Multiple endocrine neoplasia (MEN) is characterized by the development of multiple tumors in endocrine organs in a patient and close relatives. The syndrome is divided into three types: MEN 1, MEN 2a, and MEN 2b. MEN 2 is defined by the combination of tissues affected and the presence of developmental abnormalities and has been the focus of extensive genetic analysis. MEN 2a is associated with medullary carcinoma of the thyroid and with hyperparathyroidism. Individuals with MEN 2b have medullary carcinoma of the thyroid, pheochromocytoma, and developmental abnormalities involving hyperplasia of intestinal autonomic nerve plexuses and growth of nerve axons in the lips, oral mucosa, and conjunctiva, which give rise to the characteristic facies. A syndrome related to MEN 2 is familial medullary thyroid carcinoma, in which patients have only medullary carcinoma of the thyroid. MEN 2a, MEN 2b, and familial medullary thyroid carcinoma have an autosomal dominant pattern of inheritance and account for approximately 25% of all cases of medullary carcinoma of the thyroid.<sup>2</sup>

In 1993, it was established that mutations in the RET protooncogene were responsible for the hereditary predisposition to medullary thyroid cancer.<sup>3,4</sup> This genetic breakthrough has allowed accurate identification of kindreds at high risk for developing medullary carcinoma of the thyroid and has permitted families to consider the risks and benefits of prophylactic thyroidectomy.

In 1994, Wells et al.<sup>5</sup> reported the first experience with prophylactic thyroidectomy based on identification of RET protooncogene mutations. Thirteen patients were confirmed to carry a mutation in the RET protooncogene in association with MEN 2a and underwent immediate thyroidectomy. In each patient, the resected thyroid gland demonstrated C-cell hyperplasia. No metastases were found in regional nodes, and all patients had normal postoperative stimulated plasma calcitonin levels. Subsequent reports have confirmed the validity of this approach, and prophylactic thyroidectomy is now recommended for these patients at approximately 6 years of age.

Kebebew et al.<sup>6</sup> reported a review of ten published series of patients that had prophylactic thyroidectomy for RET protooncogene germline mutations. Two hundred and nine patients were included in this review, and only 3.4% of these patients had normal thyroid histology. A central node dissection was performed on 139 of these patients, and 12 individuals (8.6%) were found to have cervical node metastases. These 12 patients ranged in age from 14 to 70 years. Overall, the morbidity from total thyroidectomy was low. These investigators have recommended that a central node dissection be included when prophylactic total thyroidectomy is performed for patients with RET protooncogene mutations.

A second technical issue is whether to include the routine use of total parathyroidectomy and parathyroid autotransplantation in asymptomatic children with MEN 2a. Decker et al.<sup>7</sup> reported on the strategy of leaving parathyroid tissue preserved *in situ*. These authors recommended this approach because only 10% to 20% of these individuals develop parathyroid disease, and when parathyroid disease does develop in this population, it is usually focal.<sup>7</sup>

Prophylactic thyroidectomy has become the treatment of choice for patients with RET protooncogene mutations and, if done at an early age, the cure rate should be 100%. The identification and management of these patients is perhaps the best example of prophylactic surgery in patients known to be at risk for an inherited malignancy. Genetic testing allows the accurate identification of patients at high risk of developing an invasive cancer, and the organ at risk is removed surgically with low morbidity.

## BARRETT'S ESOPHAGUS AND ESOPHAGEAL CANCER

Barrett's esophagus is a premalignant condition in which the stratified squamous epithelium in the distal esophagus is replaced to a variable extent by metaplastic columnar epithelium. It is significant from an oncologic perspective because of the close association between Barrett's esophagus and the development of adenocarcinoma of the esophagus. Barrett's esophagus develops as a sequela of chronic inflammation caused by reflux of gastric contents, including acid, pepsin, and bile acids. Esophageal motility studies and pH monitoring suggest that these patients exhibit weak lower esophageal sphincter tone and slow clearance of gastric acid.<sup>8,9,10,11</sup> and <sup>12</sup> Although Barrett's esophagus can be recognized or suspected by its appearance on endoscopy, a definitive diagnosis of Barrett's esophagus must be based on biopsy and histologic analysis. The histologic features of Barrett's esophagus should include a demonstration of goblet cells interspersed among mucin-type columnar cells. This represents the so-called specialized columnar epithelium and is pathognomonic of the process.<sup>13</sup>

It is difficult to determine the incidence of Barrett's esophagus. The majority of individuals with Barrett's esophagus in the general population are probably asymptomatic and therefore do not seek medical attention.<sup>14</sup>

Historically, Barrett's esophagus has been taken to mean specialized columnar epithelium that was determined to be more than 3 cm in length, and consequently, much of the published information regarding the incidence and natural history was generated by analyzing patients with long segments of the disease. It is now recognized that intestinal metaplasia of less than 3 cm in length should be classified as Barrett's. It has been reported that up to 33% of all patients undergoing upper endoscopy may have histologic evidence of Barrett's esophagus.<sup>15,16,17</sup> and <sup>18</sup> Approximately 10% of patients with frequent reflux symptoms will have a long segment of Barrett's esophagus identified.<sup>19</sup>

Numerous reports have confirmed that patients with Barrett's esophagus are at increased risk to develop adenocarcinoma of the esophagus.<sup>20,21,22</sup> and <sup>23</sup> In a review of 18 published series, Tytgat<sup>22</sup> estimated the median incidence of esophageal adenocarcinoma in patients with the disease to be approximately 1 cancer per 100 patient-years of follow-up. The overall risk was approximately 40 times higher than that of the general population.<sup>22</sup> The annual rate of cancer development in these patients is estimated to be approximately 0.8%.<sup>23</sup> Information on the risk of developing adenocarcinoma in short segments (less than 3 cm) of Barrett's esophagus is more limited, but the available data suggest it is associated with significant potential for malignant degeneration.<sup>20,21</sup>

The detection of esophageal epithelial dysplasia is an important clinical factor used to stratify patients with Barrett's esophagus. Dent et al.<sup>24</sup> reviewed eight published series and reported the outcome of 50 patients with high-grade dysplasia in Barrett's esophagus. These individuals were followed for up to 5 years, and adenocarcinoma developed in 16 patients (32%). Eleven patients had a resection for dysplasia where no malignancy was found in the specimen.<sup>24</sup> Hameeteman et al.<sup>25</sup> published a prospective study of 50 patients with Barrett's esophagus. All patients were without carcinoma at entrance to the study and were followed for a mean of 5.2 years. Six patients had low-grade dysplasia, and one patient had high-grade dysplasia at the start of the study. By the end of the observation period, five patients had developed adenocarcinoma, ten scored as low-grade dysplasia, and three were scored as high-grade dysplasia.<sup>25</sup> Thus, it is suggested that low-grade dysplasia may be helpful in identifying individuals who are likely to progress to high-grade dysplasia or adenocarcinoma. It is clear, however, that not all high-grade dysplasia progresses to cancer, and regression of a short segment of Barrett's esophagus that contained high-grade dysplasia has been reported.<sup>26,27</sup>

The optimal management of Barrett's esophagus has not been established. No prospective randomized trials have compared alternative treatment strategies. Comparing published series can be problematic because of biopsy sampling errors, differences in pathologic interpretation, and variations and improvements in endoscopic and surgical techniques. Although complete agreement has not been reached regarding the best approach for these patients, most experts depend on the degree of dysplasia associated with Barrett's esophagus to guide treatment recommendations.

### BARRETT'S ESOPHAGUS WITHOUT DYSPLASIA

No role for esophagectomy has been established in patients with Barrett's esophagus and no evidence of dysplasia. The clinical issues surrounding these patients involve questions about the efficacy of screening and the effects of medical or surgical therapy to prevent progression to dysplasia. The exact risk of a patient with Barrett's esophagus without dysplasia for developing cancer is unknown, but it has been estimated to be 0.2% to 2.1% per year, which is an incidence 30 to 125 times that of the general population.<sup>28</sup> Consequently, most patients who are surgical candidates are enrolled into surveillance programs. Currently, most patients are treated medically with weight reduction, head of bed elevation, and H<sub>2</sub>-receptor antagonists or proton pump inhibitors. The goal of therapy is symptomatic relief of gastroesophageal reflux. Although symptoms of reflux often improve with therapy, no evidence suggests that medical therapy consistently induces regression of the metaplastic columnar epithelium.<sup>29,30</sup> In addition, there is little evidence to suggest that antireflux surgery has an important impact on this process. DeMeester<sup>31</sup> reported a review of 11 published series that followed patients with Barrett's esophagus after an antireflux procedure. A total of 340 patients were followed for a mean of 4.4 years. Seventy-four percent of these patients showed no change in their Barrett's mucosa, 17% showed progression, 12% showed partial regression, and only 4% achieved a complete regression of Barrett's esophagus.

The current recommendation for patients with Barrett's esophagus without dysplasia is to have endoscopic surveillance and biopsy performed every 1 to 2 years. This recommendation assumes that the patient is a satisfactory surgical candidate.<sup>23,24</sup>

### BARRETT'S ESOPHAGUS WITH LOW-GRADE DYSPLASIA

There is no role for esophagectomy in patients with low-grade dysplasia associated with Barrett's esophagus. Clearly, the risks of developing severe dysplasia or adenocarcinoma of the esophagus are significant. Medical therapy and antireflux procedures do not appear to influence the natural history of the condition. The current recommendation for healthy patients with low-grade dysplasia associated with Barrett's esophagus is to undergo histologic surveillance every 6 to 12 months. Innovative techniques, such as mucosal ablation, photodynamic therapy, and chemoprevention, are under active investigation.

### BARRETT'S ESOPHAGUS WITH HIGH-GRADE DYSPLASIA

The treatment of patients with high-grade dysplasia associated with Barrett's esophagus is controversial. Most experts recommend that healthy patients undergo esophagectomy by an experienced surgeon. The pathologic diagnosis should be independently confirmed.<sup>23,24,31,32</sup> Because a wide spectrum of mortality has been reported after esophagectomy (1.4% to 21.0%) and because not all patients with high-grade dysplasia develop adenocarcinoma, some experts have made a case for aggressive surveillance for these patients. Levine et al.<sup>33</sup> described and reported on an aggressive biopsy protocol with up to 12 biopsy specimens per centimeter of Barrett's mucosa in patients with high-grade dysplasia. Seventy patients with high-grade dysplasia were followed, and 12 were found to have early-stage adenocarcinomas of the esophagus within an average of 2 months after the diagnosis. In the remaining 58 patients, 15 (23%) progressed to early-stage cancer after an average of 1.1 years of follow-up. None of the remaining 43 patients (74%) developed cancer when followed an average of 2.5 years. These results have not been confirmed at other institutions. It should be noted that more than 25% of these patients developed esophageal adenocarcinoma. In addition, the described surveillance protocol may be impractical for most physicians to follow. Physicians managing healthy patients with severe dysplasia associated with Barrett's esophagus should seriously consider prophylactic esophagectomy.

The recommendation for surgery or surveillance should take into account the mortality and morbidity of esophagectomy weighed against the risk and expected prognosis associated with invasive cancer. Most surgical series report an operative mortality of less than 10% when esophagectomy is performed for malignant disease. The mortality for prophylactic esophagectomy may be less than the mortality associated with surgery for malignant disease, because many patients with malignant disease are debilitated. In addition, prophylactic esophagectomy does not require an extensive nodal dissection. Either a transhiatal or multiincisional approach with cervical anastomosis appears to be appropriate. The reported 5-year survival rate for patients undergoing esophagectomy for known invasive cancer is estimated to be 18% to 32%.<sup>35</sup> The survival of patients with invasive adenocarcinoma detected during a rigorous surveillance program may be higher.

## BREAST CANCER

It has been estimated that 5% to 10% of women with breast cancer have hereditary breast cancer.<sup>36,37,38</sup> and <sup>39</sup> BRCA1 was identified on the long arm of chromosome 17 (17q21) in 1990, and more than 500 different mutations in this gene have been identified.<sup>37,38</sup> and <sup>39</sup> BRCA1 is transmitted as an autosomal dominant gene with high penetrance, so that 50% of the children of carriers inherit the trait. It has been estimated that women with a BRCA1 gene mutation have between a 56% to 85%

lifetime risk of developing breast cancer.<sup>39,40</sup> Frequently, these patients develop invasive cancer before the age of 50.<sup>41</sup>

A second breast cancer susceptibility gene, BRCA2, was identified and localized to the long arm of chromosome 13 (13q12-13).<sup>42,43</sup> and<sup>44</sup> Women with BRCA2 germline mutations are estimated to have a lifetime risk of breast cancer that is similar to that of BRCA1 carriers.

The optimal management strategy for patients with BRCA1 and BRCA2 mutations has not been established. The clinical options for managing a patient known to have a BRCA1 or BRCA2 mutation are obvious and include increased surveillance or prophylactic bilateral total mastectomy. No prospective trials have compared these options. Furthermore, serious questions remain regarding the efficacy of both surveillance and prophylactic mastectomy in this patient population. Chemoprevention using tamoxifen has been shown to reduce the incidence of breast cancer in women at high risk for breast cancer, but the results in women with an inherited susceptibility to breast cancer are not known. Clearly, counseling regarding any option must take into account the uncertainties associated with the estimation of cancer risk; the lack of definitive research regarding risk; and the social, medical, and psychological status of the patient. Ideally these factors should be reviewed during counseling that occurs before genetic screening.

The most obvious management strategy, and one that appears currently to be most popular among clinicians, is for patients with BRCA1 or BRCA2 mutations to depend on increased surveillance. This strategy is based on the assumption that an invasive cancer will be detected at an early stage, which is associated with a good prognosis. The current recommendations for surveillance in these women include monthly self-examination beginning by age 18, annual or semiannual clinician breast examination, and annual mammography beginning at age 25 to 35 years.<sup>45</sup>

These recommendations reflect a commonsense approach to attempt to reduce the risk of breast cancer–related mortality. However, the evidence to support such a strategy is limited. The one randomized trial that assessed the efficacy of breast self-examination showed no difference in the stage of detected cancers and no reduction in mortality from breast cancer in the trained cohort.<sup>46</sup> The sensitivity of clinician breast cancer examination varies widely based on tumor size, breast density, and experience of the clinician.<sup>47,48</sup> Palpation of a breast mass of less than 10 mm is problematic, even for the most experienced clinician.

Mammography has been firmly established to reduce breast cancer mortality by up to 30% to 40% when used for women 50 to 70 years of age.<sup>49</sup> For women 40 to 49 years of age, the benefit of mammography has been inconsistent.<sup>50,51</sup> and<sup>52</sup> Screening mammography has not been effective in younger women, because the density of their breast tissue limits the quality of x-rays. The sensitivity and specificity of mammography for detecting nonpalpable breast cancers in young women with BRCA1 or BRCA2 mutations is unknown.

Prophylactic mastectomy is a second option for reducing breast cancer risk. This procedure had fallen out of favor because of multiple case reports of breast cancer after prophylactic mastectomy, combined with a lack of credible evidence to support the efficacy of the intervention. Breast tissue can be detected in the chest wall, axilla, and abdomen, which are distant to the typical surgical field during subcutaneous or total mastectomy. Residual breast tissue remains after mastectomy, with larger amounts of breast tissue presumed to be present after subcutaneous mastectomy compared to total mastectomy.<sup>53,54</sup> and<sup>55</sup>

Hartmann et al.<sup>56</sup> published a retrospective study based on the Mayo Clinic experience with prophylactic mastectomy (Table 24-2). This report represents the first indication that prophylactic mastectomy may reduce the incidence of breast cancer in women at high risk for developing invasive cancer. The study included 639 women that had undergone prophylactic mastectomy between 1960 and 1993. Patients were assigned into either a high- or moderate-risk group based on family history. The high-risk cohort had a family history that suggested an autosomal dominant predisposition to breast cancer. All other women were considered to be at moderate risk for developing breast cancer. A control study group of sisters was used for the analysis of the high-risk probands. The Gail model was used to predict the expected number of breast cancers and breast cancer–related deaths for women in the moderate-risk group. The authors found that four breast cancers developed in the 425 moderate-risk patients, although the Gail model predicted 37.4 cases of cancer. In the high-risk group, 3 of 214 women developed breast cancer after prophylactic mastectomy. Among their 403 sisters who had not undergone a prophylactic mastectomy, 115 cases of breast cancer were diagnosed before their sibling's decision for prophylactic surgery, 38 cases were diagnosed after their sibling's decision for prophylactic surgery, and the time of diagnosis was unknown in three. The authors concluded that bilateral prophylactic mastectomy was associated with at least a 90% reduction in the incidence of breast cancer for these women. Women in both the high-risk and moderate-risk cohorts appeared to have a significant reduction in the risk of dying from breast cancer after prophylactic surgery. Interestingly, all seven women who developed breast cancer after prophylactic surgery had undergone bilateral subcutaneous mastectomy. No patient who had bilateral total mastectomy developed breast cancer (7 of 575 vs. 0 of 64;  $P = .38$ ). Most experts recommend bilateral total mastectomy as the procedure of choice for patients who choose prophylactic mastectomy.

	Patients Undergoing BPM	Sister-Sibling Controls	Reduction in Risk
<b>Patients at high risk for breast cancer (family history suggested autosomal dominant cancer)</b>			
Number of patients	214	403	—
Observed cases of breast cancer	3 (1.4%)	126 (31%) (12 before sibling BPM, 114 after sibling BPM; 5 diagnosed time unknown)	88%
Observed deaths from breast cancer	2	33 (26%)	93.8%
	Patients Undergoing BPM	Gail Model Prediction*	Reduction in Risk
<b>Patients at moderate risk for breast cancer (all other patients during BPM)</b>			
Number of patients	425	—	—
Observed cases of breast cancer	4 (0.9%)	37.4 (predicted cases)	88.5%
Observed deaths from breast cancer	0	33.4 (predicted deaths)	76.0%

\*Adjusted for overestimation bias.  
The Gail model was used to predict the incidence and risk of death from breast cancer.

**TABLE 24-2.** Efficacy of Bilateral Prophylactic Mastectomy (BPM) in Women with a Family History of Breast Cancer—The Mayo Clinic Experience, 1960–1993

Additional support for preventative surgery can be found in a report by Robson et al.<sup>57</sup> These investigators followed women of Ashkenazi Jewish descent who underwent lumpectomy and radiation therapy for invasive breast cancer. Outcomes were compared for women with or without BRCA1 or BRCA2 mutations. Women with BRCA1 or BRCA2 mutations were more likely to develop ipsilateral local cancer recurrence, although this finding was not statistically significant. Women with mutations were also significantly more likely to have cancer before the age of 50, were more likely to develop contralateral breast cancer, and were more likely to have metastatic nodal involvement. Distant disease-free survival and breast cancer–specific survival rates were shorter at 10 years for women with BRCA1 or BRCA2 mutations.

Two reports of the estimated benefit of prophylactic mastectomy for women with BRCA1 or BRCA2 mutations have been based on decision analysis using a Markov model to determine survival. Grann et al.<sup>58</sup> estimated the probability of developing breast cancer based on a literature review of women with BRCA1 or BRCA2 gene mutations and based on the mortality rates associated with breast cancer from Surveillance, Epidemiology, and End Results data. They assumed a 90% reduction of risk with the procedure and concluded that a 30-year-old woman would improve her survival by 2.8 to 3.4 years.<sup>58</sup> Schrag et al.,<sup>59</sup> using a similar model, estimated an 85% reduction in breast cancer incidence with prophylactic mastectomy and concluded that a 30-year-old woman with a BRCA1 or BRCA2 mutation would gain 2.9 to 5.3 years of life expectancy from the surgery.

The psychological effects of prophylactic surgery in patients have not been thoroughly evaluated. Reconstructive surgical techniques that include autologous tissue transfer have dramatically improved the cosmetic results of breast surgery. Although the surgical morbidity associated with bilateral mastectomy is low, it is inevitably increased when breast reconstruction is added. There is a clear need to define the efficacy of surveillance strategies, as well as the efficacy of chemoprevention and prophylactic surgery in this challenging population. Until more accurate clinical information is available, women must be counseled based on the limited information available.

### LOBULAR CARCINOMA *IN SITU*

Lobular carcinoma *in situ* (LCIS) is a histopathologic entity characterized by cellular proliferation originating in the lobules and terminal ducts of the breast. Women found to have LCIS on breast biopsy are known to be at increased risk of developing invasive ductal and lobular carcinoma of the breast. The critical clinical features of LCIS are that it is a noninvasive process, frequently found to be multifocal and bilateral, and it generally lacks clinical and mammographic signs. The precise

incidence of LCIS is unknown, but it is estimated to be identified in approximately 0.5% to 1.5% of all benign breast biopsies and in approximately 2% of breast specimens obtained for mammographic abnormalities.<sup>60,61 and 62</sup>

Women with LCIS are clearly at increased risk for developing subsequent invasive carcinoma. Six series of women with LCIS who were followed for an average of at least 15 years have been published. These series reported that between 12.5% and 34.5% of women with LCIS developed invasive breast cancers.<sup>60,61,62,63,64 and 65</sup> A metaanalysis of 389 cases of LCIS followed for a mean of 10.9 years noted that invasive breast cancers developed in 16.4% of these women, and the breast cancer mortality rate was 2.8%.<sup>66</sup>

Treatment options for patients with LCIS remain controversial. Close observation with or without tamoxifen is currently the most popular choice. Evidence from the National Surgical Adjuvant Breast Project tamoxifen prevention trial noted that women with LCIS treated with tamoxifen demonstrated a decrease in the incidence of invasive cancer from 12.99 per 1000 to 5.69 per 1000.<sup>67</sup> Bilateral prophylactic mastectomy is an appropriate choice for healthy women who are unwilling to accept the risks associated with LCIS or with tamoxifen chemoprevention.

## OVARIAN CANCER

Women identified as carrying the BRCA1 or BRCA2 mutation are at high risk for developing ovarian cancer as well as breast cancer. The lifetime risk of developing ovarian cancer for a woman with a BRCA1 mutation is approximately 30% to 60%, although some estimates are as high as 85%.<sup>36,41,67,68</sup> Patients with BRCA2 mutations have an estimated lifetime ovarian cancer risk of approximately 10% to 20%.<sup>42,69</sup>

The optimal management strategy for a woman with an inherited susceptibility to ovarian cancer is unclear. To date, no convincing evidence demonstrates that surveillance for ovarian cancer is effective. This may reflect the low ovarian cancer incidence of approximately 1 in 70 women in the general population.<sup>70</sup> Screening for ovarian carcinoma has been hampered by the low sensitivity and specificity of the available techniques, which include pelvic examination, serum CA-125 determinations, and transvaginal ultrasound. In addition, a laparoscopy or a laparotomy is required to make the diagnosis. Currently, routine screening in the general population has not been shown to impact on the morbidity and mortality associated with ovarian cancer, and it is not recommended. The utility of increased surveillance for patients with BRCA1 and BRCA2 mutations has not been thoroughly investigated. It is known, however, that approximately 70% of patients diagnosed with ovarian cancer have stage III or IV disease and that these patients generally have poor 5-year median survival rates.

Faced with a lack of effective screening for ovarian cancer and the poor prognosis of advanced disease, prophylactic oophorectomy has been suggested as a reasonable alternative for women considered to be at high risk for invasive cancer. The National Institutes of Health Consensus Panel on Ovarian Cancer<sup>70</sup> and the American College of Obstetricians and Gynecologists<sup>71</sup> have concluded that prophylactic bilateral oophorectomy should be recommended to women older than 35 or after childbearing is completed if there is an inherited predisposition for ovarian cancer. The Cancer Genetics Consortium reviewed the same information and concluded that the evidence is insufficient to recommend for or against prophylactic oophorectomy as a measure to reduce ovarian cancer risks.<sup>45</sup>

It is clear that prophylactic bilateral oophorectomy does not completely eliminate the risk of developing abdominal carcinomatosis that histologically resembles ovarian cancer. Tobarman et al.<sup>72</sup> reported that, among the 16 potentially inherited ovarian cancer families studied at the National Cancer Institute, prophylactic oophorectomy had been performed on 28 women. Three of these women developed ovarian-like carcinomatosis 1 to 11 years after oophorectomy.<sup>72</sup> This finding may reflect the fact that the peritoneum has the same embryologic origin as the ovarian epithelium and that the entire peritoneum may be at risk for malignant degeneration. Alternatively, occult ovarian cancer may have been present at the time of surgery. Struewing et al.<sup>73</sup> reported an analysis of 12 families with inherited breast/ovarian cancers and noted a reduction in ovarian cancer in oophorectomized women compared with women who had not undergone surgery. Compared with adjusted Connecticut Tumor Registry data, a 24-fold excess of ovarian cancer was found among nonoophorectomized women, and a 13-fold excess of "ovarian-like" cancer was found among the women who had undergone oophorectomy.<sup>73</sup> These results were not statistically significant.

Patients with BRCA1 and BRCA2 mutations are obviously at risk for both breast and ovarian cancer. Clinical decisions regarding prophylactic surgery are difficult when breast and ovary are considered independently, and the decisions become more challenging when they are considered together. Rebbeck et al.<sup>74</sup> analyzed 43 women with BRCA1 mutations who underwent bilateral prophylactic oophorectomy and had not had bilateral prophylactic mastectomy. Control subjects included women with BRCA1 mutations who had not had oophorectomy and had no prior history of breast or ovarian cancer. These authors reported a statistically significant reduction in breast cancer risk after oophorectomy when compared to the control cohort. The reduction in breast cancer risk appeared to increase over time. The use of hormone replacement therapy did not negate the reduction in breast cancer risk after oophorectomy in these patients.<sup>74</sup>

Evidence indicates that the use of oral contraceptives is associated with a decreased risk of ovarian cancer. The use of oral contraceptives has not been analyzed in patients with BRCA1 and BRCA2 mutations, and what effect, if any, these medications would have on the incidence of breast cancer in these patients is unknown.

## COLORECTAL CANCER

Approximately 75% of all colorectal cancers occur in patients with no known risk factors for colon cancer. Individuals with ulcerative colitis, familial adenomatous polyposis (FAP), and hereditary nonpolyposis colorectal cancer (HNPCC) are at increased risk for developing the disease, but these patients probably account for fewer than 10% of all colorectal cancer cases. Despite the low incidence of these conditions in the general population, understanding and managing these patients has provided insights into the etiology of cancer and the potential role of surgery in the prevention of cancer.

### ULCERATIVE COLITIS

Ulcerative colitis is a nonspecific inflammatory bowel disease of unknown etiology that involves the rectum, usually all or part of the colon, and, frequently, the distal terminal ileum as a result of colonic reflux. The clinical course of ulcerative colitis is variable, ranging from intermittent to chronic, and the severity of attacks also vary widely from mild to fulminant. The incidence of ulcerative colitis is relatively low at approximately 8 to 15 cases per 100,000 people.<sup>75,76,77 and 78</sup> From an oncologic perspective, ulcerative colitis is important because of its association with colorectal cancer. Although only a small fraction of colon cancer occurs in the setting of ulcerative colitis, colorectal cancer is the major cause of the increased morbidity and mortality of patients with this inflammatory disease.<sup>78,79 and 80</sup>

It is difficult to precisely determine the risk of colorectal cancer in patients with ulcerative colitis. Most but not all<sup>81,82</sup> studies have noted a significant increase in the risk of colorectal cancer in this population. The duration of disease and the extent of colonic involvement at the time of diagnosis are the two most important clinical factors that determine the degree of increased cancer risk. In patients with pancolitis, the cancer risk is approximately 0.5% to 1.0% per year after 10 years of disease.<sup>83</sup> A disease duration of 20 years in patients with pancolitis is associated with an estimated cumulative incidence of malignancy of between 5% and 35%.<sup>76,84,85</sup> The cumulative risk of malignancy increases over time and is reported to be as high as 75% after 40 years of disease.<sup>86</sup>

Patients with pancolitis are known to be at higher risk of developing cancer compared with patients with left-sided colitis. Ulcerative colitis, when limited to the left colon, is associated with an estimated cumulative incidence of cancer of between 1% and 5% at 20 years.<sup>78,85,87</sup> Patients with only proctitis appear to be at only average risk for colorectal cancer compared with the general population.<sup>85</sup> The impact of other related clinical factors, including the age of onset of the disease and family history of colon cancer, is not known.<sup>88</sup>

The optimal management strategy for patients with long-standing ulcerative colitis remains controversial and varies from prophylactic colectomy after 10 to 20 years of disease to vigilant surveillance with colonoscopic examination and multiple random biopsies to exclude dysplasia. In the latter strategy, colectomy is recommended based on the presence and degree of dysplasia. The differences in management strategies is not surprising given the heterogeneous nature of inflammatory bowel disease and the patient population and the absence of randomized clinical trials to support one strategy over another.

There is widespread agreement that colonic dysplasia is a strong but imperfect marker for identifying patients likely to develop colorectal cancer. Colonic surveillance is performed with the assumption that a dysplastic lesion can be detected before invasive cancer has developed. Invasive cancer can be found in approximately 10% of patients with ulcerative colitis at initial screening. Patients with no dysplasia identified on biopsy have a 3% cumulative risk of developing cancer when followed over time. Patients found to have indefinite or low-grade dysplasia are thought to progress to invasive cancer or severe dysplasia between 16% and 54% at the time. Forty percent to 45% of patients with ulcerative colitis identified to have high-grade dysplasia or dysplasia associated with a mucosal mass develop colorectal cancer.

Many of these patients already have evidence of nodal metastasis.<sup>88,90 and 91</sup> It is also important to recognize that although the risk of developing colorectal cancer if there is no histologic evidence of dysplasia appears to be low, up to 25% of patients with ulcerative colitis–associated invasive cancer demonstrate no dysplasia in the resected specimens.<sup>90,92,93</sup>

No well-controlled trials have been conducted that confirm the efficacy of colonic surveillance to reduce the mortality of ulcerative colitis–associated colorectal cancer. Lennard-Jones<sup>94</sup> reported a review of four published series that included 423 patients who were screened regularly by colonoscopy over a period of 12 to 15 years. Eleven patients were operated on for precancerous lesions, and only three Duke's class A lesions and one Duke's class B lesion were found. No cancer deaths were reported during the surveillance period. The author suggested that surveillance colonoscopy should be performed only in individuals with long-standing ulcerative colitis involving the entire colon.<sup>94</sup>

Despite the limitations and lack of data to support surveillance for colonic dysplasia, physicians appear reluctant to recommend prophylactic colectomy for patients with long-standing ulcerative colitis. The fact that surgery eliminates the symptoms of ulcerative colitis, including bleeding, diarrhea, anemia, steroid dependence, and cyclosporin therapy, as well as eliminating the risk of colorectal cancer may be underappreciated. Several surgical alternatives are available for patients undergoing colectomy, and the operation should be tailored to the individual and the clinical situation. In the setting of acute colitis, for example, most surgeons recommend a subtotal colectomy and ileostomy. In the elective surgical setting, many options are available, including protocolectomy and ileostomy, colectomy and ileorectal anastomosis (assuming the rectum is free of inflammation), protocolectomy and Kock continent ileostomy, or ileal pouch–anal anastomosis. Each procedure is associated with reported complications; however, surgery for ulcerative colitis is extremely safe for most patients, and the reported operative mortality is less than 1%, even in the emergency setting.<sup>95</sup> Although comparing the outcomes of each procedure is difficult and controlled studies do not exist, most patients report a high quality of life regardless of the procedure performed.

It is evident that some consideration of colectomy should be taken 10 years after the diagnosis of ulcerative colitis in patients with pancolitis. After a 20-year disease interval, a stronger case for prophylactic colectomy can be made for patients, even in the absence of dysplasia. Colonic surveillance for dysplasia is an option favored by many clinicians, and it is most appropriate for patients with disease limited to the left colon or rectum and for patients with a short duration of disease. Any surveillance strategy that recommends colectomy based on histologic evidence of dysplasia will miss some patients with invasive cancer. The precise number of patients in this situation is unknown. If surveillance is the adopted strategy, then it is recommended that, in the absence of dysplasia, colonoscopy and multiple biopsies should be performed every 2 years until 20 years of disease. At 20 years of disease, surveillance colonoscopy should be performed annually.<sup>91</sup>

## HEREDITARY COLORECTAL CANCER

It is estimated that up to 20% of patients with colorectal cancer may have some form of inherited susceptibility.<sup>96</sup> Hereditary colon cancer currently includes FAP and HNPCC. Although many of the clinical issues surrounding these syndromes are similar, each syndrome is considered separately because of differences in the genetics, in the phenotypic presentations, and in the accepted management strategy.

### FAMILIAL ADENOMATOUS POLYPOSIS

FAP is a rare autosomal dominant inherited disease in which patients develop hundreds to thousands of adenomatous polyps. The clinical diagnosis is based on the histologic confirmation of at least 100 adenomas. These polyps are similar on histologic examination to sporadic adenomatous polyps and usually appear during the second or third decade of life.<sup>97</sup> The genetic cause of FAP is a mutation of the adenomatous polyposis coli (APC) gene located on chromosome 5 (5q21).<sup>98</sup> The genetic alterations found in patients with FAP are similar to those identified in sporadic colon cancer, except an APC mutation is present as a germline mutation.<sup>99</sup> Genetic tests for APC mutations are commercially available.

The obvious phenotypic appearance of FAP coupled with the fact that more than 90% of patients with FAP develop colon cancer by age 40 has helped to establish standard treatment for this disease.<sup>100</sup> Elective prophylactic colectomy is the current mainstay of therapy and has been performed for FAP since the 1930s. No trials have compared surgery with surveillance. The current recommendations for treatment of this genetic disorder include annual sigmoidoscopy beginning by age 10 years and prophylactic colectomy in the teen years or when colonic polyps are detected at endoscopy.<sup>101</sup> Patients that elect to have colectomy and ileorectal anastomosis face the risk of subsequently developing rectal cancer. Estimates of the risk of rectal cancer after subtotal colectomy vary widely and have been reported to be as high as 55% at 30 years. Patients with ileorectal anastomosis require lifelong endoscopic surveillance.

The choice of operations for patients with FAP includes proctocolectomy with ileostomy, proctocolectomy with ileal distal rectal anastomosis, and proctocolectomy with ileal-anal anastomosis. Each of these operations has strengths and weaknesses. Overall, these procedures are performed with low morbidity. The choice of operations should be tailored to patient preference and the experience of the operating surgeon.

FAP is associated with extracolonic manifestations of disease, which can include desmoid tumors and osteomas. Polyps may occur at other intestinal locations, and carcinomas of the upper intestine have been reported as the most common fatal malignancy in patients after prophylactic colectomy.<sup>102</sup> It is recommended that these patients undergo upper endoscopy every 6 months to 3 years starting by age 20.<sup>101</sup> Many agents, including sulindac, vitamin C, and indomethacin, have been investigated as chemopreventive agents. Although some agents have shown promise, none has been proven to be effective in reducing the number of polyps or the risk of cancer in FAP patients.<sup>103</sup>

### HEREDITARY NONPOLYPOSIS COLORECTAL CANCER

HNPCC describes a clinical syndrome of colorectal cancer that occurs with early onset and in multiple family members. In contrast to FAP, HNPCC has no antecedent phenotype, and malignancy develops in the absence of adenomatous of the colon and rectum. The expression of disease may be limited to the colorectum (Lynch syndrome I) or coexist with extracolonic tumors, typically endometrial cancer (Lynch syndrome II). Other associated malignancies include stomach, small intestine, hepatobiliary, pancreas, breast, ovary, brain, and skin cancers.<sup>103,104,105 and 106</sup>

In 1991, the International Collaborative Group on HNPCC established the minimum clinical criteria required to help identify families with HNPCC. The so-called Amsterdam criteria are: (1) colorectal cancer in three or more relatives, one of whom is the first-degree relative of the other two; (2) at least two generations of affected individuals with colorectal cancer; and (3) one or more of the cancers has been diagnosed before the age of 50. FAP must be excluded.<sup>107</sup> One genetic cause of the syndrome was identified in 1993. Peltomaki et al.<sup>108</sup> identified a locus on chromosome 2 that was linked to HNPCC in several families. The genetic basis of HNPCC has been identified as a germline mutation in one of a set of genes responsible for DNA mismatch repair.<sup>109,110,111,112 and 113</sup> Additional loci have since been identified. More than 90% of the identified mutations are in two genes, MSH2 (MutS homologue 2) and MLH1 (MutL homologue 1), located on chromosome 2p and 3p, respectively.<sup>114</sup> These genes are dominantly inherited, with a penetrance of approximately 90%. Consequently, gene carriers have a 90% likelihood of developing colorectal cancer.<sup>115</sup> Patients suspected of carrying an APC mutation can be tested for at least two mismatch repair gene mutations in commercial laboratories.

HNPCC gene carriers develop colorectal cancer at an average age of 45 years. These tumors occur more commonly in the right colon and tend to be more poorly differentiated.<sup>116,117</sup> Synchronous and metachronous cancers are frequent, and should a segmental colectomy be performed for a primary cancer, there is a 45% risk for a new primary cancer within 10 years.<sup>115</sup> Lynch and Smyrk<sup>118</sup> have reported that colonic polyps can be identified in up to 17% of first-degree relatives during colonoscopic screening. Adenomas are more likely to grow and progress to invasive cancer in this patient population than in the general population.<sup>119,120</sup>

The optimal management strategy for HNPCC gene carriers has yet to be established. Substantial evidence from uncontrolled studies suggests that surveillance colonoscopy and polypectomy are effective in reducing the risk of invasive cancer in these patients. Jarvinen et al.<sup>120</sup> reported a 62% decrease in the diagnosis of colorectal cancer in HNPCC patients in a screening program at a medium follow-up of 117 months compared with patients not followed by colonoscopy at 10 years. Bulow et al.<sup>121</sup> reported a decreased incidence of cancer and improved survival rate of patients with HNPCC who had surveillance and experiments compared with probands. Therefore, it has been recommended that surveillance colonoscopy be performed on gene carriers starting at age 20 and be repeated every 1 to 2 years. Patients older than 35 years of age should have annual colonoscopy.<sup>115,122</sup>

Currently, no consensus among experts has been reached regarding the role of prophylactic subtotal colectomy for patients with HNPCC.<sup>115,123</sup> Given the high penetrance of the disorder and the high rate of synchronous and metachronous disease among mutation carriers, a strong case can be made for prophylactic surgery in patients with this disease. A subtotal colectomy is currently the procedure of choice, and it can be performed with minimal morbidity and mortality. Patients who

elect to undergo a subtotal colectomy require colonoscopic surveillance of the remaining rectum. Patients undergoing prophylactic surgery may still face the risk of extracolonic cancers. Patients electing not to consider prophylactic surgery must commit to lifelong surveillance, and should a colon cancer be detected, a subtotal colectomy is then indicated. No prospective clinical trials in patients with HNPCC have been conducted, and given our current understanding of the increased risk of colorectal and extracolonic malignancy in these patients, the suggested benefit of surveillance colonoscopy, and the low morbidity of prophylactic subtotal colectomy, either vigilant surveillance or prophylactic surgery are reasonable management strategies.

## TESTICULAR CANCER AND CRYPTORCHIDISM

Cryptorchidism, or undescended testis, is characterized by absence of at least one testis in the scrotum and is the most common genitourinary disorder of childhood. Approximately 3% of children born at full term and up to 30% of children born prematurely will have an undescended testis.<sup>124</sup> A well-known but poorly understood association has been made between cryptorchidism and testicular cancer. In 1929, Cooper<sup>125</sup> noted that the longer a testis remained cryptorchid and the higher the testis lay from the scrotum, the more likely it was to be histologically abnormal. The reported risk for malignancy in cryptorchidism is 48.9 per 100,000, which is more than 20 times the risk of testicular cancer in the general population.<sup>126</sup> It has been estimated that approximately 10% of testicular tumors arise from an undescended testis.<sup>127</sup>

Either orchiopexy in association with observation or observation alone is recommended for patients with cryptorchidism. There are multiple reasons for correcting an undescended testis in a child, including the desire to correct a visible defect, to prevent psychological problems associated with the defect, to enhance the possibility of future fertility, and to place the testis in a site where it can be easily examined. Correction of an undescended testicle may be achieved using hormonal therapy or surgery. Most experts agree that this should be accomplished as early as 12 months of age.<sup>128</sup>

It is not clear that correction of an undescended testicle alters the risk of developing testicular cancer. Reports in the literature conflict regarding the protective effects of correcting cryptorchidism, and virtually no information is available on patients who had an undescended testicle corrected at younger than 2 years of age.<sup>129,130</sup> and <sup>131</sup> Most reports are population-based case-controlled studies. It is known that patients with unilateral cryptorchidism have been found to have an increased risk of testicular cancer in both the undescended and the normally descended testis.<sup>132,133</sup>

Management of an undescended testis in a postpubertal patient population has been extensively addressed by Farrer et al.<sup>133</sup> These authors completed a statistical analysis that compared the estimated risk of death from a germ cell testis tumor in patients with cryptorchidism to the risk of death from an orchiectomy. They concluded that the risk of death from orchiectomy is greater than the risk of death from testicular cancer in patients older than 32 years of age. The authors recommended that orchiectomy be considered only for patients younger than 32 years with postpubertal unilateral cryptorchidism.<sup>133</sup> Other experts recommend orchiopexy or observation in older patients, depending on patient preference and assuming the testicle is palpable.<sup>134</sup> General agreement exists that a nonpalpable undescended testicle should be removed.

#### INTRODUCTION

The goal of cancer screening is a very practical one—to detect cancer at an early stage when it is treatable and curable. However, the reality is quite complex. For a screening test to be useful, the test or procedure should detect cancer earlier than would occur otherwise *and* there should be evidence that earlier diagnosis results in an improved outcome.<sup>1</sup> Advances in genetics and molecular biology herald the era when it may be possible to detect cancer at earlier and earlier stages along the carcinogenesis pathway. Because of this progress, the line between prevention and screening may narrow further. Moreover, screening will be used to detect susceptibility as well as early markers of disease. Yet, in spite of the promises of molecular diagnostics, screening still must be evaluated according to its present reality, which is to detect asymptomatic disease when it is potentially curable.

The purpose of this chapter is to provide an overview of cancer screening—what it is, key terms, measures of effectiveness, and consequences. We also review briefly the status of screening for several prevalent cancers (breast, cervical, skin, prostate, colorectal, and lung). The recommendations are for the general population, but not for people with identified mutations in cancer susceptibility genes. Currently, no randomized clinical trial data are available to guide practice in this area. However, the Cancer Genetics Studies Consortium, sponsored by the National Human Genome Research Institute, issued provisional recommendations for individuals who are known to carry the breast cancer gene mutations *BRCA1* or *BRCA2*.<sup>2</sup> Generally, it is recommended that people with these and other relevant mutations (e.g., *HNPCC*, *p53*) be screened at an earlier age, and more frequently, for the cancers to which they are predisposed.

This chapter cannot provide comprehensive information on any of the cancer sites reviewed, because the literature for each is vast. Rather, the chapter provides a succinct summary of the field and a perspective for clinicians to use in determining the efficacy of particular screening tests. Several texts provide good overviews of the issues related to screening for specific kinds of cancer.<sup>3</sup> The National Cancer Institute's (NCI) Physician Data Query (PDQ) [World Wide Web site <http://cancernet.nci.nih.gov/pdq.htm>] also is an excellent source for the latest data on the specific screening tests discussed here.

#### WHAT IS CANCER SCREENING?

Appropriate cancer screening should lead to the early detection of asymptomatic or unrecognized disease by the application of acceptable, inexpensive tests or examinations in a large number of persons.<sup>4,5</sup> The results of a screening test should then be applied expeditiously to separate apparently well persons who probably have disease from those who probably do not. The main objective of cancer screening is to reduce the morbidity and mortality from a particular cancer among the persons screened. The screening procedure itself is not diagnostic, and positive or suspicious findings must be evaluated further to determine diagnosis and appropriate treatment. Characteristics that distinguish screening tests from diagnostic tests are listed in [Table 25-1](#).

Screening	Diagnosis
Applied to asymptomatic groups	Applied to symptomatic individuals
Lower cost per test	Higher cost; all necessary tests applied to identify disease
Lower yield per test	Higher probability of case detection
Lower adverse consequences of error	Failure to identify true positives can delay treatment and worsen prognosis

TABLE 25-1. Characteristics of Screening Tests versus Diagnostic Tests

Several characteristics make particular cancers suitable for screening. These include (1) substantial morbidity and mortality; (2) a high prevalence in a detectable preclinical state; (3) the possibility of effective and improved treatment because of early detection; and (4) the availability of a good screening test with high sensitivity and specificity, low cost, and little inconvenience and discomfort. Although there are more than 100 different cancers, most of them lack proven screening interventions. Only cancers of the breast, cervix, skin, colon-rectum, prostate, and testes have widely accepted screening interventions,<sup>6</sup> and there is controversy over some aspects of each. Only breast, cervical, and colorectal screening have met the rigorous criteria of the U.S. Preventive Services Task Force.<sup>7</sup>

The benefits of the investment in cancer screening occur over many years.<sup>8</sup> Cancer screening affords both benefits and disadvantages; therefore, it is important to evaluate the effectiveness of screening programs by specifying criteria to meet the program's objectives. For screening to be a benefit, treatment given during the detectable preclinical phase must result in a better prognosis than therapy given after symptoms develop, thereby possibly requiring less radical treatment. Cervical cancer is a good example of a disease with a preclinical phase that can be detected in a preinvasive stage, in this case, using the Papanicolaou (Pap) smear.<sup>9</sup> Finally, there are economic costs associated with cancer screening, and these should be evaluated before a cancer screening test is recommended on a population basis.

