to be a field effect) has focused on cervical cancer, the third most common gynecologic cancer in the United States. Extension of those studies to vulvar cancer have led to support for two separate etiologies of vulvar cancer: one related to human papillomavirus (HPV), with epidemiologic risk factors similar to that for cervical cancer, and the other not appearing to be HPV-related.

### HUMAN PAPILLOMAVIRUS

That HPV is a critical factor for cervical carcinogenesis and that the HPV E6 and E7 genes are oncogenic is clearly established. Infection of human keratinocytes by the oncogenic HPV subtypes leads to abnormalities in differentiation and growth; however, only after long-term culture of immortalized cells does an occasional clone become tumorigenic in nude mice, suggesting that HPV infection alone is not sufficient for cervical carcinogenesis. This theory is supported by data from transgenic mice studies, in which E6/E7 genes can give rise to hyperplastic and neoplastic lesions of epithelial cell types after a latent period; however, epidermoid cervical cancers have not been noted. Cervical cancers of mesenchymal origin were noted to arise after a long latent period in some of the female progeny of transgenic mice into whom HPV-18 LCR/E6/E7 was introduced.<sup>59</sup> Although the majority of invasive cancers contain integrated forms of HPV, usually at fragile sites, which result in *cis* activation of protooncogenes such as *c-myc*, and the large majority of dysplasias contain episomal forms of HPV, this is not always the case. In invasive cancers, HPV-18 is always found to be integrated in the host genome, whereas HPV-16 can be found in an episomal location one-third of the time. When DNA integration occurs, it does so by preferentially disrupting the E2 open reading frame (thus the negative effect of the E2 protein on E6/E7 transcriptional activity) or in such a way that transcriptional initiation from host sequences give rise to overexpression of E6/E7. High-level transcription of E6/E7 is seen in cervical intraepithelial neoplasia grade 3 (CIN 3) and invasive cancers when compared to CIN 1 and CIN 2. On immortalization of normal cells, E7 appears to be responsible for chromosomal instability and aneuploidy, whereas E6 may have a promoting effect by inhibition of DNA repair through interfering with wild-type p53 function. When inoculated in nude mice, those clones that are not tumorigenic display low-level E6/E7 transcription, whereas those which are tumorigenic continue to express high levels of E6/E7.

### HUMAN PAPILLOMAVIRUS E6/E7 GENES

On binding with the retinoblastoma (Rb) protein, E7, a potent viral oncoprotein that cooperates with activated ras in transforming assays, frees key cell-cycle proteins from Rb-imposed negative transcriptional regulation. Whereas for the high-risk HPV subtypes 16/18, E7/Rb binding is five- to tenfold more efficient than for HPV 6/11, mutations that affect E7 binding to Rb do not interfere with the capacity to confer immortalization. Similarly, mutations that interfere with E7's transforming properties do not appear to affect Rb binding; thus, the picture is complex.

Likewise, the mechanism for E6 promotion of oncogenesis is not clear. E6 promotes ubiquitin binding to p53, which tags such cells for degradation; thus, on DNA damage, the normal cellular response of induction of wild-type p53 is not seen in HPV-infected cells. Experimental evidence suggests that a p53 polymorphism with

arginine at codon 72 is more susceptible to E6-induced degradation *in vivo* than with proline at that site.<sup>60</sup> However, the observation that individuals homozygous for the arginine-encoding allele may be more susceptible to HPV-associated squamous cell cancers than heterozygotes<sup>60</sup> has not been confirmed by larger studies.<sup>61</sup> The suggestion has been made that, instead, this p53 polymorphism may predispose to the development of cervical adenocarcinomas in Asians.<sup>62</sup> Although E6 binds to p53 protein in HPV 16/18 subtypes (not in HPV 6/11), no such correlation is seen *in vivo* between low p53 expression and E6 overexpression. Furthermore, there is evidence that endogenous p53 protein in HPV-infected cancer cells is competent to activate a downstream target gene, despite coexpression of the viral E6 protein.<sup>63</sup>

The development of HPV vaccines has been an intense focus of investigation. Prophylactic HPV vaccine strategies have used noninfective, non-viral DNA-containing, antigenic papilloma virus-like particles. Development of therapeutic HPV vaccines has been somewhat more problematic in that sustained cellular immunity against oncogenic E6 or E7 proteins has been difficult to achieve. New approaches include the use of autologous dendritic cells pulsed with HPV-specific tumor antigens, such as E7, to stimulate tumor-specific cytotoxic T lymphocytes (CTLs).<sup>64</sup> Dendritic cells are thought to be effective stimulators not only to produce and maintain primary CTLs, but also to stimulate established CTL lines.

## MOLECULAR COFACTORS IMPORTANT TO CERVICAL CARCINOGENESIS

Because HPV infection is not sufficient for cervical carcinogenesis, attention has focused on molecular cofactors important to this process, such as co-infection by herpes simplex virus 2, and the presence of activated Ha-ras; the latter results in rearrangements and amplifications of the HPV-16 sequence. Many positive and negative transcriptional regulators of E6/E7 transcription have been identified. The presence of the glucocorticoid response element 5' of the HPV genome probably underlies the clinical progression of HPV infection seen in pregnancy. Although retinoic acid represses HPV transcription in normal and malignant cells, its induction of retinoic acid receptor beta is restricted to normal cells. Both the retinoic acid receptor beta gene and a locus on chromosome 11q23 may have tumor-suppressive properties in squamous cell cancers. Loss of heterozygosity studies demonstrate allelic loss of many chromosomes, including 11q, but most frequently involving 3p, 6p, and 18q (see Table 36.1-1).<sup>65</sup>

The immune response is likely to be key in determining malignant transformation of HPV-infected cervical epithelium. The consequences of human immunodeficiency virus (HIV) infection include a dramatic increase in the risk for cervical dysplasia and invasive cancer, the degree of which correlates with the level of immunosuppression. Loss of expression of HLA class I alleles, along with interference with the transporter associated with antigen presentation in cervical cancers, is common; such changes may influence specific immunogenic presentation by tumors.<sup>66</sup> In addition, the finding of certain HLA class II haplotypes in the cancer (when compared to cervical DNA from controls), which may influence the immune response to specific HPV-encoded epitopes, may contribute to the development of cervical neoplasia.<sup>67</sup> In fact, the HLA DQB1 locus shows evidence for allelic association with invasive cervical cancer in HPV-positive patients.<sup>68</sup> This genotype thus appears to increase the risk for development of cervical cancer in these patients. Similar findings are seen when HLA class II haplotypes in CIN were compared to controls; the HLA DQB1 haplotype was significantly more highly associated with CIN.<sup>69</sup>

In general, more than 90% of squamous cell cervical cancers contain HPV DNA, and only rarely are p53 mutations seen. Nuclear c-myc expression is correlated with the presence of HPV; c-myc can transactivate the HPV-16 promoter,<sup>70</sup> as it can transactivate HIV-1 and c-myc. In most studies, HPV status was not a strong independent prognosticator of outcome in cervical cancer patients<sup>71</sup>; however, there appears to be a trend for HPV-negative tumors to do worse. Among HPV-negative cancers, p53 mutations appear to be more common, although HPV-negative cancers that do not contain p53 mutations exist. The latter also do not contain MDM2 gene (capable of binding to p53) amplifications.<sup>72</sup> Among HPV-negative tumors, c-myc overexpression has been associated with an increased risk of metastasis in early-stage disease.

## MOLECULAR ABNORMALITIES IN CERVICAL ADENOCARCINOMAS

The presence of both HPV-16 and -18 has been demonstrated in cervical adenocarcinomas, with HPV-18 predominating in cervical adenocarcinoma cell lines. p53 mutations in this disease are associated with advanced-stage and high-grade cases, whereas those tumors containing HPV DNA tend to be of an early stage and low grade. Overexpression of HER-2/*neu* is seen in 25% of cervical adenocarcinomas, which is strongly associated with advanced stage. Reduced expression of nm23 and overexpression of HER-2/*neu* may relate to poor prognosis in these tumors.<sup>73</sup> Molecular findings in cervical adenocarcinomas appear to differ from those seen in adenocarcinomas arising in the endometrium, which do not contain HPV DNA. The frequency of K-ras mutations and the pattern of p53 mutations differ between the two groups<sup>74</sup>; K-ras mutations appear to be an infrequent event in cervical cancers in most studies, which is in contrast to endometrial adenocarcinomas.

## NON-HUMAN PAPILLOMAVIRUS-RELATED MOLECULAR ABNORMALITIES IN CERVICAL CANCERS

Expression of cell-cycle genes, such as bcl-1 and bcl-2, have been studied in cervical cancer. Bcl-1 (cyclin D1) is capable of binding to the Rb protein and is overexpressed or amplified in the majority of cervical and vulvar cancer cell lines<sup>75</sup>; its level of expression is elevated by activated c-fms. Overexpression of bcl-2, which protects against apoptosis and differentiation, was not found to relate to HPV status but was more likely to be seen in CIN 3 rather than low-grade dysplasias. Thus, its expression may be an early event important to malignant transformation.<sup>76</sup> *In vitro*, increased bcl-2 expression is noted in cervical cancer cell lines which contain an inactive p53.<sup>77</sup> *In vivo*, overexpression of bcl-2 is strongly correlated with radioresistance,<sup>78</sup> and on multivariate analysis, poor outcome.<sup>79</sup> Overexpression of EGFR also is found to be an independent predictor for poor prognosis in cervical cancer.<sup>80</sup>

Proteinases capable of degrading extracellular matrix may underlie the propensity of cervical cancer to invade adjacent tissues. Both the expression<sup>81</sup> and activity of metalloproteinases have been described in cervical cancers, with more activity seen in this disease than in ovarian or endometrial cancers.<sup>82</sup> Expression of MMP-2 is correlated with that of TIMP-2 in cervical cancer cells, and their coexpression is associated with advanced stage and poor survival.<sup>83</sup> The opposite finding is seen for expression of TIMP-1, a specific inhibitor of the matrix metalloproteinases. In fact, the ratio of matrix metalloproteinases to TIMP-1 is increased in those cervical cancers and their surrounding stroma that have a poor prognosis.<sup>81</sup> Furthermore, morphologic and immunohistochemical markers of angiogenesis correlate with poor outcome in cervical cancer.<sup>84</sup> Many cervical cancers secrete significant levels of VEGF, the adenocarcinomas in particular.<sup>85</sup>