#### EVALUATION OF A SCREENING TEST

In the evaluation of a screening test, it is essential to answer questions concerning the test's ability to accurately predict the presence or absence of disease. If the

test is *abnormal*, what are the chances that disease is present? If the test result is *normal*, what are the chances that the disease is absent? The validity of a screening test is measured by its ability to classify correctly those persons who have preclinical disease as test-positive and those without the preclinical disease as test-negative.

*Sensitivity* and *specificity* address the validity of the test. Sensitivity is the probability of testing positive if the disease is truly present. As the sensitivity of the test increases, the number of persons with the disease who are classified as test-negative (false-negative) decreases. Specificity is the probability of screening negative if the disease is truly absent. A highly specific test rarely is positive in the absence of disease and therefore results in a lower proportion of persons without disease who are incorrectly classified as test-positive (false-positive). Two measures that directly address the estimation of probability of disease are the *positive predictive value* (PV+) and the *negative predictive value* (PV-). The PV+ is an estimate of the accuracy of the test in predicting the presence of disease, and the PV- is an estimate of the accuracy of the test in predicting the absence of disease. The predictive value is a function of the sensitivity, specificity, and prevalence of disease. The *accuracy* of a test is a measure of the percent of all results that are true results, whether positive or negative, or the total correct test results. [Table 25-2](#) summarizes the relationship between results of a screening test and the actual presence of disease as determined by an appropriate diagnostic test.

Screening Test Results	Truth (Diagnostic Classification)	
	Cancer Present	Cancer Absent
Positive	TP	FP
Negative	FN	TN

$Sensitivity = TP / (TP + FN) \times 100$   
 $Specificity = TN / (FP + TN) \times 100$   
 $PV+ = TP / (TP + FP) \times 100$   
 $PV- = TN / (TN + FN) \times 100$   
 $Accuracy = (TP + TN) / (TP + FN + FP + TN) \times 100$

FN, false-negative (number of subjects with cancer who are incorrectly classified as cancer-free by the test); FP, false-positive (number of cancer-free subjects who are incorrectly classified as having cancer by the test); TN, true-negative (number of cancer-free subjects who are correctly classified by the test); TP, true-positive (number of subjects with cancer who are correctly classified by the test).

**TABLE 25-2.** Definitions of Criteria for Evaluating a Screening Test

Sources of bias are of particular importance in the evaluation of a screening program. People who choose to participate in screening programs (volunteers) are likely to be different from the general population in ways that pertain to survival; thus, *volunteer bias* is a concern.<sup>4</sup> *Lead-time bias* is defined as the interval between diagnosis of disease at screening and when it would have been detected due to the development of symptoms.<sup>4</sup> If lead-time bias is not taken into account, survival may appear to be erroneously increased among screen-detected cases as compared to unscreened cases. Finally, *length bias* is the overrepresentation among screen-detected cases of those with a long preclinical period (thus less rapidly fatal), leading to the incorrect conclusion that screening was beneficial.<sup>4</sup>

## MEASURES OF EFFECTIVENESS

Several measures have been used to judge the effectiveness of screening. The most definitive measure of the efficacy of a breast cancer screening program and least subject to bias is breast cancer mortality as determined by the comparison of screened and unscreened groups in a randomized clinical trial.<sup>4,10</sup> There are excellent epidemiology texts<sup>4,11</sup> and reviews<sup>10</sup> that discuss the measures in more detail than can be presented here.

Other outcome measures have been proposed, including case finding and survival. Each has limitations. The problem with case finding is that it is subject to lead-time bias. Survival may appear to have been advanced, but only because cancer is found earlier in the screened group.<sup>11</sup> Because of length bias, screening may appear effective, but in fact, it has not made a difference in mortality; slow-growing cancers may contribute to the apparent success of the screened group. Thus, length bias limits the value of survival data as outcome measures. Survival, in itself, does not establish that the natural history of the disease has been altered or that mortality has been reduced.<sup>12</sup>

Another potential outcome is improved quality of life (QOL).<sup>13</sup> However, none of the international breast cancer screening trials have good QOL data. These data are being collected as part of the NCI's Prostate, Lung, Colorectal, Ovarian Cancer (PLCO) screening trial. This is an important area for further exploration and, in future trials, QOL should be measured. Cost per quality-adjusted life-years saved would be a good measure, but it has been used rarely.<sup>14</sup> QOL may include a reduction in psychologic morbidity for a woman and her family.<sup>15</sup> QOL also may be enhanced by providing better or more acceptable treatment choices. For example, Tabar and colleagues<sup>16</sup> have argued that even if mammography does not reduce breast cancer mortality for women in their 40s, it may be beneficial because it avoids disfiguring and debilitating surgery. And de Koning and colleagues<sup>17</sup> showed that breast cancer screening could reduce health care costs and improve QOL by preventing advanced disease, which also could be true for cervical and colorectal cancer screening. However, Harris<sup>18</sup> has expressed concern that a woman's QOL could be diminished by living longer with breast cancer.

In assessing the effectiveness of screening technologies, the randomized clinical trial (RCT) has been the gold standard. It is the most powerful methodology for demonstrating the value of screening in comparison to an unscreened group.<sup>19</sup> RCTs overcome the biases inherent in other designs. The RCT with the end point of mortality avoids the two most important biases noted earlier, lead-time and length bias,<sup>19</sup> as well as selection bias and overdiagnosis.<sup>20</sup> However, case-control studies also can provide useful information, and at less cost than RCTs, and may be used to supplement RCT data. In addition, increasingly sophisticated statistical modeling techniques may be appropriate to assess the impact of screening, especially in situations where large RCTs cannot be conducted. The U.S. Preventive Services Task Force,<sup>7</sup> the PDQ system,<sup>21</sup> and others have ranked levels of evidence; the RCT is uniformly regarded as the highest level of evidence.

## POSITIVE AND NEGATIVE CONSEQUENCES OF SCREENING

Every medical activity has positive and negative consequences, and screening is no exception. The benefits include (1) improved prognosis for those with screen-detected cancers, (2) the possibility of less radical treatment, (3) reassurance for those with negative test results, and (4) resource savings if treatment costs are reduced because of less radical diagnosis. The optimal outcome is a reduction in cancer mortality. The assumption is that screening can detect cancer when it is early and curable, if cancer is present, or indicate that cancer is not present, if that indeed is the case. But because no medical test is perfect, there are several potential negative consequences of screening that also must be considered. These include the economic and psychologic consequences of false-positives<sup>22,23,24,25</sup> and <sup>26</sup> and false-negatives,<sup>27,28</sup> the potential for overdiagnosis,<sup>29,30,31</sup> and <sup>32</sup> the potential carcinogenic effects of screening, and the labeling phenomenon.

Screening in the community usually means that many people will require additional tests for what will later be recognized as false-positives.<sup>33</sup> This is one of the predictable costs of cancer screening. A consideration of the negative consequences of screening is essential,<sup>34</sup> because screening is offered to presumably healthy people.<sup>8,11</sup> The negative consequences should not override the potential benefits. However, accumulating evidence in the area of breast cancer screening suggests that although there are negative psychologic consequences of abnormal test results, they appear to be relatively short-lived.<sup>35</sup> On the plus side, abnormal results may increase the likelihood that women will be screened in the future.<sup>24,36,37</sup> However, the data regarding negative psychological consequences are still sparse and related primarily to breast cancer. More data are needed in other areas, such as colorectal cancer screening. Overdiagnosis is an important area that has not been well studied. As understanding of cancer biology increases, it will become easier to classify overdiagnosis.

For all kinds of cancer screening, physicians should engage patients in discussions of the risks and benefits of cancer screening. Because most people overestimate the risks for certain types of cancers (e.g., breast),<sup>38</sup> they may inflate both the need for screening and the potential benefits.<sup>39</sup> For some cancers, such as colorectal cancer, people may underestimate their personal susceptibility and may need encouragement to consider screening, with both the positive and negative consequences. In the case of prostate cancer, where the evidence is still equivocal and population-based screening is not recommended, it is especially important that men understand the limitations of screening.<sup>40</sup> Harris<sup>35</sup> encouraged that screening discussions begin with the possible outcomes of screening, making sure the patient's information is accurate. Then, the physician should define and clarify the patient's perceptions and values. Together, the patient and physician then weigh the benefits of screening versus the costs and benefits. This has been called *shared decision making*.<sup>41</sup>

Austoker<sup>42</sup> outlined the topics that should be included when helping patients to make informed decisions about cancer screening. These include the purpose of screening; the likelihood of positive and negative findings and the possibility of false-positive or false-negative results; the uncertainties and risks involved; any significant medical, social, or financial implications of screening; and follow-up plans.

## BREAST CANCER SCREENING

In 1999, 176,000 new invasive cases of breast cancer and approximately 43,700 deaths due to the disease were reported in the United States.<sup>43</sup> Widely accepted techniques for breast cancer screening, but with differing levels of evidence, include mammography, clinical breast exam (CBE), and breast self-examination (BSE). As with other screening techniques, the purpose of breast cancer screening is to find breast cancer early, while the disease is curable, to reduce mortality for breast cancer. As Tabar et al.<sup>44</sup> and others have shown, tumor size, lymph node status, and malignancy grade are major prognostic factors in survival. No cancer screening test has been studied more than mammography (with or without CBE). Yet, after more than 35 years of trials, many questions remain regarding at what age and at what interval women should be screened. The breast cancer screening trials provide clear evidence of benefit for screening women older than age 50 until approximately age 70, and increasing evidence of a small but statistically significant benefit of mammography for women aged 40 to 49 years.

Eight randomized trials have been conducted over more than 35 years to assess the impact of mammography. Together, these trials have included more than 500,000 women, with 180,000 women aged 40 to 49.

The eight international randomized clinical trials have varied greatly<sup>27</sup> (Table 25-3). Most trials have included women in their 40s, although two trials began accrual at 45, and one of the Canadian trials [the first National Breast Cancer Screening Study (NBSS1)] was designed to examine mammography and CBE versus usual care for women in their 40s, with a separate study (NBSS2) to assess mammography and CBE versus CBE only for women aged 50 to 59. The studies also varied in (1) whether they used one-view or two-view mammography; (2) the screening interval, which varied from 12 to 24 months; and (3) the level of compliance achieved. The problems in the trials also have varied. For example, cluster randomization resulted in socioeconomic status differences with the study groups in the Edinburgh trial.<sup>45</sup> Other trials experienced higher than desired contamination, most often because of higher than expected levels of screening in the control groups. For most of the studies, women's breast cancer risk factors were not known; only the Health Insurance Plan of New York (HIP) and NBSS assessed and published data on the breast cancer risk factors for women in the study.<sup>46</sup>

Study (Year)	Age at Entry (yr)	Screening Modality	Periodicity (mo)	Randomization	Sample Size		Number of Breast Cancer Cases (%)	Mortality (%)
					Screening	Control		
HIP (1963)	40-64	Two-view mammography and CBE	12	Individual	62,000	62,000	47	1.6
Stockholm (1981)	40-64	Two-view mammography	28	Cluster	43,000	43,000	48	1.6
Edinburgh (1978)	45-64	Two-view mammography	12-24	Cluster	25,000	25,000	74	1.7
NBSS1 (1980)	40-49	Two-view mammography and CBE	12	Individual	53,000	53,000	81	1.4
NBSS2 (1980)	50-59	Two-view mammography and CBE	12	Individual	43,000	43,000	84	1.4
Gothenburg (1982)	40-49	Two-view mammography	18	Individual	50,000	50,000	81	1.6
Edinburgh (1978)	45-64	Two-view mammography and CBE	12-24	Cluster	25,000	25,000	81	1.6
Gothenburg (1982)	40-49	Two-view mammography	18	Individual	50,000	50,000	81	1.6
Gothenburg (1982)	50-59	Two-view mammography and CBE	12	Individual	43,000	43,000	84	1.4

TABLE 25-3. Selected Characteristics of Eight Randomized Controlled Trials of Breast Cancer Screening

## RANDOMIZED CLINICAL TRIALS

Although mammography was first reported in 1913, it was not until 1963 that the first RCT—and the only U.S. RCT—commenced at HIP. HIP included women aged 40 to 64 at entry. Nearly 62,000 women were randomized to the study (two-view mammography and CBE) or control group (usual care). Two-view mammography and physical examination were offered every 12 months during the 4-year study period, and follow-up was continued for 18 years.<sup>27</sup>

The Swedish Two-County Trial in Kopparberg and Ostergotland began in 1977–1978 with an enrollment of almost 135,000 women randomized to one-view mammography every 24 months (younger than age 50) or 33 months (older than age 50). Within those geographic areas, all women were invited to enroll by letters of invitation, using the population registry list. Screening continued for four rounds for younger women and three rounds for older women.<sup>47</sup> The Kopparberg arm used single-view mammography without grids; Ostergotland used a grid.<sup>48</sup>

The Malmö Trial was begun in 1976 in one city in Sweden.<sup>27,28,49</sup> It was one of only two trials that began screening at age 45, and it stopped entry at age 69. It used two-view mammography every 18 to 24 months for five rounds; randomization was by cluster based on birth cohort. Approximately 59,000 women were enrolled in this trial.

The Stockholm Study began in 1981 and enrolled approximately 43,000 women aged 40 to 64 who received single-view mammography every 28 months. Like the Malmö trial, randomization was by birth cohort within clusters.<sup>27</sup>

The final Swedish study was conducted in Gothenburg, starting in 1982. The trial began with nearly 50,000 women aged 40 to 59 who received two-view mammography every 18 months. Randomization of women aged 40 to 49 was by individual, whereas clustered randomization was used for women aged 50 to 59. Verified results have not yet been published,<sup>47</sup> but additional data were provided in 1997 for the National Institutes of Health Consensus Conference on Breast Cancer Screening in women aged 40 to 49.

The Edinburgh Trial began in 1978 as a randomized component of the larger, nonrandomized United Kingdom trial of The Early Detection of Breast Cancer. Approximately 25,000 women aged 45 to 64 were randomized to two-view mammography plus CBE on either a 12- or 24-month schedule. The purpose was to assess the impact of mammography and CBE in reducing mortality from breast cancer.<sup>50,51 and 52</sup>

The National Breast Cancer Screening Study (NBSS1) was designed to examine the value of two-view mammography and CBE compared to usual care in women aged 40 to 49. Nearly 53,000 women were enrolled, starting in 1980, and received follow-up yearly for 5 years. Unlike the other trials, the women were recruited as volunteers and then randomized. As Miller and colleagues<sup>53</sup> have reported, these women were different from the Canadian population in several ways—for example, they were less likely to smoke, and they had higher levels of education.

The second Canadian study, the NBSS2, also begun in 1980, enrolled nearly 43,000 women aged 50 to 59 and was designed to compare two-view mammography and CBE against CBE only. In other words, the question was whether there is a benefit of mammography over and above CBE in this age group. This is the only trial planned to assess the additive impact of mammography in addition to CBE.<sup>32</sup> Critiques of this trial have appeared by several authors.<sup>54,55</sup> The criticisms are probably overstated, and the results should not be discounted.

## NONRANDOMIZED CLINICAL TRIALS

A number of nonrandomized trials have been conducted around the world. Much can be learned from these studies. However, because of a number of design limitations, they should not be used alone in establishing screening guidelines and policies.<sup>56</sup> The largest study of mammography and CBE was the U.S. Breast Cancer Detection Demonstration Project (BCDDP): 280,000 women aged 35 and older were recruited and screened in 28 centers annually with mammograms and CBE during the 1970s.<sup>20,49</sup> The BCDDP was sponsored jointly by the NCI and the American Cancer Society (ACS). Because the BCDDP participants were not a random sample of the population, there were some important differences from women in the general population. Most notably, the BCDDP population was at much higher risk, with a substantially higher incidence of breast cancer. Moreover, because it was not an RCT, the case fatality rate was used to assess the impact of

screening. A subset of women were followed as part of a case-control study conducted by Morrison and colleagues<sup>57</sup> to examine case fatality rates within the BCDDP. Breast cancer mortality was approximately 20% less than expected from national data.<sup>57</sup> There was a benefit for younger women, but it was less than for older women.

## EVIDENCE FOR MAMMOGRAPHY

More than 3.5 million women-years of observation have been recorded for women of all ages, and more than 2.7 million women-years for women aged 40 to 49 at entry from the breast cancer screening RCTs.<sup>27,58</sup> One of the challenging aspects of tracking these trials is the constantly shifting nature of the data. The trialists provide updates at different points in time, and some reports use nonverified data. Thus, at any given point, review articles may vary substantially in the numbers they report. [Figure 25-1](#) and [Figure 25-2](#) illustrate the mortality outcomes for women of all ages and for those younger than age 50, with 18 years of follow-up for HIP,<sup>46</sup> 14 years for the Edinburgh trial,<sup>45</sup> 10.5 years for the Canadian trials,<sup>59</sup> and 7 to 13 years for the Swedish trials.

**FIGURE 25-1.** Mortality impact of the randomized clinical trials (all ages) by relative risk and upper and lower confidence intervals. Adjusted for socioeconomic status differences.<sup>45</sup> HIP, Health Insurance Plan of New York; NBSS2, second Canadian National Breast Cancer Screening Study.

**FIGURE 25-2.** Mortality impact of the randomized clinical trials (women aged 40 to 49 years at entry) by relative risk and upper and lower confidence intervals. Adjusted for socioeconomic status differences.<sup>45</sup> HIP, Health Insurance Plan of New York; NBSS1, first Canadian National Breast Cancer Screening Study.<sup>58</sup>

In 1993, the International Workshop on Breast Cancer Screening<sup>27</sup> created considerable controversy when it concluded that for women aged 40 to 49, randomized controlled trials consistently demonstrated no benefit from screening in the first 5 to 7 years after entry and a marginal benefit after that. More recently, in reviewing the same trials, Kerlikowske and colleagues<sup>60</sup> confirmed this conclusion and suggested that the same benefit could be achieved by screening women after age 50. However, several years later, with most of the international RCTs now having more than 10 years of follow-up, the trends are clearer: Six of the trials show reductions in mortality for women who were in their 40s at entry. But a large variability remains in the relative risk of dying from breast cancer for women younger than 50. There also is significant controversy over many of the reported numbers.

Although the randomized trials have included too few women older than age 70 to offer guidance about screening for older women, the Forum on Breast Cancer Screening<sup>61</sup> recommended regular mammograms for women aged 70 years who are otherwise healthy. A case-control analysis in the Nijmegen study<sup>62</sup> confirmed the benefit of mammography for women older than 70.

Six different published metaanalyses, including the two mentioned earlier, have examined the effect of the mammography trials on women aged 40 to 49 ([Table 25-4](#)). When Elwood and colleagues<sup>19</sup> conducted a metaanalysis and included all the data except for the controversial Canadian study, they found an overall relative risk of 0.99, suggesting no difference between the screened and control groups. With the Canadian data included, there was a slight increase in the relative risk for the experimental group (relative risk, 1.08). The overall relative risks found in the metaanalyses have ranged from 0.85 to 0.99 without the NBSS data and 0.93 to 1.08 with the NBSS data. Eckhardt and colleagues<sup>63</sup> found a nonsignificant 7% reduction in mortality. In a 1995 metaanalysis, Smart and colleagues<sup>64</sup> found a significant 24% mortality reduction for women in their 40s. Hendrick et al.<sup>56</sup> combined recent follow-up data on women aged 40 to 49 at entry. They found a statistically significant 18% mortality reduction. This is similar to the 18% reduction Berry<sup>8</sup> found when an assumption of homogeneity was made. However, the benefit was not statistically significant when he assumed heterogeneity. The benefit occurs approximately 15 years after the start of screening.<sup>21</sup> The benefit for women in their 50s is larger and also significant: an approximately 25% to 30% reduction in mortality. It is reasonable to conclude that there is a small but statistically significant reduction in mortality for women in their 40s. Nevertheless, most of the benefit actually is achieved when they are in their 50s.<sup>65</sup> For women in their 50s and 60s, there is general agreement about the benefits of mammography.

**TABLE 25-4.** Metaanalyses of Trials for Women Aged 40 to 49 Years

## BREAST CANCER SCREENING GUIDELINES

The question, "At what age should women begin getting regular mammograms?" has been one of the most contentious in science and medicine. The issue became even more inflamed after a 1997 National Institutes of Health Consensus Conference on Breast Cancer Screening for Women Aged 40 to 49.<sup>66</sup> The report, contrary to

expectations, found insufficient data to recommend that women in their 40s get regular mammograms. Disagreement still exists over whether the modest reduction in mortality warrants a recommendation that all women in their 40s be screened.<sup>67</sup> The argument turns primarily on the small population benefit achieved. Most of the benefit occurs when the screened women are in their 50s. As Ransohoff and Harris<sup>67</sup> noted, only 1 to 2 women's lives would be extended per 1000 women of 40 to 50 years of age who are screened annually for 10 years. However, in agreeing on a reduction in breast cancer mortality of 18%, both the ACS and the NCI changed their screening recommendations, with the ACS now advising annual mammograms for women aged 40 and older. Annual screening for women in their 40s is based on the assumption of a shorter lead time for younger women.<sup>44</sup> The NCI recommends mammograms every 1 to 2 years for average-risk women aged 40 and older.<sup>68</sup> For the first time since 1993, however, the recommendations are compatible; both organizations now endorse regular mammograms for women older than age 40 ( [Table 25-5](#) ).

**TABLE 25-5.** Screening Guidelines for Breast, Colorectal, Prostate, and Cervical Cancers for Selected Health Care Organizations

The evidence suggests that a 5% to 20% additional benefit in mortality reduction can be achieved by adding a high-quality CBE.<sup>19,27</sup> Although the recommendations of different medical organizations vary, it seems prudent to encourage women to have a CBE yearly (see [Table 25-3](#) ).

## CERVICAL CANCER SCREENING

In 1999, an estimated 12,800 new cases of invasive disease and 4800 deaths resulted from cervical cancer.<sup>43</sup> A steady decline in mortality was observed after the initiation of widespread Pap testing in the mid-twentieth century.<sup>69</sup> From 1970 through 1995, mortality continued to decrease by 40%.<sup>69</sup> This decline represents a major success in cancer control in the United States. Mortality associated with invasive cervical cancer is no longer common compared to other cancers. However, cervical cancer is the second most common cancer worldwide,<sup>70</sup> and fatalities from this disease in developed countries should be entirely avoidable with currently available technology. Continued efforts to improve cervical cancer screening practices are, therefore, well justified both nationally and internationally.

Dr. George Papanicolaou introduced the test that bears his name in the 1930s. An RCT has never been conducted to confirm its efficacy because wide-scale adoption and diffusion of the Pap test into medical practice made assignment to a nonscreened control group unethical and, therefore, untenable. Nevertheless, one would expect screening to be effective because cervical cancer is accessible and has a relatively long preclinical detectable phase. Numerous observational studies have demonstrated its efficacy beyond a reasonable doubt. Large national screening programs in Nordic countries, Canada, and the United States have been associated with marked drops in mortality from cervical cancer.<sup>69,71,72</sup> Analysis of these studies and others suggested that the probability of invasive cancer could be reduced up to 90% for frequencies up to every 3 years.<sup>73,74</sup> Case-control studies of women with invasive cervical cancer in varied geographic areas, including Italy, Columbia, Scotland, and Denmark, have documented risks three to ten times greater associated with women who have not been screened.<sup>75,76,77</sup> and <sup>78</sup>

Controversy remains about the appropriate screening interval for Pap testing. Guidelines from major expert groups have continued to recommend annual screening, with less frequent intervals after three normal smears (at the discretion of the physician). However, after its review of the evidence, the U.S. Preventive Services Task Force left the interval from 1 to 3 years<sup>7</sup> (see [Table 25-5](#) ). The literature that bears on this question is limited.

Inadequate data are available to recommend an upper age limit for regular screening. Because mortality increases with advancing age and 40% to 50% of all women who die from cervical cancer are older than 65 years of age,<sup>79</sup> it seems prudent to screen older women. However, national survey data document a marked fall-off in regular screening for older women.<sup>80</sup> There is concern that Pap testing is less sensitive in older women who have a receded squamocolumnar junction of the cervix. However, it is likely that the primary reason for invasive cervical cancer in older women is lack of screening.

For women who have had hysterectomies, the practice of cytologic screening with vaginal smears is still common. However, at least for women who have had a hysterectomy for benign conditions, the likelihood of detecting vaginal dysplasia is extremely low and the false-positive rate is high,<sup>81</sup> thus suggesting that the practice is unnecessary.

## SKIN CANCER SCREENING

The incidence of skin cancer has increased worldwide, with U.S. incidence data mirroring this trend.<sup>82,83</sup> In the United States, the incidence rate of melanoma has increased approximately 4% per year since the early 1970s, with a 162% increase in male melanoma cases and 95% in women.<sup>43,84</sup> It is unclear whether this increase is due to actual changes in prevalence or is a function of increased awareness with subsequent diagnosis, improved reporting by tumor registries, or both. In 1999, 54,000 new cases of skin cancer were projected, with 44,200 new cases of melanoma and 7300 deaths.<sup>43</sup> Melanoma now ranks sixth in incidence among cancers in males and seventh in incidence among cancers in females.<sup>43</sup> Approximately 800,000 nonmelanoma skin cancers are diagnosed each year.<sup>43,85</sup> The United States lags behind many other countries in the creative application of interventions to reduce the incidence of and mortality from melanoma and other skin cancers. Australia, which has the highest reported incidence of melanoma anywhere, has mounted successful population-based programs that have had dramatic effects.<sup>86,87</sup>

Although national data are lacking on either population or health professional behavior, at least one study suggests that most physicians do not examine the areas of the skin where melanoma is likely to occur, and most people do not routinely examine their skin for changes. Skin cancer screening consists of a medical history and a whole body examination under strong lighting.<sup>85,88,89,90</sup> and <sup>91</sup> There is a lack of consensus about the routine provision of preventive services in dermatologists' offices.<sup>92</sup> Although no randomized trials proving the impact of skin cancer screening have been performed to date, research results from the efficacy studies that have been conducted suggest that skin cancer screening may lower mortality from skin cancer, especially melanoma, by improving rates of early detection.<sup>93,94,95,96,97,98</sup> and <sup>99</sup> However, more evidence is needed.

Experts have not agreed about screening guidelines for skin cancer. The U.S. Preventive Services Task Force recommends "routine screening for individuals at high risk" (e.g., those having a family or personal history of skin cancer, clinical evidence of precursor lesions, and increased exposure to sunlight). The Task Force neither defines what is meant by routine screening nor reports on the specific recommendations for skin self-examination.<sup>7,85,100,101</sup> The ACS recommends a cancer-related checkup, including a skin examination, every 3 years and "more frequently" for persons at risk.<sup>43,101</sup> The ACS further suggests that "screening for the presence of skin cancer is well within the domain of the well-trained generalist."<sup>101</sup> The NCI also recognizes the benefits of skin cancer screening, but offers no specific guidelines for such screening.<sup>102</sup> Other experts recommend yearly skin cancer screenings,<sup>90,97,98</sup> regular screening for the elderly,<sup>87,103,104</sup> and skin cancer screening for every new patient seen by a dermatologist.<sup>105</sup>

## PROSTATE CANCER SCREENING

Prostate cancer is the most commonly diagnosed cancer among men in the United States and is the second leading cause of male cancer deaths. In 1999, 179,000 new cases of prostate cancer were identified, and there were 37,000 deaths. However, consensus is lacking concerning recommendations for prostate cancer screening. There are several reasons for the controversy surrounding screening tests for prostate cancer. First, no definitive evidence suggests that prostate cancer

of the colon and at the same time provide access for biopsy and removal of polyps.<sup>138</sup> A comprehensive review of colorectal cancer screening with clinical guidelines has been developed by a multidisciplinary panel under the aegis of the Agency for Health Care Policy and Research.<sup>139</sup>

### **Fecal Occult Blood Test**

Support for the use of FOBT comes from several large randomized controlled trials, including a Minnesota trial of 46,501 participants between the ages of 50 and 80 years of age.<sup>140,141</sup> This study found that annual FOBT with rehydration of the samples decreased the 13-year cumulative mortality from colorectal cancer by 33% and biennial screening by 21%.<sup>140,141</sup> Most (75% to 84%) of this reduction resulted from the test rather than from incidental discovery of cancers by follow-up colonoscopy.<sup>142</sup> Earlier RCTs in England of 152,850 individuals,<sup>143</sup> as well as a large study of 62,000 persons in Denmark,<sup>144</sup> demonstrated that biennial FOBT without rehydration reduced mortality by 15% to 18%. An additional study of 27,000 persons in Sweden, aged 60 to 64 years of age, is ongoing.<sup>145</sup> A fifth trial in the United States evaluated FOBT as a supplement to annual rigid sigmoidoscopy in 21,756 subjects and found a nonsignificant decrease in colorectal cancer mortality.<sup>146</sup> Data from case-control studies are generally consistent with the conclusions of these trials. In a health plan population, a decreased mortality of 31% was associated with having had at least one screening FOBT in the previous 5 years.<sup>147,148</sup> Other case-control studies in Japan and Washington also have demonstrated protective effects on mortality.<sup>149,150</sup>

When used in unscreened populations the FOBT is positive in 1% to 5%; 2% to 10% of these have cancer and 20% to 30% have adenomas.<sup>151,152</sup> Concern remains about the lack of specificity of FOBT and the necessity to follow positive results with colonoscopic examination or barium enema.<sup>153</sup> However, the evidence is mounting that FOBT saves lives from colorectal cancer. Physicians must weigh the benefits of possible early detection of colorectal cancer against the possible complications and expense of follow-up procedures.<sup>138</sup>

### **Flexible Sigmoidoscopy**

The advantage of sigmoidoscopy screening over FOBT is that it frequently includes the actual removal of cancer or a precancerous lesion in a biopsied polyp, thus combining prevention (through removal of polyps), screening, and treatment in one step.<sup>146</sup> Another advantage is that it needs to be performed infrequently, perhaps every 5 to 10 years.<sup>147,148</sup>

At least two large randomized trials of flexible sigmoidoscopy screening are in progress. The NCI's PLCO trial is evaluating the efficacy of examinations every 3 years in 74,000 men and women, 55 to 74 years of age, with an equal number of controls.<sup>154</sup> A trial in the United Kingdom, with 200,000 men and women aged 55 to 64 years, is evaluating the efficacy of one sigmoidoscopy delivered for reducing colorectal cancer mortality.<sup>155</sup>

Meanwhile, supporting evidence for efficacy comes from several case-control studies. In the first, screening sigmoidoscopy, primarily with the rigid sigmoidoscope, reduced mortality from cancer of the rectum and distal colon by 60% (adjusted odds ratio, 0.41; 95% confidence interval, 0.25 to 0.69) in a large Kaiser Permanente California health plan population.<sup>148</sup> Confirmation came from a smaller second study of 66 cases and 196 controls in another health plan population in Wisconsin.<sup>156</sup> A third large case-control study in American veterans, with 4358 cases and 16,199 matched controls, reported a 59% reduction in mortality from any prior colorectal procedure.<sup>157</sup> The first two case-control studies were judged sufficiently convincing that the U.S. Preventive Services Task Force upgraded the evidence and recommends screening with sigmoidoscopy or FOBT annually for persons older than 50.<sup>7</sup>

## **LUNG CANCER SCREENING**

Lung cancer screening is not currently recommended due to lack of evidence that any available screening procedure, even for smokers, can identify tumors early enough to reduce mortality. This remains a major challenge to research and technology because of the tremendous burden caused by this cancer. In 1999, an estimated 171,600 new cases of disease and 158,900 deaths were due to lung cancer, making it by far the most common killer from cancer in both men and women and accounting for 28% of all cancer deaths.<sup>43</sup>

The decision to actively discourage lung cancer screening by x-ray was made based on the results of RCTs performed in the 1970s.<sup>158</sup> None of four randomized trials showed any benefit of reducing mortality from lung cancer.<sup>159,160,161</sup> and <sup>162</sup> The Mayo Lung Project, the primary trial contributing to this evidence, demonstrated that screening with either chest x-rays or chest x-rays plus sputum cytology could lower the stage at presentation and increase survival. Neither approach had any effect on lung cancer mortality.<sup>162</sup> The lack of connection between improved survival and the absence of a mortality benefit can be attributed to lead-time and length biases. This study and its contemporaries have, however, been criticized because of study design and analytic issues, including a lack of statistical power.<sup>163</sup> Recent preliminary results from the Early Lung Cancer Action Project in New York indicated that low-dose spiral computed tomography used in 1000 symptom-free former smokers older than age 60 detected 27 cancer cases versus 7 cases detected by chest radiograph.<sup>164</sup> Although this is not an RCT and, therefore, susceptible to lead-time and length-time bias, these preliminary results suggest that newer noninvasive imaging technologies may hold promise. Efforts to prevent initiation of smoking, especially by young people, and cessation of tobacco use remain the physician's main tools for combating this most common of all cancers.

## **THE FUTURE OF SCREENING**

Many challenges lie ahead for cancer screening. Better detection methods are urgently needed, and molecular detection methods may surpass current techniques. At the same time, more effort is required to encourage adherence to the proven cancer screening modalities. Adherence to screening is less than optimal for all the major recommended screening techniques.<sup>165</sup> With the discovery of mutations in susceptibility genes that predispose for cancer, new challenges in cancer screening arise with the need for appropriate screening recommendations and programs for high-risk subgroups. Not only are those who have inherited a mutation for cancer susceptibility at higher risk for developing some cancers, but often the age at onset among such individuals is younger than the age at onset in the general population. This creates challenges for those who recommend and promote screening regimens. The example of the *BRCA1* susceptibility gene for breast cancer illustrates a perplexing situation in which recommendations for screening with mammography do not address the early age at onset of this disease. Moreover, there are no good population data on which to base guidelines. Further study is needed to establish efficacious screening protocols for those who are genetically predisposed to cancer. Finally, there are new screening modalities on the horizon, such as low-dose helical computed tomography scans for detecting early lung cancers.<sup>164</sup> Among the challenges of the future is how to evaluate new screening technologies in a world where large RCTs may be increasingly difficult to conduct. In screening, as in other areas of medicine and public health, the inclination to recommend screening tests on the basis of an intriguing and promising study must be balanced by a careful assessment of the evidence.

#### INTRODUCTION

The traditional role of the surgical pathologist has been the morphologic evaluation of human tumors in a search for clues of their histogenesis and anticipated behavior. Over the years, this quest has benefited from the application of specialized techniques, which have become part of the pathologist's armamentarium. The diagnosis of cancer involves the analysis of tissue and cytology samples for features correlated with malignant transformation. Specimens of tissues and cells are obtained through several procedures, including surgical biopsy, endoscopic biopsy, core or aspirational needle biopsy, venipuncture, spinal tap, scraping of tissue surfaces, and collection of exfoliative cells from urine or sputum. The acquired tissue or cell specimens are subjected to a series of analytic modalities for diagnostic purposes.

Light microscopy, assessing morphologic features of the procured specimens, was used as almost the sole approach for many years, and it remains the standard diagnostic method to which all novel methods must be compared. The use of enzyme histochemistry and electron microscopy expanded the primary microanatomic evaluation to include biochemical and subcellular structural features. More recently, cytogenetics, analysis of DNA content, molecular genetic assays, and immunohistochemistry (IHC) have been added as valuable adjuncts to light microscopy in cancer diagnosis. These methods, particularly the latter, have greatly enhanced our ability to precisely define the lines of differentiation of human tumors, which constitutes the basis for the current classification schemes. As important as the "histogenetic" categorization provided by these techniques is, it addresses only indirectly other aspects of human neoplasia that are more relevant to their biologic behavior and response to therapy. These include rate of proliferation, capacity for invasion and metastases, and development of resistance mechanisms to certain treatment agents. This chapter reviews the contributions of novel approaches to the diagnosis and classification of tumors.

#### ROLE OF MOLECULAR PATHOLOGY IN CLINICAL ONCOLOGY AND TRANSLATIONAL RESEARCH

Molecular pathology studies the origins and pathogenesis of disease at the molecular level. Because cancer is a hereditary disease of the cell, much of the mechanistic studies of the cancer cell are based on the characterization of acquired or somatic mutations and subsequent structural or regulatory alterations of the gene products. In this regard, it differs from medical genetics, in which the main objective is to determine the genetic abnormalities associated with inherited disorders and carried as germline mutations. Molecular pathology of neoplasia aims at identifying and understanding those aberrations involved in the development and progression of neoplastic diseases. Clinically relevant objectives include (1) establishing a definitive diagnosis and classification of tumors based on the recognition of complex profiles ("fingerprints") or unique molecular alterations that occur in specific tumor types; (2) providing early detection of tumor cells using sensitive molecular techniques, thus anticipating therapeutic intervention; (3) rendering prognostic information of clinical relevance through the assessment of molecular predictors of outcome; and (4) assisting in the selection of individualized treatment regimens, saving unnecessary drug toxicity. Protocols based on molecular markers increase the chances for cure by opting for the right management approach, and they improve the quality of life of patients with cancer.

Molecular pathology also serves as a bridge between clinical and basic biomedical sciences. The translational aspects of research in molecular pathology are bidirectional, involving both the active transfer of relevant observations that are the result of the analysis of primary tumors and clinicopathologic correlations to basic laboratory studies, as well as the effective transfer of laboratory findings into clinical analyses and protocols. In promoting such transfers, molecular biology facilitates and maximizes the transfer of biologic discoveries into diagnostic, prognostic, and therapeutic applications.

The use of molecular techniques has led to remarkable progress in the understanding of cell growth, differentiation, maintenance of genomic integrity, and programmed cell death, these being key issues in tumor development and progression. Biologic markers, such as alterations of TP53, which correlate with tumor behavior when detected in specific tumor types, await validation studies. Similarly, prospective clinical analyses using well-characterized cohorts of patients and properly selected pairs of normal and tumor samples are needed to better delineate the role of mutations occurring in these genes, because they may impact on the management of patients affected with cancer. The implementation of objective predictive assays to the diagnostic and prognostic tools will enhance the ability to assess tumor biologic activities and to design effective treatment regimens.

#### USE OF HUMAN TISSUE SAMPLES FOR MOLECULAR ANALYSES

Discrepancies of reported results aimed at the identification of gene mutations and altered patterns of gene expression in primary tumors could be explained by the use of distinct probes and methods. Critical caveats include assurance for the presence of viable tumor, extent of necrosis, normal cell to tumor cell ratio, and the stage and grade of the lesion being studied. Often, distinct methods are available to detect a given marker, these approaches differing in specificity, sensitivity, speed and cost, and appropriateness for particular clinical situations.

Strategies have been developed whereby, from a single tissue sample, different techniques can be performed in search of the molecular phenotype and genotype.<sup>1,2</sup> One of these strategies is illustrated in [Figure 26-1](#). Briefly, using consecutive tissue sections cut at different thicknesses and deposited either on glass slides or microtubes, one can (1) evaluate morphology (i.e., hematoxylin and eosin staining), (2) perform expression assays [i.e., IHC and *in situ* hybridization (ISH)], (3) identify molecular alterations [i.e., Southern blot, polymerase chain reaction/single-strand conformation polymorphism (PCR-SSCP), and sequencing], and (4) conduct high-throughput assays (i.e., expression array technologies). Tissue microdissection assays can be implemented to remove normal contaminating cells, enriching the neoplastic cell content of the tumor sample when needed.<sup>3</sup> This method can also be used to study low-grade and high-grade tumor foci in a single tissue sample or to analyze minimal lesions, such as carcinoma *in situ*. Evaluation of gene mutations and altered patterns of expression can be performed using a combination of techniques, including deletion studies by restriction fragment length polymorphism and comparative multiplex PCR, point mutation screening by PCR-SSCP and confirmation by direct sequencing, and assessment of altered expression by IHC and ISH. More recently, the introduction of microchips and other technologies allows the detection of missense mutations in certain genes with great sensitivity.<sup>4</sup>

**FIGURE 26-1.** Use of tissue for research and diagnostic purposes can be prepared to yield a variety of tissue-derived products that can be treated using different technological approaches. The ability to analyze nucleic acids and proteins from small numbers of cells makes it possible to obtain a comprehensive profile of the tissue. These data can then be correlated to the histopathologic appearance and to clinical characteristics of the lesion. Properly annotated samples stored in a tissue bank constitute a precious resource to test the efficacy of newly discovered biomarkers and diagnostic or predictive tests. F/U, follow-up; H&E, hematoxylin and eosin; IHC, immunohistochemical; NB, Northern blot; PCR, polymerase chain reaction; RFLP, restriction fragment length polymorphism; Rx, medication; SB, Southern blot; WB, Western blot.

Manual microdissection of tumor samples, to enrich neoplastic cell aliquots to be used in specific techniques, is achieved by the use of a magnifying lens and sterilized scalpels. It can be also performed using scraping devices mounted on specially designed stereotactic microscopes. More refined, laser-based microdissection instruments have been developed and are commercially available ( Fig. 26-2). One of the strategies, the laser-capture method, is based on adhering cells to a material after it is thermally activated by a laser beam.<sup>3</sup> Tissues to be microdissected are viewed through a video microscope, and the position of the slide is adjusted so that the desired cells are under the targeting light. Activation of the laser causes the desired cells to adhere to the special coverslip, which is mounted on a plastic cap and positioned over the targeted cells. The cap is then separated from the tissue section, pulling the desired cells for study. The dissected material can be reviewed for morphology and nonspecific transfers before placing it in a tube containing the appropriate digestion buffer for nucleic acid extraction. Protocols for the dissection of tumor cells from frozen and formalin-fixed paraffin-embedded tissue have been developed that allow the extraction of nucleic acids, mainly DNA. It is possible to select cell populations based on their phenotypic features determined by IHC. Isolation of intact RNA transcripts is difficult, if not impossible, to achieve through this procedure. The distortion produced during the application of the laser beam appears to be responsible for the partial degradation of most RNA species.

**FIGURE 26-2.** Laser microdissection enables researchers to capture and characterize microscopic normal or pathologic structures. The efficacy of the approach can be appreciated in genotyping a single crypt obtained from colonic epithelium. Verification of the donor section after capture clearly demonstrates the ability to precisely capture well-defined groups of cells making up a structure. In this manner, specific regions from the DNA from cells constituting a single crypt profile can be amplified and analyzed.

The application of the full spectrum of molecular-based methods to the evaluation of tissue and cell specimens, and the implementation of novel therapeutic modalities aimed at specific molecular targets, has led to changes in the established patterns of tissue procurement, processing, and tissue banking. Advanced diagnostic technology should be included in tissue analysis carried out during the diagnostic investigation of any potentially neoplastic lesion. Diagnosticians should “think molecular.” Protocols should be implemented and constantly updated to guarantee that samples are handled in a way that will not preclude optimal application of molecular testing. In daily practice, this means that part of the specimen, whenever possible, should be set aside prospectively for advanced diagnostics. The advent of advanced diagnostics is forcing operational changes that ensure fast delivery of specimens to the laboratory, where pathologists can select an aliquot of tissue or cells that will be used to resolve questions pertinent to the management of the lesion or set aside a sample “in reserve” for molecular analysis if necessary.

One of the most common ways to preserve samples is by snap freezing in liquid nitrogen. However, this procedure does not allow for preservation of microanatomic detail. Rapid freezing of tissue in a block with cryopreservative solution maintains morphology and yields frozen sections that can be used for different assays. This method is favored in building frozen tumor banks from which enough genomic DNA or complementary DNA (cDNA) can be generated from a thick section to produce useful reagents for subsequent analyses. In addition, monoclonal antibodies, purified antisera, and riboprobes can easily be used on thin sections, usually 5  $\mu\text{m}$ , by implementing IHC or ISH protocols. In today’s practice, one of the ideal moments to procure tissue is at the time of an intraoperative consultation, when tissue is sampled for diagnostic frozen section examination. It is important to realize that the tissue procured for advanced diagnostics remains usable when and if required for routine morphologic analysis. Tissue procurement and tissue banking are different tasks that should be well delineated if this kind of valuable resource is to be implemented with maximum efficiency.

When using archival tissue for research, including both discovery and validation studies, issues of patient confidentiality and informed consent should be carefully considered and resolved through established institutional and national guidelines. Institutional review boards and human investigation committees must be made aware of the ever-growing complexities involved in the use of human tissues for research. These issues grow in complexity because of the rapid development of new technology and bioinformatics. The existence of large databanks containing comprehensive information on disease susceptibility, pharmacogenomics, and other biologic data that can be potentially linked to an individual are of obvious concern to researchers and ethicists.