## MOLECULAR ABNORMALITIES IN VULVAR CANCERS

Molecular studies support two etiologies of vulvar cancer: (1) vulvar intraepithelial neoplasia grade 3 associated with basaloid and warty carcinomas, the majority of which appear to be associated with the presence of HPV and epidemiologic risk factors similar to that seen for cervical cancer, such as smoking and herpes simplex virus 2 infection; and (2) keratinizing squamous cell carcinomas, which contain little HPV DNA.<sup>86</sup> Thus, HPV is detected less often in vulvar cancers (approximately one-half of the cases contain HPV-16 or -18) than in cervical cancers, with those being HPV-positive having a better prognosis.<sup>87</sup> Similar to cervical cancers, there is higher prevalence of p53 mutations in HPV-negative vulvar cancers when compared to HPV-positive tumors,<sup>88</sup> and p53 overexpression in vulvar cancers appears to relate to poor overall survival.<sup>89</sup> Vulvar squamous cell carcinomas exhibit a broad range of allelic losses, irrespective of HPV status.<sup>90</sup> Furthermore, the divergent patterns of loss of heterozygosity observed suggest that only some, but not most, genetic alterations in adjacent vulvar epithelium or vulvar intraepithelial neoplasia are related to the invasive cancers.<sup>91</sup>

## CARCINOMA OF THE CERVIX

### EPIDEMIOLOGY

The American Cancer Society estimated that 12,800 new cases of invasive cervical cancer would be diagnosed in the United States in 1999.<sup>1</sup> During the same year, 4800 patients were expected to die of cervical cancer; this represents approximately 1.8% of all cancer deaths in women and 18% of deaths from gynecologic cancers. However, for women aged 20 to 39 years, cervical cancer remains the second leading cause of cancer deaths after breast cancer.<sup>1</sup> In the United States, age-adjusted death rates from cervical cancer have declined steadily since statistics on the disease were first collected in the 1930s. Although this improvement is primarily because of the adoption of routine screening programs including pelvic examinations and cervical cytologic evaluation, the death rates from cervical cancer had begun to decrease before the implementation of Papanicolaou (Pap) screening, suggesting that other unknown factors may have played some role.<sup>2,3</sup>

Squamous cell carcinoma of the cervix and its intraepithelial precursor follow a pattern typical of sexually transmitted disease. The risk of cervical cancer is increased in prostitutes and in women who have first coitus at a young age, have multiple sexual partners, have sexually transmitted diseases, or bear children at a young age. Promiscuous sexual behavior in male partners is also a risk factor.<sup>4,5</sup> Other factors that may be associated with cervical cancer include cigarette smoking, immunodeficiency, vitamin A or C deficiency, and oral contraceptive use.<sup>6</sup> In the United States, the incidence of cervical cancer is greatest in American Indian, African American, Vietnamese, and Hispanic women.<sup>7,8</sup> and <sup>9</sup>

International incidences of cervical cancer tend to reflect differences in cultural attitudes toward sexual promiscuity and the penetration of mass screening programs. Some of the lowest incidences are in the United States, China, North Africa, and the Middle East, where estimated crude rates of cervical cancer are less than 10 per 100,000.<sup>10</sup> However, cervical cancer continues to be the leading cause of cancer deaths for women in many developing countries. Incidences are particularly high in Latin America, Southern and Eastern Africa, India, and Polynesia.<sup>10,11</sup> In the United States, Hispanic women have approximately twice the incidence and Vietnamese women approximately five times the incidence of white women.<sup>12</sup> The incidence is also higher in African Americans than in whites, although this difference has been steadily decreasing, particularly for women less than 50 years old.

A number of studies suggest that the incidence of cervical adenocarcinoma has been increasing, particularly among women in their 20s and 30s.<sup>13,14</sup> and <sup>15</sup> Several investigators have reported a correlation between cervical adenocarcinoma and prolonged oral contraceptive use.<sup>16,17</sup> However, the likelihood of a causative relationship is less certain because of the many potential confounding risk factors.<sup>18</sup>

Molecular and epidemiologic studies have demonstrated a strong relationship between human papillomavirus (HPV), cervical intraepithelial neoplasia (CIN), and invasive carcinomas of the cervix.<sup>19,20</sup> HPV DNA has been identified in more than 95% of cervical carcinomas<sup>21</sup>; HPV DNA transcripts and protein products have also been identified in invasive cervical carcinomas.<sup>22,23</sup> and <sup>24</sup> In high-grade CIN and invasive carcinoma, papillomavirus DNA is typically integrated into the human genome rather than remaining in an intact viral capsid.<sup>25</sup> It has been theorized that integration of HPV DNA in the human genome, possibly at the E2 site, causes persistent transcription of the E6 and E7 genes. Functional inactivation of p53 by E6 protein or of Rb by E7 protein disrupts normal cell-cycle control mechanisms.<sup>26,27</sup> and <sup>28</sup> As the sensitivity and specificity of tests for HPV DNA have improved, it has become increasingly apparent that most of the covariables that have historically been associated with an increased risk of cervical cancer (e.g., age at first coitus, number of partners, socioeconomic status, and so forth) are surrogates for HPV infection.<sup>29,30</sup> Investigators have suggested a number of cofactors that may contribute to disease progression. However, in more recent epidemiologic studies, cigarette smoking was the only consistent independent contributor to the risk of cervical cancer development after controlling for HPV infection.<sup>31</sup> Taken together, the molecular and epidemiologic data provide compelling evidence that HPV infection plays a central causative role in the development of cervical neoplasia.<sup>29,30</sup> and <sup>31</sup>

More than 100 HPV subtypes have been identified, and many of these have now been isolated, sequenced, and cloned.<sup>32,33</sup> Approximately 25 subtypes are tropic to the genital tract mucosa. Types 6 and 11 usually cause benign genital warts (condyloma acuminata) but are occasionally associated with invasive cervical lesions. Types 16, 18, 31, 35, and 39 are commonly associated with high-grade CIN and invasive cervical cancer ( [Table 36.2-1](#) ).<sup>34</sup> HPV 18 has been associated with poorly differentiated carcinomas, an increased incidence of lymph node involvement, a poor response to treatment, and a high rate of disease recurrence, whereas HPV 16 has been associated with large cell keratinizing tumors and a lower recurrence rate.<sup>35,36</sup> and <sup>37</sup> Although the overall prevalence of HPV DNA is similar between countries, significant variation has been found in the prevalence of some less common HPV types; for example, HPV 45 is most common in western Africa, whereas HPV 39 and HPV 59 are rarely found outside Central and South America.<sup>21</sup> The strong correlation between high-risk HPV subtypes and carcinoma has led to the suggestion that HPV detection and typing be incorporated into mass screening programs<sup>36,39</sup> and has encouraged efforts to develop a prophylactic HPV vaccine.<sup>40</sup>

Viral Type	Cervical Lesions				Total
	Normal/ Mild Atypia	Low-Grade Squamous Intraepithelial Lesion	High-Grade Squamous Intraepithelial Lesion	Cancer

**TABLE 36.2-1.** Relationship between Human Papillomavirus Type and Cervical Pathology

In 1993 the Centers for Disease Control and Prevention added cervical cancer to the list of acquired immunodeficiency syndrome–defining neoplasms.<sup>41</sup> However, the impact of acquired immunodeficiency syndrome and human immunodeficiency virus (HIV) on the incidence and virulence of cervical cancer remains uncertain.<sup>42,43,44,45</sup> and <sup>46</sup> Although several studies suggest that the incidence of CIN is higher in HIV-positive women than in the general population,<sup>47,48</sup> overlap in risk factors for the two diseases may influence these results. Although Serraino et al.<sup>46</sup> reported a possible increase in the risk of invasive cervical cancer in European HIV-positive women, several studies in Africa<sup>42</sup> and a large epidemiologic study in the United States<sup>44</sup> have failed to reveal any significant linkage. However, changes in cell-mediated immunity may play a role in the development of cervical cancer,<sup>48,49</sup> and some investigators<sup>43,51,52</sup> have suggested that cervical cancer is a more aggressive disease in immunosuppressed patients. For these reasons, regular surveillance with Pap smears, pelvic examination, and colposcopy (when indicated) should be part of the routine care of HIV-positive women.

**NATURAL HISTORY AND PATTERN OF SPREAD**

Most cervical carcinomas arise at the junction between the primarily columnar epithelium of the endocervix and the squamous epithelium of the ectocervix. This junction is a site of continuous metaplastic change; this change is most active *in utero*, at puberty, and during a first pregnancy and declines after menopause. The greatest risk of neoplastic transformation coincides with periods of greatest metaplastic activity. Virally induced atypical squamous metaplasia developing in this region can progress to higher grade squamous intraepithelial lesions.

The mean age of women with CIN is approximately 15 years younger than that of women with invasive cancer, suggesting a slow progression of CIN to invasive carcinoma.<sup>53,54</sup> In a 13-year observational study of women with CIN 3, Miller<sup>55</sup> found that disease progressed in only 14%, whereas it remained the same in 61% and disappeared in the remainder. Syrjanen et al.<sup>56</sup> reported spontaneous regression in 38% of high-grade HPV-associated squamous intraepithelial lesions. However, in a large prospective study, Richart and Barron<sup>57</sup> reported mean times to development of carcinoma *in situ* of 58, 38, and 12 months for patients with mild, moderate, or severe dysplasia, respectively, and predicted that 66% of all dysplasias would progress to carcinoma *in situ* within 10 years.

Once tumor has broken through the basement membrane, it may penetrate the cervical stroma directly or through vascular channels. Invasive tumors may develop as exophytic growths protruding from the cervix into the vagina or as endocervical lesions that can cause massive expansion of the cervix despite a relatively normal-appearing cervical portio. From the cervix, tumor may extend superiorly to the lower uterine segment, inferiorly to the vagina, or into the paracervical spaces by way of the broad or uterosacral ligaments. Tumor may become fixed to the pelvic wall by direct extension or by coalescence of central tumor with regional adenopathy. Tumor may also extend anteriorly to involve the bladder or posteriorly to the rectum, although rectal mucosal involvement is a rare finding at initial presentation.

The cervix has a rich supply of lymphatics organized in three anastomosing plexuses that drain the mucosal, muscularis, and serosal layers.<sup>58</sup> The lymphatics of the cervix also anastomose extensively with those of the lower uterine segment, possibly explaining the high frequency of uterine extension from endocervical primary tumors. The most important lymphatic collecting trunks exit laterally from the uterine isthmus in three groups (Fig. 36.2-1).<sup>58,59</sup> The upper branches, which originate in the anterior and lateral cervix, follow the uterine artery, are sometimes interrupted by a node as they cross the ureter, and terminate in the uppermost hypogastric nodes. The middle branches drain to deeper hypogastric (obturator) nodes. The lowest branches follow a posterior course to the inferior and superior gluteal, common iliac, presacral, and subaortic nodes. Additional posterior lymphatic channels arising from the posterior cervical wall may drain to superior rectal nodes or may continue upward in the retrorectal space to the subaortic nodes overlying the sacral promontory. Anterior collecting trunks pass between the cervix and bladder along the superior vesical artery and terminate in the internal iliac nodes.