## OVERVIEW OF THE TECHNOLOGICAL APPROACHES TO MOLECULAR DIAGNOSTICS

The value of molecular markers for cancer diagnosis and patient management depends on their accessibility to detection by various analytic methods. Often, several strategies are available to detect the same marker, and these strategies differ in several aspects, including specificity, sensitivity, and appropriateness for particular clinical situations. With the exception of DNA content, there are two broad categories of strategies for the detection of molecular markers: biochemical molecular techniques that can be applied to analyze carefully chosen tissue samples or, alternatively, reagents can be applied *in situ* on tissues, cells, or chromosomes to detect and demonstrate the presence and spatial distribution of the marker. At present, the development of new clinical tests depends mainly on low-throughput assays, but it seems likely that the high-throughput, comprehensive analytic techniques described in the following sections will have a major impact in the near future. Some understanding of these techniques is central for the appreciation of their capabilities, advantages, and limitations when analyzing clinical material.

### LOW-THROUGHPUT TECHNIQUES

#### DNA Content and Flow Cytometry

Individual cells harboring many genetic alterations, including genes regulating growth and apoptosis programs, often contain an abnormal amount of nuclear DNA that can be measured by flow cytometry. Deviations in cell DNA content relative to normal cells (DNA index) may indicate duplications or losses of individual chromosomes

(aneuploidy) or extra haploid sets of chromosomes (polyploidy). In addition, the profile of DNA content among the cells of a tissue reflects the fraction of cells in S and G<sub>2</sub> phases of the cycle. A high number of cells in these fractions correlate with poorer prognosis in certain cancers.<sup>5,6</sup> The amount of DNA per cell can also be measured by static image cytometry on cell smears and be combined with other morphometric parameters, such as nuclear contour and shape.<sup>7</sup> Flow cytometry allows for simultaneous measurement of several parameters, whereas a suspension of cells flows by stationary detectors at a rate of approximately 10,000 cells per second. To measure DNA content per cell, flow cytometry is performed on disaggregated cells or on nuclear suspensions. The latter can be obtained fresh or from paraffin blocks.<sup>8</sup> In either case, the cells are stained with dyes that bind stoichiometrically to DNA—fluorescent dyes for flow cytometry, and Feulgen dyes for static measurements through a specially equipped light microscope. The data acquired from each individual cell are compiled in a histogram, indicating the distribution of the DNA content among the cells in the tissue. Total DNA measurements permit the evaluation of ploidy and an estimation of the fraction of cells traversing the S phase of the cell cycle. Both parameters have been found to be of prognostic relevance in certain tumors, such as breast cancer, and aneuploidy has been reported as a favorable prognostic feature in neuroblastoma.<sup>9</sup>

### **DNA Alterations and Detection Assays**

Native DNA extracted from either tissues or cells can be directly sequenced or analyzed by Southern blotting, restriction fragment length polymorphism, and comparative genomic hybridization (CGH). These techniques are capable of detecting alterations present in the genome of neoplastic cells that serve as markers, including point mutations, translocations, amplifications, deletions, microsatellite length instability, and altered methylation. Point mutations are the most common dominant oncogene alterations found in human cancer. The amino acid change produced by the mutations causes the gain of function that contributes to the transformed state of the cell. Amplification of an oncogene is usually associated with protein overexpression and is another mechanism for gain of function. Amplification constitutes an easily detectable and measurable change; thus, it is a good diagnostic and potential prognostic marker. In translocations, protooncogenes are subjected to a strong promoter-enhancer or removed from a physiologic regulatory control element. The net effect is an inappropriate increase in product that provides excess function.

Alternatively, a translocation can produce a novel gene by fusion of the two partners participating in the translocation and generate a chimeric product with aberrant function. Missense or nonsense point mutations can cause loss of function of tumor suppressor genes that are important in maintaining control of cell growth and differentiation. In the case of a dominant-negative tumor suppressor gene, the product of the allele inactivated by mutation suffices to contribute to the neoplastic state by binding and abrogating the function of the wild-type product. For the majority of tumor suppressor genes, however, inactivation of the second allele is necessary to completely lose function. The second hit is often effected by the deletion of genomic information, often registered by loss of heterozygosity assays. Loss of function can also be produced by hypermethylation of the promoter or intragenic regions, resulting in silencing or extinction of its expression. The genetic instability inherent to many cancer cells can be manifested by microsatellite instability. Changes in the length of repeats can be caused by lesions in the DNA repair genes (i.e., hMSH1, hMSH2, hPMS1, hPMS2) giving rise to the so-called mutator phenotype.

An additional category of markers is based on the clonal nature of neoplastic proliferations. When there is a question about whether abnormal cells are the consequence of nontumoral tissue response (regenerative atypia) or represent a neoplastic proliferation, clonality assays may provide the answer. If the suspicious cells or tissues can be shown to be clonal, they are likely to represent a neoplastic process, because cells in hyperplastic or reactive lesions are polyclonal. Assays of clonal markers measure the fraction of cells within a tissue or cytology sample that carry the same form of the marker and are thus presumed to be issued from a single cell. Prime examples of diagnostically useful clonal markers are antigen receptor gene rearrangements in lymphoid proliferations.<sup>10</sup> Inactivation of the X chromosomes in females heterozygous for some X-linked genes have been widely used to confirm the clonality of tumors by the examination of isotypes of proteins or the analysis of methylation in X chromosome DNA.<sup>11</sup> If a tumor is known to harbor a specific mutation in a given gene, the altered sequence can, under some conditions, also serve as a marker for clonality. The fundamental requirements are (1) that the sequence be altered early in the genesis of the tumor; (2) that the sequence should not be further altered or lost during tumor progression; and (3) that there be enough diversity in the observed mutations of the specific gene to make it unlikely that two diverse populations of cells, arising from two independent metachronous tumors, would harbor the same mutated sequence.

Southern blotting<sup>12</sup> is the procedure that identifies a specific DNA by using a complementary sequence (probe) that hybridizes to a fragment of the DNA after it has been transferred from an agarose gel to a nitrocellulose filter. This technique was one of the first used for diagnostic testing. It still provides a robust way for detecting changes in DNA nucleotide sequence, particularly when these differences involve rearrangements of sizable stretches of DNA (translocations, large deletions, or amplifications). The major drawback of the Southern blot is its relative lack of sensitivity, because it can detect only 1 cell in 100. Another limitation is the requirement of several micrograms of DNA per test. The term *restriction fragment length polymorphism* defines the use of specific restriction enzymes to cut recognizable DNA fragments, followed by a blotting procedure, and it is mainly used for deletion analysis.

### **Fluorescence In Situ Hybridization**

Fluorescence *in situ* hybridization (FISH) overcomes many of the practical problems of conventional cytogenetics by permitting the specific staining of any given region of the genome.<sup>13,14</sup> In addition, the staining can be done using metaphases or interphase nuclei. ISH of DNA probes to metaphase chromosomes deposited on microscope slides or to chromatin within intact interphase cells in smears or tissue sections is usually monitored by fluorescence, and it is therefore referred to as FISH. The DNA probes used for FISH may consist of mixtures of DNA fragments covering whole chromosomes, fragments containing chromosome-specific repeated sequences, or fragments containing unique nonrepetitive sequences. The lower limit of fragment size for unique sequence fragments is approximately 4 kilobases (kb), but in practice, fragments of approximately 25 kb, such as those propagated in bacterial cosmids or in yeast artificial chromosomes, give the most consistent results. The probes hybridized to specific chromosomal sequences are tagged with a marker (digoxigenin or biotin) that can be detected with an antibody specific to the tag and labeled with a fluorochrome. Up to seven probes can be used simultaneously, and changes not detectable in expanded banding preparations can be identified with this approach. The number of simultaneous probes that can be applied is growing, and with the aid of confocal microscopy and image processing, this method can be carried out in paraffin-embedded tissue sections. Used on histologic sections, FISH allows for correlation of genetic findings with the histology, a feature not shared by the analysis of metaphase chromosomes. FISH is well suited for the detection of numerical changes in chromosomes or regions of chromosomes, including microdeletions. In addition, chromosomal translocations can be detected by the simultaneous use of two probes containing DNA sequences known to reside on either side of a translocation breakpoint in one of the two reciprocal translocation products. Apposition of two of the four dots present in diploid cells indicates the presence of a translocation. Identification of such a result is facilitated by labeling the two probes with different tags that are recognized with antibodies conjugated to two different fluorochromes. When used in interphase cells, for the diagnostic or monitoring purposes discussed in the following section, FISH has the advantage over PCR that it is a quantitative technique, because the results can be expressed as the percentage of a class of cells containing the diagnostic abnormality.<sup>15</sup>

The limitation of FISH—providing information only on the regions covered by the probe(s) used—is partially overcome by CGH.<sup>16,17</sup> In this procedure, tumor DNA ultimately recognized by a red fluorochrome and normal DNA recognized by a green fluorescent dye are mixed at equimolar concentrations and then allowed to compete for hybridizing to a normal metaphase spread. If a region of the genome is equally represented in the tumor and in the normal DNA, the chromosomal region appears painted in an orange-yellow signal. If a gene is missing in the tumor, it is painted green. In contrast, if a region of the genome is amplified many-fold in the tumor, this region appears in red. CGH allows assessment of the entire genome, albeit at a relatively rough scale, but it is a technically demanding and lengthy procedure. Although it constitutes a powerful research and discovery tool, it is unlikely to receive widespread diagnostic application as a clinical test.

The simultaneous use of probes labeled with different fluorochromes and cameras capable of sensing and computing different spectra have made it possible to paint each chromosome (or chromosomal regions) with a different color attributed to the individual spectra. This technique, known as *spectral karyotypic analysis*,<sup>18</sup> adds considerable ease, specificity, and potential automation to the detection and identification of translocations and other chromosomal anomalies (see [Chapter 5](#)).

The application of molecular techniques to diagnosis has been greatly facilitated by the introduction of the PCR.<sup>19,20 and 21</sup> PCR-based approaches make it possible to use very small samples of tissue, and therefore, well-defined microscopic lesions can be used as the source of nucleic acid to be analyzed. The products of PCR can be investigated by a variety of methods. PCR can be designed to demonstrate (1) genetic alterations, including microsatellite instability (i.e., using single-strand conformation polymorphism or PCR-SSCP, which reveals band shifts in tumor lanes when compared to normal tissue lanes); (2) point mutations (i.e., using PCR products in sequencing assays); and (3) loss of genetic material (i.e., using multiplex PCR). PCR combined with Southern blot analysis is capable of detecting a unique target sequence within the total DNA of approximately 100,000 human genes in a single reaction. These numbers are only limited by the amount of DNA (approximately 2 mg, equivalent to  $2 \times 10^6$  cells) that can be tested in a single amplification reaction; selection procedures to restrict the target DNA to the genomic fragment of interest allows a significant expansion of the sample to be analyzed. The extreme sensitivity of PCR-based techniques constitutes their main drawback. Because a single template can give rise to a positive result, contamination of the reaction by exogenous amplifiable sequences can be a problem, even in laboratories that exercise the greatest care to guard against such occurrences. In most instances, the source of contamination is the inadvertent transfer of small amounts of product from one reaction to the ingredients of another reaction that uses the same primers. Measures taken to prevent artifactual results caused by contamination

include ultraclean and separate rooms for pre-PCR, PCR, and post-PCR manipulation of the samples; use of pipetting devices containing aerosol barriers; and UV irradiation of the reaction mixture before addition of the polymerase and template DNA. Additionally, control reactions from which template DNA is omitted should always be performed and analyzed in parallel with any PCR test to ensure that the reagents, other than the template, are not contaminated. Products can also be precisely sized on gels, analyzed by Southern blot hybridization, or subjected to nucleotide sequence analysis to distinguish bona fide products expected for a specific amplification reaction from artifactual products that may have been amplified during the reactions. The advantages of PCR, however, far outweigh the disadvantages. The amplification capabilities of the procedure mean that very small numbers of total cells are sufficient for analysis. The small size of the amplification target (as small as 40 to 50 base pairs) makes PCR possible on partially degraded DNA or on the highly fragmented DNA normally obtained when extracting from formalin-fixed paraffin-embedded tissue. PCR is a fast procedure, because standard amplifications that comprise 25 to 30 cycles can be completed in a few hours, facilitating timely turnaround of tests. Furthermore, if maximum sensitivity is not a concern, analysis can be carried out with nonradioactive probes. For all these reasons, PCR has been used in most of the molecular diagnostic tests relevant to cancer. It is the sensitivity of PCR that makes it the method of choice for the staging of cancer, as well as for the monitoring of residual disease after therapy.

A productive application of PCR has been to amplify specific genomic sequences obtained from paraffin sections by microdissection ( Fig. 26-3). By using random primers, the entire DNA extracted from a small number of cells can be amplified in an unbiased fashion. Efficient protocols for “whole genomic amplification” make it possible to perform CGH experiments, starting from a microscopic lesion.<sup>22</sup>

**FIGURE 26-3.** Cytologic samples that are suspicious but not diagnostic of cancer can be resolved when known genetic alterations are found in a significant proportion of the cell population examined. In the proper clinical context, a mutation in a tumor gene present at the 10% level or higher is a reliable indicator of tumor. DNA obtained from a portion of the cytology sample has been extracted, and exons 5 to 7 of the p53 gene amplified and examined by single-strand confirmation polymorphism (SSCP). A mutation in exon 7 (ATG @AGG transversion) is confirmed by repeating the procedure and sequencing the anomalous migrating band.

### RNA-Based Methods

ISH is performed to detect RNA transcripts within cells deposited on microscope slides or on tissue sections.<sup>22,23 and 24</sup> The probe can be radiolabeled or linked to a molecular tag, such as biotin. The main diagnostic application is for the tissue typing of neoplasms, revealing the specific transcript for a determined cell product, or demonstrating viral nucleic acids. In the tumors known to be associated with viruses, viral nucleic acids, as well as their encoded proteins, can be used as tumor markers. The most significant viruses in this context are human T-cell leukemia virus type I (associated with adult T-cell leukemia/lymphoma), Epstein-Barr virus (associated with Burkitt's lymphoma and with non-Hodgkin's lymphoma in immunosuppressed patients and those with Hodgkin's disease), and papillomavirus strains associated mainly with cervical cancer. Viral proteins synthesized in the tumor cell contribute to the transformation process, and infection with the virus precedes the development of the tumor. In some instances, such as the case of Epstein-Barr virus infection in nasopharyngeal cancer, the viral integration site serves as a clonal marker for the tumor cells.

A more quantitative estimation of a specific message is obtained by Northern blotting.<sup>25,26</sup> In an analogous way to the Southern procedure, Northern blots identify specific RNA sequences by hybridization against a panel of RNA molecules spread on a gel. The synthesis of cDNA from messenger RNA (mRNA) using reverse transcriptase makes it possible to analyze the messenger molecules after PCR amplification, a procedure known as *reverse transcriptase-PCR* (RT-PCR).<sup>27,28</sup> This technique makes possible the detection of few transcripts coding for a specific message against a large background of mRNAs. In this fashion, a few circulating tumor cells can be detected in peripheral blood. The mRNA coding a cell-specific protein serves as a target that can be used to detect a specific cell type in a background of 10 million cells. This strategy has been used to detect circulating melanoma cells by demonstrating tyrosinase transcripts in peripheral blood, circulating prostatic cells (detecting prostate-specific antigen mRNA), thyroid cells (identifying thyroglobulin mRNA), and breast cancer (finding mRNA for keratin 19).<sup>29,30 and 31</sup> The advent of real-time PCR instrumentation has brought quantitative PCR to the laboratory and obviates one of the shortcomings of this kind of amplification technology.<sup>32</sup>

### Analysis of Proteins

One of the most favored techniques for unraveling the phenotype, based on detection of specific protein sequences and preserving the microanatomic detail, is IHC. The ever-increasing number of commercially available antisera and monoclonal antibodies is expanding the resolution capabilities of this assay by demonstrating the presence of antigenic determinants in cells and tissue components ( Table 26-1). Everything from surface receptors to intercellular matrix components to hormones can now be determined with relative ease and used to pinpoint the cell type, the degree of immunophenotypic differentiation, and even the functional state of the cell. IHC has greatly reduced the number of undifferentiated or unclassified tumors and has been of major assistance in defining metastatic tumors of unknown primary site. The category of unclassified sarcomas has been reduced from approximately 15% of cases to less than 5%. A relatively simple battery of antibodies recognizing intermediate filaments and surface antigens is very effective in sorting out undifferentiated carcinomas from anaplastic lymphomas, melanomas, and sarcomas, thus reducing the number of undifferentiated malignant tumors. Perhaps the best-established use of IHC has been in the diagnosis and classification of lymphomas. The demonstration of surface lymphoid determinants continues to be important in the everyday practice of diagnostic hematopathology. For example, the demonstration of the CD5 surface determinant is helpful in distinguishing mantle cell tumors (positive) from nodular lymphoma (negative).<sup>33</sup> In solid tumors, such as breast carcinomas, IHC is becoming a required complement of predictive clinical value, determining estrogen and progesterone receptor status, and, more recently, with the advent of antibody-based anti-Her-2/Neu therapy, also assessing the expression pattern of this tyrosine-kinase receptor.<sup>34,35</sup>

**TABLE 26-1.** Selected Antigens Analyzed by Immunohistochemistry in the Diagnosis and Characterization of Tumors

IHC is a powerful tool to dissect the different cell components present in tumoral tissues. It can show two different phenotypes of tumor cell differentiation most dramatically when two antigens specific for each cell type are shown simultaneously on the same slide, and thus, it has contributed to the elucidation of the composition of tumors showing diverse lines of differentiation. It can also separate reactive cells infiltrating the tumor when distinction of tumor cells from reactive cells

is unreliable using routine histologic stains. Such an instance is seen in the so-called T-cell-rich B-cell lymphomas, which consist of neoplastic lymphocytes of B lineage accompanied by a heavy infiltrate of nonneoplastic T cells. The latter sometimes constitute the majority of the cellular elements visible on a slide. At least some of the cases classified as malignant histiocytosis on the basis of finding neoplastic cells admixed with "atypical" histiocytes demonstrating erythrophagocytosis have been shown to be T-cell lymphomas infiltrated by activated histiocytes.<sup>36</sup>

IHC can sometimes contribute to the distinction between benign and malignant tumors. The demonstration of the ectopic chorionic gonadotropin-b subunit in islet cell tumors of the pancreas strongly suggests malignancy.<sup>37</sup> Many tumor markers can be localized in tumoral tissues, contributing to both tumor classification and identification of tumor cells in distant sites. Demonstration of cells containing neuron-specific enolase antigenic determinants in their cytoplasm has increased the sensitivity of detecting bone marrow involvement in neuroblastoma, thus improving the precision of the staging of children with this tumor. Pathologic staging has become more precise when the involvement of lymph nodes is established using IHC to detect breast tumor cells in axial lymph nodes. IHC is a very useful diagnostic adjunct to resolve controversial cases in cell type and to unequivocally identify the presence of small numbers of tumor cells. To maximize the efficiency and usefulness of IHC in clinical practice, it is best to use batteries of antisera chosen to solve specific problems in a critical and systematic fashion. Together with the availability of automated staining devices, this algorithmic approach helps manage the laboratory and facilitates periodic evaluation of test performance and efficiency of operations.

With the explosion of molecular medicine, IHC used mostly to investigate disease in a correlative mode is progressively being applied to attack mechanistic questions. Monoclonal antibodies are capable of recognizing subtle structural changes that are directly related to the function of the molecule and are thus excellent tools for molecular analysis. An example of dissection of molecular function using antibodies is provided by monoclonal antibodies directed to the phosphorylated peptides of growth factor receptors. The erbB-2 receptor is phosphorylated on activation. Antibodies that discriminate between the phosphorylated and nonphosphorylated protein provide an accurate assessment of the number of activated molecules present in a cell. Preliminary data suggest that this measurement will provide a better predictor of prognosis than the estimation of total erbB-2 in the tumor cells of patients with breast cancer.<sup>38</sup>

Antibodies directed against the proteins involved in the regulation of the cell cycle are playing an increasing role in the pathologic evaluation of tumors. Antibodies to cyclins D1 and E have been reported to be of interest in the evaluation of breast carcinoma and squamous cell carcinoma of the head and neck.<sup>39,40</sup> IHC also has been used to assess the status of tumor suppressor genes, such as p53 and RB (retinoblastoma). Numerous studies suggest the relevance of determining the patterns of expression of these genes to determine the prognosis in a variety of tumors. We are near to being able to determine the status (overexpression or absence) of many of the key proteins controlling the progression through the cell cycle, and thus we are poised to extensively characterize tumors and guide therapy accordingly.

The expression patterns of gene products involved in accessing apoptotic pathways can also be investigated by IHC. Such an evaluation is likely to be relevant, because drugs and radiation therapy cause apoptotic cell death. Hence, the inability of a cell to access the pathway after DNA damage can cause resistance to certain therapies. Data are beginning to accumulate and indicate that the status of p53 as assessed by IHC in several tumor types, such as breast and bladder carcinomas, correlates with the ability to respond to therapy. Bcl-2, a protooncogene that extends cell survival, is overexpressed in many tumor types, and its detection has been associated with lack of response to therapy and poor outcome.<sup>41</sup>

All the advantages of IHC can be nullified if it is used with lack of technical rigor and in an uncritical fashion. Strict adherence to laboratory practices must also be observed. Results must always be interpreted in the appropriate context, and the use of antibody panels is recommended when first characterizing a diagnostically problematic lesion. Technical advances in antigen retrieval augment the power of tissue immunohistology but also increase the potential for false-positive results. The possibility of antigenic loss that is known to occur in precut preparations is sometimes ignored as a cause of false-negative results.

Another method that allows quantitation and verification of the antigen being identified is Western blotting, also known as *immunoblotting*.<sup>42</sup> This technique combines the resolution of gel electrophoresis with the specificity of immunochemical detection. In this procedure, proteins are first extracted from cells or tissue samples and resolved in an electrophoresis gel. The products are then transferred to a membrane support, usually nitrocellulose membranes or nylon sheets. After blocking nonspecific binding sites, membranes are incubated with appropriately diluted primary antibodies, which are detected by the subsequent application of labeled secondary antibodies. The major limitation of this method, when using clinical samples, is that it requires a significant amount of tissue to obtain a suitable quantity of extracted proteins.

### **Assessment of Apoptotic Index**

Apoptotic cell death can be demonstrated at the microanatomic levels by the application of the terminal transferase to elongate and label the double-stranded DNA cut at the internucleosomal regions. The incorporated labeled nucleotides are detected with an immunoenzymatic approach. This type of assay, also known as *in situ DNA nick end labeling*,<sup>43,44</sup> can quantitate the fraction of cells in apoptosis and may serve to predict behavior or response to therapy.

### **HIGH-THROUGHPUT TECHNIQUES**

The manual sequencing method most widely used is the Sanger dideoxy sequencing technique.<sup>45</sup> This procedure uses base-specific termination during *in vitro* synthesis of DNA and is also known as the *chain termination method*. The basis for terminating the elongation of the DNA chain is the use of a nucleoside triphosphate containing a reduced ribose sugar termed *dideoxynucleoside triphosphate* (ddNTP). When such ddNTPs are mixed with the four normal dNTPs at the appropriate concentrations, chain termination occurs. The four normal dNTPs are mixed with the respective ddNTPs in four different test tubes, and reactions are compared for the growing DNA chain. In these reactions, the normal dNTPs are labeled at the 3' position, usually with phosphorus 32, to incorporate the radioactive signal needed for detection. These products are separated using acrylamide gel electrophoresis. The gels are dried and then imaged using autoradiography, producing a ladder sequence. Besides the technological restraints, this procedure has several drawbacks, including the resolution of the bands and the "compressed" or clustered migrated bands in the top and bottom of the gel. New, automated high-throughput technologies have been developed to increase the sensitivity and speed the analysis of gene sequencing. Incorporating a fluorescent-labeled nucleotide in the newly synthesized DNA strand and coupling a fluorescence emission detector next to gel, fluorescence can be identified while the gel runs. Instead of a photographic image, electropherograms are automatically read and printed. The use of capillary machines and four-color automated fluorescent sequencing produce well-defined peaks in a highly sensitive and reliable fashion. Several genetic analyzers, or automated sequence detection systems, are commercially available that greatly enhance the analytical ability with respect to mutation detection. Moreover, the use of fluorescent-labeled dNTPs allows laboratories to move away from radioactive, gel-based systems. Using fluorescent-labeled microsatellite markers, some of these apparatus also have the capability of detecting genetic losses.<sup>46</sup>

The main technological revolution of more recent years has been the development and implementation of DNA and expression microchip technologies.<sup>47,48</sup> Oligonucleotide microchips are miniaturized devices that enable large genomic studies. These systems allow sequencing analysis of determined genes and expression analysis of mRNA transcripts, including genes or expressed sequence tags. Expression studies can monitor quantitatively and simultaneously the expression of thousands of genes and sequences. Each transcript is typically represented on a microarray by multiple probe pairs, which differentiate among closely related members of gene families. These thousands of oligonucleotide-selected probes hybridize with complementary genetic information provided by the mRNA extracted from the target tissue or cell sample to be analyzed. Expression arrays typically use 20 pairs of specific oligonucleotide probes to interrogate each transcript, minimizing the effects of nonspecific hybridization and background signal. Probe arrays identify mRNA expression changes of greater than twofold between experiments and are able to detect transcript levels, even if only a few copies per cell are present.<sup>49,50 and 51</sup> The software linked to such automated systems allows processing and analysis of data, thus enabling control of the whole procedure and providing high quality and reproducible results.<sup>52,53 and 54</sup> These programs often interface raw data with online databases, such as GenBank, converting data acquired to expression levels, base calls, or genotype. The inclusion of reference standard genes as intraassay and interassay controls normalizes data, allowing comparison of multiple different experiments on a quantitative level. The gene-chip arrays (Affimetrix) are constructed so as to allow quantitative and robust monitoring of the expression level of thousands of genes simultaneously. These arrays are made using a combination of semiconductor-based lithography and solid-phase chemical synthesis. Specific DNA probes are synthesized, and then each probe is affixed to a predefined position in the array. An alternative process that brings great flexibility to the construction of cDNA microarrays is the spotting of PCR-prepared arrayable DNA or the spotting of synthetic oligonucleotides on glass slides that are then used for hybridization with labeled RNAs. The synthesis of oligonucleotide probes bypasses the need for handling a large number of clones and PCR products. In addition, probes can be specifically designed to detect alternatively spliced species of mRNA.<sup>55,56</sup> The construction of oligonucleotide arrays lends itself as a target for "artificial CGH." Instead of using normal metaphase chromosomes as a target, an array of DNA, such as provided by yeast artificial chromosomes (YACs) or bacterial artificial chromosomes (BACs), can be used as the target for competition between normal and genomic DNA. The option of using thousands of synthetic oligonucleotides will no doubt be reduced to practice in the near future.

The acquisition and processing of hybridization intensity data obtained by probe arrays is being applied in multiple areas, including the study of differential expression patterns and genotyping or analysis of polymorphisms. The potential for generating a novel molecular nosology of tumors, selecting the most effective therapy for an individual patient, determining molecular staging and grading, and discovering new therapeutic strategies is great and, to many, self-evident. For the data to be analyzed, correlated, and exchanged, however, a unified informatics platform must exist for collecting, storing, retrieving, and interrogating the databases. The development of a specific branch of bioinformatics designed to handle a large volume of data, create appropriate clusters to define entities, and find ways to display the results is common to many of the comprehensive technologies, such as proteomics and even tissue arrays.

Two-dimensional gel electrophoresis of proteins has held the promise of comprehensive analysis of the protein constituents of a tissue or a population of living cells. The development of immobilized pH gradients lowered the barrier to the widespread application of two-dimensional gel analysis to tumors.<sup>57,58</sup> The potential value of proteomics for the accurate classification of tumors was well demonstrated in the mid-1980s by the use of polypeptide phenotyping of acute leukemia in children.<sup>59</sup> Advances in two-dimensional gel analysis and biophysical instrumentation suggest that comprehensive analysis of the proteins expressed in a tissue or population of cells will yield information capable of differentiating different tumor types. As in the case of mRNA profiling, it is hoped that this technique may help select therapies and identify novel targets for therapy. A promising advance is the use of MALDI-TOF (matrix-assisted laser desorption/ionization–time of flight) technology and variations thereof to construct “protein chips” that detect and identify proteins at the femtomole scale directly from their native environments.<sup>60,61</sup> By using modified surfaces to capture molecules on the basis of specific binding kinetics, this type of approach can probe the function of some molecules in an exquisite way, thus significantly contributing to the knowledge of functional genomics. Technological platforms for nucleic acid identification can be modified to greatly enhance the sensitivity of IHC, and molecular counting can be made possible on the basis of rolling circle amplification (RCA) technology.

As a consequence of genomics and proteomics, antibodies will be raised against a very large number of novel antigenic determinants. The task of characterizing the patterns of tissue reactivity and the prevalence of the potential marker in even the most common tumor types appears out of reach of most laboratories. Although still in its early stages of development, tissue microarrays may enable investigators to rapidly characterize novel antisera. Tissue microarrays ( Fig. 26-4) make it possible to analyze hundreds, even thousands, of tissue specimens from patients in different stages of disease and to assess the diagnostic, prognostic, and therapeutic importance of emerging cancer gene candidates.<sup>62</sup> *In situ* detection of DNA, RNA, and protein can be performed on consecutive sections of tissue microarrays. In this fashion, hundreds to thousands of samples can be analyzed simultaneously. Although the labor needed to construct a tissue microarray is considerable, and many issues in array design, image acquisition, and data storage are yet to be resolved, it is clear that all barriers will be lowered to facilitate the widespread use of this approach. One of the advantages of tissue arrays is that each human tissue sample is greatly expanded. A regular paraffin block can easily yield twenty 0.2-mm cores, and 300 sections can be obtained from a microarray master block. Thus, 6000 sections can be analyzed from each tumor block. Mutation detection in cytologic specimens and in tissues is now a possibility using a new reporter system, the RCA.<sup>63</sup> RCA is an isothermal amplification driven by a polymerase that replicates circularized oligonucleotide probes. The reaction can be set up to take place with either linear or geometric kinetics and is amenable to use in a variety of formats ranging from surface immobilized DNA to cytologic specimens ( Fig. 26-5).

**FIGURE 26-4.** Microdissection of preneoplastic lesions makes it possible to test whether demonstration of genetic lesions accumulated in the somatic cells enhances the microscopic interpretation of the lesion and allows a more accurate prediction of its potential for progression. Core needle biopsy of a mammographically detected lesion with the phenotypic features of “atypical ductal hyperplasia” shows an abnormal acquired genotype. Microdissection and analysis of stromal cells showing a normal genotype rules out the possibility of an inherited germline mutation. PCR, pathologically confirmed complete remission; SSCP, single-strand conformation polymorphism; WT, wild-type. (Courtesy of Dr. Deborah Dillon, Yale University School of Medicine, New Haven, CT.)

**FIGURE 26-5.** Schematic representation of the potential application of rolling circle amplification (RCA) for the demonstration of mutations by *in situ* hybridization. It is relatively simple to construct two independent reporter systems for two sequences differing by a single nucleotide. The fact that the RCA reaction is tethered to the target renders the system ideal for the topologic demonstration of mutations. C, circle; Mu, mutant; oligos, oligonucleotides; Wt, wild-type. (Courtesy of Dr. Paul Lizardi, Yale University School of Medicine, New Haven, CT.)

## APPLICATIONS OF MOLECULAR MARKERS: DIAGNOSTIC MOLECULAR PATHOLOGY

Molecular markers and the techniques to demonstrate them in cells and tissues can be exploited for a series of paradigmatic clinical purposes that are succinctly discussed in the following paragraphs. As knowledge of the basic pathogenesis of human tumors advances and technology develops, new applications will come to the fore and molecular diagnosis can be truly described as a rapidly evolving and expanding field.

### RISK ASSESSMENT

A significant number of inherited predispositions to develop tumors has been identified, and the genetic defect underlying the predisposition has been fully characterized for many of the inherited tumor syndromes (see Chapter 13). Assessing inherited risk of developing a tumor because of a germline mutation is the province of clinical geneticists and of cancer prevention programs. Many of the genetic defects causing inherited tumor syndromes are also the rate-limiting initiating events for the sporadic tumors of the same histotype. The adenomatous polyposis coli (APC) gene altered in familial polyposis is found mutated in more than 90% of sporadic adenomatous polyps of the colon. An analogous situation exists for the Rb gene responsible for initiating the mutation of both inherited and sporadic retinal neoplasms. Thus, finding these genes mutated in acquired preneoplastic conditions could possibly contribute to assessing the risk of a given tissue for developing a tumor. Evidence is emerging that lesions preceding adenocarcinoma of the lung harbor cells that show loss of alleles in chromosomes 3p and 9p and that these events are followed by mutations in the ras gene that occur at more advanced morphologic stages (carcinoma *in situ*).<sup>64</sup> Studies in Barrett’s esophagus suggest that the subset of patients showing an increased G<sub>2</sub> fraction or aneuploidy is at increased risk for progression to high-grade dysplasia and cancer and should therefore be under closer surveillance. It will be of interest to see if patients known to be at increased risk for certain tumors can be screened to detect the lesions at an early stage. Studies suggest that detection of microsatellite expansion in cells sloughed from transitional epithelium lining the urinary tract may fulfill this goal.<sup>65</sup> For patients

with severe, long-standing ulcerative colitis, microsatellite instability has been more prevalent than for patients with dysplasia.

## DIAGNOSIS

In the proper hands, cytology and histopathology are highly efficient diagnostic tests, but in a number of instances, these tests do not provide a decisive answer as to whether a lesion is a tumor or not. In many instances, determining the specific tumor type is facilitated by IHC; however, because of suboptimal material in some cases, the interpretation of the test results may be rendered difficult. Molecular markers can in many instances contribute to the reliable characterization and diagnosis of a sample.

Among the most useful markers are the different translocations that are specific for certain tumor types. Among the cancers on which molecular diagnostics has had the greatest impact is chronic myelogenous leukemia (CML). The marker of this disease has been the Philadelphia chromosome (Ph1) t(9;22) (q34;q11), demonstrable in 95% of cases of CML.<sup>66,67</sup> The translocation is demonstrable by conventional cytogenetics, FISH, Southern blot hybridization, and PCR. The Philadelphia translocation joins the 5' portion of the BCR gene located on chromosome 22 to the 3' portion of the ABL gene on chromosome 9. The chimeric gene is transcribed into a novel 8.5-kb mRNA, which in turn is translated into a 210-kD protein. The precise position of the breakpoints within the DNA varies considerably from case to case. This is due to the fact that the breaks occur within introns, the sequence of which is excised from the initial forms of the BCR-ABL transcript to produce a mature 8.5-kb mRNA. The variability in the positions of the breaks in DNA preclude the use of a single pair of primers to amplify DNA across the breakpoint. To circumvent this problem, investigators have devised the so-called reverse PCR. In the first step of the procedure, BCR-ABL mRNA is transcribed with an ABL primer into single-stranded cDNA using reverse transcriptase. Nucleotide sequences in the cDNA are then amplified with primers for the BCR and ABL exons. It is important to perform control amplifications using primers for an omnipresent mRNA to ensure that the quality of the RNA to be tested is adequate.

Up to 6% of children and 20% of adults with acute lymphoblastic leukemia (ALL) also have a Ph1 chromosome indistinguishable cytogenetically from the one found in CML. However, the precise position of the breakpoints in DNA differ between CML and ALL, and molecular techniques are the only way to reliably distinguish a lymphoid blast crisis of CML from *de novo* ALL. Other practical contributions of the demonstration of the Ph chromosome in ALL is that ALL patients with the translocation seem to have a poorer prognosis than those with Ph-negative ALL. Protocols for the demonstration of an increasing number of translocations linked to the pathogenesis of hematolymphoid neoplasms are available and constantly being improved.<sup>68</sup>

A group of tumors that very often presents a diagnostic challenge is the so-called small round cell tumors of childhood. By light microscopy, it is often very difficult to distinguish rhabdomyosarcoma from lymphoma and from primitive neuroectodermal tumors or Ewing's sarcoma. Translocations that are specific for a number of malignant tumors of the soft tissues (Table 26-2) are beginning to bring the resolutive power of molecular diagnostics to this area. Defining the underlying genetic defects in these tumors not only clarifies their pathogenesis, but also provides the tool for a precise and decisive classification.<sup>69,70</sup>

Disease	Molecular Genetic Marker
Chronic Myelogenous Leukemia (CML)	t(9;22)(q34;q11) Philadelphia chromosome
Acute Lymphoblastic Leukemia (ALL)	t(9;22)(q34;q11) Philadelphia chromosome
Acute Myelogenous Leukemia (AML)	t(8;21)(q22;q22) inv(16)(p11;p13) t(15;17)(q24;q31) t(11;22)(q23;q12)
Colorectal Cancer	Ki-RAS mutation
Bladder Cancer	Microsatellite DNA markers
Pancreatic Cancer	Ki-RAS mutation
Lymphoma	Clonal rearrangement of B- and T-cell receptors
Ewing's Sarcoma	t(11;22)(q24;q12)
Rhabdomyosarcoma	t(12;21)(p13;p11)
Neuroblastoma	N-MYC amplification

TABLE 26-2. Selected Molecular Genetic Markers in Cancer Diagnosis Listed by Disease

The demonstration that a mass lesion is composed of cells issued from a single progenitor cell is the single most reliable sign that the mass is a tumor. Hence, methods to demonstrate clonality are important adjuncts to the morphologic evaluations of bioptic tissues. The first tumor in which clonality as assessed by molecular methods had a significant diagnostic impact was lymphoma. Clonal rearrangement of B- and T-cell receptors indicates that a lymphoid mass is a tumor, although not necessarily malignant, and also provides information as to the lymphoid cell lineage of the neoplasm. PCR protocols to demonstrate monoclonal populations are available for both B- and T-cell receptors.<sup>71</sup> This technique makes it possible to determine clonality in small tissue samples, and the demonstration of monoclonality helps to establish the neoplastic nature of lymphoid proliferations of the stomach.

Clonality assays applied to cell smears promise to greatly enhance the diagnostic efficiency of cytology. The differential diagnosis between reactive mesothelial cells and mesothelioma can be resolved by showing clonality of the cells by FISH.

Demonstration of point mutations in the Ki-RAS gene can be an important diagnostic feature of malignant pancreatic tumors. Determining that mutated alleles of the Ki-ras gene are present in cells aspirated from a pancreatic mass strongly suggests a malignant tumor, and the efficiency of diagnosis of pancreatic masses by fine-needle aspiration is significantly increased by the simultaneous use of Ki-ras assessment and carcinoembryonic antigen levels.

Microsatellite DNA markers are useful clonal markers for the detection of cancer, and microsatellite changes matching those found in the primary tumor can be detected in the urine sediment of 95% of patients diagnosed with bladder cancer. It is of interest that, in the same series of patients, conventional cytology was positive in only 50% of the patients. Thus, microsatellite analysis might possibly be a viable method to screen for bladder cancer.<sup>72</sup>

## MOLECULAR GRADING AND STAGING

The purpose of grading is to predict the risk for local and distant spread of a tumor. Improving the capacity to predict whether a tumor has metastasized will have a significant impact on therapy and prognosis. The concept that neoplasia is accumulation of mutations makes it possible to think that, if the molecular pathways of tumor progression are defined, determining the alterations present in a tumor could provide accurate indication of the stage of progression and, thus, complement and refine the prognosis based on conventional grading and staging. It has been suggested that a certain class of mutations of the Ki-ras gene encountered in colorectal cancer could identify the more aggressive neoplasms.<sup>73</sup>

Evaluation of the expression of proteins linked to cell division, such as Ki-67 (MB) and PECAN, have been extensively used to evaluate the percentage of proliferating tumor cells in biopsies or resection specimens. In lymphomas, for example, when the percentage of Ki-67-positive cells is high, the prognosis is significantly worse. For many tumors, a high percentage of cycling cells correlates with bad prognosis. This finding is not surprising and is in keeping with the number of mitotic figures, one of the classic parameters used for tumor grading.

Genotypic characteristics can sometimes predict the behavior of a lesion, as illustrated in the case of fibromatosis. Trisomy of chromosome 8 is found in lesions that recur, whereas lesions with low potential for recurrence have a balanced genetic complement. The status of TP53 (wild-type vs. mutated) has been found to contribute prognostic information in bladder, colon, and breast carcinoma.<sup>74,75</sup> and <sup>76</sup> Abrogation of TP53 function can lead to a loss of G<sub>1</sub> arrest in response to DNA damage or can interfere with apoptosis. In the first instance, mitosis without repair could fix mutations contributing to the cumulation of genetic lesions in the same cell. Loss of apoptosis could contribute to an increase in cell number and lack of responsiveness to therapy. The concept that loss of competence for apoptosis could contribute to tumor formation has led to investigation of the pathogenetic role of genes involved in cell survival, such as BCL-2.<sup>77</sup> Overexpression of BCL-2 has been found to correlate with lymph node metastases in ductal carcinoma of the breast.

Neuroblastoma is perhaps the tumor that is most often graded by molecular means in many centers. The status of N-MYC amplification and the level of expression of TRK-A are among the most significant prognostic parameters for tumors of matched stage and morphology. Together with ploidy and loss of chromosome 1p, they

complete the molecular staging and grading of neuroblastoma. <sup>78,79</sup>

Gene expression array profiling studies are being reported, disclosing the potential contributions they may be able to make in the molecular classification of neoplastic diseases. They also offer significant novel information regarding differentiation states; global alterations affecting particular cellular programs, such as growth regulation; and host response mechanisms. If current classification schemes still lump together different diseases with distinct clinical phenotypes, differential gene expression will distinguish molecular heterogeneity and produce biologically more accurate, and probably clinically more useful, diagnostic and predictive information.

Few original studies have been reported as proof of principle for the approach using specific entities as “test cases.” For example, Golub et al. <sup>80</sup> attempted to produce a molecular classification of acute leukemias based on gene expression monitoring by DNA microarrays and containing 6817 human genes. After producing a teaching set of genes highly correlated with acute myeloblastic leukemia (AML)-ALL class distinction, these investigators then tested the validity of such a class of predictors. The final 50-gene set of predictors derived from cross-validation tests correctly assigned 36 of 38 samples as either AML or ALL, the remaining two cases resulting in “uncertain” phenotypes. <sup>80</sup> The authors concluded that class prediction provides an unbiased general approach to prognostic tests. They also cautioned that sample collection, appropriate histopathologic documentation, and integrity of data sets are critical requirements for reaching robust conclusions. In a more recent study, Alizadeh et al. <sup>81</sup> reported the distinct molecular nature of diffuse, large B-cell lymphomas (DLBCLs), an aggressive malignancy of mature B lymphocytes. This group of investigators had previously produced a specialized microarray, the so-called lymphochip, which holds selected genes preferentially expressed in lymphoid cells and their derived malignancies. Using a modification of this basic tool, they were able to molecularly subclassify DLBCLs into two groups: germinal-center B-like tumors and activated peripheral B-like cell neoplasms. Moreover, this molecular classification not only pointed out what was previously an ill-defined histogenesis, but it also incorporated novel data relating to proliferation and state of differentiation. Patients with germinal-center B-like DLBCL had a significant prolonged overall survival when compared to those with activated B-like DLBCL, revealing the clinical significance of molecular subtyping of neoplastic diseases. <sup>81</sup>

To reach acceptance and clinical applicability, individual tumor markers and “class prediction sets” of biologic determinants must undergo methodical analysis. However, stringent criteria for the development of such studies, which should bring basic laboratory findings to clinical investigations and finally to standard of care, have not been well delineated. Certain groups of clinical investigators have proposed using a strategy similar to the one used by drug discovery programs for evaluating and implementing new therapeutic agents. In this exercise, phases of development and clinical application are well defined (see [Chapter 17](#)). Briefly, phase I deals with toxicity, phase II determines dose escalation and definition of therapeutic index, phase III is designed to ascertain efficacy, and phase IV is the final validation before commercialization and routine use. A similar analogy could be implemented that would take into account the process of discovery through validation of any given biologic predictor. Phase I should deal with issues regarding biologic properties of the marker and the methodologies that could better identify the marker in the context of using clinical material. Phase II should include pilot studies aimed at determining the specificity and sensitivity of such an assay; the definition of the cutoff value, if needed; and the potential clinical significance of detecting the marker as an adjunct to the already available clinicopathologic information. Phase III studies should aim at validating the marker by using (if possible) set(s) of well-characterized, prospectively accrued cases in specific clinical protocols designed for such a purpose. Finally, phase IV studies should incorporate multiinstitutional efforts to delineate intra- and interlaboratory variability, define and implement a standardized assay (using the selected cutoff value, if required), and demonstrate the clinical usefulness of the marker. This does not signify a final proposal of the sequential steps that must be fulfilled by a potentially clinically significant tumor marker or set of markers. It is just meant to draw attention to the lack of specific criteria for such an exercise and the need to reach some generally approved system if it is thought that such applications deserve to be translated to the routine clinical practice.

## DETECTION OF MINIMAL DISEASE

Detection of minimal disease has benefited greatly from the availability of molecular markers and, perhaps with diagnosis, is one of the most fruitful areas of expansion in molecular diagnostics. It plays a role in three clinical circumstances: (1) evaluation of minimal residual disease, (2) early detection of recurrence, and (3) evaluation of local extension. These applications are based on the high specificity of the molecular markers and the very high sensitivity afforded by the PCR-based techniques.