Table 36.2-2 summarizes the reported incidences of pelvic and paraaortic node involvement for patients who underwent lymphadenectomy as part of primary surgical treatment or before radiotherapy for cervical carcinomas.<sup>60,61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80,81,82</sup> and <sup>83</sup> The incidences reported for patients who underwent radical hysterectomy vary widely, probably reflecting differences in the criteria used by surgeons to select patients for radical surgery rather than for primary radiation treatment. Many series excluded patients with extrapelvic disease. Variations in the completeness of lymphadenectomies and histologic processing may also lead to underestimates of the true incidence of regional spread from carcinomas of the cervix.<sup>60,84</sup>

**TABLE 36.2-2.** Rates of Lymph Node Metastasis in Patients with Carcinoma of the Cervix

Cervical cancer usually follows a relatively orderly pattern of metastatic progression initially to primary echelon nodes in the pelvis, then to paraaortic nodes and distant sites. Even patients with locoregionally advanced disease rarely have detectable hematogenous metastases at initial diagnosis of their cervical cancer. The most frequent sites of distant recurrence are lung, extrapelvic nodes, liver, and bone.<sup>85,86</sup> Although early studies suggested that the lumbar spine was a relatively frequent site of skeletal metastases, more recent studies using abdominal imaging demonstrate that most patients with isolated lumbar spine involvement actually have direct extension of disease from paraaortic nodes.<sup>87</sup>

**PATHOLOGY**

**Cervical Intraepithelial Neoplasia**

Several systems have been developed for classifying cervical cytologic findings ( Table 36.2-3). Although criteria for the diagnosis of CIN vary somewhat between pathologists, the important characteristics of this lesion are cellular immaturity, cellular disorganization, nuclear abnormalities, and increased mitotic activity. The degree of neoplasia is determined on the basis of the extent of the mitotic activity, immature cell proliferation, and nuclear atypia. If mitoses and immature cells are present only in the lower third of the epithelium, the lesion is usually designated CIN 1. Lesions involving the middle or upper third are diagnosed as CIN 2 or CIN 3, respectively.

Bethesda System	Dysplasia/CIN System	Papanicolaou System
Widespread normal	Normal	Class I
Infection (specify organism)	Inflammatory vaginitis (specify)	Class II
Reactive and reparative changes		
Suspicious of abnormality	Squamous atypia	
Atypical squamous cells of undetermined significance	Minor dysplasia	Class III
Low-grade squamous intraepithelial lesion	CIN I	
	Major dysplasia	Class III
	CIN II	
High-grade squamous intraepithelial lesion	Severe dysplasia	Class III
	CIN III	
Invasive squamous carcinoma	Carcinoma in situ	Class IV
	Invasive squamous carcinoma	Class V

CIN, cervical intraepithelial neoplasia.

**TABLE 36.2-3.** Comparison of Cytology Classification Systems

The term *cervical intraepithelial neoplasia*, as proposed by Richart,<sup>88</sup> refers only to a lesion that may progress to invasive carcinoma. Although CIN 1 to 2 is sometimes referred to as mild to moderate dysplasia, *CIN* is now preferred over *dysplasia*. Because the word *dysplasia* means “abnormal maturation,” proliferating metaplasia without mitotic activity has sometimes been erroneously called dysplasia.

The Bethesda system of classification, designed to further standardize reporting of cervical cytologic findings, was developed after a National Cancer Institute consensus conference in 1988 and was refined in 1991.<sup>89</sup> This system, which separates condylomata and CIN 1, classified as low-grade squamous intraepithelial lesions, from high-grade squamous intraepithelial lesions, is meant to replace the Papanicolaou system and is now widely used in the United States. The Bethesda system introduced the term *atypical squamous cells of undetermined significance*. This uncertain diagnosis is now the most common abnormal Pap test result.<sup>90</sup> In United States laboratories, 1.6% to 9.0% of Pap smears are reported as having atypical squamous cells of undetermined significance.<sup>91</sup> Although most reflect a benign process, approximately 5% to 10% are associated with underlying high-grade squamous intraepithelial lesions, and one-third or more of high-grade squamous intraepithelial lesions are heralded by a finding of atypical squamous cells of undetermined significance on a Pap smear.<sup>92</sup>

**Adenocarcinoma In Situ**

The diagnosis of adenocarcinoma *in situ* (AIS) is made when normal endocervical gland cells are replaced by tall, irregular columnar cells with stratified, hyperchromatic nuclei and increased mitotic activity, but the normal branching pattern of the endocervical glands is maintained and there is no obvious stromal invasion. Approximately 20% to 50% of women with cervical AIS also have squamous CIN, and AIS is often an incidental finding in patients operated on for squamous carcinoma.<sup>93,94</sup> Because AIS is frequently multifocal, cone biopsy margins are unreliable.<sup>93,95</sup>

**Microinvasive Carcinoma**

Because the definition of microinvasive carcinoma is based on the maximum depth and linear extent of involvement, this diagnosis can only be made after examination of a specimen that includes the entire neoplastic lesion and cervical transformation zone. This requires a cervical cone biopsy.

The earliest invasion appears as a protrusion of cells from the stromaeoepithelial junction; these cells are better differentiated than the adjacent noninvasive cells and have abundant pink-staining cytoplasm, hyperchromatic nuclei, and small- to medium-sized nucleoli.<sup>96</sup> As the tumor progresses, invasion occurs at multiple sites, and its depth and linear extent become measurable. The depth of invasion should be measured with a micrometer from the base of the epithelium to the deepest point of invasion. Lesions that have invaded less than 3 mm [International Federation of Gynecology and Obstetrics (FIGO) stage IA1] rarely metastasize; 5% to 10% of tumors that invade 3 to 5 mm (FIGO stage IA2) have positive pelvic lymph nodes.<sup>97,98 and 99</sup>

Although investigators occasionally label small adenocarcinomas as *microinvasive*, the term probably should not be used for these tumors. Because invasive adenocarcinomas may originate either from the mucosal surface or from the periphery of underlying glands, no reliable method has been found for measuring the depth of invasion of these tumors. For this reason adenocarcinomas are generally classified as either AIS or invasive carcinoma (FIGO stage IB).

**Invasive Squamous Cell Carcinoma**

Between 80% and 90% of cervical carcinomas are squamous. A number of systems have been used to grade and classify squamous carcinomas, but none have consistently been demonstrated to predict prognosis. One of the most commonly used systems categorizes squamous neoplasms as large cell keratinizing, large cell nonkeratinizing, or small cell carcinoma.<sup>100</sup> Small cell squamous carcinomas have small- to medium-sized nuclei, open chromatin, small or large nucleoli, and abundant cytoplasm. Most authorities believe that patients with small cell squamous carcinoma have a poorer prognosis than those with large cell neoplasms with or without keratin. However, small cell squamous carcinoma should not be confused with anaplastic small cell carcinoma. The latter resembles oat cell carcinoma of the lung because it contains small tumor cells that have scanty cytoplasm, small round to oval nuclei, small or absent nucleoli, finely granular chromatin, and high mitotic activity.<sup>101</sup> Approximately 30% to 50% of anaplastic small cell carcinomas display neuroendocrine features. Small cell anaplastic carcinomas behave more aggressively than poorly differentiated small cell squamous carcinomas; most investigators report survival rates of less than 50% even for patients with early stage I disease.<sup>102,103 and 104</sup>

**Adenocarcinoma**

Invasive adenocarcinoma may be pure or mixed with squamous cell carcinoma (adenosquamous carcinoma). A wide variety of cell types, growth patterns, and degrees of differentiation have been observed. Approximately 80% of cervical adenocarcinomas are made up predominantly of cells whose differentiated features

resemble endocervical glandular epithelium with intracytoplasmic mucin production. The remaining tumors are populated by endometrioid cells, clear cells, intestinal cells, or a mixture of more than one cell type. By histologic examination alone, some of these tumors are indistinguishable from those arising elsewhere in the endometrium or ovary.

Minimal-deviation adenocarcinoma (adenoma malignum) is a rare, extremely well differentiated adenocarcinoma that is sometimes associated with Peutz-Jeghers syndrome.<sup>105,106</sup> Because the branching glandular pattern strongly resembles normal endocervical glands, minimal-deviation adenocarcinoma may not be recognized as malignant in small biopsy specimens. Earlier studies reported a dismal outcome for women with this tumor, but more recently, patients have been reported to have a favorable prognosis if the disease is detected early.<sup>107,108</sup>

Young and Scully<sup>109</sup> have described a villoglandular papillary subtype of adenocarcinoma that primarily affects young women, appears to metastasize infrequently, and has a favorable prognosis. Glucksmann and Cherry<sup>110</sup> were the first to describe glassy cell carcinoma, a form of poorly differentiated adenosquamous carcinoma with cells that have abundant eosinophilic, granular, ground-glass cytoplasm; large round to oval nuclei; and prominent nucleoli. Other rare variants of adenosquamous carcinoma include adenoid basal carcinoma and adenoid cystic carcinoma.<sup>111</sup> Adenoid basal carcinoma is a well-differentiated tumor that histologically resembles basal cell carcinoma of the skin and tends to have a favorable prognosis. Adenoid cystic carcinomas consist of basaloid cells in a cribriform or cylindromatous pattern and tend to have aggressive behavior with frequent metastases, although the natural history of these tumors may be long. Whether the prognoses of these rare subtypes are different from those of other adenocarcinomas of similar grade is uncertain.

A variety of neoplasms may infiltrate the cervix from adjacent sites presenting differential diagnostic problems. In particular, it may be difficult or impossible to determine the origin of adenocarcinomas involving the endocervix and uterine isthmus. Although endometrioid histology suggests endometrial origin and mucinous tumors in young patients are most often of endocervical origin, both histologic types can arise in either site.<sup>112</sup> Metastatic tumors from the colon, breast, or other sites may involve the cervix secondarily. Malignant mixed Müllerian tumors, adenosarcomas, and leiomyosarcomas arise occasionally in the cervix but more often involve it secondarily. Primary lymphomas and melanomas of the cervix are extremely rare.

## CLINICAL MANIFESTATIONS

Preinvasive disease is usually detected during routine cervical cytologic screening. Early invasive disease may not be associated with any symptoms and is also detected during screening examinations. The earliest symptom of invasive cervical cancer is usually abnormal vaginal bleeding, often following coitus or vaginal douching. This may be associated with a clear or foul-smelling vaginal discharge. Pelvic pain may result from locoregionally invasive disease or from coexistent pelvic inflammatory disease. Flank pain may be a symptom of hydronephrosis, often complicated by pyelonephritis. The triad of sciatic pain, leg edema, and hydronephrosis is almost always associated with extensive pelvic wall involvement by tumor. Patients with advanced tumors may have hematuria or incontinence from a vesicovaginal fistula caused by direct extension of tumor to the bladder. External compression of the rectum by a massive primary tumor may cause constipation, but the rectal mucosa is rarely involved at initial diagnosis.

## DIAGNOSIS, CLINICAL EVALUATION, AND STAGING

### Diagnosis

The long preinvasive stage of cervical cancer, the relatively high prevalence of the disease in unscreened populations, and the sensitivity of cytologic screening make cervical carcinoma an ideal target for cancer screening. In the United States, screening with cervical cytologic examination and pelvic examination has led to more than a 70% decrease in the mortality from cervical cancer since 1940.<sup>113</sup> Only nations with comprehensive screening programs have experienced substantial decreases in cervical cancer death rates during this period.

Authorities disagree about the optimal frequency of cervical cancer screening. In a 1988 consensus statement, the American Cancer Society and other medical groups recommended annual Pap smears beginning at age 18 years or with the onset of sexual activity and added that, after three or more consecutive normal annual examinations, the cytologic evaluation could be performed less frequently at the discretion of the physician.<sup>114,115</sup> For patients who have had repeated negative test results, the marginal gain from screening more often than every 3 years decreases sharply.<sup>116,117</sup> and <sup>118</sup> The United States Preventative Services Task Force has recommended that screening be discontinued after age 65 years if results have been consistently normal, and the Canadian Task Force suggests that the screening interval be extended to 5 years after age 35 if previous studies have been normal.<sup>115</sup> Although these groups have suggested tailoring the frequency of Pap smears to patient risk, practical definitions of low and high risk remain controversial. As a result, most clinicians continue to recommend that their patients be screened more frequently than recommended by the national guidelines.<sup>115</sup> The rate of false-negative findings on the Pap test is approximately 10% to 15% in women with invasive cancer.<sup>53,54,114</sup> The sensitivity of the test may be improved by ensuring adequate sampling of the squamocolumnar junction and the endocervical canal; smears without endocervical or metaplastic cells are inadequate and must be repeated. Because AIS originates near or above the transformation zone, it may be missed with conventional cervical smears. Detection of high endocervical lesions may be improved when specimens are obtained with a cytobrush. Also, because hemorrhage, necrosis, and intense inflammation may obscure the results, the Pap smear is a poor way to diagnose gross lesions; these should always be biopsied.

Patients with abnormal findings on cytologic examination who do not have a gross cervical lesion must be evaluated by colposcopy and directed biopsies. Following application of a 3% acetic acid solution, the cervix is examined under 10- to 15-fold magnification with a bright, filtered light that enhances the acetowhitening and vascular patterns characteristic of dysplasia or carcinoma. The skilled colposcopist can accurately distinguish between low- and high-grade dysplasia,<sup>119,120</sup> and <sup>121</sup> but microinvasive disease cannot consistently be distinguished from intraepithelial lesions on colposcopy.<sup>122,123</sup>

If no abnormalities are found on colposcopic examination or if the entire squamocolumnar junction cannot be visualized in a patient with an atypical Pap smear result, endocervical curettage should be performed. Some authorities advocate the routine addition of endocervical curettage to colposcopic examination to minimize the risk of missing occult cancer within the endocervical canal.<sup>122,123</sup> and <sup>124</sup> However, it is probably reasonable to omit this step in previously untreated women if the entire squamocolumnar junction is visible with a complete ring of unaltered columnar epithelium in the lower canal.

Cervical cone biopsy is used to diagnose occult endocervical lesions and is an essential step in the diagnosis and management of microinvasive carcinoma of the cervix. The geometry of the cone is individualized and tailored to the geometry of the cervix, the location of the squamocolumnar junction, and the site and size of the lesion. Cervical cone biopsy yields an accurate diagnosis and decreases the incidence of inappropriate therapy when (1) the squamocolumnar junction is poorly visualized on colposcopy and a high-grade lesion is suspected, (2) a high-grade dysplastic epithelium extends into the endocervical canal, (3) the cytologic findings suggest a high-grade dysplasia or carcinoma *in situ*, (4) a microinvasive carcinoma is found on directed biopsy, (5) the endocervical curettage specimens show high-grade CIN, or (6) the cytologic findings are suspicious for AIS.<sup>55,114,125</sup>

### Clinical Evaluation of Patients with Invasive Carcinoma

All patients with invasive cervical cancer should be evaluated with a detailed history and physical examination, with particular attention paid to inspection and palpation of the pelvic organs with bimanual and rectovaginal examinations. Standard laboratory studies should include a complete blood cell count and renal function and liver function tests. All patients should have chest radiography to rule out lung metastases and an intravenous pyelogram [or computed tomography (CT)] to determine the kidney's location and to rule out ureteral obstruction by tumor. Cystoscopy and either a proctoscopy or a barium enema study should be done in patients with bulky tumors.

Many clinicians obtain CT or magnetic resonance imaging (MRI) scans to evaluate regional nodes, but the accuracy of these studies is compromised by their failure to detect small metastases and because patients with bulky necrotic tumors often have enlarged reactive lymph nodes.<sup>126,127</sup> In a large Gynecologic Oncology Group (GOG) study that compared the results of radiographic studies with subsequent histologic findings, Heller et al.<sup>126</sup> found that 79% of the cases with paraaortic lymph node involvement were detected by lymphangiography, whereas only 34% were detected by CT. Unfortunately, lymphangiography is no longer available in many centers. More recent studies suggest that positron emission tomography may be a sensitive noninvasive method of evaluating the regional nodes of patients with cervical cancers.<sup>128</sup> MRI can provide useful information about the distribution and depth of invasion of tumors in the cervix<sup>129,130</sup> and <sup>131</sup> but tends to yield less accurate assessments of the parametrium.<sup>132,133</sup>

**FIGURE 36.2-2.** Relationship between tumor diameter and the disease-specific survival rates of 1526 patients with stage IB squamous cell carcinomas of the cervix treated with radiotherapy at M. D. Anderson Cancer Center. Numbers in parentheses represent the number of patients at risk at 10 or 20 years. (Reprinted from ref. 148, with permission.)

Lymph node metastasis is also an important predictor of prognosis. For patients treated with radical hysterectomy for stage IB disease, survival rates are usually reported as 85% to 95% for patients with negative nodes and 45% to 55% for those with lymph node metastases. <sup>61,63,158</sup> Inoue and Morita <sup>159</sup> reported that survival was correlated with the size of the largest node, and several authors have reported correlations between the number of involved pelvic lymph nodes and survival. <sup>62,150,158,160</sup> Survival rates for patients with positive paraaortic nodes treated with extended-field radiotherapy vary between 10% and 50% depending on the extent of pelvic disease and paraaortic lymph node involvement ( [Table 36.2-5](#)). <sup>77,78,80,81,140,161,162,163,164,165,166,167</sup> and <sup>168</sup>

**TABLE 36.2-5.** Results of Extended-Field Radiation Therapy to the Paraaortic Nodes for Biopsy-Proven Paraaortic Node Metastases from Carcinoma of the Cervix

For patients treated with radical hysterectomy, other histologic parameters that have been associated with a poor prognosis are lymph-vascular space invasion (LVSI) ( [Table 36.2-6](#)), <sup>62,150,151,158,169,170,171,172</sup> and <sup>173</sup> deep stromal invasion (greater than or equal to 10 mm or greater than 70% invasion), <sup>62,63,67,71,150,151,158</sup> and parametrial extension. <sup>62,71,155,174</sup> Roman and colleagues <sup>175</sup> reported a correlation between the quantity of LVSI (percent of histopathologic sections containing LVSI) and the incidence of lymph node metastases. A strong inflammatory response in the cervical stroma tends to predict a good outcome. <sup>176</sup> Uterine body involvement is associated with an increased rate of distant metastases in patients treated with radiation or surgery. <sup>177,178,179</sup> and <sup>180</sup>

**TABLE 36.2-6.** Relationship between Lymph-Vascular Space Invasion, Pelvic Node Involvement, and Recurrence Rate in Patients Treated with Radical Hysterectomy

Several investigators have reported similar survival rates for patients with squamous carcinomas and those with adenocarcinomas. <sup>84,181,182,183,184</sup> and <sup>185</sup> However, other investigators have drawn the opposite conclusion, noting unusually high pelvic relapse rates in patients treated surgically for adenocarcinomas and poorer survival rates among patients treated with surgery or irradiation for cervical adenocarcinomas. <sup>186,187,188,189,190</sup> and <sup>191</sup> In a multivariate analysis of 1767 patients treated with radiation for FIGO stage IB disease, Eifel and colleagues <sup>188</sup> reported a highly significant independent correlation between histologic features and survival. Using Cox regression analysis, the relative risk of death from cancer for 106 patients with adenocarcinomas 4 cm or more in diameter was determined to be 1.9 times that for patients with squamous tumors ( $P < .01$ ) ( [Fig. 36.2-3](#)). Pelvic disease control rates were similar for patients with squamous carcinomas and those with adenocarcinomas, but there was a significantly higher incidence of distant metastases in patients with adenocarcinomas. Although the prognostic significance of histologic grade has been disputed for squamous carcinomas, there is a clear correlation between the degree of differentiation and the clinical behavior of adenocarcinomas. <sup>189,192,193,194</sup> and <sup>195</sup>

**FIGURE 36.2-3.** Relationship between histologic type and the disease-specific survival rates of 903 patients treated at M. D. AC, adenocarcinoma; SCC, squamous cell carcinoma. (Reprinted from ref. 188, with permission.)

Several studies have demonstrated a relationship between hemoglobin level and prognosis in patients with locally advanced cervical cancer. <sup>196,197</sup> and <sup>198</sup> The strongest evidence that anemia plays a causative role in pelvic recurrence comes from a small 1978 randomized study conducted at the Princess Margaret Hospital. <sup>196</sup> All patients were maintained at a hemoglobin level of at least 10 gm%, but those in the treatment arm were maintained, through the use of transfusions, at hemoglobin levels of at least 12.5 gm%. The locoregional recurrence rate was significantly higher for the 25 anemic patients in the control arm than it was for the patients who received transfusions. Unfortunately, the results of this small study have never been confirmed, and subsequent studies aimed at overcoming the theoretical radiobiologic consequences of intratumoral hypoxia (hypoxic cell sensitizers, hyperbaric oxygen breathing, neutron therapy) have not been

successful.<sup>199,200,201,202,203,204 and 205</sup> Several investigators have correlated low intratumoral oxygen tension levels with a high rate of lymph node metastases and poor survival.<sup>206,207 and 208</sup>

The serum concentration of squamous cell carcinoma antigen appears to correlate with the stage and size of squamous carcinomas and the presence of lymph node metastases.<sup>209,210,211 and 212</sup> However, investigators disagree about the independent predictive value of this test. Other clinical and biologic features that have been investigated for their predictive power, with variable results, include patient age,<sup>158,213,214,215 and 216</sup> peritoneal cytology,<sup>217,218</sup> platelet count,<sup>219,220</sup> tumor vascularity,<sup>221,222</sup> DNA ploidy or S phase,<sup>223,224</sup> and HPV subtype.<sup>35,225,226</sup> In two studies of patients with histologically negative lymph nodes, investigators have reported higher rates of disease recurrence when a polymerase chain reaction assay of the lymph nodes was strongly positive for HPV DNA.<sup>227,228</sup>

## TREATMENT

A number of factors may influence the choice of local treatment, including tumor size, stage, histologic features, evidence of lymph node involvement, risk factors for complications of surgery or radiation, and patient preference. However, as a rule, intraepithelial lesions are treated with superficial ablative techniques; microinvasive cancers invading less than 3 mm (stage IA1) are managed with conservative surgery (excisional conization or extrafascial hysterectomy); early invasive cancers (stages IA2 and IB1 and some small stage IIA tumors) are managed with radical surgery or radiotherapy; and locally advanced cancers (stages IB2 through IVA) are managed with radiotherapy. Selected patients with centrally recurrent disease after maximum radiotherapy may be treated with radical exenterative surgery; pelvic recurrence after hysterectomy is treated with irradiation. The results of randomized trials<sup>229,230,231,232 and 233</sup> have led to the addition of concurrent cisplatin-containing chemotherapy to radiotherapy for patients whose cancers have a high risk of local-regional recurrence.