Detection of circulating cells harboring the bcl-2 translocation is an important prognostic predictor of relapse in patients with t(14:18)-positive B-cell lymphoma treated with high-dose chemotherapy and autologous bone marrow or peripheral blood stem cell support. <sup>82</sup> A correlation exists between the relapse rate and both the degree of contamination of the autograft and the efficacy of purging, suggesting that contamination is in part responsible for treatment failures. Similar strategies are being explored for other malignancies. <sup>83,84</sup> and <sup>85</sup> Detection of cytokeratin 19 transcripts by RT-PCR in a sample of bone marrow, peripheral stem cells, or peripheral blood, indicates the presence of epithelial cells for patients with breast carcinoma. <sup>82</sup> Other tumor-specific transcripts, such as tyrosinase for melanoma, <sup>83</sup> prostate-specific antigen for prostate cancer, <sup>84</sup> and thyroglobulin for thyroid cancer, <sup>85</sup> also have been exploited for the detection of circulating cells. In general, these assays achieve the detection of one tumor cell in a background of  $10^{10}$  cells. Circulating soluble Ki-RAS DNA bearing the same mutated sequences as the primary tumor can be detected in plasma and other fluids of patients with pancreatic carcinoma or ovarian cancer. <sup>86</sup> The clinical significance of these findings is not yet established, but when quantitative assays become available, the level of circulating tumor-specific DNA can perhaps be used as a marker to follow therapy and for early detection of recurrence.

A different use of the ability to detect tumor cells with high sensitivity is the analysis of tissues for the presence of a specific mutation that identifies the primary tumor being treated. It is indeed possible to verify the local spread of a tumor by testing the surgical margins, not just by light microscopy but also using the sensitive PCR-based approach. Proof of the worthiness of this strategy is provided by studies in head and neck cancer that show that “molecular margins” are superior in predicting local recurrence when compared to the conventional approach of assessing resection margins by intraoperative frozen section. <sup>87</sup> Should sequencing of short cDNA fragments in minutes become feasible, intraoperative molecular assessment of margins for tumors genotyped at the time the first diagnostic biopsy is obtained may possibly become a real option.

## RECURRENCE VERSUS SECOND PRIMARY

With cure rates and survival rates of patients with malignant tumors increasing, it is more important in clinical practice to identify second primary tumors. When a second tumor has its presentation in the same organ system as the first, the question invariably arises about distinguishing between a recurrence and a second primary. Morphologic comparison and an extended immunophenotypic profile of the two lesions can sometimes resolve the question, but the presence of a clonal mutation or a broader constellation of genetic alterations is the most direct way to establish a link between the two lesions or to strongly suggest that the metachronous tumors represent independent events. An adenocarcinomatous lesion in the lung of a patient in long-term remission for a primary adenocarcinoma elsewhere is another situation that benefits from a molecular approach to distinguish between a second primary and a metastasis. Clearly, it is best not to rely on the alterations present on a single gene but to attempt to establish a broad genotypic characterization of the two lesions to maximize the effectiveness of the interpretation of the results. Microsatellite alterations at multiple loci can be useful. Relying on differences or similarities in gene sequence in genes that show a wide spectrum of mutations (e.g., TP53) clearly is more effective than using genes exhibiting a limited repertoire of mutations (e.g., Ki-RAS). Molecular analysis of multiple tumors of the transitional epithelium in the urinary bladder has demonstrated that the multiple lesions arise from a single progenitor cell that seeds the bladder mucosa, explaining the high risk for recurrence encountered in these patients. <sup>88,89</sup>

## CONSIDERATIONS FOR THE FUTURE

The practice of conventional histopathology based on light microscopy was changed and complemented in the second half of the twentieth century by three technological advances: ultrastructure, IHC, and molecular diagnostics. The first two represented incremental gains in diagnostic power and efficiency but did not force substantial changes in the practice of morphologic tissue analysis. However, molecular medicine is profoundly changing the approach to tissue analysis. Perhaps more important, molecular medicine is altering the pathway for advancement. The elucidation of the molecular pathogenesis of tumors has led directly to the discovery and application of molecular tumor markers. Diagnosis and prognosis have, in many cases, been enhanced by the use of the marker(s). Finally, the marker (e.g., Her-2/neu) may constitute a therapeutic target. With the advances in biotechnology and bioinformatics, the preceding sequence of events can be predicted to change. Rather than elucidating a molecular pathway, we will have a complete view of the molecular biology of a given tumor type. This comprehensive understanding will lead to the development of specific therapies and to the rational selection of therapeutic modalities for a specific patient. Molecular tests will allow an accurate assessment of the response and modification of therapy when required. The detailed molecular knowledge of the natural history of tumors will yield markers for inherited and acquired risks, and these, in turn, will make improved design and monitoring of prevention a reality.

#### INTRODUCTION

Computed tomography (CT) has long been a mainstay of diagnostic imaging in cancer patients. CT offers noninvasive and accurate results for most disease processes and is both widely available and relatively low in cost. The number of CT examinations performed in the United States continues to increase at a rate of approximately 10% per year.<sup>1</sup> CT has remained a vital and important imaging modality because it has continued to evolve, with spiral (helical) CT, multiphase imaging, and multidetector scanning being the notable recent innovations.<sup>2,3 and 4</sup> The current diagnostic capabilities and the accuracy of CT continue to improve. With spiral CT, data acquisition can be timed with the administration of contrast material during multiple phases of enhancement, optimizing cancer detection and diagnosis. In addition, new techniques centered on three-dimensional (3D) and virtual CT imaging are being refined to take advantage of some of the capabilities of spiral CT.<sup>5,6 and 7</sup> These techniques will prove valuable in planning surgical procedures and radiation therapy. CT is also ideally suited for the guidance of interventional procedures often necessary to confirm malignancy and allow subtyping of tumors.<sup>1</sup> This section reviews some of the key current applications of CT scanning and defines its role in patient treatment and management.

#### LIVER

Spiral CT currently is the study of choice for the evaluation of the liver and biliary tree. Spiral CT can both detect and characterize hepatic pathology by providing detailed information as to the presence, extent, and vascularity of a lesion. Accurate localization of tumor to specific hepatic segments can be performed when key vascular structures are defined. The enhancement pattern, as well as lesion attenuation values, allow specific classification of a lesion as benign (cyst or hemangioma) or malignant (primary vs. metastases) in most cases. Specific CT characteristics may also suggest whether a lesion is a primary or metastatic lesion, although there is significant overlap in many cases.<sup>8,9,10 and 11</sup> Identification of the characteristics that differentiate benign from malignant lesions is critical because many smaller liver lesions (1 cm or less), even in oncology patients, are benign ( [Fig. 27.1-1](#), [Fig. 27.1-2](#) ).<sup>12,13</sup>

**FIGURE 27.1-1.** Adenocarcinoma of the liver. Cystic tumor mass grows through the liver capsule. Ascites is also seen.

**FIGURE 27.1-2.** Cholangiocarcinoma of the liver. **A:** A 10-cm intrahepatic mass is partially calcified on non-contrast-enhanced scans. **B:** After infusion of contrast, the vascularity and necrotic nature of the tumor are best defined.

There has been much discussion over the last several years, with various conclusions, as to the optimum imaging protocol for the detection of hepatic tumors. Before the introduction of spiral CT, the optimal CT technique for imaging the liver was CT during arterial portography.<sup>14,15</sup> The limitations of that technique include the need for catheterization of the superior mesenteric artery as well as problems with flow-related defects in up to 25% of patients. Newer CT techniques have essentially the same detection rate (or better) but without the related limitations. Kuszyk et al.<sup>16</sup> found that with portal-phase contrast-enhanced spiral CT, 91% of lesions larger than 1 cm can be detected. Hollett et al.<sup>17</sup> found that by using a dual-phase CT technique, almost 10% more lesions were detected than with portal-phase images only. As CT technology is constantly evolving, the prospect of greater accuracy in the ability to detect lesions is fairly optimistic. The most recent work, utilizing multidetector spiral CT scanning, uses very narrow collimation (2.5 mm) for optimal lesion detection, with excellent results.<sup>4</sup>

In addition to the detection of tumor, CT coupled with 3D reconstruction of data represents the next step in CT imaging. The image data are presented in a form that combines the best of angiography and CT scanning.<sup>18</sup> These 3D images can be displayed in real time and can be supplemented by stereoscopic displays to optimize lesion definition and extent. The information generated can help with surgical planning. By combining a vascular map from the arterial phase with a venous map from the portal phase, the radiologist can generate key road maps and vascular anatomy in a noninvasive format. With technical advances such as this, curative resection of some primary and metastatic tumors is now possible. In addition, the number of relatively invasive preoperative studies often needed to document tumor resectability, including conventional angiography and CT portography, have been markedly reduced.<sup>1</sup>

CT is also valuable in monitoring patient treatment. Accurate tumor volumetrics can be accomplished and captured to measure and quantify therapeutic response accurately. Three-dimensional size measurements have been shown to be reproducible and clinically useful for following up response of liver tumors to treatment.<sup>19</sup> Enhancement pattern changes as well as changes in normal liver volumes also are often helpful in assessing treatment success. New techniques to measure liver enhancement after intravenous (IV) injection of contrast material can be used to quantify arterial blood flow to the liver and may be useful in determining which patients are at risk for subsequent development of liver metastases.<sup>20</sup>

## PANCREAS

The role of CT in the evaluation of the pancreas typically centers on the detection and staging of pancreatic adenocarcinoma. Although the 5-year survival rate for pancreatic cancer in general remains poor, in selected patients, survival can be increased. Patients with a mass of 2 cm or less limited to the pancreatic head or patients without major vessel encasement or spread to lymph nodes who are treated with a pancreaticoduodenectomy (Whipple procedure) have a 30% or greater 5-year survival.<sup>21</sup> The key roles for CT in this patient population are accurate staging and triage.

The use of spiral CT has increased the accuracy of CT in staging pancreatic cancer by allowing detection of smaller lesions and by its ability to improve definition of vascular encasement.<sup>22,23</sup> and <sup>24</sup> With modern spiral CT scanners, tumor detection approaches 96%.<sup>24</sup> The number of indeterminate cases (i.e., the inability to distinguish between glandular enlargement due to inflammation and carcinoma) based on spiral CT findings has also decreased substantially. Pancreatic adenocarcinoma is usually a hypodense lesion relative to the normally enhancing pancreatic gland.<sup>25</sup> In the past, a pancreatic mass was typically detected based on a gross contour change within the pancreatic gland. However, such an obvious contour change usually indicated a relatively large mass. With the optimal IV contrast delivery of spiral CT, smaller lesions can now be detected. The key roles for CT in this patient population are accurate staging and triage.

Optimal IV contrast enhancement also provides for better assessment of key arterial and venous structures, such as the portal vein, celiac axis, and superior mesenteric artery, to help to determine their patency and relation to tumor extension ( Fig. 27.1-3). The degree of major vascular involvement by pancreatic cancer is useful in predicting which patients will have surgically resectable tumors. Major vessels with less than one-fourth of their circumference involved by tumor are almost always resectable; tumors that surround more than three-fourths of the circumference are almost always unresectable.<sup>23</sup> Hommeyer et al.<sup>26</sup> analyzed the caliber of the peripancreatic veins and found that dilation of these vessels to more than 7 mm also suggests early vascular invasion and unresectability.<sup>26</sup> Conventional angiography is no longer necessary for preoperative planning in most cases, since the sensitivity of CT and that of angiography are nearly identical, and 3D imaging can produce angiography-like images ( Fig. 27.1-4). Metastatic disease to the liver and lymph nodes is easier to detect, particularly for lesions that are hypodense and measure at least 1 cm in diameter. The characteristic CT appearance of other pancreatic masses may allow a diagnosis on the basis of appearance alone. CT can also be used to monitor response to adjuvant therapy and to detect any potential sites of tumor recurrence.

**FIGURE 27.1-3.** Adenocarcinoma of the pancreas. Sequence of spiral computed tomography scans demonstrate a 2.5-cm low-density mass in the body of the pancreas, with a dilated distal pancreatic duct.

**FIGURE 27.1-4.** Pancreatic adenocarcinoma. Three-dimensional image reveals narrowing of the confluence of the portal vein and superior mesenteric vein (arrowheads) from an unresectable cancer.

## KIDNEY

One of the major roles of CT in the oncology patient is in detecting, classifying, and staging renal tumors ( Fig. 27.1-5, Fig.27.1-6, and Fig.27.1-7).<sup>27</sup> Common diagnostic problems in renal imaging are the detection and the characterization of a renal mass. Spiral CT has been shown to be accurate for the evaluation of renal masses and accurately can distinguish between a simple cyst and a solid tumor. In a small percentage of cases, there is an overlap, and an indeterminate diagnosis is made. In these cases, ultrasonography or magnetic resonance imaging (MRI) may be helpful, although usually these techniques are subject to the same limitations as CT.

**FIGURE 27.1-5.** Renal cell carcinoma. Computed tomography demonstrates a vascular tumor of the left kidney, with paraaortic nodes. Metastases to the mediastinal nodes are also seen.

**FIGURE 27.1-6.** Renal cell carcinoma. Sequence of computed tomography scans demonstrates tumor extension into the renal vein and the inferior vena cava. Tumor extends up to but does not involve the right atrium.

**FIGURE 27.1-7.** Non-Hodgkin's lymphoma involving the kidneys. Multiple solid bilateral renal masses are due to lymphoma. The kidneys are not enlarged.

One of the current controversies in imaging the kidney is the timing of data acquisition in relation to contrast injection. <sup>28,29</sup> and <sup>30</sup> Specific acquisitions can be obtained during the arterial phase, nephrogenic phase, or delayed phase of renal enhancement. Most authors now agree that scans during two, if not all three, of these phases are necessary for optimal CT imaging of renal masses. <sup>31</sup> Lesion detection approaches 100% with modern CT scanners. <sup>31</sup> Arterial-phase images (20 to 30 seconds after IV contrast administration) are crucial for evaluating renal artery and tumor vascularity. Nephrogenic phase imaging (90 to 120 seconds after IV contrast administration) is ideal for lesion detection in the central portions of the kidney. Suspected renal vein or inferior vena cava involvement and collecting system opacification require a more delayed scan (3 to 5 minutes after IV contrast administration).

In addition, spiral CT serves as an excellent modality for multiplanar reconstruction and 3D imaging of the kidneys. These techniques are important if such procedures as partial nephrectomy are being considered. <sup>32</sup> The 3D spiral CT study provides a valuable tool to define the location of the renal mass and its relationship to the renal vasculature and perinephric tissues ( [Fig. 27.1-8](#)). The 3D images assist the surgeon by providing preoperative information in a flexible display that aids in determining whether nephron-sparing surgery is possible. <sup>32</sup>

**FIGURE 27.1-8.** Renal cell carcinoma. Three-dimensional image demonstrates mass in the upper pole of the right kidney ( *curved arrow*). The renal vein ( *straight arrow*) is patent. Three-dimensional images such as this are valuable for preoperative planning.

CT is also useful for evaluation of tumors in the renal pelvis and collecting system, such as transitional cell carcinoma. <sup>33</sup> In these cases, delayed CT scans are necessary to define accurately the true extent of tumor infiltration. Metastases to the kidney from such processes as lymphoma or lung cancer are best detected on these delayed scan examinations, especially since these tumors may not distort the renal outline and are best seen only with differential contrast enhancement.

## ADRENAL GLAND

CT scanning can clearly identify the adrenal glands in nearly all patients. The normal adrenal has two limbs, which have a maximum thickness of 3 to 4 mm. Adrenal enlargement can be due to a wide range of pathologies, from adrenal adenoma and hyperplasia to primary and metastatic adrenal tumors. <sup>34,35</sup> and <sup>36</sup> The specific clinical criteria used to characterize an adrenal mass include patient history, age, medical history, and the presence of any biochemical or physiologic abnormalities. The specific CT criteria used include mass size, whether it is unilateral or bilateral, the density of the mass, the presence of calcification or fat within the lesion, and the presence of other signs suggestive of malignancy.

Even in the oncology patient, the most common adrenal mass is a benign adrenal adenoma. Adenomas range in size from 1 to 5 cm and are typically of low CT attenuation (–20 to 20 Hounsfield units) values. Several articles have reported successfully differentiating benign from malignant adrenal masses based on CT attenuation of the mass. <sup>37,38</sup> In these studies, all small adrenal masses with CT attenuation below 18 HU on noncontrast evaluation were benign. In practice, then, adrenal masses that are 4 cm or less and are of low CT attenuation can be followed up conservatively with follow-up CT scanning. In the remaining patients with a potentially significant indeterminate adrenal mass, chemical shift MR imaging can be used to characterize the lesion confidently. <sup>39</sup> Percutaneous biopsy may still be necessary in some patients.

Malignant adrenal lesions can be divided into primary and metastatic lesions ( [Fig. 27.1-9](#), [Fig. 27.1-10](#)). <sup>34,35</sup> and <sup>36</sup> It may be impossible to distinguish a primary adrenal carcinoma from a metastatic lesion based on its CT appearance alone. Other adrenal tumors that can be confused with a primary adrenal malignancy include pheochromocytoma (which is malignant in up to 10% of cases), neuroblastoma (usually in younger patients), and myelolipoma (usually containing fat and calcification).

**FIGURE 27.1-9.** Primary adrenal carcinoma. A 12-cm, left upper quadrant mass with foci of calcification can be seen. The left kidney (not shown) was displaced inferiorly.

**FIGURE 27.1-10.** Bilateral adrenal metastases from a non–small cell lung cancer. The masses are unusually cystic.

## SMALL BOWEL AND COLON

CT is typically not the first study to suggest the presence of a small bowel or colon neoplasm. Nevertheless, with the increased use of CT as the initial study for bowel obstruction or an acute abdomen, there has been an increased detection rate of primary gastrointestinal tract tumors.<sup>40,41</sup> In most cases, CT is used in tumor staging to define the extent of the primary mass and to define spread to adjacent structures. Although the CT appearances of small bowel tumors may overlap, several signs are indicative of the etiology of the mass. Small bowel carcinoid tumor, for example, will typically present with an associated calcified mesenteric mass with a desmoplastic reaction.<sup>42</sup> Small bowel adenocarcinoma is variable in appearance and may be an infiltrating lesion, a bulky mass, or an ulcerating lesion. Lymphoma of the small bowel also varies in appearance but is usually bulkier and more extensive than an adenocarcinoma ( [Fig. 27.1-11](#) ).

**FIGURE 27.1-11.** Small bowel lymphoma. Large ulcerating mass involves the proximal jejunum. The differential diagnosis would include a small bowel adenocarcinoma.

Adenocarcinoma of the colon is a diagnosis usually made by colonoscopy or barium enema, with CT typically reserved for staging spread of disease ( [Fig. 27.1-12](#) ). In some centers, double-contrast CT of the colon is performed, to stage better the extent of tumor locally and local spread. In other centers, the key role of CT is the detection of extracolonic disease, particularly to the liver or lung.<sup>43</sup>

**FIGURE 27.1-12.** Adenocarcinoma of the transverse colon. Large necrotic left upper quadrant mass invaded the stomach, producing a gastrocolic fistula.

Recent advances in rapid volumetric CT scanning, combined with 3D imaging and computer graphics, have extended CT imaging into the “virtual” realm. Perhaps no other area has generated as much clinical interest and promise as that of virtual colonoscopy.<sup>44,45</sup> With this technique, CT combined with 3D visualization provides a virtual endoscopic view of the mucosal surface of the colon ( [Fig. 27.1-13](#) ). This rapidly growing application has gained attention as a noninvasive test for screening of colon polyps and cancer. It has also proven effective in evaluating portions of the colon not accessible or readily seen at conventional colonoscopy.<sup>46</sup> Authors have reported 84% to 100% sensitivity for the detection of polyps larger than 10 mm and 70% to 95% sensitivity for polyps ranging from 6 to 9 mm.<sup>44</sup> Sensitivity remains poor for polyps measuring less than 5 mm but, with such technologic innovations as rapid-speed multidetector CT scanning and improved computer processing, there is great hope for improvement in the detection of tiny polyps.

**FIGURE 27.1-13.** Virtual colonoscopy. Data from spiral computed tomography can be manipulated with three-dimensional imaging to produce images that simulate the appearance of a barium enema (A) or colonoscopy (B). The virtual colon view demonstrates a small polyp (arrow).

## ESOPHAGUS AND STOMACH

The role of CT in evaluating the upper gastrointestinal tract is somewhat controversial. Published results on the accuracy of CT for staging esophageal and gastric cancer have been variable and depend in large part on the extent of disease and the specific parameter evaluated.<sup>47,48</sup> For example, in the evaluation and staging of esophageal cancer, CT has been shown to be fairly accurate in detecting invasion of the trachea and airway as well as in detecting nodes in the region of the gastrohepatic ligament. Recently, CT has been used increasingly for the follow-up and monitoring of patient status after therapy for esophageal cancer, whether with surgery, chemotherapy, or radiation therapy. Recent progress suggests that CT can be used not only to monitor response but for treatment planning.

Technologic advances have expanded the clinical role of CT in evaluation of the stomach ( Fig. 27.1-14, Fig. 27.1-15, and Fig. 27.1-16). The use of double-contrast spiral CT produces a more detailed evaluation of the stomach than conventional CT. Initial studies suggest that this technique permits earlier detection and more accurate staging of small gastric tumors.<sup>49</sup> The most commonly encountered stomach tumor is adenocarcinoma. Less common malignancies include lymphoma, leiomyosarcoma, and metastases.<sup>50,51</sup> The CT appearance of each of these lesions has findings that are often helpful for diagnosis. Despite these features, there may be some overlap between all these tumors and other malignancies, such as metastatic disease to the stomach, or benign processes, such as *Helicobacter pylori*, which can simulate a malignant process.<sup>52</sup>

**FIGURE 27.1-14.** Adenocarcinoma of the stomach. The patient presented with gastric outlet obstruction. Tumor encases the gastric antrum, with carcinomatosis seen.

**FIGURE 27.1-15.** Gastric lymphoma. Computed tomography demonstrates diffuse involvement of the gastric fundus extending into the gastroesophageal junction.

**FIGURE 27.1-16.** Gastric leiomyosarcoma. Large necrotic mass arises off the gastric fundus. A small focus of calcification is seen in the mass.

## LUNGS AND MEDIASTINUM

CT remains the study of choice for a wide range of oncology challenges in the thorax.<sup>53,54,55,56,57 and 58</sup> Spiral CT has further enhanced the potential of CT in thoracic studies because of the single breath-hold capability, which essentially eliminates the problem of patient motion and breathing misregistration responsible for suboptimal examination.<sup>59,60 and 61</sup> There are four major indications for CT scanning in the oncology patient with thoracic pathology: (1) staging a known tumor, such as lung cancer, lymphoma, or thymoma; (2) detecting possible lung metastases from an extrathoracic primary tumor, such as a renal cell carcinoma; (3) evaluating a known or suspected mediastinal mass (i.e., widened mediastinum on a routine chest radiograph); and (4) evaluating by high-resolution CT the lung parenchyma in suspected complications of therapy, including radiation injury, drug reactions, and such secondary infections as in the immunosuppressed bone marrow

transplantation patient.

For staging most chest tumors, IV contrast material is required (Fig. 27.1-17, Fig. 27.1-18, and Fig. 27.1-19). Contrast delineates the normal vascular structures and defines the presence and extent of tumor and lymphadenopathy. Spiral CT can accurately depict the hilar lymph nodes and their major anatomic relationships.<sup>62</sup> In lung cancer staging, we can determine the extent of disease, including vascular encasement or chest wall involvement. CT scans can also be used as a guide for fiber-optic bronchoscopy to optimize tissue sampling. CT combined with 3D visualization can provide a virtual endoscopic view of the trachea and can be useful for evaluating areas beyond high-grade tumor stenoses (Fig. 27.1-20).<sup>63</sup>

**FIGURE 27.1-17.** Superior vena cava syndrome due to small cell lung cancer. Spiral computed tomography demonstrates tumor encasement of the superior vena cava. The azygous vein is enlarged.

**FIGURE 27.1-18.** Hodgkin's lymphoma. Computed tomography demonstrates right hilar adenopathy. Vascular enhancement optimizes definition of the nodes.

**FIGURE 27.1-19.** Metastatic breast cancer. Computed tomography demonstrates lymphangitic spread of tumor into the right upper lung.

**FIGURE 27.1-20.** Virtual bronchoscopy. Three-dimensional image from spiral computed tomography data can produce images that can see the inside of the trachea and bronchi.

CT evaluation of primary mediastinal masses is useful in defining the extent of disease and can suggest a specific diagnosis in many cases. Specific CT findings, including location of the mass (anterior, middle, or posterior mediastinum), the presence of fat or calcification, enhancement characteristics, and mass size and other sites of disease are often helpful in diagnosis.<sup>64,65</sup> Clinical history (e.g., myasthenia gravis), patient age, and medical history are also critical for achieving the correct diagnosis. CT can stage most of these processes and is a useful guide for planning appropriate therapy, such as surgery, radiation therapy, or chemotherapy. CT also plays a major role in monitoring response to therapy.

Another major advantage of CT is the ability to display an entire cross section of anatomy. This is especially important when staging such disease processes as lymphoma. Studies have shown a change in therapy or treatment protocol in approximately 10% of patients based on information from chest CT, as compared with information from chest radiographs only.<sup>66,67,68</sup> and <sup>69</sup>

Spiral CT provides a more accurate detection rate for pulmonary nodules than conventional chest radiography. Small nodule detection is important clinically, as lesions 1 cm or smaller are malignant in a large percentage of patients, especially in patients with a history of previous malignancy.<sup>70</sup> Spiral CT also allows for accurate density readings of lesions to aid in detecting the presence of fat or calcification, which is helpful in determining the nature of any given nodule. Enhancement characteristics of pulmonary nodules can also be used to characterize and predict their malignant potential.<sup>71</sup> Recently, much attention has been focused on the use of "low-dose" spiral CT as a screening test for patients at high risk for the development of lung cancer. Spiral CT with dose reduction to 10% to 25% of standard CT has been shown to be very accurate in the detection of pulmonary nodules and can be used to exclude or confirm the presence of a nodule in a

patient with an equivocal chest radiograph.<sup>72</sup>

Finally, the use of what is commonly referred to as *high-resolution CT scanning* is particularly valuable in detecting and defining the presence of parenchymal lung injury, whether from radiation therapy (radiation pneumonitis) or from infections, such as invasive pulmonary aspergillosis after a bone marrow transplant. This CT technique uses very thin sections and a high spatial resolution algorithm. It is important to remember that the high-resolution CT scanning may be positive for disease even with a “normal” plain radiograph.

## MUSCULOSKELETAL SYSTEM

The role of CT in the musculoskeletal system changed significantly with the introduction of MRI. It became the dominant examination for staging musculoskeletal tumors, largely because of its superior soft tissue definition and evaluation of the bone marrow. CT, however, has continued to have specific advantages, especially when evaluation of the bony skeleton is required. CT is particularly useful when there is a conflict between radiographic studies (i.e., plain radiographs and bone scans) or between radiology studies and the clinical examination or patient complaints. CT is especially good at defining bone destruction in purely lytic lesions where lesion aggressiveness may produce less than optimal bone scans. Specific areas where CT is invaluable are the bony pelvis, scapula, and the shoulder girdle ( [Fig. 27.1-21](#)). Similarly, imaging the thoracic and lumbar spine can be successfully performed with CT. Three-dimensional volumetric reconstruction can be useful for preoperative planning and surgical simulation.

**FIGURE 27.1-21.** Giant cell tumor. A large lytic lesion involves both the right iliac wing and the sacrum. The study was conducted to emphasize bony detail.

## CENTRAL NERVOUS SYSTEM

CT became the dominant force in neurooncologic imaging in the early 1980s, before the introduction of clinical MRI. However, with the diffusion of MR technology, MRI is now the dominant force in imaging the central nervous system. CT, however, still has specific applications, particularly when a detailed analysis of the calvarium or spine is required. CT, with high-resolution bone detail algorithms, provides an optimal look at a complex anatomic region, such as the base of the skull, the temporal bone, or the maxillofacial region. Subtle destruction or invasion by adjacent tumor is easily defined on these studies. Similarly, involvement of the spine by primary or metastatic disease may be detected with CT. In these cases, CT may be used when there is a question as a result of bone scan findings or when clinical symptoms and other study results are contradictory.

## SUMMARY

CT scanning is a mainstay in oncology imaging because of its ability to survey multiple organs and organ systems in a single examination with both high sensitivity and specificity. The introduction of spiral CT that is coupled with rapid advancements in 3D imaging technology ensures that CT will continue to remain a key study in both the detection and staging of diseases. Future progress likely will center on organ-specific contrast agents as well as blood pool agents. Newer technologies, such as real-time 3D imaging and virtual reality displays, will surely expand the role of CT and move it from a diagnostic to a therapeutic modality.

#### BASIC PRINCIPLES

Magnetic resonance imaging (MRI) is based on the effect of large magnetic fields on the spinning motion of certain nuclei within biologic tissues. Due to the laws of electromagnetics, spinning nuclei with odd mass numbers have a net charge and align themselves in the presence of an external magnetic field. In the human body, the hydrogen nucleus (mass number of 1) is most often used in clinical MRI due to its abundance in water and lipid tissues. When a patient is placed in the bore of a magnet, the hydrogen nuclei partially align themselves with the direction of the external magnet, which generates the net magnetization vector (NMV) of the patient. In addition, these hydrogen molecules are spinning (a process called *precession*) at a specific frequency that varies with the strength of the external magnetic field. This frequency is called the *Larmor frequency*. Based on the principle of resonance, a radiofrequency pulse emitted by a transmitter at the Larmor frequency can displace the alignment of the hydrogen nuclei NMV through a flip angle that depends on the amplitude and duration of the radiofrequency pulse. Once the pulse is turned off, the hydrogen nuclei relax back into their previous alignment with the external magnetic field. It is during this process of relaxation that the spinning hydrogen nuclei produce a radiofrequency electromagnetic signal, which can be detected by a receiver coil placed on or around the patient. The information from this signal can be processed by a computer to generate an image via a mathematical algorithm known as a *Fourier transform*.

The magnetization of the NMV exists in the planes of three-dimensional space. When the NMV is aligned with the external magnetic field, the magnetization is said to be in the longitudinal plane. After a radiofrequency pulse, the NMV is usually flipped into the transverse plane. When the pulse is turned off, the relaxation of the NMV back into the longitudinal plane is called *T1 relaxation*. The decay of transverse plane magnetization is called *T2 relaxation*. Different tissues in the body relax at different rates. Fat has very short T1 and T2 relaxation times, whereas water has considerably longer T1 and T2 relaxation times. Neoplastic tissue also generally relaxes at rates different from the tissues surrounding it. The varying relaxation times of tissues generate different strengths of signal at specific points in measurement times. Hence, it is the difference in relaxation between tissues and the varying strength of the signals they generate that determine the contrast between tissues on MR images. Tissues that appear bright on MR images are said to have high signal intensity, whereas dark-appearing tissues demonstrate low signal intensity. In addition to relaxivity times, the strength of tissue signal also depends on the number of hydrogen nuclei present in the tissue (i.e., “proton density”). The ability of MRI to demonstrate superior contrast between different tissue types ([Table 27.2-1](#)) constitutes a major advantage over other cross-sectional imaging modalities, such as computed tomography (CT).

Tissue	T1 Weighted	T2 Weighted
Adrenal	Intermediate	Moderately bright
Cortex (stroma)	Dark	Dark
Brain		
Cerebrospinal fluid	Dark	Very bright
Grey matter	Intermediate to dark	Intermediate to bright
White matter	Bright	Intermediate to dark
Cortical bone	Very dark	Very dark
Muscle	Dark	Dark
Lung	Very dark	Very dark
Liver	Intermediate to bright	Intermediate to dark
Pancreas	Intermediate to bright	Intermediate to dark
Prostate		
Central	Intermediate	Dark
Peripheral	Intermediate	Bright
Spleen	Intermediate	Bright

Adapted from Schwartz LH, Castleman RA. Magnetic resonance imaging. In: DeVita VT, Hellman S, Rosenbergs, eds. *Cancer: principles and practice of oncology*, 5th ed. New York: Lippincott-Raven, 1997.

TABLE 27.2-1. Relative Signal Intensities of Tissues

It is possible to “weight” an image by varying the repetition time (TR) between radiofrequency pulses and varying the time to sample the signal, called the *echo time* (TE) ([Fig. 27.2-1](#)). One can choose the weighting of an image to emphasize the T1 relaxivity properties of tissues, the T2 relaxivity, or the proton density. Tissues with short T1 relaxivity times, such as fat, appear brighter on T1-weighted images. Tissues exhibiting long T2 relaxivity, such as water, appear brighter on T2-weighted images ([Table 27.2-2](#)). In general, T1 weighting is useful for demonstrating anatomic detail, whereas T2 weighting may be preferred when imaging pathology, such as neoplastic tissue.

FIGURE 27.2-1. The basis of T1 and T2 weighting. **A:** Because fat has a shorter T1 relaxivity than does water, a short repetition time (TR) can maximize the T1 signal difference between fat and water, prior to full recovery of longitudinal magnetization. Hence, a short TR [and a short echo time (TE), which minimizes T2 effects] results in T1 weighting of a magnetic resonance image. **B:** The T2 signal decay of fat is faster than that of water; hence, a long TE can maximize signal differences from T2 signal between fat and water. As a result, a long TE (in combination with a long TR, which minimizes T1 effects) results in T2 weighting of an image.

TR	TE	Image Type	Fat	Water
Short	Short	T1-weighted	Bright	Dark
Short	Long	Proton density	Intermediate	Intermediate
Long	Short	Proton density	Intermediate	Intermediate
Long	Long	T2-weighted	Intermediate-dark	Bright

TE, echo time; TR, repetition time.  
 Note: Short TR: 400–600 msec; long TR: >1500 msec; short TE: <50 msec; long TE: >90 msec.

**TABLE 27.2-2.** Characteristics of Image Weighting

The use of contrast agents can also improve the detection of tumors and other pathology by MRI. The most commonly used agent is gadolinium, a paramagnetic rare earth metal that slows the tumbling of adjacent hydrogen molecules. This results in a large reduction in the T1 and T2 relaxivities of the tissues that take up the contrast. Hence, tissues into which gadolinium diffuses appear bright on T1-weighted images. MRI of tumors exploits this property of gadolinium because tumors are often hypervascular and demonstrate increased contrast agent uptake relative to the surrounding normal tissues. Further, tumor vessels are disorganized and “leaky,” so that there is increased extracellular fluid in the tumor. Hence, many tumors “enhance” after contrast administration. The distinct enhancement pattern of some tumors on sequential images taken at multiple time points after contrast administration (known as *dynamic MRI*) can also separate tumor from surrounding tissues. The risks and side effects of gadolinium are minimal as compared with those of iodinated contrast agents used for CT.

An ever-increasing number of different radio frequency pulse sequences are available for use in MRI. The gold standard for most imaging is the spin-echo pulse sequence, in which an initial variable flip-angle pulse is rephased by a magnetic gradient to produce an echo signal. Gradient echo sequences reduce scan times and are particularly useful for demonstrating flow on MR angiograms. The most recent advances have been made in developing very fast pulse sequences that can acquire several image slices in a single breath hold. Faster imaging reduces artifacts from breathing and other movements, and new ultrafast sequences are continually expanding the applications and widening the range of anatomy that can be accurately imaged by MRI.

The basic MR imager consists of the gantry, operating console, and computer with software that coordinates the acquisition and processing of images. During imaging, the patient is placed inside the gantry, surrounded by the primary magnetic coils that generate the main external magnetic field and by the secondary magnetic coils that generate various magnetic field gradients. These magnetic gradients are what allow signal to be localized to precise locations within the patient. The use of gradients also allows MR images to be obtained in multiple planes, including coronal, axial, sagittal, and oblique. Most commercially available “high-field” MRI magnets use field strengths of 1.0 or 1.5 tesla. “Low-field” and “open” MRIs use magnetic strengths from 0.2 to 0.5 tesla. Different radiofrequency receiver coils are available, depending on the anatomy to be imaged, and commonly include shoulder, body, or head coils placed on the patient. Exposure to the magnetic fields of an MR imager is generally considered much safer than exposure to the ionizing radiation of some other imaging modalities. However, MRI is contraindicated in patients with pacemakers and may pose problems for patients with aneurysm clips made prior to 1980 and with several other ferromagnetic implants.

## BRAIN

MRI is the imaging technique of choice for evaluating brain tumors. MRI has significant advantages over CT, such as multiplanar capabilities, which allow better assessment of the origin of tumors and their involvement of adjacent structures. In addition, MRI offers both better imaging detail of posterior fossa tumors and superior tissue contrast. MRI can also show the secondary effects of some brain tumors, such as hydrocephalus, hemorrhage, and edema. MRI is also useful in identifying the best location for surgical biopsy. Two disadvantages of MRI are difficulties in detecting calcifications that occur in some tumors, such as oligodendrogliomas, and decreased ability to delineate tumor invasion into bone. In such cases, a CT scan, which can detect these phenomena, can be complementary to MRI.

The characteristic MRI appearance of the majority of brain tumors is a hyperintense signal on T2-weighted images. In addition, gadolinium contrast is used in every MRI workup of brain tumors. Most normal brain tissue does not take up contrast, owing to the integrity of the blood–brain barrier. However, with malignancy, there is breakdown of the blood–brain barrier and neovascularity and, hence, most tumors enhance. Some tumors would not be seen without contrast administration. Gadolinium contrast administration can also help to distinguish tumor margins from surrounding edema on T1-weighted images. The intensity of contrast enhancement correlates in a rough sense with the tumor grade, probably because generally higher-grade lesions have increased neovascularity. Therefore, higher-grade lesions may enhance more intensely than well-differentiated brain tumors. In addition, the amount of vasogenic edema and hemorrhage adjacent to tumor may roughly correlate with the degree of malignancy. Hence, a low-grade fibrillary astrocytoma may demonstrate little contrast enhancement and no edema or hemorrhage, whereas a high-grade glioblastoma may show intense heterogeneous contrast enhancement, with prominent edema and hemorrhage. However, this rule is not always reliable. An exception is low-grade pilocytic astrocytoma, which shows a paradoxical marked contrast enhancement ( [Fig. 27.2-2](#)). Hence, MRI can help to assess the aggressiveness of brain tumors, but tumor diagnosis and grading must depend on the histopathologic analysis of surgical material.

**FIGURE 27.2-2.** Pilocytic astrocytoma. A large enhancing mass is present, arising from the region of the hypothalamus. Gadolinium contrast has been administered, resulting in heterogeneous enhancement of the mass. The extent of the tumor is well depicted on magnetic resonance imaging, as is the adjacent mass effect on the brain, with mild dilatation of the lateral ventricles.

Other brain tumors may demonstrate some distinguishing characteristics on MRI. Meningiomas are isointense to normal brain on all pulse sequences but enhance intensely with contrast administration. Meningiomas can also demonstrate a focal thickened collar of enhancement adjacent to the tumor’s dural attachment, known as the *dural tail sign*.<sup>1</sup> Ependymomas and choroid plexus papillomas may be associated with hydrocephalus seen on MRI. Metastatic lesions often appear at the gray-white interface, enhance intensely, and can demonstrate edema. MRI is the most sensitive modality for imaging brain metastasis,<sup>2</sup> and single lesions on CT can sometimes be revealed as multiple intracranial lesions when imaged with contrast-enhanced MRI.

MRI is also useful in assessing patients after surgery, irradiation, or chemotherapy. However, changes secondary to both surgery and irradiation can cause findings that may mimic residual or recurrent tumor.<sup>3</sup> One solution is to reimagine the postoperative patient within 4 days after surgery to establish a baseline prior to the development of postoperative processes simulating tumor.<sup>4</sup> In addition, positron emission tomography scanning may be able to differentiate recurrent tumor from the changes of radiation injury.<sup>5</sup>

## SPINE

MRI is the primary imaging technique used to evaluate neoplastic disease of the spine. MRI is preferred over CT and plain-film myelography and does not require the infusion of intrathecal contrast. Intramedullary tumors appear with decreased signal intensity relative to cord on T1-weighted images. Cord expansion by tumor can also be seen. Contrast enhancement aids in the detection and characterization of tumors and is also helpful in detecting “drop metastases” that have spread from intracranial and extracranial tumors to the spine via the subarachnoid space. Common extramedullary-intradural tumors (e.g., schwannomas and meningiomas) and extradural tumors (e.g., osseous hemangioma, myeloma) can also be detected on images. MRI accurately assesses for the presence of spinal cord compression by neoplasm (Fig. 27.2-3), with a reported sensitivity of 92% and specificity of 90%.<sup>6</sup>

**FIGURE 27.2-3.** Breast cancer metastatic to spine. The T2-weighted sagittal view of the spine shows areas of increased signal intensity diffusely throughout the spine, owing to metastatic disease (e.g., *small arrows*). In the lower thoracic spine, a pathologic compression fracture has occurred (*large arrow*), resulting in mild compression of the spinal cord at this level.

## HEAD AND NECK

MRI is now a primary imaging modality for evaluating many tumors of the head and neck, including tumors of the sinuses, oropharynx, nasopharynx, salivary glands, and larynx. The abilities of MRI to image in multiple planes and to detect subtle differences in soft tissue boundaries render MRI superior to CT in staging and localizing many tumors for guidance in therapeutic decision making. The main advantage of MRI of the sinuses is that malignant tissue can be distinguished from adjacent inflammatory disease and secretions in the sinuses.<sup>7</sup> This is because on T2-weighted images, most sinus tumors have little intercellular and intracellular free water and appear hypointense, whereas inflammatory tissues are high in free water and appear hyperintense. Squamous cell carcinomas of the sinuses can erode into bone, a critical finding that affects treatment choices. MRI can demonstrate bony erosion by the absence of signal void normally present within cortical bone. However, in evaluating certain critical areas, such as the orbit, pterygopalatine fossa, and central skull base, a CT should be ordered to improve detection of small focal bony erosions.<sup>8</sup> In the oropharynx, MRI can image without artifacts from dental amalgam and without beam-hardening artifacts from the mandible, both of which limit CT examination of this area. In the nasopharynx, MRI is superior to CT at identifying tumor infiltration beyond the pharyngobasilar fascia, detecting enlarged retropharyngeal lymph nodes, and demonstrating possible intracranial involvement.<sup>9</sup> MRI has replaced CT for imaging major salivary glands.<sup>10</sup> MRI is often used to determine the location of salivary gland tumors relative to the facial nerve so as to optimize treatment approaches that will preserve facial nerve function. The larynx and hypopharynx are regions that are readily accessed by clinical examination, which makes possible the diagnosis of malignancy through endoscopy and biopsy. However, coronal MRI images can complement clinical examination by delineating the depth of extension and submucosal involvement of laryngeal and hypopharyngeal tumors.<sup>11</sup>

## BREAST

Contrast-enhanced MRI is the most sensitive imaging modality for detecting breast pathology and can improve the detection of breast cancer in selected patient populations. The majority of invasive carcinomas are hypervascular and demonstrate intense enhancement with contrast administration. When morphologic criteria are combined with characteristic tumor enhancement patterns, MRI in many studies demonstrates greater than 90% sensitivity for detecting invasive breast carcinomas.<sup>12,13</sup> Despite the improved sensitivities of MRI over mammography for detecting breast cancer, MRI should not be used for cancer detection in unselected patient populations, owing to false-positive rates and the higher cost of the examination. Instead, MRI is primarily indicated for detecting malignancy in high-risk patients when mammography is compromised owing to radiographically dense breasts, silicone-augmented breasts, or scarring due to remote surgery or trauma. MRI can detect many tumors that mammography may miss in these patients. When combined MRI and conventional imaging are used in these patients, sensitivities greater than 98% can be routinely achieved for detecting invasive breast carcinomas.<sup>14</sup> MRI may also be useful in the search for a primary tumor when a patient presents with positive axillary nodes but no evidence of breast cancer on conventional imaging or physical examination (Fig. 27.2-4).<sup>15</sup>

**FIGURE 27.2-4.** Breast cancer. On a sagittal image of the breast, an intensely enhancing focus of invasive ductal carcinoma is present. This patient had enlarged lymph nodes in the axilla, which were subjected to biopsy and were found to be positive for breast cancer. However, mammogram results were negative. In this circumstance, magnetic resonance imaging is useful for detecting the primary lesion. Although magnetic resonance imaging should not be used for screening for breast cancer, it is useful in younger patients with dense breast tissue and, in certain cases, in determining the extent of the lesion before planned lumpectomy versus mastectomy.