### Preinvasive Disease (Stage 0)

Patients with noninvasive squamous lesions can be treated with superficial ablative therapy (cryosurgery or laser therapy) or with loop excision if (1) the entire transformation zone has been visualized colposcopically, (2) directed biopsies are consistent with Pap smear results, (3) endocervical curettage findings are negative, and (4) there is no suspicion of occult invasion on cytologic or colposcopic examination. If patients do not meet these criteria, a conization should be performed.

With cryotherapy, abnormal tissue is frozen with a supercooled metal probe until an ice ball forms that extends 5 mm beyond the lesion. Because cryonecrosis tends to be patchy and may be inadequate after a single freeze, the tissue should be frozen a second time after it has visibly thawed.<sup>234,235</sup> Another common and equally effective technique ablates tissue with a carbon dioxide laser beam. After laser ablation there is less distortion and more rapid healing of the cervix, but the procedure requires more training and more expensive equipment than does cryosurgery.

Many practitioners now consider loop diathermy excision to be the preferred treatment for noninvasive squamous lesions. With this technique, a charged electrode is used to excise the entire transformation zone and distal canal. Although control rates are similar to those achieved with cryotherapy or laser ablation,<sup>236</sup> loop diathermy is easily learned, is less expensive than laser excision, and preserves the excised lesion and transformation zone for histologic evaluation.<sup>237,238,239 and 240</sup> However, some authorities think that low-grade lesions may be overtreated with this method.<sup>241</sup> Because loop excision may inadequately treat disease within the cervical canal and complicate further treatment, this technique should not be considered an alternative to formal excisional conization when microinvasive or invasive cancer is suspected or for patients with AIS.

Cryotherapy, laser excision, and loop excision are all outpatient office procedures that preserve fertility. Although recurrence rates are low (10% to 15%) and progression to invasion rare (less than 2% in most series), life long surveillance of these patients must be maintained. The risk of recurrence may be somewhat increased in women with HPV type 16 or 18.<sup>236</sup> Treatment with vaginal or type I abdominal hysterectomy currently is reserved for women who have other gynecologic conditions that justify the procedure; invasive cancer still must be excluded before surgery to rule out the need for a more extensive operative procedure.

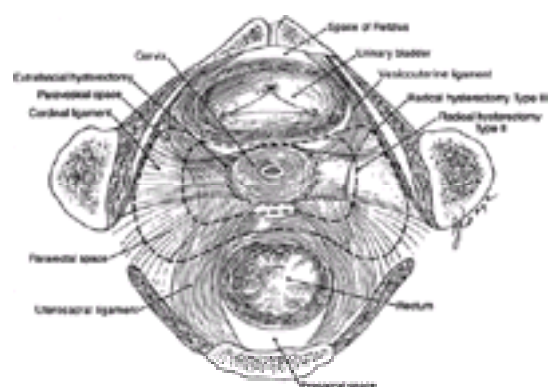

### Microinvasive Carcinoma (Stage IA)

The standard treatment for patients with stage IA1 disease is total (type I) or vaginal hysterectomy. Because the risk of pelvic lymph node metastases from these minimally invasive tumors is less than 1%, pelvic lymph node dissection is not usually recommended.<sup>71,123,242</sup>

Selected patients with tumors that meet the Society of Gynecologic Oncologists' definition of microinvasion (FIGO stage IA1 disease without LVSI) and who wish to maintain fertility may be adequately treated with a therapeutic cervical conization if the margins of the cone are negative. In 1991, Burghardt et al.<sup>243</sup> reported one recurrence (which was fatal) in 93 women followed for more than 5 years after therapeutic conization for minimal (less than 1 mm) microinvasion. Morris et al.<sup>244</sup> reported no invasive recurrences in 14 patients followed for a mean of 26 months after conization for tumors invading 0.5 to 2.8 mm. However, patients who have this conservative treatment must be followed closely with periodic cytologic evaluation, colposcopy, and endocervical curettage.

Diagnostic or therapeutic conization for microinvasive disease is usually performed with a cold knife or carbon dioxide laser on a patient under general or spinal anesthesia. Because an accurate assessment of the maximum depth of invasion is critical, the entire specimen must be sectioned and carefully handled to maintain its original orientation for microscopic assessment. Complications occur in 2% to 12% of patients, are related to the depth of the cone, and include hemorrhage, sepsis, infertility, stenosis, and cervical incompetence.<sup>245</sup> The width and depth of the cone should be tailored to produce the least amount of injury while providing clear surgical margins.

For patients whose tumors invade 3 to 5 mm into the stroma (FIGO stage IA2), the risk of nodal metastases is approximately 5%.<sup>65,96</sup> Therefore, a bilateral pelvic lymphadenectomy should be performed in conjunction with a modified radical (type II) hysterectomy. Modified radical hysterectomy is a less extensive procedure than a classic radical hysterectomy (Fig. 36.2-4). The cervix, upper vagina, and paracervical tissues are removed after careful dissection of the ureters to the point of their entry to the bladder. The medial half of the cardinal ligaments and the uterosacral ligaments are also removed. With this treatment, significant urinary tract complications are rare and cure rates exceed 95%.<sup>246,247 and 248</sup>

**FIGURE 36.2-4.** The pelvic ligaments and spaces. Dotted lines indicate the tissues removed with a type II or type III hysterectomy. (Reprinted from ref. 541, with permission.)

Although surgical treatment is standard for *in situ* and microinvasive cancer, patients with severe medical problems or other contraindications to surgical treatment can be successfully treated with radiotherapy. Grigsby and Perez<sup>249</sup> reported a 10-year progression-free survival rate of 100% in 21 patients with carcinoma *in situ* and in 34 patients with microinvasive carcinoma treated with radiation alone. Hamberger et al.<sup>250</sup> reported that all patients with stage IA disease and 89 (96%) of 93 patients with small stage IB disease (less than one cervical quadrant involved) were disease free 5 years after treatment with intracavitary irradiation alone.

## Stages IB and IIA

Early stage IB cervical carcinomas can be treated effectively with combined external-beam irradiation and brachytherapy or with radical hysterectomy and bilateral pelvic lymphadenectomy. The goal of both treatments is to destroy malignant cells in the cervix, paracervical tissues, and regional lymph nodes. Studies indicate that selected subgroups of patients who require radiotherapy also benefit from concurrent chemotherapy. [229,230](#) and [231](#)

Overall survival rates for patients with stage IB cervical cancer treated with surgery or radiation usually range between 80% and 90%, suggesting that the two treatments are equally effective ([Table 36.2-7](#)). [63,66,67,72,148,149,251,252,253,254,255,256,257,258,259,260,261](#) and [262](#) However, biases introduced by patient selection, variations in the definition of stage IA disease, and variable indications for postoperative radiotherapy or adjuvant hysterectomy confound comparisons about the efficacy of radiotherapy versus surgery. Because young women with small, clinically node-negative tumors tend to be favored candidates for surgery and because tumor diameter and nodal status are inconsistently described in published series, it is difficult to compare the results reported for patients treated with the two modalities.

**TABLE 36.2-7.** Five-Year Survival Rates for Patients with International Federation of Gynecology and Obstetrics Stage IB Carcinoma of the Cervix

In 1997, Landoni and colleagues reported results from the only prospective trial comparing radical surgery with radiotherapy alone. [263](#) In their study, patients with stage IB or IIA disease were randomly assigned to receive treatment with type III radical hysterectomy or a combination of external-beam and low dose-rate intracavitary radiotherapy. In the surgical arm, findings of parametrial involvement, positive margins, deep stromal invasion, or positive nodes led to the use of postoperative pelvic irradiation in 62 (54%) of 114 patients with tumors 4 cm or smaller in diameter and in 46 (84%) of 55 patients with tumors measuring less than 4 cm. Patients in the radiotherapy arm received a relatively low total dose of radiation to the cervix, with a median dose to point A of 76 Gy. With a median follow-up of 87 months, the 5-year actuarial disease-free survival rates for patients treated in the surgery and radiotherapy groups were 80% and 82%, respectively, for patients with tumors that were 4 cm or smaller and 63% and 57%, respectively, for patients with larger tumors. The authors reported a significantly higher rate of complications in the patients treated with initial surgery, and they attributed this finding to the frequent use of combined modality treatment in this group.

For patients with stage IB1 squamous carcinomas, the choice of treatment is based primarily on patient preference, anesthetic and surgical risks, physician preference, and an understanding of the nature and incidence of complications with radiotherapy and hysterectomy (described in detail here). For patients with similar tumors, the overall rate of major complications is similar with surgery and radiotherapy, although urinary tract complications tend to be more frequent after surgical treatment and bowel complications are more common after radiotherapy. Surgical treatment tends to be preferred for young women with small tumors because it permits preservation of ovarian function and may cause less vaginal shortening. Radiotherapy is often selected for older, postmenopausal women to avoid the morbidity of a major surgical procedure.

Some surgeons have also advocated the use of radical hysterectomy as initial treatment for patients with stage IB2 tumors. [264,265](#) and [266](#) However, patients who have tumors measuring more than 4 cm in diameter usually have deep stromal invasion and are at high risk for lymph node involvement and parametrial extension. Because patients with these risk factors have an increased rate of pelvic disease recurrence, surgical treatment is usually followed by postoperative irradiation, which means that the patient is exposed to the risks of both treatments. Consequently, many gynecologic and radiation oncologists believe that patients with bulky (stage IB2) carcinomas are better treated with radical radiotherapy.

Two prospective randomized trials [229,230](#) indicate that patients who are treated with radiation for bulky central disease benefit from concurrent administration of cisplatin-containing chemotherapy. A third study suggests that patients who require postoperative radiation because of findings of lymph node metastasis or involved surgical margins also benefit from concurrent chemoradiation. [231](#) These studies are discussed in more detail in the following sections.

**RADICAL HYSTERECTOMY.** The standard surgical treatment for stage IB and stage IIA cervical carcinomas is radical (type III) hysterectomy and bilateral pelvic lymph node dissection. This procedure involves *en bloc* removal of the uterus, cervix, and paracervical, parametrial, and paravaginal tissues to the pelvic side walls bilaterally, with removal of as much of the uterosacral ligaments as possible (see [Fig. 36.2-4](#)). The uterine vessels are ligated at their origin, and the proximal third of the vagina and paracolpium are resected. For women younger than 40 to 45 years, the ovaries usually are not removed. If intraoperative findings suggest a need for postoperative pelvic irradiation, the ovaries may be transposed out of the pelvis.

Intraoperative and immediate postoperative complications of radical hysterectomy include blood loss (average 0.8 L), ureterovaginal fistula (1% to 2%), vesicovaginal fistula (less than 1%), pulmonary embolus (1% to 2%), small bowel obstruction (1% to 2%), and postoperative fever secondary to deep vein thrombosis, pulmonary infection, pelvic cellulitis, urinary tract infection, or wound infection (25% to 50%). [267](#) Subacute complications include lymphocyst formation and lower extremity edema, the risk of which is related to the extent of the node dissection. Lymphocysts may obstruct a ureter, but hydronephrosis usually improves with drainage of the lymphocyst. [268](#) The risk of complications may be increased in patients who receive preoperative or postoperative irradiation.

Although most patients have transient decreased bladder sensation after radical hysterectomy, with appropriate management severe long-term bladder complications are infrequent. However, chronic bladder hypotonia or atony occurs in approximately 3% to 5% of patients, despite careful postoperative bladder drainage. [269,270](#) Bladder atony probably results from damage to the bladder's innervation and may be related to the extent of the parametrial and paravaginal dissection. [271,272](#) Radical hysterectomy may be complicated by stress incontinence, but reported incidences vary widely and may be influenced by the addition of postoperative radiotherapy. [273,274](#) Patients may also experience constipation and, rarely, chronic obstipation after radical hysterectomy.

**RADIOTHERAPY AFTER RADICAL HYSTERECTOMY.** The role of postoperative irradiation in patients with cervical carcinoma is still being defined. Most investigators have reported that postoperative irradiation decreases the risk of pelvic recurrence in patients whose tumors have high-risk features (lymph node metastasis, deep stromal invasion, insecure operative margins, or parametrial involvement). [275,276,277,278,279](#) and [280](#) However, because the patients who received postoperative radiotherapy in these studies were selected for the high-risk features of their tumors, it is difficult to determine the impact of adjuvant irradiation on survival.

The GOG [281](#) reported results of a prospective trial testing the benefit of adjuvant pelvic irradiation in patients who have an intermediate risk of recurrence after radical hysterectomy for stage IB carcinoma. Patients were eligible if they had at least two of the following risk factors: greater than one-third stromal invasion, lymphatic space involvement, or clinical diameter of at least 4 cm. Patients with metastases to the pelvic lymph nodes were excluded. After radical hysterectomy, 277 patients were randomly assigned to receive 46.0 to 50.6 Gy of adjuvant radiotherapy to the pelvis or no further treatment. Overall, there was a 47% reduction in the risk of recurrence with adjuvant radiotherapy ( $P = .008$ ). In this preliminary analysis, follow-up was too immature for a significance level to be assigned to the overall survival comparison, but there were 18 deaths (13%) in the radiotherapy arm versus 30 (21%) in the radical hysterectomy only arm (relative mortality, 0.64). [281](#)

Although pelvic irradiation also reduces the risk of recurrence for patients with pelvic lymph node metastases or parametrial involvement, the risk of pelvic and distant recurrence remains high for these women. [278,282](#) Some authors have hypothesized that the dose of radiation that can be given safely after surgery may be inadequate to control microscopic disease in a surgically disturbed, hypovascular site. [283](#) If this were true, it would be an argument for primary radiotherapeutic management of

**FIGURE 36.2-5.** Relationship between International Federation of Gynecology and Obstetrics stage and the actuarial survival rates of 1383 patients with invasive carcinoma of the cervix treated with radiotherapy. (Reprinted from ref. 253, with permission.)

External-beam irradiation is used to deliver a homogeneous dose to the primary cervical tumor and to potential sites of regional spread. An initial course of external irradiation may also improve the efficacy of subsequent intracavitary treatment by shrinking bulky endocervical tumor (bringing it within the range of the high-dose portion of the brachytherapy dose distribution) and by shrinking exophytic tumor that might prevent satisfactory placement of vaginal applicators. For this reason, patients with locally advanced disease usually begin with a course of external-beam treatment. Subsequent brachytherapy exploits the inverse square law to deliver a high dose to the cervix and paracervical tissues while minimizing the dose to adjacent normal tissues.

Although many clinicians delay intracavitary treatment until pelvic irradiation has caused some initial tumor regression, breaks between external-beam and intracavitary therapy should be discouraged, and every effort should be made to complete the entire treatment in less than 7 to 8 weeks. The favorable results documented in reports from large single-institution studies have been based on policies that dictate relatively short overall treatment durations (less than 8 weeks),<sup>300</sup> and several studies in patients with locally advanced cervical cancer have suggested that longer treatment courses are associated with decreased pelvic disease control and survival rates.<sup>301,302,303,304 and 305</sup>

**EXTERNAL-BEAM TECHNIQUE.** High-energy photons (15 to 18 MV) are usually preferred for pelvic treatment because they spare superficial tissues that are unlikely to be involved with tumor. At these energies, the pelvis can be treated either with four fields (anterior, posterior, and lateral fields) or with anterior and posterior fields alone (Fig. 36.2-6). When high-energy beams are not available, four fields are usually used because less-penetrating 4- to 6-MV photons often deliver an unacceptably high dose to superficial tissues when only two fields are treated. However, lateral fields must be designed with great care because clinicians' estimates of the location of potential sites of disease on a lateral radiographic view may be inaccurate. In particular, standard anterior and posterior borders that have been described in the past may shield regions at risk for microscopic regional disease in the presacral and external iliac nodes and in the presacral and cardinal ligaments; care must also be taken not to underestimate the posterior extent of central cervical disease in patients with bulky tumors.<sup>306,307 and 308</sup>

**FIGURE 36.2-6.** Typical fields used to treat the pelvis with a four-field technique. When lateral fields are used to treat cervical cancers, particular care must be taken to adequately encompass the primary tumor and potential sites of regional spread in the radiation fields.

The caudad extent of disease can be determined by placing radiopaque seeds in the cervix or at the lowest extent of vaginal disease. Information gained from radiologic studies can also improve estimates of disease extent. Lymphangiograms are helpful in tailoring blocks, particularly at the anterior border of lateral fields. MRI and CT scans can improve clinicians' understanding of uterine position and thus help clinicians design anterior and posterior field borders. In fact, some investigators have argued that these studies should be obtained routinely for patients with bulky disease to avoid errors in lateral field design.<sup>309</sup> However, when all these factors are considered, differences in the volume treated with a four-field or a high-energy two-field technique may be small. For this reason, some clinicians prefer to use the simpler technique for patients with bulky tumors.

Tumor response should be evaluated with periodic pelvic examinations to determine the best time to deliver brachytherapy. Some practitioners prefer to maximize the brachytherapy component of treatment and begin as soon as the tumor has responded enough to permit a good placement (with very bulky tumors this may still require greater than or equal to 40 Gy). Subsequent pelvic irradiation is delivered with a central block. A somewhat higher total paracentral dose can be delivered with this approach, but greater reliance is placed on the complex match between the brachytherapy dose distribution and the border of the central shield. This may result in overdoses to medial structures such as the ureters<sup>310</sup> or underdosage of posterior uterosacral disease.<sup>311</sup> For these reasons, other clinicians prefer to give an initial dose of 40 to 45 Gy to the whole pelvis, believing that the ability to deliver a homogeneous distribution to the entire region at risk for microscopic disease and the additional tumor shrinkage achieved before brachytherapy outweighs other considerations. However, external-beam doses of more than 40 to 50 Gy to the central pelvis tend to compromise the dose deliverable to paracentral tissues and increase the risk of late complications.<sup>154</sup>

**ROLE OF PARAAORTIC IRRADIATION.** The role of extended field irradiation in the treatment of cervix cancer is still being defined. Numerous small series of patients with documented paraaortic node involvement demonstrate that some enjoy long-term survival (see Table 36.2-5).<sup>77,80,140,161,162,163 and 164,166,167</sup> Patients with microscopic involvement have a better survival than do those with gross lymphadenopathy, but even 10% to 15% of patients with gross lymphadenopathy appear to be curable with aggressive management. Survival is also strongly correlated with the bulk of central disease. A 1991 study by Cunningham et al.<sup>167</sup> reported a 48% 5-year survival rate in patients who had paraaortic node involvement discovered at exploration for radical hysterectomy that was then aborted. This experience with patients who had small, radiocontrollable primary disease demonstrates that patients with paraaortic node metastases can often be cured if their primary disease can be sterilized. This indicates that patients may have extensive regional spread without distant metastases and provides an argument for surgical staging in high-risk patients.

Two randomized prospective trials have addressed the role of prophylactic paraaortic irradiation in patients without known paraaortic node involvement. In a study conducted by the Radiation Therapy Oncology Group, 367 patients with primary stage IIB or stage IB or IIA tumors more than 4 cm in diameter were randomly assigned to receive either standard pelvic radiotherapy or extended-field radiotherapy before brachytherapy.<sup>312</sup> No consistent method was used to evaluate the paraaortic nodes. For the 337 evaluable patients, absolute survival was significantly better for those treated with extended fields than for those treated with standard pelvic radiotherapy (67% vs. 55% at 5 years;  $P = .02$ ) (Fig. 36.2-7). There was no significant difference in disease-free survival ( $P = .56$ ).

**FIGURE 36.2-7.** Overall survival rates for patients with stage IB, IIA, or IIB carcinoma of the cervix treated with irradiation to the pelvis alone or to the pelvic and paraaortic nodes on Radiation Therapy Oncology Group study 79-20. (Reprinted from ref. 312, with permission.)

A second trial, from the European Organization for Research and Treatment of Cancer, involved a similar randomization between pelvic irradiation and extended fields but had very different eligibility criteria.<sup>313</sup> This study included patients with bulky stage IIB (involving distal vagina or lateral parametrium) and III disease and patients with stage I disease or less bulky stage IIB disease who had positive pelvic nodes on lymphangiography or at surgery. The 4-year disease-free survival rates for patients treated with pelvic or extended fields were not significantly different (49.8% and 53.3%, respectively). However, the rate of paraaortic node recurrence was significantly higher in the pelvic field group, and for patients in whom local control was achieved, the rate of distant metastases was 2.8 times greater if treatment was with pelvic irradiation only ( $F < .01$ ).

Both studies revealed an increased rate of enteric complications in patients treated with extended fields. In the Radiation Therapy Oncology Group study,<sup>312</sup> most small bowel obstructions occurred in patients who had undergone pretreatment transperitoneal staging. The European Organization for Research and Treatment of Cancer<sup>313</sup> did not mention a relationship between surgical staging and enteric complications.