There are also a number of emerging indications for the use of MRI in the preoperative staging and posttreatment monitoring of breast cancer, based on preliminary investigations. In considering breast conservation therapy, it is important to determine preoperatively whether a detected breast malignancy is unifocal, multifocal, or multicentric, as multicentric disease is a contraindication for breast conservation therapy. MRI appears to be markedly more sensitive than mammography in detecting multifocality or multicentricity within breast carcinomas.<sup>16,17 and 18</sup> The preoperative staging of breast cancer by MRI in one study was shown to alter the subsequent treatment in 18% of cases.<sup>18</sup> MRI also has shown promise in assessing the results of induction chemotherapy in reducing tumor burden prior to breast conservation surgery.<sup>19</sup> A recent review has suggested using MRI prior to lumpectomy to help to decrease the number of reexcisions due to positive pathologic margins.<sup>20</sup> In addition, the use of high-resolution RODEO (rotating delivery of off resonance) MRI has recently been demonstrated to improve the evaluation of ductal carcinoma *in situ*.<sup>21</sup> After conservative breast surgery, MRI has been shown to be superior to mammography in diagnosing recurrent malignant foci. In one study, 4 of 11 local recurrences were detected only by MRI.<sup>22</sup> However, MRI should be performed not less than 6 months after surgery and 12 months after irradiation to reduce false-positive rates.<sup>23</sup>

## LIVER

With the development of fast breath-hold scanning techniques that reduce motion artifact, the role of MRI in detecting and characterizing focal hepatic lesions has advanced greatly. MRI may be superior to CT and sonography in detecting hepatocellular carcinoma (HCC), as T2-weighted images may demonstrate characteristic morphologic features of HCC, such as mosaic or nodules-in-nodule patterns of signal intensity.<sup>24</sup> In addition, HCC demonstrates a pattern of dynamic signal enhancement distinct from the surrounding liver after bolus injection of contrast agents, owing to a prominent arterial blood supply for HCC. MRI can also detect early HCC arising within regenerating nodules associated with cirrhosis, even when the  $\alpha$ -fetoprotein level is normal and biopsy is negative for tumor.<sup>25</sup>

Metastatic lesions can appear mildly hypointense on T1-weighted images and hyperintense on T2-weighted images ( Fig. 27.2-5) and can contain areas of central necrosis of different intensity from the surrounding tumor. New contrast agents containing superparamagnetic iron oxide particles have recently been approved for clinical use and have improved the accuracy of hepatic metastasis detection.<sup>26</sup> These particles are taken up selectively by Kupffer cells within the liver, causing dropout in the signal of normal liver. Metastatic lesions, which do not contain Kupffer cells and do not take up the particles, appear as high-intensity signal against the low signal of the surrounding liver.

**FIGURE 27.2-5.** Metastatic colon cancer to the liver. In the right lobe of the liver, there is a rounded lesion ( arrow) with an internal area of high signal intensity characteristic of metastatic disease in the liver for presurgical evaluation as well as to evaluate indeterminate lesions on computed tomography scan. In addition, patients with parenchymal liver disease, such as cirrhosis, benefit by magnetic resonance imaging scans of the liver, owing to increased detection rate of hepatocellular cancer, compared to other noninvasive imaging modalities.

Cavernous hemangiomas are the most common benign tumors of the liver. They are often incidentally discovered on various abdominal imaging studies and must be distinguished from malignant lesions. MRI can make this distinction with greater than 90% sensitivity and specificity, owing to the inherently higher T2 values of hemangiomas (Fig. 27.2-6) and to the characteristic appearance of hemangiomas on dynamic gadolinium-enhanced images.<sup>27</sup>

**FIGURE 27.2-6.** Hemangioma of the liver. In the left lobe of the liver, there is an intensely bright lobulated lesion on this T2-weighted image ( arrow). Hemangiomas are extremely common, present in approximately 5% of patients. Frequently, these present diagnostic dilemmas on computed tomography scans of the liver. On magnetic resonance imaging, the appearance is characteristic and diagnostic, so biopsy of these lesions can be avoided.

## ADRENAL GLANDS

With the use of chemical shift imaging, MRI has become the most effective noninvasive method for distinguishing between commonly found benign adrenal adenomas and malignant masses. MRI can accurately make this distinction, owing to the fact that, unlike malignant adrenal tumors, most adrenal adenomas contain a large amount of cytoplasmic lipid. On application of chemical shift imaging techniques to MRI of the adrenals, tissues that contain both lipid and water demonstrate low signal intensity relative to other tissues containing mostly water. This is because fat and water protons have different precessional frequencies, owing to the size differences in the electron clouds surrounding them. When the appropriate TE is chosen, fat and water are maximally out of phase, and their radiofrequency waves cancel each other, resulting in signal loss. Most adenomas, which contain both fat and water, demonstrate signal loss on chemical shift imaging ( Fig. 27.2-7), whereas both primary adrenal malignancies and metastatic lesions, which do not contain fat, have signal intensities similar to other organs, such as liver and spleen. Exploiting this difference, chemical shift MRI has been reported to have a sensitivity for identifying benign adrenal lesions of 80% and a specificity of 100%.<sup>28</sup>

**FIGURE 27.2-7.** Adrenal adenoma. A 3-cm left adrenal mass is present (arrows). On the left-hand images, the mass shows similar signal intensity as compared to the spleen. On the right-hand image, chemical shift imaging was used. In areas that contained fat and water at the cellular level, there is decreased signal using this technique. On the right-hand image, the adrenal lesion is now seen to have lower signal intensity as compared to the spleen. This method is chemically specific for intracellular lipid and is diagnostic of adrenal adenoma. The specificity of this technique approaches 100%.

MRI is particularly useful for characterizing incidental adrenal masses found in patients with known malignancies. In these patients, the finding of a metastatic lesion to the adrenals may profoundly influence treatment of the primary tumor. To date, no lesion metastatic to the adrenals has demonstrated signal loss with chemical shift imaging comparable to that demonstrated by benign lesions. This allows accurate differentiation of metastases from adenomas. In the case of fat detected on chemical shift MRI, an adrenal biopsy is unnecessary. In addition to this application, MRI is the imaging modality of choice in localizing pheochromocytoma and

extraadrenal paraganglioma and for evaluating vascular invasion by adrenal carcinoma.

## KIDNEY

In staging renal cell carcinoma (RCC), CT and MRI are comparably accurate, their accuracy ranging from 67% to 96%.<sup>28</sup> Hence, given its lower cost, CT is generally the preferred modality for staging RCC. However, because of its high tissue contrast and multiplanar imaging capabilities, MRI offers improvement over CT for delineation of RCC extension into the renal veins, inferior vena cava, and right atrium ( Fig. 27.2-8).<sup>30</sup> MRI can also distinguish tumor thrombus from bland thrombus in the inferior vena cava<sup>31</sup> and offers improved detection of venous wall invasion. Hence, MRI is the preferred modality for RCC staging when iodine contrast is contraindicated, CT results are inconclusive, or it is necessary to determine the extent of venous invasion by tumor to guide surgical approaches for thrombectomy.

**FIGURE 27.2-8.** Renal cell cancer. A large mass obscuring the normal anatomy of the left kidney is present. In addition, there is adenopathy surrounding the aorta. However, there is no evidence of linear or tubular involvement of the left renal vein, and the inferior vena cava is not involved by the tumor. Magnetic resonance imaging is very sensitive for detecting renal vein involvement by renal cell cancer. Staging examinations can depict the extent of tumor in the inferior vena cava if present, to determine surgical management of the patient.

## UTERUS

T2-weighted images depict three distinct zones of signal intensity within the uterus. A central hyperintense stripe corresponds to the endometrium. This is surrounded by a hypointense zone representing the junctional zone, which is the inner myometrial layer. The remaining segment of the myometrium is of intermediate signal intensity. Endometrial carcinoma can be identified as tissue with signal intensity intermediate between normal endometrium and myometrium. By use of MRI, tumor can be seen confined to the endometrium ( Fig. 27.2-9), extending into the junctional zone, or invading into the deep myometrium.

**FIGURE 27.2-9.** Endometrial cancer. Within the uterus, the central signal due to high signal glandular tissue is markedly thickened ( *small arrow*). The darker ring around the inner portion of the uterus, termed the *junctional zone*, is intact, indicating that the cancer has not spread into the superficial layer of the myometrium. Additionally, there is a large mass in the left adnexa due to endometriosis involving the left ovary ( *large arrow*). MRI has been found to be useful for staging endometrial cancer. For ovarian tumors, lesions containing fat, such as dermoids, can be specifically identified and determined to be benign in certain cases.

The primary indication for MRI in patients with proven uterine carcinoma is preoperative staging. Importantly, the presence of greater than 50% myometrial invasion predicts poorer prognosis and requires more extensive surgery, including paraaortic lymphadenectomy. MRI can make this determination with an accuracy of 75% to 95%.<sup>32,33</sup> In addition to determining the depth of myometrial invasion, MRI accurately depicts the extension of endometrial carcinoma to endocervical glands and to cervical stroma. However, MRI staging accuracy is limited when the zonal architecture of the uterus is distorted by uterine anomalies or leiomyomas or when the junctional zone is absent, which can occur in postmenopausal women.<sup>34</sup> Because the MRI appearance of noninvasive endometrial carcinoma is nonspecific, MRI cannot be used as a screening technique.<sup>35</sup>

## CERVIX

On T2-weighted images, the normal cervix demonstrates an inner hyperintense signal zone representing the endocervical canal. Adjacent to this is a hypointense zone that corresponds to the cervical stroma. The outer zone, which is continuous with the myometrium, is isointense to myometrium. Parametrial tissues (composed of vessels, ligaments, and fat) surround the cervix and are hyperintense. Most cervical carcinomas have at least intermediate or high signal intensity on T2-weighted images, which provides good contrast between tumor and the hypointense cervical stroma.

MRI is considered the most reliable imaging modality for staging cervical cancer and planning its treatment. In a comparative study, the overall staging accuracy of MRI (83%) was higher than CT (63%) or clinical staging (70%).<sup>36</sup> Although preinvasive microscopic disease (stage IA) is not well identified on T2-weighted images, MRI can accurately depict the depth of stromal invasion (stage IB), the presence of parametrial extension (stage IIB), invasion of the vagina or pelvic wall (stages IIA and III), and bladder or rectal invasion (stage IV).<sup>37</sup> Of particular importance is determining whether tumor has extended to the parametrium, as patients who present with parametrial invasion are not usually surgical candidates. The presence of a completely intact ring of hypointense cervical stroma excludes parametrial involvement.<sup>38</sup> However, there are false-positive outcomes associated with disruption of the stromal ring. MRI is also useful for distinguishing recurrent tumor from fibrosis if imaged 12 months or more after treatment. The use of MRI has been shown to decrease the number of procedures and invasive studies ordered (e.g., excretory urography, barium enema, lymphography), with a resultant cost benefit.<sup>39</sup>

## OVARY

In the evaluation of ovarian masses, MRI is useful in delineating the internal architecture of ovarian tumors. MRI can depict complex tumor structures, such as irregular mural thickening, septations, and solid components, as well as associated findings, such as ascites, visceral lesions, adenopathy, and peritoneal implants.<sup>40</sup> Such findings can be associated with malignancy. However, these findings can be nonspecific; hence, the differentiation of benign from malignant ovarian masses can be difficult for all cross-sectional imaging modalities, including MRI. Accuracy rates for contrast-enhanced MRI in identifying malignancy have ranged from 78% to 95%.<sup>41,42</sup> MRI can accurately identify some benign ovarian masses, such as dermoid cysts, endometriomas, and fibromas. MRI identifies dermoid cysts with an accuracy of 99% by demonstrating the presence of intraluminal fat.<sup>43</sup> In addition, MRI can determine whether a mass is truly ovarian in origin and can accurately differentiate subserosal leiomyomas from ovarian masses. In the preoperative staging of ovarian malignancy, MRI and CT demonstrate generally equivalent accuracy; hence, CT is the primary imaging modality for preoperative staging, given its lower cost and ready availability. Regarding postoperative monitoring, MRI can often

detect macroscopic recurrent tumors larger than 2 cm (considered nonresectable), thus eliminating the need for second-look surgery in such patients.<sup>44</sup> However, MRI is less successful in detecting smaller implants or microscopic disease.

## PROSTATE

The most common indication for MRI of the prostate is for staging prostate cancer after a biopsy diagnosis has been made ( Fig. 27.2-10). The use of an endorectal surface coil alone or with anterior phased-array coils allows MRI identification of the tumor, the prostate capsule, the neurovascular bundles, and the seminal vesicles. Capsular penetration is demonstrated on MRI with the finding of gross tumor extension into the periprostatic fat or with capsular thickening, irregularity, or bulging.<sup>45</sup> Tumor invasion of the neurovascular bundles can manifest as asymmetric enlargement of the bundle. Signs of seminal vesicle invasion on T2-weighted images include a low-signal-intensity mass within the seminal vesicle or wall thickening. MRI can also screen for the presence of enlarged pelvic lymph nodes and bone metastases but cannot detect the presence of tumor in normal-sized nodes. Because MRI offers superior anatomic detail, owing to improved soft tissue contrast, it is considered by some to be superior to CT and ultrasonography in staging prostate cancer.<sup>46</sup> However, there have been wide ranges of sensitivities and specificities reported for MRI staging of prostate cancer, with accuracy ranging from 51% to 92%.<sup>47,48</sup> These variations are in part dependent on the experience of the radiologist performing the readings.<sup>49</sup> Some have proposed that MRI data are best used in combination with other clinical parameters, such as patient's age, prostate-specific antigen, digital rectal examination, and the biopsy Gleason score. In particular, D'Amico et al.<sup>50</sup> have reported that MRI improves staging accuracy for patients at intermediate clinical risk for invasive disease, as indicated by prostate-specific antigen levels of 10 to 20 ng/mL and Gleason scores of 5 to 7. Similar to CT and ultrasonography, MRI is not recommended for initial cancer detection and screening because of its low sensitivity for demonstrating central zone cancers and its difficulty in distinguishing malignant from benign lesions.

**FIGURE 27.2-10.** Prostate cancer. T2-weighted magnetic resonance image of the pelvis showed low signal intensity in the peripheral zone of the prostate, owing to multifocal cancer (arrows). The tumor is contained within the capsule of the prostate.

## BLADDER

The use of dynamic imaging after the administration of gadolinium has improved the evaluation of bladder carcinoma with MRI. The tumor usually enhances prior to enhancement of the remainder of normal bladder wall after contrast administration. MRI is the most accurate imaging modality for staging bladder carcinoma and has superior ability to detect perivesical spread and to assess the penetration of tumor through the deep muscle layers of the bladder ( Fig. 27.2-11).<sup>51</sup> Precise staging is critical to the selection of the therapy most appropriate for bladder cancer. Recent studies have demonstrated MRI staging accuracy of 84% to 93%.<sup>52,53</sup> A challenge for MRI has been the differentiation between postbiopsy or irradiation changes and tumor. However, the use of dynamic, fast gradient-echo sequences has recently improved the ability of MRI to make this distinction.<sup>54</sup>

**FIGURE 27.2-11.** Bladder cancer. T2-weighted image of the base of the bladder shows a large mass (arrow) primarily within the bladder. There is a high degree of contrast between the fluid in the bladder, which is bright, and the darker surrounding cancer. The margins of the bladder are obscured at the 12-o'clock to 3-o'clock position, indicating extension of cancer into the perivesical fat.

## MUSCULOSKELETAL SYSTEM

Plain film, MRI, and nuclear medicine play complementary roles in the evaluation of bone tumors. When a bone tumor is suspected, plain film is the initial study to show the lesion and its origin, location, morphology, and aggressivity. After plain film, if the lesion may be something other than an inactive asymptomatic benign tumor, MRI can confirm the initial plain-film findings and add additional diagnostic information. In known malignant lesions, MRI is the best study to determine accurate tumor localization and staging,<sup>55</sup> which is critical to optimizing the success of limb salvage techniques and other surgery. MRI can accurately determine the intraosseous extent of lesions, as bone marrow demonstrates high contrast with tumor. MRI can delineate tumor from adjacent fascia and muscle. "Skip" lesions, which can occur with osteosarcomas, can be detected with sagittal and coronal views that image long bones in their entirety. The detection of neurovascular bundle involvement and the determination of lesion distance from the joint are also MRI capabilities useful in surgical planning. MRI can show the response of tumor to adjuvant chemotherapy prior to resection and can detect residual or recurrent tumor after resection. T1-weighted images are very accurate for detecting metastatic lesions within the marrow compartment ( Fig. 27.2-12). Hence, MRI is indicated in symptomatic patients with suspected bony metastases or positive bone scans but with negative or inconclusive plain films. MRI is also extremely sensitive in detecting marrow replacement by myeloma, leukemia, or lymphoma on T1-weighted images and can differentiate these lesions from osteoporosis.<sup>56</sup> MRI is, however, similar to CT in that it is generally nonspecific in determining tumor cell type. A common pitfall of MRI is that it is possible for some bony lesions to appear benign when, in actuality, the lesion represents a high-grade malignancy. This is particularly true in patients older than 40, in whom even benign-appearing lesions commonly represent metastases or myeloma.<sup>57</sup> In younger patients, however, lesion morphology correlates in a very rough sense with its malignancy potential, though MRI still at times over- or underestimates tumor malignancy.

**FIGURE 27.2-12.** Bone metastasis. This patient had a primary leiomyosarcoma in the abdomen and presented with pelvic pain. T1-weighted magnetic resonance images show a large lesion (arrows) involving the left iliac bone as well as extension to the adjacent iliacus and gluteal muscles. The extent of bone involvement is precisely delineated on the magnetic resonance images. T1-weighted images are extremely sensitive for bone metastasis in adult patients and are frequently used in conjunction with nuclear medicine bone scan to determine precisely the extent and location of metastatic bone lesions. Magnetic resonance imaging is particularly useful in the pelvis, where overlapping structures can render diagnosis on plain radiographs difficult.

Owing to excellent soft tissue contrast, MRI displays outstanding anatomic detail of soft tissue lesions and is, therefore, the imaging modality of choice for evaluating soft tissue tumors.<sup>55</sup> Plain films, however, should still be additionally obtained. MRI is diagnostic of several common benign tumors, including lipomas ( Fig. 27.2-13), ganglion cysts, some hemangiomas, and simple neurofibromas.<sup>56</sup> There is some debate about whether MRI can consistently distinguish lipoma from liposarcoma.<sup>59,60</sup> In general, a thin-rimmed homogeneous high signal on T2-weighted images may represent a simple cyst. Heterogeneous high internal signal on T2-weighted images may indicate a solid lesion with high water or mucin content, a complex thick-walled lesion, calcification, necrosis, or hemorrhage, all of which can be associated with malignancy. MRI can be indeterminate in many of these cases, and MRI is helpful in determining the need for biopsy in suspicious-appearing lesions. In cases of known sarcoma, MRI is the best imaging modality to stage the mass accurately, determining its location relative to fascial planes and muscular structures, invasion into neurovascular or osseous tissues, and the distance of lesions from joints.<sup>55</sup> It is possible for some high-grade sarcomas, however, to display a nonaggressive, benign appearance.

**FIGURE 27.2-13.** Lipoma of the posterior thigh. This patient felt an enlarging mass in the thigh, which was palpable on clinical examination. Magnetic resonance imaging examination showed a high-signal-intensity mass (arrow) on this T1-weighted image. The appearance on magnetic resonance imaging is chemically specific for lipoma due to the presence of macroscopic fat. In the case of a characteristic soft tissue mass, such as lipoma, a biopsy is not necessary for diagnosis, given the magnetic resonance imaging findings.

#### INTRODUCTION

Unique to functional imaging is the provision of unperturbed physiologic information. While pathologists increasingly apply the highly sensitive and accurate techniques of molecular biology to histologic examination, those techniques, when applied to functional imaging, promise even more relevant and timely data. Together with advances in molecular biology, advances in the generation of new imaging agents and in imaging science compel us to rethink cancer diagnosis and treatment. Soon, cancer patients will no longer be categorized according to the primary organ involved; rather, their disease will be diagnosed and treated according to their predominant underlying genetic abnormality. In this fashion and in the spirit of molecular medicine (i.e., the idea that human disease proceeds from biochemical imbalance), the diagnosis and staging of cancer will be tailored to each patient. Tumor characterization will consequently become more accurate and treatment more effective.

The uses of functional imaging in current cancer practice include (1) detection of malignancy, particularly if the primary site is unknown; (2) differential diagnosis of lesions found on anatomic imaging studies; (3) tumor grading; (4) disease staging; (5) assessing for recurrence; and (6) therapeutic monitoring. <sup>1</sup>Table 27.3-1 lists metabolic processes amenable to measurement in humans by functional imaging. Only [<sup>18</sup>F]fluorodeoxyglucose–positron emission tomography (FDG-PET) and proton magnetic resonance spectroscopy (MRS) are used in routine clinical practice for oncology. Optical imaging techniques are also being developed but have been applied to humans on a limited basis to date.

Physiologic Processes	Methods
Glucose metabolism	FDG-PET*
Blood flow or volume	[ <sup>15</sup> O]H <sub>2</sub> O-PET, perfusion MRI
Tissue oxygenation	Nitroimidazole-PET, MRI
Tissue pH	<sup>31</sup> P-MRS
Protein synthesis	Amino acid-PET
Cell proliferation (mitotic rate)	Thymidine-PET
Receptor concentration or occupancy	PET
Enzyme kinetics	PET
Endogenous metabolite concentration	MRS(1)*
Water diffusion	DWI
Tissue anisotropy	DTI
Drug pharmacokinetics/dynamics	PET, MRS
Vascular permeability	Dynasize MR

DTI, diffusion tensor imaging; DWI, diffusion-weighted MR imaging; FDG, [<sup>18</sup>F]fluorodeoxyglucose; fMRI, functional magnetic resonance imaging; MR, magnetic resonance; MRS(1), magnetic resonance spectroscopy-spectroscopic imaging; PET, positron emission tomography.  
 \*Technique used routinely in clinical practice for oncology.

#### TECHNIQUES FOR FUNCTIONAL AND METABOLIC IMAGING

##### POSITRON EMISSION TOMOGRAPHY

###### Technical Considerations and Imaging Protocol

PET is the most sensitive functional imaging technique used in clinical practice, with the ability to quantify processes that occur at subnanomolar concentrations. Although its resolution is an order of magnitude inferior to that of magnetic resonance imaging (MRI), that obtained with current PET scanners approaches 4 mm. As with many other functional techniques, the initial application of PET was to the study of brain physiology and pathology. <sup>2</sup> PET relies on the detection of coincident photons that result from the annihilation of a positron and an electron. <sup>3</sup> Because the annihilation event occurs up to several millimeters away from the site of decay and the coincident photons do not separate at an angle of precisely 180degrees, physical and geometric constraints limit the resolution of imaging with PET. <sup>4</sup> Nevertheless, neither clinical nor even high-resolution small-animal imaging systems have reached the resolution limit imposed by those constraints. <sup>5</sup> Radionuclides most commonly used include <sup>11</sup>C, <sup>13</sup>N, <sup>15</sup>O, and <sup>18</sup>F, all of which are isotopes of atoms that are found in molecules of biologic importance (<sup>11</sup>C, <sup>13</sup>N, and <sup>15</sup>O) or that can be substituted without significant disruption of molecular structure (<sup>18</sup>F). Because the physical half-lives of radionuclides for PET range from 2 minutes (<sup>15</sup>O) to 110 minutes (<sup>18</sup>F), a premium is placed on synthetic efficiency. Images are generally reconstructed using algorithms, such as filtered back-projection. PET imaging is performed increasingly frequently on dual-head coincidence (DHC) gamma cameras. <sup>6</sup> Although FDG-DHC imaging is less expensive than is dedicated FDG-PET, the resolution of the former system is lower (13.5 mm vs. 4 mm), suggesting that FDG-DHC not be recommended for detection of lesions less than 1.5 cm in size.

FDG is the mainstay of PET oncologic imaging. As with all radiopharmaceuticals, distribution of FDG throughout the body obeys the tracer principle: It is administered in such small amounts (<10 µg) that while portraying the pathway of interest, it leaves that pathway completely intact. There is no pharmacologic or toxic effect. Neoplastic cells undergo accelerated glycolysis, even under aerobic conditions, a phenomenon known as the *Warburg effect*.<sup>7</sup> That metabolic difference between normal and cancer cells is exploited in FDG-PET imaging. Increased levels of glucose transporters and hexokinase and decreased levels of glucose-6-phosphatase contribute to the relatively increased glucose metabolism of cancer cells. <sup>8</sup> Unlike glucose, because FDG lacks a hydroxyl group at the 2 position, it cannot undergo further metabolism (phosphorylation) and remains trapped within the cell.

Because glucose competes with FDG for glucose transporters and hexokinase, elevated blood glucose levels tend to decrease FDG uptake. <sup>9</sup> Patients are fasted for 4 hours before intravenous administration of FDG (370 MBq, 10 mCi) and for 12 hours to reduce interfering myocardial uptake when searching for mediastinal adenopathy. The study is not performed if blood glucose levels exceed 200 mg/dL. Careful measurement and titration of blood glucose levels with insulin are unnecessary and may actually confound the study, owing to propagation of errors in blood glucose measurement. <sup>10</sup> Patients are scanned approximately 1 hour after FDG administration.

Deep organs may experience a 50-fold attenuation in photon detection relative to those at the surface. <sup>11</sup> Transmission scans using a <sup>68</sup>Ge source are accordingly performed to account for such geometric distortions. Transmission scans are time-consuming, particularly for whole body imaging that requires 10 gantry positions (for a 15-cm axial field-of-view scanner), each in turn requiring an 8- to 10-minute transmission scan. Transmission scans are not generally obtained for whole body imaging, and their use is controversial. Nevertheless, attenuation correction is necessary for coregistration of PET images with other modalities and for application of semiquantitative measurements, such as the standard uptake value (SUV).<sup>12</sup> True quantification of FDG-PET data, including kinetic modeling and arterial blood sampling or other surrogate methods for determining the input function, is noted frequently in the recent literature. <sup>13,14</sup> and <sup>15</sup> For those reasons, attenuation correction will likely be applied increasingly to clinical imaging. Furthermore, acquiring postinjection transmission scans or using iterative reconstruction methods, such as

PET has changed surgical management in 28% of patients with colorectal cancer by identifying resectable or unresectable metastasis not identified on clinical examination or CT.<sup>22</sup> PET is of higher sensitivity (see [Table 27.3-2](#)) than is CT arterial portography (80% to 90%) in detecting intrahepatic metastases.<sup>29</sup>

PET has not proved as useful for breast cancer as for lung cancer, primarily owing to lower glucose utilization in the breast and background activity from concurrent mastopathy.<sup>20</sup> Although PET demonstrates the highest accuracy for axillary staging of breast cancer for any noninvasive test (see [Table 27.3-2](#)), node dissection is still required for planning adjuvant therapy.<sup>20</sup>

Anatomic complexity in the head and neck region, particularly after surgery, renders PET evaluation of this area a boon to therapeutic monitoring. Tumors as small as 4 mm have been detected in the head and neck with PET.<sup>30</sup> Detection and localization of head and neck tumors may be improved by applying SUVs and anatomic coregistration ([Fig. 27.3-2](#)), in part because significant amounts of FDG are distributed to the salivary glands and adenoids.<sup>31</sup> Care must be taken when applying PET after radiation therapy because of false-positive results due to inflammation and false-negative results due to metabolic “stunning” that might occur. Postirradiation PET is, therefore, recommended 40 days to 4 months or longer after therapy.<sup>31,32</sup>

PET has been successfully applied to detecting subclinical involvement of lymph nodes in melanoma (see [Table 27.3-2](#)).<sup>20</sup> It has proved somewhat less fruitful when applied to pancreatic cancer, likely owing to the presence of concurrent inflammation and high blood glucose levels; however, correction for serum glucose did not significantly improve the accuracy of PET in several studies.<sup>22</sup> PET was more accurate than CT for pancreatic cancer, and surgical management was altered in 43% of cases when PET and CT were used together.<sup>33</sup> PET has also proved useful, even superior to gallium imaging, in staging lymphoma and detecting residual disease after therapy.<sup>20</sup> PET may be useful to evaluate adjuvant therapy in osteosarcoma<sup>34</sup> and in assessing prognosis in malignant pleural mesothelioma.<sup>35</sup> It has proved less useful for genitourinary cancers, primarily because of high background activity in the bladder.<sup>20</sup> Nevertheless, recent applications of PET to cervical and prostate cancers, primarily for detecting local disease recurrence (cervix) and for staging (prostate), show promise.<sup>36,37</sup>

### Tracers Other Than FDG

As stated, FDG has limitations. Its tissue uptake may be dictated by factors other than viable tumor cell fraction, such as degree of hypoxia,<sup>38</sup> inflammation,<sup>23</sup> and recent therapy.<sup>32</sup> High FDG levels in cerebral cortex can cloak tumors and metastases. Processes germane to cancer other than glucose uptake (e.g., blood flow, proliferation rate, protein synthesis rate, or tissue oxygenation) may be sought, as they may have prognostic and therapeutic implications as well. For those reasons, new tracers have been developed and include radiolabeled amino acid analogs,<sup>20,39,40</sup> and <sup>41</sup> thymidine analogs,<sup>42,43</sup> markers of tissue oxygenation (imidazoles and thiosemicarbazones),<sup>44,45</sup> and <sup>46</sup> substrates for multidrug resistance efflux pumps,<sup>47</sup> and such metabolites as choline<sup>48</sup> and acetate.<sup>49</sup> Radiolabeled analogs of chemotherapeutic agents, such as [<sup>18</sup>F]fluorouracil, have been synthesized to assess for their pharmacokinetics and metabolism. The concentration of [<sup>18</sup>F]fluorouracil in metastatic colorectal cancer correlated with patient survival.<sup>50</sup> Sex steroid receptor–based imaging agents enable measurement of estrogen receptor status *in vivo* and may be useful in therapeutic monitoring of certain subtypes of breast and prostate cancers.<sup>43</sup>

Among the amino acid analogs, [<sup>11</sup>C]methionine (MET) and [<sup>11</sup>C]tyrosine (TYR) have received the most attention. MET may be superior to FDG for brain tumor imaging, particularly for low-grade tumors, owing to minimal brain background activity.<sup>51</sup> Recent studies compared MET and FDG in a variety of tumors.<sup>52,53</sup> and <sup>54</sup> MET demonstrates a high negative predictive value (94%) for mediastinal node staging of lung cancer.<sup>55</sup> Because it undergoes less metabolism than MET, TYR may be used to measure protein synthesis rate and has been applied to head and neck cancers and soft tissue sarcomas.<sup>31,56</sup> For metastases due to head and neck cancer, TYR demonstrated higher specificity than FDG.

Developed in search of a noninvasive marker of tumor proliferation, carbon 11–labeled thymidine analogs, particularly those labeled at the 5-methyl moiety, undergo extensive, rapid metabolism, thereby prohibiting routine use.<sup>43</sup> More stable <sup>18</sup>F-labeled analogs have been synthesized and have shown promise in an initial study ([Fig. 27.3-3](#)).<sup>57</sup>

**FIGURE 27.3-3.** Computed tomography (A) and 3'-deoxy-3'-[<sup>18</sup>F]fluorothymidine–positron emission tomography (FLT-PET) (B) images in a patient with breast cancer metastatic to the mediastinal lymph nodes (arrows in A, arrowheads in B). The FLT-PET image was obtained 30 to 60 minutes after injection. FLT is retained in normal sternal and vertebral marrow (top, bottom arrows, respectively, in B) and ribs as well as within mediastinal tumor. (Courtesy of Anthony F. Shields, M.D., Detroit, MI.)

### Future Developments in Oncologic Positron Emission Tomography

Chemists have synthesized a vast array of selective, high-affinity radiopharmaceuticals in positron-emitting form; however, combinatorial chemistry and phage display libraries will generate even more promising lead molecules for oncologic imaging. More generalized use of old probes, such as [<sup>18</sup>F]fluoroethylspiperone, may enable gene transcription imaging in tumors with a variety of genetic perturbations.<sup>5</sup> Based on a principle similar to imaging with FDG (i.e., metabolic trapping), radiolabeled herpes simplex virus (HSV) thymidine kinase substrates for imaging gene transfer and expression are nearing clinical trials.<sup>58</sup> Generator-produced PET radionuclides, such as <sup>62</sup>Cu, which can render PET available to imaging facilities without a cyclotron on site, have been incorporated into appropriate ligands and used for tumor imaging.<sup>55</sup> Improvements in whole body PET are being sought by performing three-dimensional acquisition, routine attenuation correction, and application of statistical, iterative methods to reconstruct imaging data. If PET is to reach its true potential in oncologic imaging (i.e., measuring genomic events), quantitative techniques developed over the last 15 years for brain imaging must be adapted to tumor imaging. Concurrent recent advances in other imaging modalities and in understanding the microenvironment of tumors ([Fig. 27.3-4](#)) are serving to demystify the heterogeneity problem and will facilitate quantitative PET for oncology in the future.

**FIGURE 27.3-4.** Multimodality, functional radiologic-pathologic correlation of the mammary tumor model MDA-MB-435 in the mammary fat pad of a severe combined immunodeficiency mouse. **A:** Hematoxylin-eosin stain shows a pink hue centrally indicative of dead and dying cells. **B:** Vascular volume map [snapshot-fast low-angle shot (FLASH) magnetic resonance image] with gadolinium-albumin contrast (40 mL/g) shows decreased volume centrally in the area of necrosis. **C:** Vascular endothelial growth factor (VEGF) map generated from polyclonal antibodies to VEGF depicts increased VEGF protein in areas of necrosis. VEGF is a potent modulator of vascular permeability. **D:** Vascular permeability map (snapshot-FLASH magnetic resonance image; 1.27 mL/g/min shows increased vascular permeability (*arrow*) where vascular volume is lowest (i.e., centrally). Such multimodality correlation enables better understanding of the tumor microenvironment. (Courtesy of Dmitri Artemov, Ph.D., Meiyappan Solaiyappan, B.E., and Zaver M. Bhujwalla, Ph.D., Baltimore, MD.)

## MAGNETIC RESONANCE IMAGING

MR-based techniques are less well established for functional imaging than are those based on PET.<sup>60</sup> They include diffusion-weighted imaging (DWI), perfusion or cerebral blood volume imaging, MRS(I), and functional MR imaging (fMRI). In many ways, those techniques complement PET and attempt to measure similar physiologic phenomena (see [Table 27.3-1](#)). Apart from the obvious advantages related to logistics (e.g., no need for synthesis of short-lived radiotracers or for an on-site cyclotron), the MR techniques benefit from not needing anatomic coregistration. The resolution of clinical MR is submillimeter, at least one order of magnitude superior to clinical PET. Quantification of the MR-based techniques is in its infancy, but progress is being made, particularly in the assessment of blood flow<sup>61</sup> and metabolite concentrations.<sup>62</sup> As was the case for PET, the brain has been the primary organ of initial inquiry for MR-based techniques, and most of that work, except for MRS(I), has been dedicated to hemodynamics and stroke rather than cancer.

## SPECIFIC MAGNETIC RESONANCE-BASED TECHNIQUES

MRS(I) is applied in medicine to determine the concentrations of a relatively few metabolites that are altered in disease.<sup>63,64,65</sup> and<sup>66</sup> In MRS(I), the high-resolution morphologic imaging capabilities of MRI are sacrificed to provide metabolic data that, in many cases, precede structural abnormality. Molecules containing a limited number of nuclei may be imaged, including <sup>31</sup>P, <sup>23</sup>Na, <sup>19</sup>F, and <sup>1</sup>H. Among those, <sup>31</sup>P-MRS and especially <sup>1</sup>H-MRS(I), or MRS(I) have found the most applications in oncology.

Early work focused on <sup>31</sup>P-MRS; however, owing to large volumes (voxels) required for analysis, reducing sensitivity, MRS(I) has been developed and used to a greater extent more recently. <sup>31</sup>P-MRS still finds applications in oncology because <sup>31</sup>P is incorporated into adenosine triphosphate, phosphocreatine, and pyridine dinucleotides (i.e., molecules that reflect tumor energetics). Intracellular tumor pH can be derived from <sup>31</sup>P-MRS spectra. Tumors have elevated phosphomonoesters and phosphodiesteres. <sup>31</sup>P-MRS may find its greatest application in therapeutic monitoring of soft tissue sarcomas, where metabolite changes, which occur soon after the initiation of treatment, correlate with clinical response.<sup>67</sup> <sup>31</sup>P-MRS has also been used to detect non-Hodgkin's lymphoma,<sup>68</sup> to study liver metabolism in cancer patients,<sup>69</sup> and to follow up after therapy in patients with breast cancer.<sup>70</sup>

MRS(I) is the most commonly used MR spectroscopic technique because of the high natural abundance of protons. Key metabolites include choline and lactate, which tend to be elevated in tumors. Choline is a membrane constituent, its increase hypothesized to be due to increased cell membrane synthesis in rapidly proliferating tissue. Lactate is generally present only in pathologic tissue, such as necrotic tumors and abscesses, and reflects abnormal carbohydrate metabolism. Preoperative diagnosis and grading are the goals of brain tumor MRS(I); however, MRS(I) currently is best at merely differentiating normal from malignant tissue. Preul et al.<sup>71</sup> obtained remarkable success in grading gliomas by using pattern-recognition analysis rather than simply peak ratios.<sup>71</sup> Nevertheless, that technique is rather sophisticated mathematically and not widely available. MRS(I) is becoming useful in therapeutic monitoring, challenging PET for diagnosis of recurrent tumor versus radiation necrosis in patients with gliomas.<sup>72,73</sup> One recent study showed no false-positive results when using MRS(I) to assess for radiation injury ([Fig. 27.3-5](#)).<sup>74</sup> MRS(I) has more recently been applied to head and neck,<sup>75</sup> breast,<sup>76,77</sup> and prostate<sup>78,79</sup> and<sup>80</sup> cancers ([Fig. 27.3-6](#)). Each of those tumor types displays increased choline that, in the case of head and neck tumors,<sup>75</sup> reflects tissue oxygenation status. Cystic ovarian tumors demonstrated higher levels of lactate and amino acids than their benign counterparts.<sup>81</sup> The high-resolution, multivoxel capabilities of MRS(I) are important in prostate tumor assessment, because the lesions tend to be small and their precise intraglandular location has important therapeutic implications. Difficulty in suppression of lipid peaks outside of the ROI and in shimming continue to challenge extracranial MRS(I).

**FIGURE 27.3-5.** Patient with partial resection of a grade III astrocytoma in 1996 followed by radiotherapy (60 Gy) and chemotherapy. In February 1999, imaging showed a large butterfly-like enhancing mass on magnetic resonance imaging. Magnetic resonance spectroscopy–spectroscopic imaging [MRS(I)] [single slice point-resolved spectroscopy (PRESS) sequence; repetition time = 1500; echo time = 136; slice thickness = 20 mm, nominal resolution of 2 mL (field of view = 160 × 160; matrix 16 × 16)] demonstrated that the enhancing areas contained large lipid peaks; there were no areas of abnormally elevated choline within or outside the lesion. The diagnosis of radiation necrosis was made, and 1 year later, the lesion remained stable by magnetic resonance imaging and MRS(I). (Courtesy of Alberto Bizzi, M.D., Bologna, Italy.)

**FIGURE 27.3-6.** Patient with stage pT3a prostate cancer (Gleason score, 5). **A:** Fast spin-echo T2-weighted (repetition time = 5000; echo time = 102) axial magnetic resonance image through the midprostate obtained using an endorectal coil. A tumor focus (*arrows* in **A**) is seen as an area of decreased signal intensity in the peripheral zone of the right gland. **B:** Histopathologic section (hematoxylin-eosin stain) confirmed tumor in the peripheral zone of the right midgland that abuts the inked prostatic margin (*a*) and is interspersed between normal prostatic glands (*b*). **C:** 0.24-cm<sup>3</sup> spectrum obtained from area 1 in the image in **A** demonstrates elevated choline and reduced citrate, consistent with cancer. **D:** Magnetic resonance spectrum within the normal left peripheral zone, area 2 in the image in **A**, that shows dominant citrate, as expected. (Modified from ref. 80, with permission.)

Clinical studies using  $^{19}\text{F}$ -MRS have centered around studying the tumor pharmacokinetics of 5-fluorouracil analogs and effects of other chemotherapeutic agents on 5-fluorouracil tumor uptake.<sup>82</sup> Those studies are performed with a view to individualizing chemotherapeutic regimens for specific patients. Several groups have used  $^{23}\text{Na}$  imaging to characterize brain tumors,<sup>83,84</sup> with new pulse sequences and high-field systems contributing to furthering the sensitivity and resolution for this nucleus.<sup>85</sup>

DWI is among the triad of functional MRI techniques, a triad that also includes perfusion imaging and fMRI.<sup>86,87</sup> Water diffusion is a random event; however, certain structures, such as intracellular organelles and white matter tracts within the brain, may impede diffusion. Applying appropriate pulse sequences and magnetic field gradients, those differences in diffusion may be detected. Resembling free water, necrotic or cystic portions of brain tumors display high apparent diffusion constants (ADCs), while the solid (enhancing) portions have lower ADCs, demonstrating the ability of DWI to distinguish various portions of a single heterogeneous lesion.<sup>88,89</sup> Coupled with the high resolution of MR systems, that finding suggests that DWI may direct biopsies, an important function, as sampling errors now lead to approximately 25% of brain tumors being undergraded.<sup>90</sup> Huang et al.<sup>91</sup> used DWI in conjunction with MRS and perfusion imaging to assess the effects of intracarotid chemotherapy on brain tumors in patients with gliomas or primary central nervous system lymphoma, showing a normalization of ADC values after treatment. In the periphery, hemangiomas (high ADC) can be differentiated from hepatocellular carcinomas (low ADC) of the liver using a turbo-fast low-angle shot sequence with DWI.<sup>92</sup> That technique enabled differentiation of malignant (low-ADC) from benign (high-ADC) ovarian cysts.<sup>93</sup> Other fast MR techniques, such as echo-planar imaging, are beginning to be applied to extracranial regions, further allowing the calculation of ADC values in abdominal organs.<sup>94</sup>

Once only a function of PET, perfusion imaging is now possible, in some cases quantitatively, with MRI.<sup>95</sup> Perfusion imaging enables calculation of blood volume, which is likely related to tumor angiogenesis, or new blood vessel formation (Fig. 27.3-7). Angiogenesis is a strong indicator of tumor grade.<sup>96</sup> Biopsy of tumor subregions with increased perfusion may prove superior to biopsy of regions of enhancement, the current practice. Areas of perfusion and enhancement often do not coincide, the latter being due to breakdown of the blood-brain barrier in the case of brain tumors. Extracranial studies using perfusion imaging are rare, although several studies of cervical cancer have appeared recently.<sup>97,98</sup> and <sup>99</sup> In the latter study, the cervical microcirculatory parameters determined with perfusion imaging did not always correlate with histology; however, they did correlate with patient outcome. Several groups have performed dynamic contrast-enhanced imaging of the breast<sup>100</sup> or prostate<sup>101</sup> in attempting to take advantage of the temporal signature of contrast uptake in tumors relative to neighboring tissue. Dynamic CT with Patlak analysis enabled measurement of perfusion in prostate tumors during therapy.<sup>102</sup>

**FIGURE 27.3-7.** Patient with a left parietal glioma. Postgadolinium T1-weighted image (A) [repetition time (TR) = 415; echo time (TE) = 18] demonstrates minimal enhancement (arrow) in the left posterior parietal lobe, where a large region of high signal intensity is identified (B, arrow) on the fluid-attenuated inversion recovery (FLAIR) image [TR = 8800; TE = 130; inversion time(TI) = 2200]. The diffusion-weighted image (C) (TR = 9999; TE = 99; B = 1000), calculated apparent diffusion constants map (D), and cerebral blood volume perfusion image (E) all demonstrate increased signal in the region of the mass favoring the diagnosis of tumor. The time-to-peak perfusion image (F) shows delayed perfusion of the mass relative to the neighboring gray matter.

fMRI detects signals based on the difference in blood oxygen tension that occurs between active and inactive brain regions (i.e., the blood oxygen level dependence effect).<sup>103</sup> Several centers are beginning to use fMRI for preoperative planning of brain tumors because eloquent, or essential, brain regions, such as motor cortex or language areas, may be mapped preoperatively and avoided during surgery for tumors and other lesions.<sup>104,105</sup> Similarly, the nonrandom orientation (anisotropy) of white matter tracts in the brain may be exploited by diffusion tensor imaging,<sup>106</sup> a variant of DWI, for preoperative planning. In diffusion tensor imaging, deep structures, such as the corticospinal tract, well beyond the domain of intraoperative cortical mapping, may be delineated and, consequently, avoided during tumor surgery.<sup>107,108</sup>

## FUTURE DEVELOPMENTS IN ONCOLOGIC MAGNETIC RESONANCE IMAGING

In a preliminary study, Enochs et al.<sup>109</sup> used a contrast agent based on long-circulating superparamagnetic iron oxide particles to delineate brain tumors that may differentiate between tumor and postoperative scar tissue. “Smart” MR contrast agents, which may be activated only within the vicinity of an enzyme of interest, are being developed and may prove useful if issues related to pharmacokinetics and metabolism can be resolved.<sup>110</sup> Further application of echo-planar imaging and other rapid MR techniques may enable multiple MR studies [e.g., MRS(I) and perfusion imaging] to be performed within a single 1-hour clinical time slot, permitting collection of correlative data.