Taken together, these data clearly indicate that some paraaortic metastases are not detected by radiographic studies and that patients with occult disease can be cured if the paraaortic nodes are included in radiation fields. However, the addition of concurrent chemotherapy to the regimen of many patients with locally advanced disease increases the importance of careful selection of patients for large field irradiation because of the greater acute toxicity when chemotherapy is combined with extended-field radiotherapy.<sup>314,315 and 316</sup>

**BRACHYTHERAPY TECHNIQUE.** Fletcher described three conditions that should be met for successful cervical brachytherapy: (1) the geometry of the radioactive sources must prevent underdosed regions on and around the cervix, (2) an adequate dose must be delivered to the paracervical areas, and (3) mucosal tolerance must be respected.<sup>317</sup> Although some clinicians have proposed a number of variations on the low-rate intracavitary brachytherapy techniques practiced at M. D. Anderson, Fletcher's conditions continue to dictate the character, intensity, and timing of brachytherapy for cervical cancer.

Brachytherapy is usually delivered using afterloading applicators that are placed in the uterine cavity and vagina. A number of different intracavitary systems have been used; in the United States, variations of the Fletcher-Suit-Delclos low dose-rate system are still used most commonly.<sup>293,317,318,319 and 320</sup> The intrauterine tandem and vaginal applicators are carefully positioned, usually with the patient under anesthesia, to provide an optimal relationship between the system and adjacent tumor and normal tissues. Vaginal packing is used to hold the tandem and colpostats in place and to maximize the distance between the sources and the bladder and rectum. Radiographs should be obtained at the time of insertion to verify accurate placement, and the system should be repositioned if positioning can be improved. Encapsulated radioactive sources are inserted in the applicators after the patient has returned to her hospital bed, reducing exposure to personnel during applicator placement. Remote afterloading devices that further reduce personnel exposure are often used in departments that treat many patients with gynecologic disease. Although <sup>226</sup>Ra was used to treat most patients before the 1980s, it has gradually been replaced by <sup>137</sup>Cs, which produces a similar dose distribution and avoids the radiation protection problems caused by the radon gas by-product of radium decay.

*Brachytherapy Dose* Ideal placement of the uterine tandem and vaginal ovoids produces a pear-shaped distribution, delivering a high dose to the cervix and paracervical tissues and a reduced dose to the rectum and bladder ( Fig. 36.2-8).

**FIGURE 36.2-8.** Posteroanterior and lateral views of a Fletcher-Suit-Delclos applicator system in a patient with invasive carcinoma of the cervix. Units on the isodose contours are cGy/h. A, point A; B, bladder reference point; R, rectal reference point.

Treatment dose has been specified in a number of ways, making it difficult to compare experiences. Paracentral doses are most frequently expressed at a single point, usually designated *point A*. This reference point has been calculated in a number of different ways, but it is usually placed 2 cm lateral and 2 cm superior to the external cervical os, in the central plane of the intracavitary system (see Fig. 36.2-8). Point A lies approximately at the crossing of the ureter and the uterine artery, but it bears no consistent relationship to the tumor or target volume. Point A was originally developed as part of the Manchester treatment system (a modification of the earlier Paris system). It was meant to be used in the context of a detailed set of rules governing the placement and loading of the intracavitary system. Today this context is often lost.

Other measures have been used to describe the intensity of intracavitary treatment. *Mg-hrs* or *mgRaEq-hrs* are proportional to the dose of radiation at relatively distant points from the system and therefore give a sense of the dose to the whole pelvis. In 1985 the International Commission on Radiation Units and Measurements recommended use of total reference air Kerma, expressed in mGy at 1 m, as an alternative to mg-hrs that allows for the use of various radionuclides.<sup>321</sup> The International Commission on Radiation Units and Measurements also defined reference points for estimating the dose to the bladder and rectum. These points have been widely, although not universally, accepted. Although normal tissue reference points provide useful information about the dose to a portion of normal tissue, several studies have demonstrated that they consistently underestimate the maximum dose to those tissues.<sup>322,323 and 324</sup>

Whatever system of dose specification is used, emphasis should always be placed on optimizing the relationship between the intracavitary applicators and the cervical tumor and other pelvic tissues. Source strengths and positions should be carefully chosen to provide optimal tumor coverage without exceeding normal tissue tolerance. However, optimized source placement can rarely correct for a poorly positioned applicator.

A detailed description of the characteristics of an ideal intracavitary system and of the considerations that influence source strength and position are beyond the scope of this chapter but can be found elsewhere.<sup>320,321,325</sup> However, an effort should always be made to deliver at least 85 Gy (with low dose-rate brachytherapy) to point A for patients with bulky central disease. If the intracavitary placement has been optimized, this can usually be accomplished without exceeding a dose of 75 Gy

to the bladder reference point or 70 Gy to the rectal reference point, doses that are usually associated with an acceptably low risk of major complications.<sup>326,327</sup> The dose to the surface of the lateral wall of the apical vagina should not usually exceed 130 to 140 Gy.<sup>325</sup> Suboptimal placements occasionally force compromises in the dose to tumor or normal tissues. To choose a treatment that optimizes the therapeutic ratio in these circumstances requires experience and a detailed understanding of factors that influence tumor control and normal tissue complications.

A total dose (external-beam and intracavitary) of 50 to 55 Gy appears to be sufficient to sterilize microscopic disease in the pelvic nodes in most patients. It is customary to boost the dose to a total of 60 to 65 Gy in lymph nodes known to contain gross disease and in heavily involved parametria.

**Brachytherapy Dose Rate** Traditionally, cervical brachytherapy has been performed with sources that yield a dose rate at point A of approximately 40 to 50 cGy/h. These low dose rates permit repair of sublethal cellular injury, preferentially spare normal tissues, and optimize the therapeutic ratio. In an effort to reduce the 3 to 4 days of hospitalization needed to deliver an appropriate dose of low dose-rate irradiation, some investigators have explored the use of *intermediate* dose-rate brachytherapy (80 to 100 cGy/h). However, in a randomized trial, Haie-Meder et al.<sup>328</sup> reported a significant increase in complications when the dose rate was doubled from 40 to 80 cGy/h, indicating that the total dose must be reduced and the therapeutic ratio of treatment may be compromised with higher dose rates. On the basis of laboratory studies, Amdur and Bedford have suggested that differences in the magnitude of the dose-rate effect between tumor and normal tissues may in part reflect differences in the half-times for repair of sublethal radiation damage.<sup>329</sup>

During the past two decades, computer technology has made it possible to deliver brachytherapy at very high dose rates (greater than 100 cGy/min) using a high-activity <sup>60</sup>Co or <sup>192</sup>Ir source and remote afterloading. High dose-rate intracavitary therapy is now being used for radical treatment of cervical cancer by a number of groups, including several in Japan, Canada, and Europe, and more recently by some groups in the United States.<sup>330,331,332,333,334,335,336,337</sup> and <sup>338</sup> Clinicians have found this approach attractive because it does not require that patients be hospitalized and may be more convenient for the patient and the physician. However, unless it is heavily fractionated, high dose-rate brachytherapy loses the radiobiologic advantage of low dose-rate treatment, potentially narrowing the therapeutic window for complication-free cure.<sup>339,340</sup> Advocates of high dose-rate treatment disagree about the number of fractions and total dose that should be delivered. Published experiences suggest that survival rates are roughly similar to those achieved with traditional low dose-rate treatment, but these experiences are difficult to compare because of the same potential problems of selection bias that confound other nonrandomized comparisons.<sup>336,339</sup> Many of the retrospective reviews provide incomplete descriptions of tumor and treatment details.<sup>336</sup> Two purported randomized trials<sup>335,337</sup> also have been criticized for methodologic flaws. The use of high dose-rate brachytherapy for cervical cancer continues to be a source of controversy.

**INTERSTITIAL BRACHYTHERAPY.** Several groups have advocated the use of interstitial brachytherapy to treat patients whose anatomy or tumor distribution make it difficult to obtain an ideal intracavitary placement. Interstitial implants are usually placed transperineally, guided by a Lucite template that encourages parallel placement of hollow needles that penetrate the cervix and paracervical spaces; needles are usually loaded with <sup>192</sup>Ir. Advocates of the procedure describe the relatively homogeneous dose distribution achieved with this method, the ease of inserting implants in patients whose uteri are difficult to probe, and the ability to place sources directly into the parametrium. Early reports were enthusiastic, describing these theoretical advantages and high initial local control rates, but these early reports rarely included sufficient numbers of patients or had long enough follow-up to provide long-term survival rates.<sup>341,342,343,344</sup> and <sup>345</sup>

In two of the larger early series, Syed and colleagues reported an encouraging projected 5-year survival rate of 53% for 26 patients with stage IIIB disease,<sup>345</sup> and Martinez and colleagues reported an 83% local control rate in 37 patients with stage IIB and IIIB disease.<sup>344</sup> However, survival results from two more recent reports have been disappointing. In a 1995 review of the combined experiences of Stanford and the Joint Center for Radiation Therapy, the 3-year disease-free survival rates for patients with stage IIB and IIIB disease were only 36% and 18%, respectively. Local control rates were 22% and 44%, respectively, and for patients with local control, the rate of complications requiring surgical intervention was high.<sup>346</sup> A 1997 report of the Irvine experience also described disappointing survival rates of 21% and 29%, respectively, for stage IIB and IIIB, again with a high rate of major complications.

Several groups have been exploring the use of transrectal ultrasound, MRI, or laparoscopic guidance,<sup>347,348</sup> and <sup>349</sup> interstitial hyperthermia,<sup>350</sup> and high dose-rate interstitial therapy<sup>351</sup> to improve local control and complication rates. However, outside of an investigational setting, interstitial treatment of primary cervical cancers should probably be limited to patients who cannot accommodate intrauterine brachytherapy and patients with distal vaginal disease that requires a boost with interstitial brachytherapy.

**COMPLICATIONS OF RADICAL RADIOTHERAPY.** During radiotherapy of the pelvis, most patients have mild fatigue and mild to moderate diarrhea that usually is controllable with antidiarrheal medications; some patients have mild bladder irritation. When extended fields are treated, patients may have nausea, gastric irritation, and mild depression of peripheral blood counts. Acute symptoms may be increased in patients receiving concurrent chemotherapy. Unless the ovaries have been transposed, all premenopausal patients who receive pelvic radiotherapy experience ovarian failure by the completion of treatment.

Perioperative complications of intracavitary therapy include uterine perforation, fever, and the usual risks of anesthesia. Thromboembolisms are rare.<sup>352,353</sup> In a review of 4043 patients who had 7662 intracavitary applications for cervical cancer, Jhingran and Eifel<sup>354</sup> reported 11 patients (0.3%) with thromboembolisms, four of which were fatal. All four fatal pulmonary embolisms were in patients with advanced pelvic wall disease.

Estimates of the risk of late complications of radical radiotherapy vary according to the grading system, duration of follow-up, method of calculation, treatment method, and prevalence of risk factors in the study population. However, most reports quote an overall risk of major complications (requiring transfusion, hospitalization, or surgical intervention) of 5% to 15%. In a report from the Patterns of Care Study, Lanciano et al.<sup>355</sup> reported an actuarial risk of 8% at 3 years. In a study of 1784 patients with stage IB disease, Eifel et al.<sup>356</sup> reported an overall actuarial risk of major complications of 7.7% at 5 years. Although the actuarial risk was greatest during the first 3 years of follow-up, there was a continuing risk to surviving patients of approximately 0.3% per year, resulting in an overall actuarial risk of 14% at 20 years. In a 1999 review of 1456 patients treated with radiation alone, Perez et al.<sup>326</sup> reported a crude incidence of severe complications (requiring surgical intervention or more than 4 weeks of hospitalization) of 5% for patients with stage IB cervical cancer and 9% to 10% for patients with more advanced disease.

During the first 3 years after treatment, rectal complications are most common and include bleeding, stricture, ulceration, and fistula. In the study by Eifel and colleagues,<sup>356</sup> the risk of major rectosigmoid complications was 2.3% at 5 years. Major gastrointestinal complications were rare 3 years or more after treatment, but a constant low risk of urinary tract complications persisted for many years (Fig. 36.2-9). The actuarial risk of developing a fistula of any type was 1.7% at 5 years.

**FIGURE 36.2-9.** Rates of major rectal and urinary tract complications in 1784 patients with stage IB carcinomas of the cervix treated with radiotherapy. Complication rates were calculated actuarially, and patients who died without experiencing a major complication were censored at the time of death. (Reprinted from ref. 356, with permission.)

Small bowel obstruction is an infrequent complication of standard radiotherapy for patients without special risk factors. The risk is increased dramatically in patients who have undergone transperitoneal lymph node dissection.<sup>141,355,356</sup> However, there appears to be little added risk if the operation is performed with a retroperitoneal approach.<sup>141</sup> Other factors that can increase the risk of small bowel complications in patients treated for cervical cancer include pelvic inflammatory disease, thin body

habitus, and the use of high doses or large volumes of external-beam irradiation, particularly with low-energy treatment beams and large daily fraction sizes.<sup>154,355,356,357 and 358</sup>

Most patients treated with radical radiotherapy have some agglutination and telangiectasia of the apical vagina. More significant vaginal shortening can occur, particularly in elderly, postmenopausal women and those with extensive tumors treated with a high dose of irradiation.<sup>356,359</sup> Vaginal function can be optimized with appropriate estrogen support and vaginal dilatation.

**CONCURRENT CHEMORADIATION.** Reports of five prospective randomized trials<sup>229,230,231,232 and 233</sup> have provided compelling evidence that the addition of concurrent cisplatin-containing chemotherapy to standard radiotherapy improves the pelvic disease control and survival rates in selected patients with local, regionally advanced cervical cancer. Although these studies differed in their inclusion criteria, treatment specifics, and control treatments, each demonstrated reduction in the relative risk of recurrence of 30% to 50% with cisplatin-containing chemoradiation ( [Table 36.2-9](#)).

**TABLE 36.2-9.** Prospective Randomized Trials That Investigate the Role of Concurrent Radiotherapy and Cisplatin-Containing Chemotherapy for Patients with Loco-Regionally Advanced Cervical Cancer

Individual investigators and multiinstitutional groups have been exploring combinations of chemotherapy and radiation in patients with cervical cancer for more than 25 years. However, until relatively recently, studies had failed to demonstrate a clear benefit. An early GOG study compared radiation alone with radiation and concurrent hydroxyurea.<sup>360</sup> This study appeared to show some benefit from the combination, but it was criticized because many patients were treated without brachytherapy or with very low doses of radiation and because 93 (49%) of the 190 patients randomized were excluded from the analysis as ineligible or unevaluable. Nevertheless, the GOG continued to include hydroxyurea in the control arm of subsequent studies. The first of these<sup>361</sup> compared hydroxyurea (80 mg/kg given twice per week during external-beam irradiation) with misonidazole, a nitroimidazole hypoxic cell sensitizer that has since been demonstrated to be of no benefit in several trials that compared misonidazole with a placebo.<sup>202,204</sup> Final analysis of this study<sup>361</sup> showed a marginal advantage in progression-free survival ( $P = .05$ ) and survival ( $P = .07$ ) for patients treated with hydroxyurea.

Two subsequent GOG studies<sup>232,233</sup> randomly assigned patients with stage IIB to IVA disease to receive either hydroxyurea or cisplatin-containing chemotherapy during external-beam irradiation. All three of the cisplatin-containing arms had local control and survival rates superior to those for the control (hydroxyurea and radiation) arms. In a third study,<sup>229</sup> patients with stage IB tumors measuring at least 4 cm in diameter were randomly assigned to receive radiation alone or radiation plus weekly cisplatin before extrafascial hysterectomy. Patients who received cisplatin were more likely to have a complete histologic response and were more likely to be disease free at the time of preliminary analysis. A fourth study, cosponsored by the Southwest Oncology Group and the GOG,<sup>231</sup> included patients who were treated with radical hysterectomy and were found to have pelvic lymph node metastases, positive margins, or parametrial involvement. Patients were randomly assigned to receive postoperative pelvic irradiation alone or combined with cisplatin and 5-fluorouracil (5-FU). In a preliminary analysis, patients who received chemotherapy in this study also had a better disease-free survival rate.

During this time, the Radiation Therapy Oncology Group<sup>230</sup> also conducted a trial in which radiotherapy alone (including prophylactic paraaortic irradiation) was compared with pelvic irradiation plus concurrent cisplatin and 5-FU. This is the only study in which chemotherapy was administered during both the brachytherapy and external-beam components of treatment. The results of this trial were released early when highly significant differences were detected in the rates of local control, distant metastasis, overall survival, and disease-free survival favoring the treatment arm that included chemotherapy. Although acute toxic effects of treatment were greater with chemotherapy, the dose and duration of radiation were similar in the two arms, and in an early analysis, there was no significant difference in the incidence of late treatment-related complications.

This work clearly demonstrates that the addition of concurrent cisplatin-containing chemotherapy benefited patients with locally advanced cervical cancer who were treated with radiation in these studies. However, all of the studies explicitly excluded patients with evidence of paraaortic lymph node metastases, poor performance status, or impaired renal function. In the future, clinicians will be challenged to determine how these favorable results can be generalized to patients with cervical cancer who may not have been included in the prospective trials because of severe medical or social problems and to the developing nations where invasive cervical cancer is epidemic.

These studies raise other interesting questions that will undoubtedly be the subjects of future studies. Of four different cisplatin-containing regimens, only two were compared directly. It is unclear from the results which regimen achieves the most favorable therapeutic ratio and whether the inclusion of 5-FU in several of the studies contributed importantly to the results. However, smaller studies have suggested that 5-FU is an effective radiation sensitizer in cervical cancers,<sup>362,363</sup> and the GOG is currently comparing radiation plus continuous-infusion 5-FU with radiation and cisplatin in patients with locally advanced disease. Other drugs that are being studied for their radiosensitizing effects in patients with advanced disease are paclitaxel,<sup>364</sup> carboplatin,<sup>365</sup> and mitomycin C.<sup>366,367</sup> Extended-field irradiation (including the aortic nodes) has proven effective in the treatment of patients with known or suspected aortic node metastasis,<sup>312</sup> but the role of extended-field irradiation needs to be clarified in the context of these new results. Combinations of extended-field irradiation and chemotherapy appear to be feasible, but the acute toxicity is considerable, and late toxicity may be greater than with extended-field radiation alone.<sup>314,316,368</sup>

**NEOADJUVANT CHEMOTHERAPY.** A number of investigators have explored the use of neoadjuvant chemotherapy for locally advanced cervical carcinoma, trying to exploit the encouraging response rates that have been reported for multiple-agent, cisplatin-containing regimens in previously untreated patients (see [Table 36.2-8](#)).<sup>297,299,369,370,371,372,373,374,375,376,377,378,379,380,381,382,383,384 and 385</sup> To test this approach, a number of prospective randomized trials were conducted comparing radiation alone with neoadjuvant chemotherapy followed by radiation ( [Table 36.2-10](#) ).<sup>373,376,377,378,379,380 and 381</sup> Unfortunately, of the seven trials that have been published, five<sup>373,377,378,380,381</sup> demonstrated no benefit from neoadjuvant therapy and two<sup>376,379</sup> demonstrated a significantly better survival rate with radiation alone. In one small trial from South America,<sup>376</sup> patients treated with bleomycin, vincristine, methotrexate, and cisplatin followed by radiation had a significantly poorer survival rate than did those treated with radiation alone. In addition, patients who failed to complete radiotherapy (and were excluded from the analysis) were more frequent in the neoadjuvant chemotherapy arm. Bleomycin toxicity (responsible for four of the deaths) contributed to the poor survival rate of patients treated with neoadjuvant chemotherapy in this study. Tattersall and colleagues<sup>379</sup> compared neoadjuvant chemotherapy (cisplatin and epirubicin) followed by radiotherapy with radiotherapy alone. This study was discontinued when an interim analysis revealed a significantly poorer outcome for patients who received neoadjuvant chemotherapy ( $P = .02$ ).

**TABLE 36.2-10.** Results of Prospective Randomized Trials That Compared Neoadjuvant Chemotherapy Followed by Radiation Therapy with Radiation Therapy Alone in Patients with Locally Advanced Cervical Cancer

In another interesting study, published by Chauvergne and colleagues,<sup>373</sup> patients who had a complete or partial response to chemotherapy followed by radiotherapy had a significantly better outcome than did those who had a poorer response to neoadjuvant chemotherapy. However, there were no significant differences in the overall response rates, disease-free survival rates, or median survival between patients treated with neoadjuvant chemotherapy and those treated with radiation alone.

In summary, despite the high rate of response of locally advanced cervical cancers to initial chemotherapy, none of the randomized studies reported to date has demonstrated an improvement in outcome when neoadjuvant chemotherapy was added to radical radiotherapy. In many ways this recapitulates the experience with treatment of locally advanced head and neck cancers, in which it has been hypothesized that the failure of neoadjuvant chemotherapy to influence outcome may reflect cross-resistance of tumor cells to drugs and radiation or accelerated repopulation of tumor clones induced by neoadjuvant chemotherapy.<sup>386,387 and 388</sup>

More recently, a number of investigators have begun to explore combinations of neoadjuvant chemotherapy with radical surgery in patients with bulky central disease.<sup>297,299,383,384 and 385,389</sup> Only one randomized trial addressing this approach has been published,<sup>299</sup> although a number of other studies have been completed or are in progress. In their study, Sardi and colleagues<sup>299</sup> randomly assigned 205 patients to receive radical hysterectomy with or without neoadjuvant chemotherapy. All patients received postoperative pelvic irradiation. The authors reported a higher rate of resectability (100% vs. 85%) and a better survival rate (81% vs. 66%) for patients treated with neoadjuvant chemotherapy. There have not yet been any comparisons between this approach and radiotherapy alone or combined with chemotherapy.