## NEW FUNCTIONAL AND METABOLIC IMAGING MODALITIES

Optical imaging techniques are entering the clinical arena. Optical coherence tomography is already being applied to microsurgery<sup>111,112</sup> and cervical cancer<sup>113</sup> (Fig. 27.3-8). Rather than *functional* imaging, however, those techniques are more akin to ultrasonography, except that light is used to obtain the image. Optical coherence tomography may almost be considered a *cellular* imaging technique, owing to its exquisite resolution, approaching cellular dimensions (1 to 15  $\mu\text{m}$ ) and one to two orders of magnitude superior to conventional ultrasonography. It is expected to prove invaluable for directed biopsy, decreasing sampling errors.

**FIGURE 27.3-8.** Optical coherence tomography (OCT) images were obtained from fresh tissue samples, within 5 minutes of excision by a loop electro-surgical excision procedure. Image acquisition time was 2.5 seconds. The instrument used delivers and collects 850-nm broadband light via an optical fiber probe that is placed in contact with the sample. Shown is a clinically normal site in the tissue sample. From the top down, the image shows a dark band corresponding to the quartz shield (S) of the optic fiber probe. Next, the surface of the sample is observed (1), followed by a layer of low-scattering epithelial tissue (E) 150  $\mu\text{m}$  deep in this image. Immediately below, approximately 325  $\mu\text{m}$  deep in the image, is the interface with a layer of highly scattering connective (C) tissue (2). This layer occupies the rest of the image, and the signal fades approximately 400 to 500  $\mu\text{m}$  into the tissue. This technique may also be used to demonstrate the optical properties of tissue *in situ*.

(Courtesy of Rebecca Richards-Kortum, Ph.D., Austin, TX.)

Either endogenous or exogenous fluorophores may be used to detect fluorescence of malignant tissues. Inaguma and Hashimoto<sup>114</sup> recently applied the former to characterizing oral carcinomas, demonstrating that tumors vary in the amount of a porphyrin-like substance responsible for fluorescence. Andersson-Engels et al.<sup>115</sup> used a porphyrin to delineate basal cell carcinomas. Schantz et al.<sup>116</sup> exploited the endogenous fluorescence of head and neck cancers and demonstrated a correlation between fluorescence maxima and tumor grade and likelihood of recurrence. Tromberg et al.<sup>117</sup> accomplished quantitative functional imaging of breast tumors using near-infrared light in conjunction with photon migration spectroscopy. Low-resolution (0.5- to 1-cm) images of tissue hemoglobin concentration, oxygen saturation, blood volume, and water and fat contents are capable with that technique.

Subtle differences in redox status, oxygenation, and intracellular pH separate normal and malignant tissues.<sup>118</sup> Redox status and oxygenation can be measured by electron paramagnetic resonance.<sup>119</sup> The detection of nitroxides, redox-sensitive probes, has been accomplished using electron paramagnetic resonance-enabled imaging of tumor heterogeneity in a rodent model, with clinical studies on the horizon.<sup>118</sup>

## SUMMARY

The use and cost-effectiveness of PET are finally being recognized in the clinic.<sup>120</sup> The proliferation of satellite suppliers of FDG to sites that use DHC gamma cameras and reimbursement for an increasing number of indications may account for the anticipated 30% increase in PET<sup>121</sup> use over the next 5 years. MR techniques are largely replacing PET for indications other than receptor- or enzyme-based imaging (i.e., blood flow) and can provide important complementary information to PET. Recent initiatives of the National Cancer Institute promote the development of research projects and centers dedicated to functional and molecular imaging of cancer. Through synergism of technologic advances, interdisciplinary research, and public support, functional imaging will soon ensure the ultimate goal of the noninvasive characterization of cancer.

#### INTRODUCTION

The field of interventional radiology has continued its rapid expansion into the world of clinical medicine and oncology. In doing so, its focus has shifted from an essentially diagnostic to a primarily therapeutic subspecialty. The interventional radiologist is now involved in direct patient care and, in many instances, has become the patient's primary care physician. This growth of interventional radiology is especially extraordinary in the field of clinical oncology, where many procedures, such as placement of tunneled central venous catheters for infusion of chemotherapy or nutritional support, inferior vena cava (IVC) filters to prevent pulmonary embolism, and catheterization of the biliary or urinary tract to decompress obstructed systems, are now performed by interventional radiologists. In addition, new procedures developed by interventional radiologists, such as transarterial chemoembolization of liver tumors, percutaneous ethanol infusion, radiofrequency ablation, or embolization techniques, have become suitable therapeutic alternatives to other traditional forms of therapy, including systemic chemotherapy, irradiation, or surgery and, in some instances, have become the mainstay of therapy. A wide range of cancer patients benefit from the services of interventional radiology. This chapter first reviews some of the well-established procedures still performed to help diagnose cancer and then addresses the many contributions of interventional radiology in the treatment of cancer patients.

#### DIAGNOSTIC PROCEDURES

Percutaneous and intraluminal biopsies of suspicious lesions are relatively easy and reliable methods of obtaining tissue for histologic or cytopathologic diagnosis. The lungs, breast, liver, pancreas, adrenal glands, kidney, and retroperitoneum (especially lymph nodes) are the most commonly targeted organs. Ultrasonography, magnetic resonance imaging, and computed tomography (CT) provide excellent image guidance and have made it possible to safely sample focal lesions as small as 5 mm.<sup>1</sup> The majority of percutaneous biopsies can be performed on an outpatient basis. By alleviating the need for diagnostic surgery, biopsy is cost-effective and can have a great impact on patient management.<sup>1</sup> Numerous types and sizes of biopsy needles are commercially available. They vary from the small aspiration needle (19- to 23-gauge), which provides a cellular slurry for cytologic examination when confirmatory diagnosis of malignancy is sought, to the large-core biopsy cutting needle and biopsy gun (18-gauge or less), which provide an actual piece of tissue for cytologic and histopathologic analysis.<sup>2,3</sup> and <sup>4</sup> The choice of a specific needle should be made according to the type of tissue to be sampled. Other considerations include the type and vascularity of the target organ, the coagulation status of the patient, and the anticipated course of the needle. Percutaneous biopsy is most commonly performed to provide a definitive diagnosis of malignancy. It can also be used for tumor staging and assessment of tumor response to therapy.

#### PERCUTANEOUS BIOPSY IN THE THORAX

Despite persistent controversy about its usefulness, transthoracic needle biopsy is still commonly performed to diagnose both benign and malignant disease of the thorax.<sup>5,6</sup> and <sup>7</sup> Aspiration or cutting needles can be used to evaluate suspicious lesions adequately in the lung parenchyma, pleura, or mediastinum. Although cutting or core needles generally provide better quality samples than those provided by aspiration needles, they are usually not required to sample parenchymal abnormalities or lung nodules and, in most instances, provide no substantial advantage over needle aspiration.<sup>2,8,9,10</sup> and <sup>11</sup> Only when the diagnosis of malignancy cannot reliably be established by fine-needle aspiration is the use of core needles indicated.<sup>5,7</sup> It is helpful to have the pathologist in attendance during the procedure to determine whether the collected sample can yield a definitive diagnosis.<sup>12</sup> If the initial biopsy sample is negative, the positioning of the needle tip should be checked to ensure that it is within the lesion. Once the needle tip is appropriately redirected, further samples should be collected. Both established and more recent series have shown the sensitivity of transthoracic needle aspiration for the detection of pulmonary parenchymal, hilar, or pleural malignancy to vary between 74% and 97%, its diagnostic accuracy to range from 76% to 99%, and its specificity to approach 100%.<sup>1,2,5,6,7,8,9,10</sup> and <sup>11</sup> Core biopsy marginally increases the diagnostic yield over that obtained with fine-needle aspiration. On the other hand, despite the increased risk of the procedure owing to the larger size of the needle, it is extremely useful when a diagnosis of lymphoma is suspected or to establish a definitive diagnosis of malignancy within the mediastinum.<sup>13,14,15</sup> and <sup>16</sup>

Fluoroscopy, CT scanning, and ultrasonography are the preferred imaging modalities for guidance of needle biopsy in the thorax. All available radiographic studies of the lesion to undergo biopsy should be reviewed before the procedure. For lung nodules, fluoroscopy is the imaging guidance of choice because it provides immediate identification and, thus, rapid sampling of the lesion. If the lesion cannot be identified by fluoroscopy, CT scanning guidance should be used. CT images provide exquisite anatomic details, and vital structures, such as major blood vessels, can thus be avoided.<sup>2</sup> These attributes render CT scanning the imaging guidance of choice for lesions involving the mediastinum, hila, or pleura. Finally, the use of ultrasonography should be reserved for superficial chest wall masses.

Although no absolute contraindications to percutaneous pulmonary biopsy exist, there are several relative contraindications, such as an uncooperative patient, pulmonary hypertension, coagulopathy, and severe bullous emphysematous disease. Severe complications from transthoracic pulmonary biopsy are extremely rare, and the overall mortality ranges from 0.01% to 0.05%.<sup>17,18</sup> and <sup>19</sup> On the other hand, the incidence of pneumothorax (by far the most common complication) varies between 14% and nearly 60%, but only 4% to 13% of these cases require treatment by placement of a chest tube.<sup>17,18,19,20</sup> and <sup>21</sup> Note that the incidence or size of a pneumothorax is not related to either the size of the biopsy needle or the number of passes made during the biopsy.<sup>11</sup> Other complications include hemoptysis (5% of cases) and pleural pain, especially if a pneumothorax is present.<sup>17,18,19,20</sup> and <sup>21</sup>

#### BIOPSY OF OTHER ORGAN SYSTEMS

With the advent of high-quality cross-sectional imaging, percutaneous biopsy of suspicious abdominal masses has become a relatively easy, safe, and reliable method of obtaining definitive tissue diagnosis. CT guidance remains by far the most common imaging guidance modality, because it provides superb anatomic details and excellent evaluation of internal structures, thus allowing the operator to plan and choose the safest approach to a biopsy.<sup>22</sup> It is clearly the modality of choice for biopsy of the pancreas, adrenals, lymph nodes, retroperitoneal masses, and liver lesions not seen well by ultrasonography. On the other hand, ultrasonography is the guidance modality of choice for biopsy of the thyroid and breast and is frequently used for biopsy of the liver (especially if the lesions are relatively large and superficial), the pancreas, kidneys, and pelvic organs.<sup>23,24</sup> Ultrasonography offers the advantage of real-time, multiplanar imaging as well as Doppler analysis, which makes it very practical and improves safety by allowing the operator to identify and thus avoid major vessels.<sup>23,24</sup> The role of magnetic resonance imaging in biopsy guidance remains limited by the high cost of nuclear medicine examinations and the need for specialized biopsy needles owing to the magnetic field. Although both fine-needle aspiration and larger cutting needles can theoretically be used for biopsy of abdominal lesions, a fine needle is often preferred because the risk of injury to adjacent vital structures is minimized. Indeed, such structures as the liver, stomach, small bowel, and colon can safely be traversed by a fine needle. Cutting needles should be used if a definitive diagnosis cannot be established with fine-needle aspiration and only if a clear, safe pathway

to the target lesion can be established.

Percutaneous biopsy of abdominal or pelvic masses generally yields high diagnostic accuracy rates. In the liver, it ranges from 60% to 84% with fine aspiration needles to 90% to 100% with core or cutting needles.<sup>25,26,27 and 28</sup> In the pancreas, diagnostic accuracy has greatly improved over the last 10 years and now ranges between 85% using fine-needle aspiration and 92% using core needles.<sup>29,30</sup> The diagnostic accuracy for biopsy of the kidney<sup>31</sup> and adrenals is greater than 90%.<sup>32,33 and 34</sup> The use of large cutting needles for biopsy of the adrenal glands is not recommended because major vital structures, which surround the adrenal glands, could be transgressed during the procedure, thus causing major complications. For abdominal biopsies, the diagnostic accuracy is directly related to the number of needle passes made during the biopsy.

The complication rate for percutaneous biopsy in the abdomen is low (1% to 3%).<sup>29,32,35,36 and 37</sup> It is lowest in the liver (0.1%) and highest in the adrenals (8.4%).<sup>29,32,35,36 and 37</sup> Major complications, though extremely rare, include hepatic or renal hemorrhage, pancreatitis, and pneumothorax. They can usually be treated effectively by transcatheter or tract embolization (hemorrhage)<sup>38</sup> or insertion of a drainage catheter (pancreatitis or pneumothorax).<sup>37</sup>

More invasive techniques, such as transjugular liver biopsy<sup>39</sup> and percutaneous transhepatic biopsy of the biliary tree<sup>40</sup> can also be performed to obtain tissue diagnosis in the liver. In cancer patients, transjugular liver biopsy is used mainly to obtain core-like samples of liver tissue to establish the diagnosis of graft-versus-host disease. It is performed via a right internal jugular approach and requires selective hepatic vein catheterization. Once seeded within the hepatic vein, either a biopsy gun or forceps is directed inferiorly and advanced through a vascular sheath directly into the liver parenchyma to collect tissue samples. This technique is especially useful in coagulopathic patients with diffuse liver disease.

Traditional image-guided percutaneous biopsy or endoscopic brush biopsy of the biliary tract have diagnostic yields ranging only from 40% to 70%.<sup>41,42</sup> Benign and malignant biliary strictures have similar cholangiographic appearances, and distinguishing between the two entities can be extremely difficult. Percutaneous transhepatic biliary drainage allows direct access to the biliary tract once satisfactory decompression of the biliary tree has been achieved. Biopsy forceps catheters can then be used through the existing tract to obtain tissue samples of suspicious areas within the biliary tree. Sensitivity and specificity with this technique hover near 85% and 95%, respectively, and are highest when a scope, introduced percutaneously through the established tract, provides direct visualization of the biliary tree.

## VISCERAL ANGIOGRAPHY

The role of angiography in the diagnostic evaluation of hepatobiliary or pancreatic neoplastic disease has greatly diminished in the last decades. The advent of sophisticated noninvasive fast imaging modalities, such as CT, ultrasonography, and nuclear medicine, has fulfilled most of the clinician's diagnostic needs. However, angiography continues to be important not only as a visceral diagnostic test but as it provides the basis for many therapeutic interventional procedures. Visceral angiography requires selective catheterization of the celiac axis and superior mesenteric artery after which digital subtraction imaging is performed. Filming should be carried out long enough to visualize the portal venous phase. Visceral angiography is used for detailed evaluation of the splanchnic arterial anatomy, particularly the numerous potential anatomic variations in the arterial supply to the liver ( Fig. 27.4-1); documenting patency of the portovenous system; and determination of vascular encasement. When intraarterial chemotherapy administered via a surgically placed pump is being considered for treatment of liver metastases, thorough evaluation of the hepatic arterial anatomy is especially important to ensure appropriate delivery of the chemotherapy to all segments of the liver involved by the tumor.<sup>43</sup> In cases of pancreatic cancer or cholangiocarcinoma, if surgical resection is contemplated, assessment of vascular encasement is critical, since surgery offers the only hope for cure.<sup>44,45,46,47 and 48</sup> Encasement of the celiac axis, the superior mesenteric artery, portal vein, or superior mesenteric vein ( Fig. 27.4-2) usually indicate that the tumor is not amenable to surgical resection for cure, although in some cases and, depending on the surgeon's experience, such findings may not preclude surgical exploration.<sup>44,45,46,47 and 48</sup>

**FIGURE 27.4-1.** Diagnostic visceral arteriogram: variant arterial anatomy. **A:** Replaced right hepatic artery ( *arrow*) off the superior mesenteric artery. **B:** Replaced left hepatic artery ( *black arrow*) off the left gastric artery ( *open arrow*).

**FIGURE 27.4-2.** Diagnostic visceral arteriogram in a patient with pancreatic adenocarcinoma: venous encasement. **A:** Venous phase from splenic arterial injection demonstrates narrowing of the main portal vein consistent with encasement ( *arrow*). **B:** Venous phase from superior mesenteric arterial injection demonstrates encasement of main portal vein ( *arrow*).

## PORTAL VENOUS SAMPLING

Islet cell tumors of the pancreas can be elusive, and their detection by noninvasive imaging or by conventional angiography often fails. Percutaneous transhepatic portal venous sampling is used to localize islet cell tumors by measuring hormonal levels in the superior mesenteric, splenic, and portal veins. This method has a sensitivity exceeding 95% for localization of islet cell tumors.<sup>49,50,51,52,53 and 54</sup> Detection and localization of islet cell tumors is important because patients can be cured once the tumor is resected. Precise anatomic mapping of the hormonal collections is, therefore, essential to accurately locate the tumor, thereby avoiding blind surgical resection and enabling the surgeon to resect the affected segment (head, body, or tail) of the pancreas.<sup>49,50,51,52,53 and 54</sup> When the sampling procedure is completed, the transhepatic tract should be embolized with Gelfoam pledgets to prevent excessive bleeding.<sup>49,54</sup>

## THERAPEUTIC INTERVENTIONS

The second part of this chapter focuses on the most important contributions of interventional radiology in the treatment and management of hepatic, pancreatic, and

biliary malignancies; other gastrointestinal tract cancers; genitourinary tumors; superior vena cava (SVC) syndrome; as well as pulmonary thromboembolic disease.

## LIVER CANCER

The management of primary and secondary malignancies of the liver constitutes one of the most difficult challenges for oncologists. First, primary hepatic malignancies frequently escape detection because most patients remain asymptomatic for long periods. Then, if clinical symptoms are present, they may be masked by the patient's underlying liver disease and may, therefore, be difficult to attribute to a malignancy. In addition, clinical outcome is typically poor, with median survival of less than 1 year for all patients and between 3 and 6 months for unresectable presentations.<sup>55,56,57,58 and 59</sup> Hepatocellular carcinoma (hepatoma) is one of the most common fatal cancers in the world (1.2 million deaths per year) and accounts for approximately 90% of all liver cancers. It is most commonly encountered in Asia and sub-Saharan Africa, where it constitutes 20% to 40% of all malignancies. The high incidence of hepatoma in these regions can be attributed to hepatitis B, which is endemic in these regions of the world. In Europe and North America, the incidence of hepatoma is markedly lower (10,000 to 14,000 cases per year in the United States) and largely related to alcoholic cirrhosis, but it is climbing rapidly and expected to increase further given the recent rise in hepatitis C and its association with hepatoma.<sup>55,56,57,58,59 and 60</sup>

Metastatic malignant tumors of the liver are by far the most common type of hepatic malignancies in the United States (at least 20 times that of hepatoma) and occur most often secondary to colorectal carcinoma (155,000 cases and 60,000 deaths per year in the United States),<sup>61</sup> followed by ocular melanoma, neuroendocrine tumors of the pancreas, including carcinoid tumors, as well as both functional and nonfunctional islet cell tumors, and some sarcomas.<sup>62,63 and 64</sup> In many of these conditions, the liver is the only site of metastatic involvement, thus justifying a role for locoregional therapy.

Although rare, carcinoid tumor represents the most common of all endocrine tumors of the gastrointestinal tract, and the incidence of metastatic carcinoid tumor is 0.32 to 0.7 per 100,000 with the majority arising from the small bowel.<sup>62,63</sup> The tumor is usually slow growing and, therefore, associated with longer survival than hepatoma or colorectal metastatic disease, but patients can be plagued by severe symptoms due to excessive secretion of serotonin and bradykinin as part of the carcinoid syndrome (4% to 9% of cases). In cases of carcinoid syndrome, the liver is almost always involved, and locoregional palliative therapy with chemoembolization constitutes the only therapeutic option.<sup>62,63</sup>

Ocular melanoma is a very aggressive and highly lethal disease. It usually progresses very rapidly and commonly metastasizes to the liver. Once the liver is involved, fatal hepatic disease ensues. Median survival ranges from 2 to 6 months.<sup>55,64</sup> As for the other tumors involving the liver, locoregional therapy offers the best option.

For both primary and metastatic liver cancers, such surgical options as resection or transplantation offer the only hope for cure and, at the very least, have a definite impact on survival in operative candidates, with survival rates ranging from 55% to 80% at 1 year and 25% to 50% at 5 years.<sup>61,65,66,67 and 68</sup> Yet, only a minority of patients are surgical candidates (15% to 20% of all patients with either primary or secondary liver cancers).<sup>55,66,67 and 68</sup> Criteria used to determine unresectability include the size, location, and volume of the lesion to be resected; multilobar involvement; as well as the presence of limited hepatic reserve due to advanced cirrhosis or chronic hepatitis and significant concurrent disease (especially cardiac or pulmonary disease).<sup>55</sup> In addition, surgical resection continues to be plagued by fairly high morbidity and mortality rates, especially when surgery is performed in patients with underlying liver failure (15% to 30% perioperative mortality), as well as high recurrence rates (75% of patients).<sup>66,67 and 68</sup> Liver transplantation remains limited by the scarcity of liver donors (although the development of living-related liver transplantation could remedy this problem) and by a surprisingly high recurrence rate.<sup>67,68</sup> Other therapeutic options, such as systemic chemotherapy and external-beam radiotherapy, have been disappointing. The response rate from single-agent or multidrug chemotherapy is poor, as it does not exceed 15% to 20% and a clear survival benefit has not been demonstrated.<sup>55,67</sup> External-beam irradiation is limited by the extensive damage it causes to the radiosensitive hepatocytes.<sup>55,67</sup>

The limitations of the traditional weapons against cancer (surgery, chemotherapy, and radiotherapy), combined with the fact that the immense majority of patients afflicted by primary or metastatic liver cancer have liver-only disease, have led to the hunt for and development of various locoregional therapies. In addition, patients afflicted by hepatoma usually die of hepatic failure and cachexia as a result of local growth and resultant liver tissue destruction but not of extrahepatic metastatic disease.<sup>66,67 and 68</sup> Thus, control of the tumor at the regional level is essential.

The goal of locoregional therapy is to destroy the tumor while preserving as much of the normal liver tissue as possible. This can be accomplished either by direct percutaneous ablative methods, such as percutaneous ethanol injection and radiofrequency ablation, or by intraarterial delivery of embolic material with or without chemotherapeutic agents, such as transcatheter arterial chemoembolization, which is by far the most widely performed procedure in the treatment of unresectable liver cancers.

### **Transcatheter Arterial Chemoembolization**

Transcatheter arterial chemoembolization has truly become the mainstay of therapy for unresectable hepatoma and carcinoid tumors and has shown great promise against colorectal metastases.<sup>55</sup> The concept of chemoembolization evolved from practical experience obtained with two partially effective therapies, intraarterial chemotherapy and embolotherapy. Although many different chemoembolization regimens can be used, the principles and theoretic advantages of chemoembolization are identical and are based on combined infusion of a concentrated dose of chemotherapeutic drugs mixed with iodized oil and an embolic agent directly into the hepatic artery. It is well established that the normal liver draws most of its blood supply from the portal vein (approximately 75%), whereas primary or metastatic liver tumors draw most of their oxygen supply from the hepatic artery (>90%).<sup>69,70</sup> Targeting the hepatic artery for regional delivery with a mixture of chemotherapeutic agents and embolic material is, therefore, not only safe and possible but also extremely attractive to destroy the tumor. The theoretic beneficial effects of chemoembolization include delivery of a high concentration of chemotherapy to the tumor bed, marked increase in contact time between the drugs and the tumor cells, and high first-pass extraction.<sup>55,71,72</sup> These factors combine to increase the drug concentration and the retention rate within the tumor even further (100- to 400-fold increases in drug concentration have been reported), thereby minimizing the systemic toxicity of the chemotherapeutic drugs.<sup>55,71,72,73 and 74</sup> Although many different chemoembolization protocols are being used throughout the world without any compelling evidence of the superiority of one over the other, a generally accepted rule is that the chemoembolization infusion should include a mixture of iodized oil (Ethiodol) and chemotherapeutic agents. Doxorubicin is most commonly used alone in Europe, whereas the combination of cisplatin, doxorubicin, and mitomycin C is favored in the United States. Ethiodol plays a key role in the process since it not only acts as a carrier for the chemotherapeutic agents by creating an emulsion with the agents but it also prolongs contact time between the tumor cells and the agents by clogging the presinusoid arterioportal shunts, thus allowing the agents to slowly diffuse into the tumor.<sup>55,73</sup> Particulate embolization materials (Gelfoam or Ivalon) should also be injected toward the end of the procedure to reduce arterial inflow and, thus, prevent washout of the chemotherapeutic agents.

Since chemoembolization is currently only used as a palliative therapy, its impact on patients' quality of life should be given high priority. The benefits of the procedure should be weighed against the potential complications that could worsen patients' quality of life. Thus, proper patient selection should be conducted to exclude patients who could be adversely affected by the procedure, such as those with clinically apparent jaundice, hepatic encephalopathy, extensive extrahepatic metastases, poor liver function (combination of >50% liver replacement by tumor, aspartate transaminase >100, markedly elevated lactate dehydrogenase, and hyperbilirubinemia), or biliary obstruction.<sup>55</sup>

Patients scheduled to undergo chemoembolization are required to fast overnight. The day of the procedure, vigorous hydration with normal saline, prophylactic antibiotics, antiemetics, and sedatives are administered. A visceral arteriogram is then performed to define the arterial anatomy and to assess portal venous patency. With the advent of hydrophilic guidewires and catheters as well as coaxial systems with smaller diameter catheters, it is now possible to perform superselective catheterization of third- or fourth-order branches. Once the catheter has been advanced beyond the gastroduodenal artery to avoid nontarget embolization and is located within striking distance of the tumor, the chemoembolization material can be injected ( [Fig. 27.4-3](#)). The infusion should be stopped before thrombosis of the hepatic artery occurs. Patients are then admitted for pain management, continued antibiotic coverage, and hydration. The vast majority of patients requires only a 24- to 48-hour hospital stay. Although most patients experience some degree of pain, nausea, vomiting, and fever as part of the embolization syndrome, which typically lasts 3 to 10 days, chemoembolization is generally relatively well tolerated. True complications, such as liver failure, liver infarction, abscess formation, cholecystitis, nontarget embolization to the gastrointestinal tract, and biliary necrosis, are rare (3% to 4% of cases).<sup>55</sup>

**FIGURE 27.4-3.** Transhepatic arterial chemoembolization in a patient with multifocal hepatocellular carcinoma. **A:** Extensive staining of the tumor foci after chemoembolization indicating excellent uptake of the chemoembolization material by the tumor. **B:** Superselective catheterization. The catheter has been advanced to within striking distance of the tumor.

Initial enthusiasm for chemoembolization was generated by early reports<sup>75,76,77,78,79,80,81 and 82</sup> from Kanematsu,<sup>75</sup> Okamura,<sup>79</sup> and others,<sup>76,77 and 78,80,81 and 82</sup> who demonstrated that extensive tumor necrosis (60% to 90%) and high radiographic response rates (up to 80%) could be produced in patients with hepatoma. Nonrandomized, retrospective studies followed.<sup>83,84,85,86 and 87</sup> These studies by Nakamura,<sup>83</sup> Shimamura,<sup>84</sup> Nakao,<sup>85</sup> and others<sup>86,87</sup> compared chemoembolization to other therapies, such as hepatic artery embolization alone (without added chemotherapeutic agents or iodized oil), using historic controls. They showed that a clear advantage in survival could be established with chemoembolization. Indeed, cumulative probability of survival after chemoembolization ranged from 54% to 88% at 1 year, 33% to 64% at 2 years, and 18% to 51% at 3 years, whereas embolization alone yielded cumulative survival of 44% at 1 year, 29% at 2 years, and 15% at 3 years. These results also compared very favorably with a 1-year survival rate of 13% achieved with systemic chemotherapy. This improvement in survival was accompanied by a decrease in the level of serum  $\alpha$ -fetoprotein (AFP) in most cases. These impressive results helped to establish chemoembolization as the treatment of choice for unresectable hepatoma.

Recent prospective randomized trials conducted by Pelletier et al.,<sup>88</sup> Madden et al.,<sup>89</sup> the Groupe d'Etude et de Traitement du Carcinome Hepatocellulaire,<sup>90</sup> and Bruix et al.<sup>91</sup> (the only four randomized trials to date) failed to show a significant survival advantage of chemoembolization over supportive care, although a trend to prolonged survival was detected (63% vs. 44% at 1 year). Each of these studies had significant flaws in their methodology and design, severely limiting their validity. However, they managed to question the utility of chemoembolization in prolonging survival. In a landmark article published in 1991, Vetter<sup>92</sup> reported a case-control study comparing chemoembolization to supportive care, which clearly demonstrated the superiority of chemoembolization over supportive care. Survival at 1 and 2 years was 59% and 30%, respectively, in the treatment arm, whereas it was 0% at 1 year in the supportive care group. Another study by Bartolozzi et al.<sup>93</sup> confirmed the survival benefits of chemoembolization in a group of 53 patients with 93%, 70%, and 43% overall survival rate at 1, 2, and 3 years, respectively. Ngan et al.<sup>6c</sup> measured survival as a function of tumor size and found that patients with tumor less than 9 cm had a better survival than those with tumor greater than 9 cm. Overall survival at 1 and 4 years was 67% and 31%, respectively. Solomon et al.<sup>58</sup> focused on the effectiveness of chemoembolization in an exclusively Western population and found cumulative survival of 60% at 1 year, 41% at 2 years, and 16% at 3 years similar to that obtained by studies in Asian populations.

Despite the impact of these studies, the search is still on for one or more specific niches that would help to establish chemoembolization as an uncontested treatment option for hepatoma. For example, the issue of high recurrence after liver transplantation or surgical resection is perplexing, and adequate therapy against such recurrence is lacking. Recent studies<sup>94,95,96 and 97</sup> exploring the role of chemoembolization as a neoadjuvant treatment modality have shown markedly improved disease-free survival when chemoembolization was performed before surgery. Patients treated with chemoembolization before surgical resection had survival rates of 87%, 70%, and 39%, at 1, 3, and 5 years, respectively, whereas patients treated with surgical resection alone had survival rates of 79%, 38%, and 19%. Disease-free survival was also better in the chemoembolization than in the surgery-only group (40% and 28% vs. 20% and 11% at 3 and 5 years, respectively). When chemoembolization was used before liver transplantation, the 1- and 2-year disease-free survival rates were 91% and 84%, respectively.<sup>98</sup> Survival was also significantly improved when chemoembolization was used to treat intrahepatic tumor recurrence that had occurred postoperatively ( [Fig. 27.4-4](#), [Fig. 27.4-5](#) ).<sup>99</sup> The 1-, 3-, and 5-year survivals were 75%, 46%, and 30%, respectively, as opposed to 20%, 4%, and 0% when no chemoembolization was administered.<sup>99</sup>

**FIGURE 27.4-4.** Transhepatic arterial chemoembolization in a patient with recurrence of hepatocellular carcinoma in the left lobe of the liver 1 year after wedge resection of a solitary hepatocellular carcinoma in the right lobe of the liver. **A:** Two low-density nodules are clearly identified within the left lobe of the liver, consistent with recurrent hepatoma. **B:** Arterial phase from a celiac arteriogram demonstrates hypervascular tumor foci within the left lobe of the liver ( *arrows* ) consistent with the computed tomography findings.

**FIGURE 27.4-5.** Computed tomography scan of the abdomen without contrast 1 day after chemoembolization in the patient from [Figure 27.4-4](#). Excellent distribution of the chemoembolization material throughout the two tumor nodules ( *arrows* ).

Patients with hepatoma experience a wide spectrum of diseases directly related to the extent of tumor involvement and preexisting nonneoplastic liver disease. There is no doubt that outcome and survival are primarily directly related to these factors, regardless of whether treatment is administered and regardless of the form of therapy selected.<sup>100</sup> However, the available data published to date have clearly helped to define a role for chemoembolization as an effective adjuvant therapy either

preoperatively or postoperatively and establish its efficacy as a palliative therapy against unresectable hepatocellular carcinoma.

No controversies exist about the use of chemoembolization in the treatment of metastatic neuroendocrine tumors, such as carcinoid and islet cell tumors, with survival ranges from 27 to 48 months from the time of therapy.<sup>101,102,103,104</sup> and <sup>105</sup> These tumors are usually hypervascular, thus making them ideal candidates for treatment with chemoembolization; and, unlike patients with hepatoma, patients affected by neuroendocrine tumors are frequently symptomatic. The goal of therapy is clear and consists of alleviating symptoms (pain, anorexia, early satiety) related both to hormonal release and the tumor bulk itself resulting from intrahepatic involvement. Multiple studies by Therasse,<sup>62</sup> Winkelbauer,<sup>101</sup> Mavligit,<sup>102</sup> Stokes,<sup>103</sup> and Perry<sup>104</sup> have clearly demonstrated the effectiveness of chemoembolization against such tumors. Therasse and Stokes reported a 100% symptomatic response, which lasted for an average of 28 months, and a 90% decrease in hormonal levels after treatment with chemoembolization. Although earlier reports with embolization alone demonstrated high response rates, symptom-free intervals of 5 to 10 months achieved with embolization do not compare favorably with chemoembolization.

The role of chemoembolization in the treatment of colorectal liver metastases is still under investigation at several centers in the United States, and published studies remain sparse. Colorectal carcinoma is especially lethal once it has metastasized to the liver. Indeed, median survival is only 6 months after the diagnosis of hepatic metastasis is made.<sup>61</sup> Systemic chemotherapy with 5-fluorouracil or combination regimens have produced mediocre response rates rarely exceeding the 20% range and have caused significant systemic toxicity.<sup>61</sup> Hepatic artery infusion of chemotherapy with either 5-fluorouracil or 5-fluorodeoxyuridine has been shown to improve response rates to 45%.<sup>61</sup> However, despite encouraging response rates, seven separate randomized phase III studies failed to show survival benefit. Chemoembolization has, therefore, become a sort of last-resort therapy for patients who have liver-dominant disease and have failed to respond to systemic chemotherapy. Enrolling patients with such a deadly disease into clinical trials to demonstrate the worth of chemoembolization is, thus, understandably difficult. Tellez et al.<sup>106</sup> conducted a phase II clinical trial in which 30 patients with colorectal metastases to the liver were treated with chemoembolization. Median survival was 9 months after the initiation of chemoembolization and 29 months after the initial diagnosis of liver metastasis was made. In the largest study to date involving 52 patients, Daniels et al.<sup>107</sup> reported a 78% response rate using biologic criteria (decrease in carcinoembryonic antigen) accompanied by median survival of 11 months from the time of treatment. Despite evidence of promising response rates with chemoembolization, the survival benefit of the procedure is still in question. Only well-designed randomized clinical trials comparing chemoembolization to systemic chemotherapy can answer this question. Such a multicenter trial is now under way in the United States.

### **Percutaneous Ethanol Injection**

Since 1983, when it was first described,<sup>108</sup> percutaneous ethanol injection has been used primarily against unresectable hepatoma<sup>109,110,111,112,113,114,115,116,117,118,119,120</sup> and <sup>121</sup> and occasionally against colorectal metastases.<sup>111,122,123</sup> Ethanol diffuses into the tumor cells, where it causes cellular dehydration and induces coagulative necrosis.<sup>108,109</sup> and <sup>110</sup> Ethanol is more effective against hepatoma lesions because they are usually softer than colorectal lesions, thus allowing greater diffusion of the ethanol throughout the tumor.<sup>109,110</sup> Although no specific limitations to the size or number of lesions exists, percutaneous ethanol injection is most effective against tumors measuring less than 3 cm in diameter<sup>109,110,111,112,113,114,115,116,117,118,119,120</sup> and <sup>121</sup> in patients with three or fewer lesions.<sup>113,114,116</sup> The presence of multifocal or diffuse hepatoma, extrahepatic metastases, or severe coagulopathy constitutes absolute contraindications to treatment with percutaneous ethanol.<sup>109,110,111,112,113,114,115,116,117,118,119,120</sup> and <sup>121</sup>

The procedure is usually performed under ultrasonography or CT guidance. A 20- to 22-gauge needle is inserted directly into the tumor, and tumor volume (estimated from the formula on the volume of a sphere) is then calculated to determine the exact amount of ethanol required ( Fig. 27.4-6). Once adequate needle placement is confirmed, sterile 95% absolute ethanol is slowly infused. The total volume of ethanol to be injected is determined by the size of the tumor.<sup>124</sup> Volumes of 30 to 40 ml are usually required for tumors greater than 3 cm.<sup>111,125,126</sup> As ethanol diffuses throughout the tumor, the tumor becomes hyperechoic on ultrasonography owing to the presence of microbubbles within the ethanol. Nontarget injection into blood vessels or biliary ducts must be avoided. The procedure can be performed over multiple sessions if necessary, depending on the size of the tumor and the number of lesions to treat. Typically, 4 to 12 sessions are required to treat solitary lesions measuring less than 5 cm. Because the procedure is minimally invasive and highly specific to the tumor, the normal liver is usually preserved. These features render percutaneous ethanol injection especially attractive in the setting of advanced liver disease. Postprocedure imaging and tumor markers should be obtained at 1 month and then every 4 to 6 months to assess tumor response and potential recurrence. Side effects from the procedure, such as localized pain at the injection site, fever, and alcohol intoxication, are highly variable and can usually be managed conservatively.<sup>109,112,121</sup> Pleural effusion and intraperitoneal hemorrhage are the most commonly reported serious complications but are still very uncommon. In fact, the incidence of severe complications remains less than 2%.<sup>109,111,121</sup>

**FIGURE 27.4-6.** Percutaneous ethanol injection into liver tumor. (Courtesy of Matrix Pharmaceutical, Inc., Fremont, CA.)

Large series mostly from Japan and Italy (where percutaneous ethanol injection is most commonly used) have demonstrated that percutaneous ethanol injection can be very effective against hepatoma.<sup>109,110,111,112,113,114,115,116,117,118,119,120,121,122,123,124,125</sup> and <sup>126</sup> These studies have also helped to establish clear prognostic factors, such as the number of lesions, tumor size, and the degree of underlying liver disease that have a direct impact on long-term survival rates. In the largest series to date (746 patients) published by Livraghi et al.,<sup>109</sup> survival at 1, 3, and 5 years was 99%, 86%, and 48%, respectively, in patients with a solitary lesion measuring less than 5 cm and minimal underlying liver disease. On the other hand, survival in patients with larger tumors and more severe underlying liver disease fell sharply to 64% at 1 year, 12% at 2 years, and 0 thereafter. Ishii et al.<sup>127</sup> reported similar results in 177 patients with 348 lesions measuring less than 4 cm. Survival rates were 97%, 71%, and 30% at 1, 3, and 5 years, respectively. Another factor that influences survival is the AFP level. Lencioni et al.<sup>128</sup> found long-term survival to be inversely proportional to the initial AFP levels. Percutaneous ethanol injection is, therefore, most potent and effective when used against solitary and small lesions (<3 cm) rather than multiple and large lesions. In addition, patients with the least underlying liver disease fare best in terms of long-term survival.<sup>109,110,111,112,113,114,115,116,117,118,119,120,121,122,123,124,125,126,127</sup> and <sup>128</sup>

When comparison between percutaneous ethanol injection and supportive care or surgery was made, survival rates achieved with percutaneous ethanol injection were found to be markedly better than those obtained with supportive care and nearly equal to those obtained at surgery. These studies, although retrospective and thus not randomized, attempted to closely match patients between groups based on tumor size, number of lesions, and underlying liver condition. For example, Livraghi et al.<sup>129</sup> found no significant difference in 3-year survival between ethanol injection (79%) and surgical resection (71%) in 391 patients who all had a solitary lesion measuring less than 5 cm. Similar results were reported by Castells et al.<sup>120</sup> who compared clinical outcomes between surgery and ethanol injection in 63 patients with solitary lesions measuring up to 4 cm. Patients treated with ethanol injection had overall survival rates at 1 and 4 years (83% and 34%) nearly equal to those treated with surgical resection (81% and 44%). The high rate of recurrence, which typically varies between 64% and 98% within a 5-year period and is actually similar to recurrence rate after surgery, constitutes a nagging problem.<sup>109,130,131</sup> and <sup>132</sup> However, when recurrence does occur, these tumors can be treated repeatedly with ethanol injection (unlike surgery) without damaging liver functions.

The effects of percutaneous ethanol injection and chemoembolization on liver tumors can be synergistically enhanced when the two techniques are combined. Several recent reports have demonstrated the efficacy and potential benefits of such tandem therapy. In a study by Lencioni et al.,<sup>133</sup> 86 patients with mild cirrhosis and a large hepatoma (3 to 8 cm in diameter) were treated with a single cycle of chemoembolization followed by percutaneous ethanol injection. Survival rates were 92% at 1 year, 70% at 3 years, and 47% at 5 years. Tanaka et al.<sup>134</sup> reported 100% and 75% survivals at 3 and 5 years, respectively, in patients with a 3- to 5-cm

solitary hepatoma lesion and minimal cirrhosis. Finally, Allgaier et al.<sup>68</sup> compared percutaneous ethanol alone to combined administration of ethanol and chemoembolization and found that patients treated with both therapies had significantly better outcome than those treated with ethanol alone.

Percutaneous ethanol injection has been much less successful against colorectal metastases, and its role in managing these lesions remains, therefore, limited. Recent studies showed that ethanol achieved only 50% necrosis, presumably because of the hard nature of colorectal metastases, which limits the diffusion of ethanol throughout the tumor.<sup>122,123</sup> The impact of ethanol therapy on survival was also somewhat disappointing, as 3-year survival only reached 39%.<sup>122,123</sup>

### **Percutaneous Radiofrequency Ablation**

Radiofrequency ablation, used percutaneously or intraoperatively, offers an alternative method of local tissue destruction by coagulative necrosis. This technique causes frictional heat within the tissue. When the temperature reaches 41°C, a cytotoxic effect is produced, but when the temperature reaches 90°C, immediate coagulative necrosis takes place.<sup>135</sup> The monopolar design of the radiofrequency probe, which could deliver heat only to a small area and, thus, severely restricted the area of tissue destruction, constituted an early limitation of this technique.<sup>136,137</sup> Since then, the design of the probe has been changed to a multipolar one, and extensive research in animals has also been performed to maximize the destructive effects of the probe and increase the volume of tissue necrosis. However, problems inherent to the properties of radiofrequency ablation persist, such as the influence of nearby vessels on heat generation (large vessels can act as a heat sink and prevent the generation of enough heat to destroy the tumor) as well as the creation of excessive heat, which can cause tumor charring.

The procedure is usually performed under ultrasonography or CT guidance ( Fig. 27.4-7A), and the technical steps are similar to those used for percutaneous ethanol injection. The radiofrequency needle, which generally varies between a 15- and 18-gauge needle, is inserted into the tumor (see Fig. 27.4-7B, Fig. 27.4-7C). Once within the lesion, multiple electrodes are deployed, and the generator is activated to reach a temperature of 90° to 110°C. Treatment may last up to 15 minutes. The probe can then be moved to a different region of the tumor before further activation of the radiofrequency probe. Complications are rare and, despite a few reported cases of peritoneal hemorrhage, pleural effusion, and fever, the procedure is generally well tolerated.<sup>138,139</sup> and <sup>140</sup> Follow-up imaging is similar to that of percutaneous ethanol injection (1 month after procedure and 3 to 4 months thereafter).

**FIGURE 27.4-7.** Radiofrequency ablation in a patient with a solitary hepatocellular carcinoma. **A:** Computed tomography scan of the abdomen demonstrates a low-density lesion located in the posterior segment of the right lobe. **B:** Illustration of the radiofrequency probe being advanced into the tumor. **C:** Radiograph of the patient in (**A**), with the probe deployed within the tumor.

Since radiofrequency ablation is a relatively new technique—its use in patients was first described by Rossi<sup>136</sup> in 1993—its impact on long-term survival has not yet been assessed. However, several recent studies have shown promising results. Solbiati et al.<sup>139</sup> treated 16 patients with liver metastases of various sizes. Near complete necrosis (80%) was achieved in 84% of lesions, 2-year survival reached 66%, and lesions measuring less than 3 cm responded best to treatment. Livraghi et al.<sup>138</sup> compared percutaneous ethanol injection to radiofrequency ablation in 86 patients with 122 small (3 cm) hepatomas. Radiofrequency ablation achieved a greater rate of necrosis (90%) and required fewer treatment sessions (1.2 sessions) than percutaneous ethanol injection (80% necrosis and 4.8 sessions). In addition, these preliminary studies suggest a lower recurrence rate than with percutaneous ethanol injection. In a recent article, Curley et al.<sup>141</sup> used intraoperative radiofrequency ablation to treat primary and metastatic liver lesions and reported the lowest recurrence rate (1.8%) for any sizable clinical series using radiofrequency ablative technique. Such results have yet to be duplicated. Although the data remain scarce and its impact on survival is undetermined, radiofrequency ablation may have a role to play against small primary or metastatic lesions.

### **Other Techniques**

A number of other methods are currently under investigation. These techniques are performed percutaneously and consist of delivering thermal energy via various sources into tumor tissue. They include percutaneous hot saline injection, interstitial laser photocoagulation, percutaneous microwave coagulation, and high-intensity focused ultrasonography. None has shown great promise over the other currently available therapeutic options used to treat liver cancer.

Another method, consisting of direct injection of cisplatin gel into the tumor, offers a radically new approach to the treatment of liver cancer. The injectable gel is actually composed of cisplatin, epinephrine, and a protein carrier matrix, which confers unique diffusion properties to the mixture. The gel is injected percutaneously into the tumor under ultrasonographic or CT guidance and can be used for tumors measuring up to 7 cm in diameter ( Fig. 27.4-8). This treatment is currently undergoing a multicenter phase II clinical trial to assess its efficacy against hepatoma in the United States, Europe, and Asia. Early results are promising both in terms of tumor necrosis and impact on survival.<sup>142</sup>

## **CANCERS OF THE BILIARY TRACT AND PANCREAS**

Cancers of the biliary tract, which include gallbladder and bile duct carcinoma or cholangiocarcinoma, are the second most common primary hepatobiliary cancers after hepatocellular carcinoma.<sup>143</sup> Cholangiocarcinoma is more common in men, whereas gallbladder carcinoma is seen more frequently in women.<sup>144</sup> These differences can be explained by the higher incidence of sclerosing cholangitis in men and gallstones in women, which are well-known risk factors for cholangiocarcinoma and gallbladder carcinoma, respectively.<sup>144</sup> Although gallbladder carcinoma is encountered twice as frequently as cholangiocarcinoma (7500 vs. 2000 to 3000 new cases per year), most patients requiring interventional radiology procedures experience cholangiocarcinoma.<sup>143</sup>

Cholangiocarcinoma is a slow-growing tumor with a peak incidence in the sixth and seventh decades. The tumor is notorious for invading the liver parenchyma as well as hepatic arteries and portal venous system, which renders surgical resection especially difficult.<sup>145</sup> As a result of its infiltrating growth pattern within the biliary ductal system,<sup>146,147</sup> and <sup>148</sup> patients with cholangiocarcinoma usually present with symptoms (jaundice, pruritus, and color-altered stools and urine) caused by obstruction of the biliary tree.<sup>149,150</sup> When the tumor involves the common hepatic duct, the common bile duct, or the ampulla, symptoms will occur early in the course of the disease. On the other hand, when the tumor involves the perihilar region, which is the most common area of tumor involvement (approximately two-thirds of the cases), the occurrence of symptoms may be delayed significantly. Other symptoms, such as pain, fatigue, general malaise, and weight loss, are typically seen in advanced disease. Surgical resection is the only therapeutic option associated with improved survival in patients with cholangiocarcinoma. Systemic chemotherapy and external-beam radiotherapy have not significantly improved survival or quality of life.<sup>151</sup> Therefore, palliative therapy plays a critical role in the management of patients who are not surgical candidates.

Carcinoma of the exocrine pancreas carries a dismal prognosis, with median survival from time of diagnosis approaching 6 months.<sup>152</sup> There are no curative treatments, and even surgery, which can be performed only in 10% to 20% of patients with pancreatic carcinoma, does not appear to increase survival.<sup>152</sup> Thus, as for cholangiocarcinoma, the need for effective palliation is critical.

The diagnosis of cholangiocarcinoma or pancreatic carcinoma is usually established by cross-sectional imaging (ultrasonography and CT scanning). Diagnostic visceral angiography and cholangiography are reserved for determining tumor resectability. Depending on the location of the tumor, cholangiography can be performed from a percutaneous transhepatic or an endoscopic approach. The cholangiographic appearance of cholangiocarcinoma is again directly related to the infiltrating-scirrhous nature of its growth pattern.<sup>146,147</sup> and <sup>148,153</sup> Thus, cholangiocarcinoma generally presents as a focal stricture, often without a mass,<sup>153</sup> which may mimic sclerosing cholangitis if tumor involvement is diffuse (Fig. 27.4-9).<sup>146</sup> The cholangiographic appearance of pancreatic carcinoma is similar to that of cholangiocarcinoma with a short and irregular stricture, resembling a rat tail, causing massive biliary ductal dilatation (Fig. 27.4-10).<sup>154</sup> Access into the biliary tree also provides an avenue for collection of biopsy samples, which can be extremely useful to differentiate benign from malignant disease. This diagnostic technique is especially useful to distinguish biliary ductal strictures caused by pancreatic carcinoma from those due to pancreatitis.<sup>42</sup> However, in the case of bile duct tumors, establishing a definitive diagnosis of cholangiocarcinoma can be difficult owing to the intense desmoplastic reaction that the tumor generates.<sup>155,156</sup> The use of brush biopsies and cytologic examination has increased the diagnostic yield to approximately 40% to 70%.<sup>42,155,156</sup>

**FIGURE 27.4-9.** Percutaneous transhepatic cholangiogram in a patient with diffuse cholangiocarcinoma resembling the appearance of sclerosing cholangitis. **A:** Initial cholangiogram. **B:** Magnified view of the biliary system as the guidewire is being advanced into the biliary tree to secure access.

**FIGURE 27.4-10.** Percutaneous transhepatic cholangiogram in a patient with pancreatic adenocarcinoma. **A:** Complete obstruction of the common hepatic duct (arrow). An internal-external biliary stent has been successfully placed across the obstruction. **B:** Magnification view of the common hepatic duct as the guidewire is being manipulated across the stricture. Note the occluded endoscopically placed plastic stent (arrow).

The goal of palliative therapy is to relieve the symptoms associated with biliary tract obstruction. This can be accomplished via endoscopic placement of plastic stents or via percutaneous transhepatic placement of internal-external biliary drains or metallic stents. Given the less invasive nature of endoscopic techniques, endoscopic stent placement is preferred as the first line of therapy, especially when the tumor involves the extrahepatic biliary tree, and is successful in 80% to 90% of the cases.<sup>151,157,158</sup> However, it is usual for these endoscopic stents to become occluded fairly quickly after placement, thus requiring frequent stent replacement (approximately every 3 months).

Percutaneous transhepatic biliary drainage is the procedure of choice in cases of unsuccessful endoscopic stent placement, prior biliary-enteric surgical reconstruction, or high level of biliary obstruction (i.e., above the confluence of the ductal systems). In some centers, such as the Johns Hopkins Hospital, percutaneous biliary drainage is also routinely performed preoperatively to facilitate surgical reconstruction of the biliary tract.<sup>159,160,161,162</sup> and <sup>163</sup> Indeed, these biliary drainage catheters aid in the creation of biliary-enteric anastomoses by providing anatomic landmarks of the intra- and extrahepatic biliary ducts during surgery, which can be particularly helpful in patients with extensive tumor involvement. Several studies have shown that preoperative percutaneous biliary drainage reduces operative time as well as operative morbidity and mortality.<sup>159,160,161,162</sup> and <sup>163</sup> One of the critical benefits offered by percutaneous biliary drainage remains the possibility of rapid intervention to decompress the biliary tree (Fig. 27.4-11). The procedure can even be life-saving in cases of acute cholangitis or biliary sepsis. Reestablishment of bile flow usually causes rapid recovery of hepatic function, with decrease in liver enzymes, which in turn leads to relief in patient's symptomatology and improvement in overall health of the patient.<sup>164</sup> Percutaneous biliary drainage can also relieve obstruction in patients with occluded endoscopically placed plastic stents. These stents either can be removed percutaneously (snare technique) (Fig. 27.4-12) or can be pushed into the small bowel (Fig. 27.4-13A). Once access into the biliary tree is secured, either internal-external biliary stents or permanent self-expanding metallic internal stents (see Fig. 27.4-13B) can be placed to maintain biliary-enteric flow.<sup>151</sup>

**FIGURE 27.4-11.** Percutaneous transhepatic biliary drainage performed emergently secondary to biliary sepsis. **A:** Initial cholangiogram demonstrates complete obstruction of the biliary tree due to cholangiocarcinoma located at the confluence of the hepatic ducts (Klatskin tumor) ( *arrow*). **B:** Successful biliary drainage across the obstruction. The patient improved clinically.

**FIGURE 27.4-12.** Percutaneous transhepatic cholangiogram in a patient with pancreatic adenocarcinoma. **A:** Initial cholangiogram demonstrates complete obstruction of the biliary tree. The endostent placed endoscopically is occluded ( *arrow*). **B:** Using a snare (*arrow*), the endostent is removed percutaneously ( *arrow*).

**FIGURE 27.4-13.** Placement of a permanent metallic self-expanding biliary stent (Wallstent) in a patient with pancreatic adenocarcinoma. The tumor was found to be unresectable, and the decision was made, therefore, to place a metallic stent. **A:** Successful percutaneous biliary drainage demonstrating the classic appearance of pancreatic adenocarcinoma. **B:** Successful permanent stent placement. Note that the endoscopic stent was pushed into the small bowel ( *arrow*).

Internal-external biliary stents are preferred if surgical resection or debulking of the tumor is contemplated, because they provide immediate access to the surgical site for evaluation of possible complications during the perioperative period and prevent stricture formation at the biliary-enteric anastomosis, which can occur during the late postoperative period. Internal-external biliary stents offer several other advantages, such as allowing for the careful monitoring at the surgical site for possible tumor recurrence in those patients who underwent curative surgery and the exchange of stents when they become occluded. In fact, patients with internal-external stents generally have to undergo routine biliary tube changes every 2 to 3 months to maintain biliary-enteric flow and prevent biliary sepsis. On the other hand, placement of permanent metallic stents is recommended for patients with a limited life expectancy and for whom no surgical options exist.<sup>165</sup> Debilitated or nursing-home patients who cannot care for their internal-external biliary tubes should also be treated with permanent stents if at all possible. These patients usually experience marked improvement in their quality of life owing to the absence of external tubes and their associated risk of skin infection, pericatheter bile leakage, and catheter obstruction or dislodgment. Metallic stents can be deployed atraumatically, since they go through small delivery systems. Once released from the guiding catheter, they self-expand to reach a diameter approximately three times that of plastic stents. Thus, with their larger diameter and inherent radial expansile force, metallic self-expanding stents are favored over endoscopic plastic stents because they tend to stay open longer than endoscopic stents (see [Fig. 27.4-13B](#)). Several series by Boguth et al.,<sup>166</sup> Schima et al.,<sup>165</sup> and others have reported patency rates for metallic stents of approximately 6 months.<sup>165,166,167,168</sup> and <sup>169</sup> In addition, metallic stents are very flexible, rendering them especially well suited for tortuous courses. This is particularly useful when the tumor involves the confluence of hepatic ducts (Klatskin tumor). In such cases, massive dilatation of both the right and left intrahepatic bile ducts occurs, and bilateral access into the biliary tree is necessary to properly relieve the obstruction. Effective palliation with internal stents can then be provided only by self-expanding, flexible stents deployed from above the level of obstruction and extending into the common hepatic duct.<sup>165,166,167,168</sup> and <sup>169</sup>

Patients scheduled to undergo percutaneous biliary drainage should receive prophylactic broad-spectrum antibiotic coverage, and any coagulopathy should be corrected. Percutaneous transhepatic cholangiography is first performed via a 22-gauge needle inserted from a right midaxillary line. Contrast opacification of the biliary tree provides invaluable information about the nature, location, and extent of the obstructing tumor. After having successfully delineated the anatomy of the biliary tree, a duct within the right posterior ductal system is selected based on its position and course relative to the location of the tumor and accessed using a slightly larger needle (21-gauge). A guidewire is then advanced through the needle into the biliary tree to secure access into the biliary system. Steerable guidewires are then used to cross the obstruction and, thus, gain access into the duodenum. To maintain adequate biliary-enteric flow, a multi-side-hole catheter is placed across the obstruction, with side holes above and below the obstruction. The tube is typically left to external drainage for 12 to 24 hours before it is capped and functions as an internal drainage catheter. Two major types of biliary drainage catheters are available, a plastic (Percuflex), somewhat stiffer catheter, which is necessary for initial placement, or a softer, silastic catheter, which is much more comfortable for the patient and is generally favored if long-term intubation is required. If access into the duodenum cannot be achieved, the biliary tube must be connected to a drainage bag indefinitely, and oral bile salt replacement must be initiated.

Percutaneous transhepatic biliary drainage performed for palliation is markedly safer than surgical decompression. The mortality rate associated with biliary drainage varies between 0.5% and 3%, as opposed to 20% to 30% for surgery.<sup>170,171,172</sup> and <sup>173</sup> However, the complication rate is not insignificant, since it ranges from 5% to 25%. The most common complications include tube occlusion, tube dislodgment, cholangitis-sepsis, hemobilia, and pseudoaneurysm. Biliary tubes become occluded because of continued tumor growth, blood clots, or bile. As a result, biliary ductal dilatation ensues, leading to bile stasis and cholangitis or sepsis. This process, which has been reported to occur in 23% of cases, constitutes the major indication for performing biliary tube exchange.

## GENITOURINARY TRACT TUMORS

Obstruction of the urinary tract is a common urologic problem that requires prompt intervention to avoid permanent damage to the kidney.<sup>174,175,176,177</sup> and <sup>178</sup> Renal obstruction may be caused by the tumor itself (transitional cell carcinoma), blood clots, fungal infection, fibrotic changes that can occur after radiotherapy,

retroperitoneal fibrosis (Fig. 27.4-14), or extrinsic compression due to either enlarged lymph nodes or a tumor mass, such as lymphoma. In these instances, percutaneous interventional techniques play a significant role to alleviate some of the symptoms and, more important, relieve the obstruction. In fact, percutaneous drainage of the kidney or percutaneous nephrostomy is the treatment of choice for malignant obstruction of the urinary tract and has completely replaced surgical nephrostomy.<sup>174,175,176,177 and 178</sup> The diagnosis of obstruction, which can be somewhat challenging to establish, is usually made with CT scanning or ultrasonography. Cross-sectional imaging studies also provide information about the level of obstruction, the anatomy of the retroperitoneal space, and whether the obstruction is unilateral or bilateral.<sup>174,175,176,177 and 178</sup>

**FIGURE 27.4-14.** Successful percutaneous nephrostomy in a patient with retroperitoneal fibrosis. The antegrade nephrostogram demonstrates complete obstruction at the level of the proximal ureter.

There are no absolute contraindications to percutaneous nephrostomy other than noncorrectable coagulopathy. Prophylactic antibiotic therapy should be administered before the procedure and continued for at least 24 hours after the procedure. However, in cases of known pyonephrosis or urinary sepsis, antibiotic therapy should be continued for 5 to 7 days. Whether performed under CT, ultrasonography, or fluoroscopy guidance, the goal of the procedure remains the same and consists of gaining access into the renal collecting system via a posterior calyx. Entering the kidney via the posterior calyx is critical to avoid major bleeding complications, since the posterior calyx is less well vascularized than the other calyces. Once the needle is placed within the posterior calyx, an antegrade nephrostogram is performed to define the nature of the obstructing lesion and determine the precise level and extent of the obstruction or stricture. A small-caliber guidewire is then inserted through the needle to secure access into the renal collecting system. Eventually, after successive dilatation of the tract, a pigtail-type nephrostomy catheter is placed and locked into position within the renal pelvis. Initially, a small catheter (8 to 10 Fr.) is typically placed, but it can be safely up-sized to a larger caliber catheter (up to 16 Fr.) if necessary. The nephrostomy catheter usually requires minimal care and drains the urine directly into an external drainage bag, which should be emptied three to six times per day, depending on urine output. Since nephrostomy catheters provide adequate urinary decompression, they can be used indefinitely in chronically obstructed patients without damaging the kidney or altering renal function (see Fig. 27.4-14). However, conversion to a nephroureteral stent, which extends from the renal pelvis through the ureter into the bladder, is desirable and should be attempted whenever possible. The main advantage of nephroureteral stents is that they can function as an internal-external system similar to that described in the biliary system and, therefore, do not require an external bag. These stents can be used only if the obstruction is successfully crossed and require a functioning bladder or reconstructed bladder, such as an ileal loop.<sup>179</sup> The main portion of the stent is located within the patient, and the small portion of catheter residing outside the patient is usually capped off. Multiple side holes exist throughout the entire length of the catheter, allowing urine to bypass the obstruction and collect in the bladder. If fever or flank pain develops, it usually indicates stent occlusion. In such cases, the stent can first be externalized (by attaching a drainage bag) to relieve the symptoms prior to exchanging it for a new one. Common indications for the placement of nephroureteral stents include (1) ureteral strictures, which may develop after pelvic or retroperitoneal surgery or radiotherapy or at the anastomosis after creation of a neobladder and ureteral reimplantation; (2) ureteral fistulae; (3) healing of ureteral injuries postoperatively or after radiotherapy; and (4) reestablishment of urine flow from kidney to bladder in patients with urinary tract obstruction scheduled for definitive surgical repair.<sup>179,180</sup>

Internal-external nephroureteral stents can also be converted to internal double-J nephroureteral stents. These internal stents can be placed from a percutaneous approach via the kidney or from a cystoscopic approach. They offer the advantage of being entirely within the patient, thus relieving the patient of any catheter care and reducing the risk of local or systemic infection. On the other hand, when occluded, they are much more difficult to exchange than internal-external stents. Placement of double-J stents is mostly indicated when long-term drainage of the urinary system is required, such as patients with unresectable malignant urinary tract obstruction, or ureteral injury from surgery or radiotherapy. Internal stents should also be used when patients cannot tolerate or care for them.

Percutaneous nephrostomy is performed successfully in 85% to 98% of the cases and is generally well tolerated, with an incidence of major complications ranging from 4% to 6%. The mortality rate is low (0.2%) as opposed to that of surgical nephrostomy (6%). The most common complications are due to massive hemorrhage requiring surgical treatment or transcatheter embolotherapy (1%), pneumothorax (1%), and peritonitis.<sup>174,175,176,177 and 178</sup> Minor complications occur in 10% to 28% of the cases and include microscopic or gross hematuria, which usually clears within 24 to 48 hours, unsuspected retroperitoneal or perirenal hematoma, extravasation of urine (<2%), and infection (1.4% to 21%). Infection can be caused by inadequate drainage due to occlusion of the catheter secondary to encrustations or a preexisting urinary tract infection. Flushing the catheter routinely with normal saline solution is useful in preventing catheter occlusion. Finally, if the catheter becomes dislodged, the track should stay open for 72 hours, thus allowing successful reaccess into the renal collecting system.

## SUPERIOR VENA CAVA SYNDROME

Venous thrombosis or occlusion is not an uncommon occurrence in cancer patients. It may be due to direct tumor involvement, extrinsic compression by tumor, or lymphadenopathy, fibrosis secondary to radiotherapy, or long-term indwelling central venous catheters, which are often needed for systemic chemotherapy or nutritional support.<sup>181,182,183,184 and 185</sup> The central veins, such as the subclavian, innominate, SVC, and IVC, are most commonly affected. The severity of symptoms is directly related to the degree of venous obstruction. In the SVC syndrome, most often caused by lung carcinoma with extension into the mediastinum, symptoms are often dramatic. Patients typically present with swelling of the face and neck as well as dilated collateral venous channels readily visible coursing throughout the upper thorax.<sup>181,182,183,184 and 185</sup> If the degree of obstruction is severe, additional symptoms may be encountered, such as respiratory distress, edema of the conjunctiva, and neurologic disturbances.<sup>181,182,183,184 and 185</sup> Radiotherapy is the treatment of choice for SVC syndrome, and most patients respond well to therapy.<sup>186</sup> However, when radiotherapy is unsuccessful (failure to clear symptoms, recurrence of symptoms, or presence of benign postirradiation fibrotic changes), percutaneous venous interventions, such as percutaneous transluminal angioplasty or stenting, become the treatment of last resort.<sup>186,187</sup> A diagnostic study, such as central venogram or magnetic resonance venography should first be performed to delineate the extent of the thrombosed or stenosed segment of SVC (Fig. 27.4-15A). If concurrent thrombosis of the SVC is present, catheter-directed thrombolytic therapy can be used to reduce the clot burden and allow for better evaluation of the unmasked underlying stenosis. Once the stenosis is successfully crossed, angioplasty of the stenosis is usually first performed (see Fig. 27.4-15B). Although some success has been reported with angioplasty alone,<sup>188,189</sup> the recurrence or failure rate after percutaneous transluminal angioplasty is quite high because of the elastic recoil that takes place secondary to the compressing tumor or fibrosis. Therefore, stenting has become the most reliable method of establishing venous continuity. Two types of stent, a self-expandable and a balloon expandable, exist for this purpose. Because of its expansile radial force, the self-expandable stent is more commonly used (Fig. 27.4-16). Improvement in patients' symptomatology may be dramatic and usually occurs within 24 hours of therapy, with complete resolution taking place within 3 days.<sup>184,186,187,190,191 and 192</sup> Complications include stent migration or thrombosis and vessel injury or perforation during placement.

**FIGURE 27.4-15.** Superior vena cava syndrome. **A:** Multiple filling defects are visualized within the superior vena cava consistent with metastatic implants from lung carcinoma. The patient was symptomatic, with extensive venous collateral channels identified throughout the torso. **B:** Initial angioplasty is performed to open a channel.

**FIGURE 27.4-16.** Superior vena cava syndrome treated with a self-expanding stent (Wallstent). **A:** Venogram performed before stent placement. **B:** After stent placement, venogram demonstrates torrential flow across the obstruction into the right atrium. Symptoms resolved within hours.

Although the technical success rate approaches 100%, long-term results are difficult to evaluate since many of these patients have advanced malignant disease and a limited life expectancy. Percutaneous venous stenting should, therefore, be regarded as a palliative therapy and a successful outcome viewed as a patent SVC at the time of death.

### PULMONARY THROMBOEMBOLIC DISEASE AND INFERIOR VENA CAVA FILTERS

The association between venous thrombosis and malignancy has been known for more than a century and is strongest in cancers of the lung, breast, pancreas, colon, stomach, prostate, and uterus.<sup>193,194,195 and 196</sup> When venous thrombosis involves the deep system of the lower extremities, the risk of pulmonary embolism is markedly increased. In fact, the incidence of pulmonary embolism in cancer patients is three times that in the general population.<sup>193,194,195,196 and 197</sup> There are approximately 570,000 to 630,000 cases of pulmonary embolism annually in the United States, nearly one-third of which are fatal events.<sup>198,199</sup> Despite initial management with anticoagulation, a significant number of cancer patients develop recurrent pulmonary thromboemboli. Furthermore, anticoagulation therapy is contraindicated in many cancer patients because of the associated risk of hemorrhage. It is for these reasons that the use of IVC filters, which prevent thrombi from reaching the lungs, is strongly advocated in cancer patients.<sup>197,198,199,200,201,202 and 203</sup>

Multiple IVC filter designs are commercially available, including the Greenfield stainless steel and titanium filters, the Vena-Tech, the Simon Nitinol, and the Bird's Nest. These filters can be deployed from a femoral or internal jugular approach. A venogram is first performed to measure the diameter of the IVC, to determine the location of the renal veins, and to detect the presence of potential thrombus within the IVC. Filters should be placed immediately below the lowermost renal vein, but they can also be placed above the renal veins if thrombus extends to the level of the renal veins. If the diameter of the IVC exceeds 30 mm, the Bird's Nest filter is the only filter that can be placed; otherwise any of the other filters can be used. Each filter has advantages and disadvantages, and selection of a specific filter often depends on the filter availability and experience of the radiologist. Note that the Simon Nitinol filter is the most versatile of the filters since, because of its small delivery system, it can be deployed from virtually any peripheral access site.<sup>204,205</sup>

IVC patency rates vary between 91% and 97% after filter placement. Recurrence of pulmonary embolism occurs in approximately 2% to 4% of the cases. Other complications include filter migration (0% to 30%) and perforation of the IVC (0% to 40%).

#### INTRODUCTION

Advances in radiologic techniques have allowed the radiologist to make significant contributions in the diagnosis and management of cancer patients. The applications of ultrasonography (US) in oncology have rapidly increased in recent years, due to development of new technologies and therapeutic regimens as well as easy availability and noninvasiveness of US.<sup>1,2</sup> This chapter gives an overview of the current role of US in the evaluation of the oncologic patient, with particular emphasis on the sonographic diagnosis, staging, and follow-up of superficial or deep masses and discusses US guidance and techniques for abdominal, thoracic, and superficial interventional procedures.

#### ULTRASONOGRAPHY APPLICATIONS

An evaluation of the diagnostic role of US includes three particular aspects: (1) detection of a mass or lesion, (2) definition of the nature of the lesion, and (3) estimation of the extent of the lesion. Although a large number of organs can be studied by US with good sensitivities, the staging accuracies of US are limited and depend on the site of the organ. Superficial organs (thyroid, parathyroid, breast, testicles) are better evaluated than deep-seated organs. Nevertheless, tumors in the liver, biliary, tree, gallbladder, pancreas and kidney, prostate, and bladder can be detected by US with quite good sensitivities. The results are less favorable in the retroperitoneum and adrenal glands. In deep-seated tumors, US does not provide detailed evaluation of tumor spread, with exception of hepatic hilar node involvement or vascular invasion of the hepatic veins in hepatocellular carcinoma and the renal veins in renal cell carcinoma.<sup>1</sup> US may also play an important role in the follow-up of the oncologic patient in a search for or monitoring of liver metastases as well as for the assessment of response in patients with primary or secondary malignancies treated by intraarterial infusion of cytotoxic drugs. The areas wherein US plays an important role include urologic oncology, gynecologic oncology, medical oncology, and as a guidance modality for interventional diagnostic or therapeutic procedures.

#### UROLOGIC ONCOLOGY

Ultrasound plays a major role in the oncologic workup of tumors of the kidney, bladder, prostate, and seminal vesicles as well as testes.<sup>3,4</sup>

#### KIDNEY

When a renal mass is discovered on an intravenous urogram, further evaluation with US is usually performed. A benign renal cyst has a characteristic US appearance, defined as an echo-free fluid-filled lesion with a thin wall and posterior acoustic enhancement ( [Fig. 27.5-1A](#)). Any doubt about the benign nature of a renal mass or the presence of a complex lesion demands further evaluation with computed tomography (CT) to exclude a renal cell carcinoma (see [Fig. 27.5-1B](#)). Renal lymphoma is usually metastatic or from direct extension from lymphoma in adjacent retroperitoneal lymph nodes. Transitional cell carcinoma arises in the renal pelvis or ureter and presents sonographically as a filling defect in the renal collecting system ( [Fig. 27.5-2](#)). Doppler and color Doppler US (CDUS) are useful to assess renal vein or inferior vena cava invasion (or both) by tumor ( [Fig. 27.5-3](#)).<sup>5</sup>

**FIGURE 27.5-1. A:** Sagittal sonogram of a right renal cyst ( *arrow*). Note the echo-free appearance and smooth wall. **B:** Solid mass arising from the lower pole of the left kidney ( *arrows*), compatible with renal cell carcinoma.

**FIGURE 27.5-2.** Echogenic mass (*arrows*) filling the left renal collecting system, compatible with transitional cell carcinoma.

**FIGURE 27.5-3.** Tumor thrombus (*arrow*) extending into the inferior vena cava in a patient with metastatic leiomyosarcoma to the kidney.

## BLADDER

Transabdominal US permits gross evaluation of the bladder to assess for focal masses. US may have difficulty differentiating a hypertrophied median lobe of the prostate from a bladder mass. Cystoscopy is usually performed in cases of hematuria. Transurethral US may be used for staging of bladder cancers. <sup>5</sup>

## PROSTATE AND SEMINAL VESICLES

Analysis of transrectal ultrasonography as a screening tool for prostate cancer has been disappointing, due to the low specificity of a hypoechoic lesion for cancer. Likewise, sonographic criteria to predict extracapsular extension of disease or spread into the seminal vesicles have not been reliable, with sensitivities of 65% and 33%, respectively, in some series. Transrectal ultrasonography, however, is an excellent tool to detect mimics of cancer on digital rectal examination, such as cysts, calcification, or abscess, as well as a guidance modality for prostate biopsies and staging biopsies into the seminal vesicles. <sup>6,7</sup>

## TESTES

US can detect scrotal masses with an accuracy approaching 100%. The majority of intratesticular masses are malignant, whereas the majority of extratesticular lesions are benign or inflammatory in nature. Testicular tumors account for 1% to 2% of all malignant neoplasms in men and are the most common cancer in 25- to 35-year-olds. The majority of patients present with painless or mildly painful testicular enlargement. Between 90% and 95% of testicular neoplasms are of germ cell origin and include seminomas, embryonal cell cancer, teratomas, choriocarcinomas, or mixed germ cell tumors ([Fig. 27.5-4](#)). Leukemia and lymphoma are the most common metastatic tumors to the testis. Malignant lymphoma is the most common secondary neoplasm and most common testicular tumor in men older than 60 years ([Fig. 27.5-5](#)). Most are non-Hodgkin's lymphomas, and 50% of patients have extension into the spermatic cord. Leukemia is the most common metastatic testicular neoplasm. Leukemic infiltrates are common in children during bone marrow remission. The testis acts as a sanctuary during chemotherapy because of a blood–gonad barrier inhibiting concentration of chemotherapeutic agents. Other metastases to the testicle are prostate, melanoma, lung, kidney, colon, and pancreas. US is also used for the surveillance of contralateral testicles in patients with testicular tumors and to detect masses in patients with retroperitoneal masses of unknown origin. <sup>8,9</sup>

**FIGURE 27.5-4.** Well-defined hypoechoic mass in the left testicle (*arrows*), compatible with seminoma. Note small, bright, echogenic foci of microlithiasis in the remainder of the testicle.

**FIGURE 27.5-5.** Transverse sonogram of both testicles demonstrating heterogeneous enlargement of the left testicle due to infiltration by B-cell lymphoma.

## GYNECOLOGIC ONCOLOGY

### OVARY

Ovarian cancer is the least frequent but the most lethal of the three common gynecologic malignancies. US has played an increasingly important role in the evaluation of the oncologic patient with an ovarian mass. Scoring systems to differentiate between benign and malignant masses have been reported to provide encouraging results in terms of sensitivity and negative predictive values (95% to 100%); however, significant limitations exist in terms of specificity (73% to 83%) and positive predictive values (32% to 46%).<sup>10</sup> The likelihood of malignancy in an ovarian mass increases with size and complexity of the lesion. Simple cysts are almost always benign. The role of US for screening of early ovarian carcinoma needs yet to be defined. Doppler and CDUS endovaginal techniques to assess blood flow parameters are encouraging; however, the role of endovaginal CDUS for the evaluation of ovarian cancer is controversial, with limited sensitivity and specificity of this technique due to overlaps of flow velocity indices in benign and malignant ovarian masses.<sup>10,11</sup> US is useful to assess local or distant spread and detect ascites. In clinical practice, US is most often used to confirm the presence of an adnexal mass, often with characteristics of malignancy.

### ENDOMETRIUM

Endometrial cancer is the most common gynecologic malignancy in the United States. Most patients present with postmenopausal bleeding. On endovaginal US, the endometrium is thickened, inhomogeneous in echotexture, and with irregular hypoechoic areas throughout. Endovaginal US is helpful in staging the degree of myometrial invasion: The presence of an intact subendometrial halo suggests superficial carcinoma without myometrial penetration ( Fig. 27.5-6). With advanced invasive cancers, the myometrium becomes heterogeneous, with echogenic areas, and the uterus may have a lobulated appearance.<sup>12</sup> Hysterosonography (instillation of sterile saline into the uterine cavity) allows better detection and characterization of underlying pathology in a patient with a thickened endometrium.

**FIGURE 27.5-6.** Endovaginal sonogram demonstrating enlarged endometrial echocomplex (between calipers) with posterior irregularity in a patient with endometrial carcinoma with posterior myometrial invasion.

### CERVIX

Cervical cancer is the least frequent of the three common gynecologic malignancies, and most cases can be detected by clinical screening in early stages. US has been shown to be no better than the physical examination to assess the primary tumor, and it has a limited role for staging. Transrectal US has been utilized to identify irregular thickening of the parametria. Endovaginal US may demonstrate secondary signs of a cervical obstructing mass, such as hydro- or hematometra.

### GESTATIONAL TROPHOBLASTIC DISEASE

US has long been the first imaging study to diagnose molar pregnancy, demonstrating hypoechoic grape-like intrauterine structures during the first or second trimester. Recent studies have also demonstrated the use of endovaginal Doppler and color Doppler flow studies in assessing myometrial invasion in patients with persistent human chorionic gonadotropin elevation after dilatation and curettage.

### BREAST

Breast US with high-frequency probes (7 to 13 MHz) is most often used to differentiate a cystic from a solid mass detected on palpation or mammography. Recent reports have demonstrated the utility of US to differentiate benign from malignant masses, therefore limiting the need to perform a biopsy on lesions with benign features, such as sharp margins, circumscribed borders, homogeneous internal echotexture and a horizontal orientation of the lesion. Doppler and CDUS studies to differentiate benign from malignant masses are under way.<sup>13</sup> US is an exquisite guidance modality for preoperative needle localization or core biopsy of sonographically visualized and nonpalpable breast masses.

## MEDICAL ONCOLOGY

### LIVER

Liver and biliary cancers account for only 1.5% of all gastrointestinal malignancies in the United States. Liver cancers are more common in China and Africa, because of higher endemic hepatitis B carrier rates. In the United States, 60% of hepatocellular carcinoma are associated with underlying liver cirrhosis. Hepatic US in conjunction with serum  $\alpha$ -fetoprotein has been used to screen patients in Asia and Europe. Sonography in high-risk patients can detect lesions as small as 1 cm in diameter. The sonographic appearance varies with the histologic composition and size. Tumor invasion of the hepatic and portal veins may be demonstrated by CDUS. Most often, biopsy is necessary to make the definitive diagnosis and differentiate these from other benign and malignant liver masses. Hepatic lymphoma is an infiltrative neoplasm, sonographically presenting as focal, multifocal, or diffuse infiltration, often as hypoechoic masses or ill-defined areas of mixed echogenicity ( Fig. 27.5-7). Metastases to the liver may be hypoechoic, hyperechoic, or show a diffuse infiltrative pattern. Most common primary tumors are gastrointestinal, renal, pancreas, breast, lung, and thyroid cancer.<sup>14</sup>

**FIGURE 27.5-7.** Sagittal sonogram of the right hepatic lobe containing a heterogeneous mass (arrows) in this patient 9 years after heart transplantation. Biopsy demonstrated hepatic lymphoma.

## GALLBLADDER–BILIARY TREE

Gallbladder carcinoma usually presents with advanced disease. Sonographically, a focal wall mass protruding into the lumen or a diffuse infiltrative mass in the bed may be seen (Fig. 27.5-8). Cholangiocarcinoma may be intrahepatic, nodular, and mass-forming, or it may be infiltrative along the intra- and extrahepatic bile ducts. On US, it is seen as a heterogeneous hypoechoic mass, with or without ductal dilatation.<sup>15</sup>

**FIGURE 27.5-8.** Sagittal sonogram of the gallbladder in patient with gallbladder carcinoma demonstrating thickening of the fundal wall, with mass protruding into the lumen (arrows).

## PANCREAS

Pancreatic cancers include exocrine, endocrine, and cystic neoplasms and most commonly an adenocarcinoma of the exocrine duct. The tumor invades adjacent structures and vessels and commonly metastasizes to the liver. Patients most frequently present with obstructive jaundice. On US, a pancreatic mass, frequently hypoechoic, and a dilated common bile duct and pancreatic duct are identified. Sonography is less sensitive in imaging carcinoma of the body and tail of the pancreas because of overlying bowel gas. Pancreatic endocrine tumors, usually islet cell tumors, may present as small, hypoechoic masses in the gland. Mucinous cystic neoplasms may contain central calcifications.<sup>16</sup> Pancreatic cancers are usually best imaged with CT and biopsies preferably by US, sometimes, however, with CT guidance (Fig. 27.5-9).

**FIGURE 27.5-9.** Focal mass in the pancreatic head (*cross-hair*) proven to be metastatic rhabdomyosarcoma. Linear echogenic lines represent indwelling biliary stent.

## ENDOCRINE

Thyroid nodules are not infrequently detected during US performed to evaluate the carotid arteries or in patients with abnormal thyroid function tests or palpable abnormalities. Solitary or suspicious, complex masses are usually biopsied under US guidance. Local lymph node involvement in thyroid malignancies can be exquisitely demonstrated with high-resolution US. Postthyroidectomy local recurrence or lymph node spread can be imaged and proven by US guided biopsy.<sup>17</sup>

Adrenal malignancies are most commonly adrenocortical carcinoma and pheochromocytoma. CT is usually the mainstay for the evaluation of adrenal masses because of its high sensitivity and simultaneous ability to accurately stage extension into adjacent structures. US may be the study on which an adrenal mass is detected incidentally. Small masses are homogeneous, and tumors become progressively heterogeneous with enlargement, due to necrosis and hemorrhage. Right adrenal masses can cause anterior displacement of the inferior vena cava. Metastases from lung primaries are common to the adrenal gland. However, in larger series, one-third to two-thirds of patients with adrenal masses and lung cancer had incidental nonfunctioning adenomas. Fine-needle aspiration biopsy is normally performed in these patients to establish the diagnosis of metastases.<sup>18</sup>

## BONE MARROW TRANSPLANT

Sonography is frequently used to evaluate complications of high-dose therapy in bone marrow transplant patients, such as hepatic venoocclusive disease or hemorrhagic cystitis.

### *Hepatic Venoocclusive Disease*

Hepatic venoocclusive disease is caused by high-dose chemotherapy prior to bone marrow transplant salvage. Toxicity to the liver results in hepatic edema, venous compression, and stagnation, with ultimately occlusion of the small hepatic veins. Imaging with CDUS may demonstrate a heterogeneous and enlarged liver, ascites, a thick-walled gallbladder, elevated hepatic artery resistive index (>0.8), decreased hepatic vein flow, and pulsatile or reversal of portal vein flow.<sup>19</sup>

### *Hemorrhagic Cystitis*

Hemorrhagic cystitis is caused by the toxic effect of high-dose steroids to the urothelium, resulting in severe cystitis, hemorrhage, and bladder necrosis. On US, the bladder wall is thickened, and blood clots can be seen as intravesical masses (Fig. 27.5-10). US is also useful to assess the effectiveness of therapy.<sup>20</sup>

**FIGURE 27.5-10.** Vesical ultrasonography in a patient with hemorrhagic cystitis. Note bladder wall thickening and heterogeneous mass in the bladder compatible with a large blood clot.

### ACQUIRED IMMUNODEFICIENCY SYNDROME MALIGNANCIES

The most common neoplasms related to acquired immunodeficiency syndrome (AIDS) are Kaposi's sarcoma and non-Hodgkin's lymphoma. Other malignancies include cervical carcinoma, bronchogenic carcinoma, and Hodgkin's lymphoma with an unusual or aggressive presentation. AIDS patients are also at higher risk to develop testicular neoplasms, such as germ cell tumors or AIDS-related lymphoma (ARL).<sup>21</sup>

#### *Kaposi's Sarcoma*

In AIDS, Kaposi's sarcoma is an aggressive multifocal neoplasm arising from lymphatic endothelial cells. It can involve skin, lymph nodes, gastrointestinal tract, liver, spleen, lung, and pleura. On US, focal liver or splenic masses or infiltrative lesions can be seen. Infiltrative lesions may also be present in the kidney, adrenal, bladder, or prostate.<sup>21</sup>

#### *Acquired Immunodeficiency Syndrome–Related Lymphoma*

Isolated or bulky adenopathy is rare and favors chronic infections, such as *Mycobacterium avium–intracellulare* and tuberculosis. Extranodal disease usually involves the gastrointestinal tract, liver, spleen, kidney, and adrenal gland. Chest wall disease involving the spine and sternum as well as pleural effusions are common. On US, hepatic and splenic involvement present as solitary or multiple hypoechoic nodules, which may appear cystic. Renal involvement may demonstrate bilateral parenchymal or perirenal masses. The differential diagnosis for such lesions includes renal cell carcinoma, tuberculosis, candidiasis, aspergillosis, or pyogenic abscesses.<sup>21</sup>

### VENOUS COMPLICATIONS

US has become the standard primary imaging technique for the initial evaluation of patients with the clinical suspicion of deep venous thrombosis (DVT) of the extremity veins. Predisposing factors for DVT in the oncologic patient include paraneoplastic syndrome; immobilization; compression or direct invasion by the primary tumor or metastatic masses (pelvis, chest, Pancoast tumor); radiotherapy; and indwelling catheters or stents. The hallmark finding of acute DVT on gray scale, Doppler, and CDUS include distention and noncompressibility of vessels and direct visualization of tumor thrombus. In long-standing venous occlusion, abundant collateral vessels may be seen on US.<sup>22</sup>

### ULTRASONOGRAPHICALLY GUIDED INTERVENTIONAL PROCEDURES

Accurate characterization and staging of malignancies has become increasingly important for cancer patients to avail themselves of the increasing advances in treatment options. Precise localization of disease process by fluoroscopy US, CT, and magnetic resonance imaging have made possible percutaneous biopsies, aspirations of fluid collections, abscess drainages, nephrostomy, and stent placement as well as vascular access in many organ systems of the oncology patient. Advances in cytopathology diagnostic techniques and the development of smaller and safer needles coupled with cross-sectional image guidance, particularly US, facilitate accurate and safe needle placement in formerly inaccessible sites. Most biopsies in the oncology patient are performed to confirm malignancy in a radiographically suspicious lesion or to obtain a tissue diagnosis in an indeterminate lesion. Growing experience with US as a guidance modality has greatly expanded the role and scope of US-guided interventional masses in deep abdominal and superficial masses, thoracic and mediastinal applications.<sup>23,24,25,26 and 27</sup> Specific biopsy applications include liver (Fig. 27.5-11) and pancreas; renal, adrenal, retroperitoneal, splenic, neck, and musculoskeletal masses; as well as selected thoracic lesions when pleura-based or mediastinal (Fig. 27.5-12); breast lesions; endocavitary biopsy (endorectal, endovaginal); and recently intraoperative or percutaneous ablations (ethanol, cryosurgery, radiofrequency, laser, and microwave) for hepatic, renal, and prostate lesions.<sup>23,24,25,26,27,28,29 and 30</sup>

**FIGURE 27.5-11.** Ultrasonographically guided percutaneous biopsy of a small mass in the liver proved to be metastatic pancreatic carcinoma. Note biopsy trajectory (dotted lines).

**FIGURE 27.5-12. A:** Computed tomography scan of the chest demonstrating small, left-sided posterior pleural-based lung nodule. **B:** Same nodule imaged by ultrasonography as a hypoechoic mass (between dotted lines). Ultrasonographically guided biopsy revealed metastatic squamous cell carcinoma to the lung.

US is an ideal guidance modality for interventional procedures for various reasons. It allows real-time display throughout the procedure with unlimited scan plans, thus allowing creative patient positioning. Speed of the procedure; CDUS for vessel visualization; direct pressure over the lesion with the transducer in case of bleed; portability; lower cost; and nonionizing irradiation are other advantages of US. Future applications include percutaneous US-guided delivery of chemotherapy agents, drug delivery, and gene therapy as well as organ-specific delivery of substances in conjunction with contrast agents and directed local bubble destruction.

## SUMMARY

US plays an important role in the diagnostic evaluation and management of cancer patients. With further advances in US technology and an ever-increasing variety of therapeutic options, its use in the oncology patient will expand in the future.

#### INTRODUCTION

The development of molecular biology and genetics since the late 1970s has provided medical science with an unprecedented chance to understand the molecular basis of disease. Although disease is usually defined as gross structural or histopathologic abnormality, it can now be defined on the basis of abnormal deviation from normal regional biochemistry. Molecular derangements occur at the very beginning of disease processes, and anatomically detectable abnormalities occur much later.

Cancer is viewed as a failure of multiple chemical processes or genetic disease. The care of cancer patients has become a cooperative multidisciplinary endeavor. A multidisciplinary approach to the diagnosis, staging, treatment, and follow-up of cancer takes a great deal of effort, but the rewards to patients and oncologists are tremendous. It is critical for imaging specialists to embrace and participate in the multidisciplinary environment so that they are considered valued and equal partners.

Advanced imaging techniques have made it possible to diagnose localized abnormalities, often before they have produced irreversible damage. Cancers too small to be detected by physical examination can be pinpointed by imaging and treated before metastasis has occurred. Most imaging methods reveal the anatomic extent of an organ or of an abnormality within an organ. Many masses cannot be characterized clearly with imaging studies. This may be a problem when attempting to distinguish residual viable tumor from fibrosis.

Many radionuclide studies have been performed for the detection of primary and metastatic tumors. Most are organ- or receptor-specific but not tumor-specific. A few studies are highly tissue-specific, such as thyroid scans using iodine 131 sodium iodide and adrenal scans using  $^{131}\text{I}$  metaiodobenzylguanidine (MIBG) or 6-b-iodomethyl-19-norcholesterol. Radiolabeled antibodies and peptides are potentially tumor-specific. With nonspecific limited agents, abnormalities on scans represent alteration or displacement of normal tissue, and additional scans with other agents are often necessary to evaluate potential involvement of other organs. Extensive effort has been directed toward the development of specific general agents that ideally would be taken up specifically by tumor and that could be used for a broad spectrum of tumor types.

#### INDIRECT RADIONUCLIDE TUMOR IMAGING

##### NUCLEAR BONE SCANS

The bisphosphonate bone scan is the most frequently performed radionuclide study, and it is used for the early detection of metastatic bone disease. The positive bone scan ([Fig. 27.6-1](#)) reflects levels of blood flow and osteoblastic formation.<sup>1</sup> Magnetic resonance imaging (MRI) has a greater sensitivity and specificity than bone scans in detecting metastatic foci,<sup>2</sup> but bone scans remain the choice for initial screening of bony metastasis because of its ability to easily assess the whole body and because of its availability. In the follow-up of bony metastases, the *flare phenomenon*, in which the patient's clinical condition is improving but the bone scan is worsening, has been described in up to 20% of patients after a therapeutic intervention.<sup>3</sup> Bone single photon emission computed tomography (SPECT) has been helpful and complementary in differentiating degenerative joint disease or facet syndrome from metastasis. Extraskelatal uptake of technetium 99m methylene diphosphonate (MDP) has been reported in many malignant tumors with calcification or increased vascularity. Severe bone pain can be a particularly debilitating effect of metastatic disease. Strontium 89 chloride, samarium 153 ethylene diamine tetramethane phosphoric acid (EDTMP), and rhenium 186 hydroxy ethylene diphosphoric acid (HEDP) and Sn-117m DTPA (diethylenetriamine pentaacetic acid) have been effective in reducing pain in breast and prostate cancer patients.<sup>4</sup>

**FIGURE 27.6-1.** Whole body anterior (A) and posterior (P) images of follow-up bone scans using technetium 99m methylene diphosphonate show focal areas of abnormally increased activities in the left humeral head, T7, T8, T12, left sacrum, and left anterior second rib end, indicating active metastatic lesions. Note also the diffusely increased renal activities suggesting nephrotoxicity in a patient with breast cancer.

##### NUCLEAR LIVER SCANS

Cavernous hemangioma is the most common benign tumor of the liver and consists of dilated endothelium-lined blood-filled spaces. Increasing focal activity over 1 to 2 hours after injection of  $^{99\text{m}}\text{Tc}$  red blood cells is a typical diagnostic finding. SPECT is cost effective in demonstrating hemangiomas greater than 1 cm when CT or MRI findings are questionable.<sup>5</sup>

Hepatic adenoma and focal nodular hyperplasia show a contrast enhancement on CT or MRI. The adenoma presents as a cold defect on  $^{99\text{m}}\text{Tc}$  sulfur colloid liver-spleen scans but shows an uptake of  $^{99\text{m}}\text{Tc}$  iminodiacetic acid hepatobiliary agent because no Kupffer cell is present. On the other hand, focal nodular hyperplasia demonstrates uptake of  $^{99\text{m}}\text{Tc}$  sulfur colloid because of the presence of Kupffer cells.<sup>6</sup>

##### HEPATIC PERFUSION SCANS

Intraarterial chemotherapy has been used to treat many tumors in an effort to obtain better results than with systemic chemotherapy. Hepatic tumors derive 99% of their blood supply from the hepatic artery.  $^{99m}\text{Tc}$  macroaggregated albumin, usually 10 to 90  $\mu\text{m}$ , is trapped in the first capillary bed and has been useful to detect misplaced or displaced hepatic arterial catheters that require repositioning. <sup>7</sup>

## NUCLEAR CARDIOVASCULAR IMAGING

In patients undergoing chemotherapy with doxorubicin (Adriamycin), one risk is developing cardiotoxicity. Radionuclide ventriculography using  $^{99m}\text{Tc}$  red blood cells provides the left ventricular ejection fraction, and a 10% to 15% decrease of left ventricular ejection fraction or a decrease to less than 45% is considered significant. <sup>8</sup> Chemotherapy or catheterization increases the risk for thrombus formation in cancer patients. Radionuclide venograms using  $^{99m}\text{Tc}$  macroaggregated albumin for lower extremities and  $^{99m}\text{Tc}$  sulfur colloid or DTPA for upper extremities have been useful in screening hemodynamically significant venous obstruction.  $^{99m}\text{Tc}$  P-829 peptide accumulated in the platelet receptor is now being used to detect acute venous thrombosis.

## LYMPHOSCINTIGRAPHY

Approximately 20% of melanoma patients do have clinically undetectable micrometastases in the lymph nodes, and the presence of metastases in the sentinel (first draining) node indicates the need for a regional lymph node dissection. A dose of 0.5 mCi  $^{99m}\text{Tc}$  sulfur colloid in 0.25 mL is injected intradermally around the melanoma site, and the lymphatic flow is imaged dynamically for 30 minutes. Subsequent static images demonstrate the draining regional node basin and the location of the sentinel node. <sup>10</sup> The status of regional lymph node remains the most powerful predictor of survival in women with invasive breast cancer. Approximately 14% to 37% of small (less than 1 cm) invasive cancers may have axillary nodal metastases. Lymphatic drainage from breast cancer can be mapped to regional lymph nodes pre- or intraoperatively. The technique involves peritumoral injection of 0.5 mCi  $^{99m}\text{Tc}$  sulfur colloid and gamma camera imaging or gamma detection probe. In one study, <sup>11</sup> the sentinel lymph node was identified in 92% of patients, and 32% of them were found to have metastatic diseases.

## DIRECT RADIONUCLIDE TUMOR IMAGING

### GALLIUM 67 CITRATE SCANS

Gallium 67 citrate has been known to be taken up in varying degrees by many other tumors, and  $^{67}\text{Ga}$  scans have been useful as a marker of tumor viability and for evaluating the effectiveness of radiotherapy or chemotherapy.  $^{67}\text{Ga}$  citrate binds to serum transferrin, ferritin, and lactoferrin. Approximately 15% to 25% is excreted by kidneys within 24 to 48 hours, and 30% to 40% is cleared slowly through the intestinal tract.  $^{67}\text{Ga}$  citrate localizes normally within the reticuloendothelial system and lacrimal and salivary glands. A dose of 5 to 10 mCi is usually recommended for tumor imaging. High-resolution whole body images ( Fig. 27.6-2) and SPECT of chest or abdomen are obtained at 48 to 72 hours.

**FIGURE 27.6-2.** Whole body anterior (A) and posterior (P) images of follow-up gallium scans show focal areas of abnormally increased uptake of gallium 67 citrate (arrows) in the right upper and lower lungs, indicating active lymphomatous lesions confirmed by biopsy.

$^{67}\text{Ga}$  citrate probably enters the tumor extracellular space through the capillary endothelium and is bound to the tumor cell surface by transferrin receptors. It localizes in the lysosomes of tumor cells and is taken up by viable and growing tumors.  $^{67}\text{Ga}$  scans detect nodal and visceral involvement of Hodgkin's disease, and high- and intermediate-grade non-Hodgkin's lymphomas, with approximately 90% sensitivity (see Fig. 27.6-2). <sup>12</sup> The sensitivities for histocytic Burkitt's lymphoma, and poorly and well-differentiated lymphocytic lymphomas, have been reported as 89%, 85%, 70%, and 59%, respectively. <sup>13</sup> SPECT greatly improves contrast resolution, resulting in a 10% to 15% increase of diagnostic accuracy over planar imaging. Persistent  $^{67}\text{Ga}$  uptake halfway through the course of chemotherapy in patients with diffuse large cell lymphoma predicts a poor outcome, either by failure to achieve remission or by subsequent relapse. <sup>13</sup> The diagnostic sensitivity of  $^{67}\text{Ga}$  scans for lung cancer is 85% to 90%, but  $^{67}\text{Ga}$  scans are suboptimal for preoperative staging. However, enlarged nodes are not specific for tumors, and normal-size nodes can carry tumor cells. Most hepatomas and melanomas are Ga-avid, and  $^{67}\text{Ga}$  scans can be useful for differentiating hepatomas from regenerative pseudotumor nodules seen on CT in cirrhotic patients.

### THALLIUM 201 AND TECHNETIUM 99M SESTAMIBI SCANS

Thallium 201 chloride behaves in a manner that is biologically similar to potassium. Tumor blood flow influences the uptake of  $^{201}\text{Tl}$  by tumors, probably related to the action of the adenosine triphosphatase system in the cell membrane.  $^{201}\text{Tl}$  is accumulated by viable tumor tissue, and its uptake correlates with the grade of histopathologic differentiation. Planar and SPECT imaging of the lesion is usually obtained at 10 to 30 minutes after the injection of 3 mCi  $^{201}\text{Tl}$  chloride.  $^{201}\text{Tl}$  scans have been used to determine viability when CT or MRI cannot differentiate residual or recurrent brain or lung tumors from posttreatment changes or infectious lesions (Fig. 27.6-3).  $^{201}\text{Tl}$  indices, count-density ratios of tumor to nontumor area, were significantly higher in high-grade tumors than in those patients with low-grade tumors. <sup>14</sup>  $^{201}\text{Tl}$  is usually taken up only by tumors, whereas  $^{67}\text{Ga}$  is taken up in both tumor and inflammatory lesions.  $^{201}\text{Tl}$  appears valuable in detecting low-grade non-Hodgkin's lymphoma and also Kaposi's sarcoma. Some studies have found the  $^{201}\text{Tl}$  scan to be more sensitive than the  $^{131}\text{I}$  scan in the detection of thyroid cancer, although  $^{201}\text{Tl}$  is not specific for thyroid cancer and does not give predictive information on the therapeutic potential of I sodium iodide. <sup>15</sup>

**FIGURE 27.6-3.** **A:** Axial T1-weighted magnetic resonance images of the head show a contrast-enhanced lesion (arrow) in the right frontal lobe in a patient who had a treatment for anaplastic astrocytoma. **B:** Selected coronal (upper left), sagittal (upper right), and axial (lower left) single photon emission computed tomography images using thallium 201 chloride show a focal area of markedly increased activity (arrow) in the right frontal lobe, indicating active malignant tumor. Biopsy confirmed a recurrent anaplastic astrocytoma.

$^{99m}\text{Tc}$  sestamibi uptake is not tumor-specific, but it has been used to detect benign as well as malignant tumors, including parathyroid adenoma and breast cancer.  $^{99m}\text{Tc}$  sestamibi is bound by the mitochondrial proteins but is passively transferred across the cell membrane. The sestamibi scan is usually performed at 15 to 30 minutes and 2 to 3 hours after injection of 20 to 29 mCi.  $^{99m}\text{Tc}$  sestamibi uptake is inversely proportional to the level of P glycoprotein, which is a product of the multidrug resistance gene. Some studies have shown the potential of functional imaging using  $^{99m}\text{Tc}$  sestamibi to monitor cancer therapy with the multidrug resistance modulator.<sup>16</sup>

## NUCLEAR THYROID AND ADRENAL IMAGING

During the 1990s, it has become apparent that the most cost-effective diagnostic workup of a thyroid nodule is fine-needle aspiration. However, histologic and cellular details of endocrine tumors do not always establish the diagnosis of carcinoma. Both papillary and follicular cancers retain, to varying degrees, the ability to concentrate radioiodine. Medullary and anaplastic carcinomas do not concentrate radioiodine. All types of thyroid cancer do not concentrate radioiodine as avidly as normal thyroid tissue. To enhance radioiodine uptake by thyroid cancer, high levels of circulating thyroid-stimulating hormone are desired (more than 30  $\mu\text{IU/mL}$ ).

$^{123}\text{I}$  is ideal for imaging because of short physical half-life (13 hours) and optimal photon energy (159 keV). However, it is relatively expensive, and the thyroid imaging is usually performed at 4 to 6 hours after the oral administration of 0.2 mCi  $^{123}\text{I}$  sodium iodide.  $^{99m}\text{Tc}$  sodium pertechnetate is cheap and ideal for early (30 minutes) imaging with good physical properties (6-hour half-life; 140 keV optimal photon energy), although it is only trapped and not organified. Indications of radionuclide thyroid imaging are functional evaluation of palpable nodules, detection of the primary tumor in patients with known regional or distant thyroidal metastases, detection of thyroid cancer metastases, and assessment of thyroid treatments. Nonfunctioning cold nodules are common, and 6% to 20% of them are usually malignant.<sup>17</sup>

Pheochromocytoma is a tumor of adrenal medulla or sympathetic nervous tissues. Approximately 10% occur in children, 10% are familial, 10% are malignant, 10% are multifocal, and 10% are extraadrenal. CT or MRI is useful in detecting intraadrenal or other abdominal masses. MIBG is an analogue of guanethidine and localizes in cytoplasmic storage vesicles in presynaptic adrenergic nerves through the active amine transport mechanism.  $^{123}\text{I}$ - or  $^{131}\text{I}$ -labeled MIBG has been useful in surveying the entire body for the localization of pheochromocytoma or paraganglioma.<sup>18</sup>

## ANTIBODY AND PEPTIDE IMAGING

Antibodies are glycoproteins produced by plasma cells after exposure to a foreign antigen. Many tumors have antigens expressed on their cell surfaces, thus allowing antibody targeting. Major roles of immunoscintigraphy using indium 111 anti-TAG-12 (OncoScint, Cytogen Co., Princeton, NJ) or  $^{99m}\text{Tc}$  anti-carcinoembryonic antigen (CEA) (CEA-scan, Immunomedics Co., Morris Plains, NJ) (Fig. 27.6-4) in colon cancer are: (1) detection of recurrent disease in patients with elevated serum CEA level, and either negative workup or equivocal findings on CT or MRI; (2) differential diagnosis of residual or recurrent disease from posttreatment changes; and (3) exclusion of extraabdominal disease before planned resection of a presumably isolated recurrence.  $^{111}\text{In}$  antiprostase membrane antigen (ProstaScint, Cytogen Co.) scans are indicated for patients with proven prostate cancer thought to be localized clinically after standard diagnostic evaluation who are at risk for pelvic node metastasis. It is also indicated in prostate cancer patients with a rising prostate-specific antigen level and negative or equivocal standard metastatic evaluation. Antibody scans generally revealed 70 to 80% diagnostic sensitivities and should be interpreted in conjunction with CT or MRI studies.<sup>19</sup> Natural somatostatin is a tetradecapeptide produced by hypothalamus and pancreas. Five subtypes of human somatotropin-release inhibiting factor receptors, termed *somatostatin type receptors* (SSTRs), are expressed on many tumors, and SSTR2 is the predominant subtype. Tumors that have been found to express SSTRs include small cell lung cancer, endocrine pancreatic tumor, carcinoid, pituitary adenoma, paraganglioma, lymphoma, and meningioma. Octreotide is a synthetic somatotropin-release inhibiting factor analogue that has been used for treating gastroenteropancreatic tumors.  $^{111}\text{In}$  pentetretotide (Octreoscan, Mallinckrodt Co., Hazelwood, MO) has been helpful for detecting neuroendocrine tumors and evaluating their therapeutic response.  $^{201}\text{Tl}$  P-829 peptide has been approved to image somatostatin receptors in lung cancers.<sup>21</sup>

**FIGURE 27.6-4.** Anterior whole body images at 2 (left) and 20 (right) hours after the injection of technetium  $^{99m}$  anti-carcinoembryonic antigen (CEA) show focal areas of abnormally increased activity in the left inguinal (closed arrow) and iliac (open arrow) lymphatic chains in a patient with colon carcinoma and rising serum CEA levels. Note the cystic lesions in the left kidney.

#### UPPER GASTROINTESTINAL ENDOSCOPY

Endoscopy is a rapidly advancing field. Video-recording or electronic instruments use microchip technology to capture high-resolution digitized endoscopic images, leading to more accurate diagnoses and greater ease in documentation and analysis. Many internal organs can be examined by endoscopy with video documentation, endoscopic biopsy, cytology, and endoscopic sonography to determine diagnosis, operability, and staging.

Although diagnostic endoscopy remains the major component of any endoscopy program, therapeutic endoscopy is rapidly catching up. Endoscopic removal of polyps, tumor ablation with laser therapy, luminal stents, control of hemorrhage, relief of biliary obstruction, and enteral nutritional support through endoscopically placed tubes are but some of the therapeutic uses of endoscopy available at large medical centers.

Upper gastrointestinal (GI) endoscopy is the procedure of choice for the diagnosis of symptomatic esophagogastric neoplasia. Benign upper GI conditions that can mimic or complicate cancer are accurately diagnosed. Endoscopy is often the initial diagnostic procedure rather than a follow-up to radiologic examination.<sup>1</sup> Upper GI endoscopes are thin and highly maneuverable, making upper endoscopy comfortable and rapid.<sup>2</sup> Upper GI endoscopy requires only mild sedation and is safe for the patient. Although upper GI endoscopy is more invasive and more expensive than barium upper GI radiography, it is also more accurate and may avoid multiple procedures, with their associated added costs. There is no exposure to radiation, and complications are rare.<sup>3</sup> The ability to perform guided mucosal biopsy and cytology provides tissue diagnosis to complement high-resolution observation and photography.

#### DIAGNOSTIC UPPER GASTROINTESTINAL ENDOSCOPY

The diagnostic accuracy of endoscopy and biopsy for primary and metastatic upper GI cancer is in the range of 95%.<sup>1</sup> Infiltrating cancers may be less successfully subjected to biopsy, although a tissue diagnosis is still achieved in most cases with large biopsy forceps and needle aspiration cytology.<sup>4</sup> Endoscopy is recommended in all patients with gastric ulcers found on upper GI series, because some benign-appearing gastric ulcers are malignant.<sup>1</sup> If suspicion remains, repeat endoscopy is indicated in 6 to 8 weeks. This is not the case in duodenal ulcer disease, which is only rarely due to cancer, and endoscopy solely to diagnose *Helicobacter pylori* infection is not recommended.

Patients with an identifiable high risk for upper GI cancer, such as those with Barrett's esophagus, prior gastric adenomas, or previous partial gastrectomy, may be considered for periodic screening endoscopy, although the benefits of such screening remain controversial.<sup>5</sup> When high-grade dysplasia is identified on endoscopic biopsy of either the stomach or Barrett's esophagus, surgical management should be considered because there is a high likelihood of developing invasive cancer.<sup>6</sup>

In northern China, where chronic esophagitis and epidermoid carcinoma of the esophagus are endemic,<sup>7</sup> population screening programs for esophageal cancer have been carried out on a large scale with promising results. Screening has been based on esophageal cytology and confirmation with endoscopy.<sup>8</sup> Using these methods, early-stage esophageal cancers with good probability for surgical cure have been detected in asymptomatic persons. Similar screening programs, carried out in heavy smokers and drinkers in the United States, have not proven effective.<sup>9</sup> Endoscopy has identified early asymptomatic esophageal cancer in up to 5% of patients with cancers of the head and neck who are also at risk for esophageal cancer. Endoscopic staining of the esophagus with Lugol's iodine solution before endoscopy may help in detecting small areas of squamous cell malignancy.<sup>10</sup>

In Japan, where gastric cancer is a leading cause of death, mass population screening with radiography and endoscopy has led to a major improvement in the detection of early disease and subsequent survival.<sup>11</sup> Distal gastric cancer in America and Europe has been decreasing in incidence, but there is an increase in cancers affecting the proximal stomach and an increasing incidence of early gastric cancer detection.<sup>12,13</sup> Mass screening is not practical or economically feasible in low-incidence Western countries; the increased detection of early gastric cancer has been attributed to greater physician sensitivity to suggestive symptoms and more aggressive application of radiologic and endoscopic methods.<sup>14</sup>

Whether patients with partial gastrectomy for benign disease are at long-term risk for gastric cancer and merit endoscopic screening is also an open question but, in patients who have dysplasia on endoscopic biopsy, endoscopic surveillance is indicated. <sup>15</sup>

Periodic endoscopic surveillance of the stomach and duodenum in patients with familial adenomatous polyposis (FAP) and Gardner's syndrome is recommended, including the use of a side-viewing duodenoscope for better visualization of the periampullary area. Adenomas of the duodenum are common in patients with FAP. In such cases, the adenomas tend to be very flat and may be numerous.<sup>16</sup> Carcinoma in the duodenum, most often periampullary, has become a major cause of death in patients with FAP who have had a colectomy.

New endoscopic technology is continually being developed. Fluorescence spectroscopy is one such advance currently in clinical trials. Laser-generated light of a specific wavelength is used to stimulate tissue during endoscopy. Differential fluorescence can be detected from benign, dysplastic, and malignant GI tissues. This technology may become a complement to histopathology, especially in sampling large areas of the GI tract before endoscopic biopsy. <sup>17</sup>

As a rule, endoscopy is most effective in evaluating intraluminal GI disease, focal and diffuse, benign and malignant. The procedure can be informative but is less effective in assessing abnormal motility, extrinsic compression by contiguous structures, and degree of luminal obstruction. Barium radiologic and computed tomography (CT) scans provide not only better evaluation of extrinsic lesions that are causing compression and contour defects in the GI tract but better assessment of the degree of obstruction.

## THERAPEUTIC UPPER GASTROINTESTINAL ENDOSCOPY

Therapeutic applications of endoscopy include the placement of guidewires, stents, and balloons for the following purposes <sup>18,19 and 20</sup>:

1. Dilatation of benign and malignant strictures
2. Removal of foreign bodies
3. Removal of polyps by electrocautery
4. Endoscopic strip biopsy of small cancers
5. Vaporization and coagulation of cancerous tissues with neodymium:yttrium aluminum garnet (Nd:YAG) laser or with photodynamic therapy
6. Control of bleeding with electrocautery, heat, or laser probes
7. Injection of epinephrine and sclerosant solutions via needle-tipped catheters for tumor necrosis or treatment of bleeding

In patients with advanced, unresectable cancer of the esophagus or gastric cardia that is unresponsive to primary treatment, endoscopic therapy has assumed a major role in the palliation of concomitant dysphagia. The mainstays of endoscopic palliation have been the placement of endoprotheses, using either plastic stents or self-expanding metallic stents, and laser ablation with Nd:YAG laser energy. There are advantages and disadvantages to both methods. In approximately 70% of patients, laser therapy is more likely to allow a normal diet, but it must be repeated at frequent intervals. Although outpatient treatment is possible, laser sessions become increasingly time-consuming and uncomfortable for the patient as the cancer progresses. Esophageal stents ideally provide a longer-lasting palliation, and they are the treatment of choice for tumors that are primarily infiltrating, submucosal, or extrinsic. They can be used anywhere in the esophagus except near the proximal sphincter. Endoluminal stents are also useful for sealing fistulas into the tracheobronchial tree. In most centers where an Nd:YAG laser is available, laser therapy is performed first, particularly if there is bulky intraluminal tumor. However, some groups preferentially palliate esophageal and esophagogastric malignant stenoses with stents. This is especially true with the advent of self-expanding metal stents, which are easier to insert, cause less trauma, carry a lower perforation rate, but are more expensive initially than polyvinyl stents. Complications, mostly perforations, occur in approximately 5% of those treated with laser and 5% to 18% of those treated with stents. <sup>18,19</sup>

Photodynamic therapy (PDT) uses both photochemical sensitizers that preferentially concentrate in neoplastic tissue and low-powered laser light activation. This technique is, in theory, more selective and safer than the Nd:YAG laser treatment. However, one multicenter study <sup>21</sup> of advanced esophageal cancer showed no difference when the cancers were treated with either PDT or Nd:YAG laser. Perhaps the most effective use of PDT will be in the management of early cancers or premalignant conditions such as Barrett's esophagus. <sup>21,22</sup>

## COMPLICATIONS

Upper GI endoscopy is a very safe procedure with few contraindications and only rare complications. The probability of GI perforation is less than 0.1%. <sup>3</sup> This procedure can be performed safely even in patients on anticoagulants or with nadir blood counts, although therapeutic options in these patients may be limited. In weakened or comatose patients, there is an increased risk of aspiration pneumonia.

## ENDOSCOPIC ULTRASONOGRAPHY

### PRINCIPLES

Endoscopic ultrasonography (EUS) is an important new extension of diagnostic GI endoscopy. Using this modality, it is possible for the endoscopist to assess not only mucosal lesions but intramural disease processes deep to the mucosa and extrinsic abnormalities in proximity to the wall of the GI tract. <sup>23,24 and 25</sup>

EUS uses high-frequency ultrasound (more than 7 MHz) for high resolution, producing detailed views of the GI wall and surrounding structures that are unmatched by other imaging methods. The higher the ultrasound frequency, the shorter the penetration depth of ultrasound and the more limited the field of view. However, with EUS a limited field is acceptable, because the transducer can be placed immediately adjacent to the area of interest.

Using EUS, the wall of the GI tract can be imaged as a five-layer structure of alternating bright (hyperechoic) and dark (hypoechoic) bands ( [Fig. 28-1](#)). The echogenic layers consist in part of interface echoes produced as the sound waves travel between tissues of differing densities. <sup>26</sup> For clinical purposes, the first two layers correspond to the superficial and deep mucosa, the third layer to the submucosa, the fourth to the muscularis propria, and the fifth to the serosa or adventitia.

**FIGURE 28-1.** Endosonographic image of the normal gastric wall. The concentric circles in the center represent the transducer and water-filled balloon in the lumen of the stomach. From the lumen, the first two wall layers correlate with the superficial and deep mucosa (m), the third wall layer represents the submucosa (sm), the fourth layer is the muscularis propria (mp), and the fifth layer is the serosa (s).

Most clinical studies have been carried out using mechanical sector scan instruments manufactured by the Olympus Corporation, Melville, NY, principally the GF-UM3 instrument. These instruments are combination endoscopes and ultrasound probes that use an acoustic mirror rotating around a transducer with switchable 7.5- and

12-MHz frequencies and produce a 360-degree image.<sup>23,24</sup> and<sup>25</sup> In the tubular GI tract, this greatly facilitates orientation of the image. Optics are forward oblique, but the 4-cm rigid tip and the 13-mm diameter make the instrument somewhat difficult to use and limit passage through tightly stenotic areas.

Instruments using linear- or phased-array technology have the advantages of forward-viewing optics and an absence of moving parts but provide a slice-like image, which can make orientation more difficult. Pentax Precision Instruments, Orangeberg, NY, manufactures a linear-array 5- and 7.5-MHz ultrasound endoscope (FG-32UA). Doppler ultrasound technology, to aid in evaluation of vascularity and blood flow, is easily obtained on ultrasound instruments. Blind endosonography probes, rigid and flexible, mechanical and electronic, have been used in the rectum and in the esophagus. Ultrathin miniprobes that can be passed through an endoscope biopsy channel have also been developed. They have a restricted field of view and often produce less-than-satisfactory images.

## INDICATIONS AND RESULTS

EUS has been applied most extensively to the staging of esophageal, gastric, and rectal cancer. Data show that EUS is the most accurate imaging modality for staging depth of tumor invasion (T), with preoperative accuracy in the 80% to 90% range when compared with surgical pathology.<sup>27,28,29,30</sup> and<sup>31</sup> For staging esophageal and gastric cancer, T1 cancers invade the mucosa to submucosa and are imaged as a disruption of the first three endosonographic wall layers ( Fig. 28-2). T2 cancers invade the muscularis propria to the subserosa and show a hypoechoic invasion of the fourth layer. T3 cancers invade through the serosa and can be seen to penetrate the fifth layer. T4 cancers directly invade adjacent organs or structures.

**FIGURE 28-2.** Endosonographic image shows a polypoid hypoechoic disruption involving only the first three wall layers of the stomach at the angularis. A T1 cancer invading to the submucosa, but not involving the muscularis propria, was confirmed by surgical pathologic examination.

At the Memorial Sloan-Kettering Cancer Center (MSKCC), a prospective study used EUS in 50 patients for preoperative staging of esophageal cancer ( Fig. 28-3) and in 50 patients for preoperative staging of gastric cancer ( Fig. 28-4).<sup>28,29</sup> Results were compared for accuracy with surgical pathology and with CT using rapid scanners, oral contrast, and dynamic technique. EUS was significantly more accurate than dynamic CT in staging tumor extent in esophageal and gastric cancer. Most studies comparing EUS with CT for staging esophageal, gastric, and rectal cancer have found EUS superior for evaluation of tumor extent.<sup>27,28,29,30</sup> and<sup>31</sup>

**FIGURE 28-3.** Esophageal cancer staging concordance with surgical pathology. Results of preoperative staging in 50 consecutive patients who had surgery for esophageal cancer at Memorial Sloan-Kettering Cancer Center. CT, computed tomography; EUS, endoscopic ultrasonography; N, node; T, tumor.

**FIGURE 28-4.** Gastric cancer staging concordance with surgical pathology. Results of preoperative staging in 50 consecutive patients who had surgery for gastric cancer at Memorial Sloan-Kettering Cancer Center. CT, computed tomography; EUS, endoscopic ultrasonography; N, node; T, tumor.

The greatest strength of EUS is in identifying the location of tissues and not the specific histology. Biopsy and histopathologic evaluation are still required to identify the nature of any abnormality. EUS cannot reliably distinguish an inflammatory from a neoplastic process (e.g., determining whether a gastric ulcer is benign or malignant). EUS has proved less accurate in staging lymph nodes than in staging depth of tumor invasion because the node must not only be located but be characterized as benign or malignant. Lymph nodes in the 2- to 3-mm range can be detected with EUS. Some investigators use the echo character of nodes for staging.<sup>27,28</sup> and<sup>29</sup> Nodes that are rounded, sharply defined, and hypoechoic are more likely to be malignant ( Fig. 28-5). Using such criteria, staging regional lymph node metastases has been more accurate than other imaging modalities, such as CT scan, and is accurate in the range of 70% to 80%.<sup>27,28,29,30</sup> and<sup>31</sup> EUS is a sensitive method of detecting recurrent upper GI cancer in the area of the surgical anastomosis.<sup>32</sup> There have been false-positive results due to inflammation, and specificity should be improved.

**FIGURE 28-5.** A round, hypoechoic, sharply defined lymph node measuring 1.4 cm is imaged through the distal esophagus. The posterior node lies between the aorta and azygos vein. The relation of the esophagus to the left atrium is evident posteriorly. The node in a patient with cancer of the esophagogastric junction was malignant at the time of surgical resection.

Characteristic images are recognized for cysts, leiomyomas, and lipomas, but again, it is not always possible to distinguish benign from malignant lesions.<sup>33</sup> On the other hand, large gastric folds due to benign gastropathy can usually be distinguished from malignant infiltration by carcinoma or lymphoma, which tend to destroy the normal tissue architecture.<sup>34</sup> Gastric varices may be readily identified.

Imaging the pancreas through the wall of the stomach and duodenum provides a highly detailed image, allowing the detection of small tumors measuring even less than 1 cm.<sup>35</sup> Although changes due to pancreatitis can be evaluated, once again, it has not been possible reliably to distinguish neoplastic from inflammatory pancreatic masses.<sup>36,37</sup> EUS may play a role in the screening of family members of pancreatic cancer kindreds.<sup>38</sup> Staging of pancreatic, biliary, and ampullary cancer preoperatively<sup>37,39</sup> and the localization of neuroendocrine tumors have been carried out successfully with EUS.<sup>40</sup>

Linear-array endosonographic instruments facilitate the ability to perform fine-needle aspiration of small submucosal lesions or lesions outside of but adjacent to the GI tract. In 50 consecutive patients in whom the combination of EUS and fine-needle aspiration was performed, the highest yield was 93% (14 of 15) in malignant lesions extrinsic to the GI tract.<sup>41</sup> Endosonography is often challenging to perform, and image interpretation can be difficult. However, EUS has become progressively easier and more available as more experience has accumulated and instruments have improved.

## SIGMOIDOSCOPY

### PRINCIPLES

Rigid and flexible sigmoidoscopies are important for evaluating the distal colon and rectum. Rigid sigmoidoscopes are usually 25 cm long, and flexible instruments are either 35 cm or 60 cm long. Although rigid sigmoidoscopes are less expensive to purchase and maintain and are somewhat easier to use than their flexible counterparts, the flexible instruments offer greater depth of insertion, patient comfort, and acceptance.

### INDICATIONS AND RESULTS

Colorectal cancer screening represents one of the most important indications for sigmoidoscopy, because the procedure is highly sensitive and specific.<sup>42</sup> Because of its length, sigmoidoscopy misses proximal colon cancers and polyps. Sigmoidoscopic screening of large population groups remains controversial because most clinical trials have been uncontrolled and because the proposed goal of mortality reduction has not been met. In a case-control trial of rigid sigmoidoscopy, the investigators used data from 261 patients who died of distal colon and rectal cancer. Only 8.8% of these patients underwent sigmoidoscopy, as compared with 24.2% in a control population without cancer. The control patients who had undergone sigmoidoscopy within the preceding 10 years had a 60% to 70% reduction in colorectal cancer mortality.<sup>43</sup> The use of sigmoidoscopy as part of a periodic comprehensive health evaluation to prevent the lethal complications of advanced cancer is case finding and should not be confused with population screening.<sup>44</sup> The American Cancer Society recommends the use of sigmoidoscopic evaluation coupled with annual fecal occult blood testing for average-risk, asymptomatic patients every 3 to 5 years, beginning at 50 years of age.<sup>45</sup>

Sigmoidoscopy is a complement to air-contrast barium enema studies performed to evaluate colonic symptoms, such as rectal bleeding. In a comparative study, the combination of sigmoidoscopy and barium enema was almost as effective in identifying colon cancer as was colonoscopy. The identification of small and medium polyps was better with colonoscopy.<sup>46</sup> Sigmoidoscopy is also useful to assess therapy in inflammatory bowel disease patients. It may be therapeutic for sigmoid volvulus, and it is used to follow up patients with FAP after colectomy and ileorectal reconstruction or to evaluate young family members for phenotypic expression.

Sigmoidoscopy is a safe procedure. Flexible sigmoidoscopy can be easily taught to primary care physicians and nurse practitioners.<sup>47</sup> Perforation of the colon during rigid or flexible sigmoidoscopy is possible but extremely unusual. In a series of 5000 flexible sigmoidoscopies, no perforations occurred.<sup>48</sup>

## COLONOSCOPY

### DIAGNOSTIC COLONOSCOPY

Colonoscopy has become the established method of evaluating and treating diseases of the large intestine. Modern colonoscopes are easier and safer to use, and complete evaluation by direct observation of the rectum and colon to the cecum is the rule. Abnormalities seen may be photographed, subjected to biopsy and, in the case of most polypoid lesions, entirely removed.<sup>49</sup> With aggressive bowel preparation, the patients can often be ready for colonoscopy within 24 hours.

An important indication for colonoscopy is evaluation of abnormal findings on barium enema. When a potential neoplastic lesion is identified on barium enema examination, colonoscopy then is needed to determine the precise nature of the lesion, either by removing it or by biopsy. Colonoscopy also confirms that there are no synchronous lesions elsewhere in the colon. Synchronous adenomas occur in approximately 50% of patients with colon cancer, and separate synchronous colon cancers occur in from 1.5% to 5.0% of patients.<sup>49</sup>

One of the most difficult areas of barium enema interpretation is the differentiation of strictures due to diverticular disease from colon cancer. Barium enema may underestimate the degree and intensity of diverticular inflammation. Colonoscopy, with associated biopsy and cytology, is the most important tool to use in making this distinction. In 44 patients with diverticular disease, Hunt<sup>50</sup> found six (13.6%) with unexpected cancer; he was unable adequately to examine the colon in a similar number of patients.

Hematochezia and melena thought not to be from an upper GI source should be evaluated by colonoscopy. Cancer of the large bowel, particularly in the rectum and left colon, often cause rectal bleeding, whereas cancers involving the right colon are more likely to produce melanotic stools or occult bleeding, with the gradual onset of iron-deficiency anemia. Brand et al.<sup>51</sup> studied by colonoscopy more than 300 patients with recent rectal bleeding and found that the bleeding was due to cancer in approximately 8% of their patients, though in more than 20% it was due to benign colon polyps. Angiodysplasia was also an important cause of large-bowel hemorrhage in their patient population. Tedesco et al.<sup>52</sup> performed colonoscopy in 258 patients with rectal bleeding, negative proctosigmoidoscopy, and barium enemas that were either negative or showed only diverticula. In 29 patients (11.2%), cancer was found during colonoscopy.

Asymptomatic patients with a positive fecal occult blood test should also undergo colonoscopy. Data from the New York occult blood screening trial<sup>53</sup> show that, of patients initially tested for occult blood, approximately 50% have a colonic neoplastic lesion. Approximately 12% of these lesions are cancers, and the rest are adenomatous polyps. These rates increase as the age of the study population increases.

Patients who have had a colon cancer or adenomatous polyp resected are at risk for metachronous lesions. Various estimates have placed the risk for metachronous

cancer between 5% and 10%, whereas the risk of developing a metachronous adenoma can be as high as 60%, as defined in a study of 383 patients by Fowler and Hedberg.<sup>54</sup> The National Polyp Study (NPS), a multicenter randomized trial, demonstrated a polyp recurrence rate of 29% to 35%, depending on the number of colonoscopies performed and the interval between them. It is clear that these patients should be kept under surveillance by follow-up colonoscopy.<sup>55</sup> Published NPS data have demonstrated that at a follow-up interval of 3 years, as many important colonic lesions were detected as were found at a 1-year interval. Therefore, it is recommended that postpolypectomy surveillance colonoscopy be performed once every 3 years.<sup>56</sup>

Colonoscopic polypectomy, although long thought to help prevent colon cancer, now has been proven to do so. Winawer et al.<sup>57</sup> analyzed the NPS cohort of 1418 patients who had a complete colonoscopy during which at least one polyp was removed. The colon cancer incidence in the study population was compared with the incidence in three reference groups, and reductions in cancer incidence of 76%, 88%, and 90%, respectively, were observed ( $P < .001$ ).

Surveillance for colon cancer in patients with long-standing chronic ulcerative colitis represents a special problem. Although there is disagreement as to the magnitude of the cancer risk in ulcerative colitis, most investigators agree that cancer is unusual during the first 8 to 10 years of the disease and that thereafter the estimated cumulative incidence is approximately 5% at 20 years and 12% at 25 years.<sup>58</sup> Annual surveillance colonoscopy should begin after 10 years. The aim of colonoscopy is to identify those patients who are especially likely to develop colon cancer by finding high-grade dysplastic changes in the colonic mucosa on endoscopic biopsy. Dysplasia is clear-cut neoplastic change in the colonic mucosa, and high-grade dysplasia is generally what triggers intervention. Several studies of colonoscopic surveillance were summarized by Wayne.<sup>59</sup> Fifteen percent of patients studied were found to have dysplasia, and 20% of these were found to have colon cancer. However, 10% of colitis patients with cancer had no evidence of dysplasia.

Studies have confirmed that colorectal cancer occurs in first-degree relatives (i.e., parents, children, siblings) of patients with colorectal cancer, with three to four times the frequency expected by chance. There is also an increased risk for adenomatous polyps in first-degree relatives of patients with bowel cancer and an increased risk for colorectal cancer in first-degree relatives with adenomatous polyps.<sup>60,61</sup> Many physicians now recommend colonoscopy, in conjunction with annual fecal occult blood testing, as the primary diagnostic tool for first-degree relatives in colon cancer families.

Screening colonoscopy has been studied in average-risk, asymptomatic patients with negative fecal occult blood studies. In one such study, adenomatous polyps were detected at a rate that was twice that expected from flexible sigmoidoscopy alone.<sup>62</sup> Of 210 patients, 53 (25%) had adenomas, and two had cancers. The larger adenomas and both cancers were found in patients older than 60 years. A follow-up report by the same investigators confirmed the substantial prevalence of colonic neoplasia in asymptomatic people, particularly elderly men, with negative fecal occult blood tests.<sup>63</sup>

## THERAPEUTIC COLONOSCOPY: POLYPECTOMY

After a polyp is identified, colonoscopic polypectomy should be performed. If possible, the polyp is totally removed and submitted for histologic assessment. Complete colonoscopy should be performed at polypectomy to identify and remove any synchronous polyps. Biopsy of polyps is not recommended, because the results may be misleading. Small polyps ( $\leq 7$  mm in diameter) are often removed by "hot biopsy" technique: Electric current is passed through a special biopsy forceps to cauterize the base of the polyp; then the tissue in the forceps is sent to pathology. Larger polyps are removed by snare-cautery technique. A wire loop is passed around the polyp base, and an electric current transects and cauterizes the polyp base. The entire polyp is then retrieved and submitted to pathology for analysis. Most colonic polyps can be managed in this fashion. Large sessile polyps ( $>2$  cm in diameter) may need to be removed with a piecemeal approach. Submucosal saline injection has made this process safer. Occasionally, a large sessile polyp may not be removed safely during colonoscopy, and surgical resection is necessary. Marking the polypectomy site with an injection of sterile India ink has been recommended as an accurate and permanent method for future endoscopic or surgical identification.<sup>64</sup>

## COMPLICATIONS

The major complications of colonoscopy are bowel perforation and hemorrhage. In 4713 diagnostic colonoscopies reported by the American Society for Gastrointestinal Endoscopy, perforation occurred in 0.17%.<sup>65</sup> These perforations are usually the result of the mechanical force of the colonoscope shaft on the sigmoid colon, especially a sigmoid colon affected by diverticular disease or adhesions. In 1901 polypectomy patients reported by the American Society for Gastrointestinal Endoscopy, the perforation rate was 0.11%. Perforation almost always occurred at the polypectomy site and was usually related to the removal of a sessile polyp. Hemorrhage occurred more commonly after polypectomy than after diagnostic colonoscopy (2.16% vs. 0.01%). Patients should avoid aspirin for up to 2 weeks after polypectomy. Postpolypectomy abdominal pain, leukocytosis, and fever do not always represent bowel perforation and may be due to a transmural electrocautery burn. Conservative management in this setting is appropriate.<sup>66</sup>

## LAPAROSCOPY

### PRINCIPLES

Laparoscopy or peritoneoscopy involves the creation of a pneumoperitoneum and the insertion of a thin telescope through a puncture in the anterior abdominal wall. Additional punctures are commonly used for insertion of probes, biopsy needles, and other instruments. For diagnosis and for guided biopsy, laparoscopy can be performed using local anesthesia and mild sedation, similar to that used for other GI endoscopic procedures. This type of laparoscopy should be differentiated from the therapeutic procedure involved in laparoscopic cholecystectomy and other laparoscopic abdominal surgery, which requires general anesthesia.<sup>67</sup> During laparoscopy, the anterior peritoneal space is visualized, with a view of the parietal peritoneum on the anterior abdominal wall and the diaphragm.<sup>68</sup> Most of the liver surface and gallbladder can be examined, along with much of the greater omentum and serosal surfaces of the stomach, small bowel, and colon. The pelvic organs can be visualized. Less completely seen are posterior structures, such as the porta hepatis, pancreas, and spleen. The retroperitoneal lymph nodes and renal system are usually not evaluable.

### INDICATIONS AND RESULTS

The ability to see large areas of parietal and visceral peritoneum and to evaluate the cause of ascites have been major indications for laparoscopy. CT scans have a low yield in imaging small peritoneal metastases. Paracentesis and blind peritoneal biopsy are frequently nondiagnostic. Deposits of even a few millimeters in size on the peritoneum are readily identified and undergo biopsy at laparoscopy to distinguish among metastatic cancer, mesothelioma, or infections (such as tuberculosis).<sup>69</sup>

Because so much of the liver surface can be examined in fine detail, primary and metastatic liver cancers are diagnosed with an accuracy in the range of 90%.<sup>4,5</sup> The ability to see and submit for biopsy small lesions on the liver and peritoneum makes laparoscopy particularly useful in staging the extent of malignant disease. Benign focal conditions, such as fibrosis, cirrhosis, and hemangiomas, may be distinguished from malignant disease with high accuracy. Larger biopsy specimens are usually taken at laparoscopy rather than by scan-guided aspiration biopsy. Enough material can be obtained to permit special histopathologic studies. Direct-vision biopsy allows avoidance of vascular areas, and bleeding after biopsy can usually be controlled.<sup>70</sup>

Laparoscopy has been used for preoperative cancer staging, even if CT scans are normal. Experience with laparoscopic staging has been reported in patients with cancer of the pancreas, esophagus, stomach, gallbladder, and rectum.<sup>71,72,73</sup> and <sup>74</sup> Laparoscopy can increase the diagnostic yield of liver biopsy in Hodgkin's disease and non-Hodgkin's lymphoma.<sup>75,76,77</sup> and <sup>78</sup> Normal CT scans, ultrasound scans, or magnetic resonance images do not exclude the possibility that laparoscopic examination may detect liver or peritoneal malignancy.<sup>79</sup>

## COMPLICATIONS

Laparoscopy is contraindicated in acute or unstable cardiopulmonary states, although there is a continuum of relative risk in more chronic situations. An uncooperative patient should not have laparoscopy under local anesthesia, nor should patients for whom skin infections interfere with sterile insertion of the laparoscope. The procedure is contraindicated in patients with intestinal obstruction and dilated bowel loops. A small amount of ascites does not present a problem, but tense ascites must first be decreased by diuresis or paracentesis. Coagulation disorders that cannot be corrected are contraindications, but mild abnormalities may be acceptable. A history of generalized peritonitis is an absolute contraindication because of the likelihood of multiple dense adhesions, increasing the risk and decreasing the effectiveness of the procedure. Prior abdominal surgery associated with adhesions represents a relative contraindication.<sup>3</sup>

The overall complication rate from laparoscopy is in the range of 1%, with serious complications that delay discharge or necessitate surgery occurring in

approximately 0.2% and with mortality of 0.05%. Subcutaneous emphysema and pneumoventerum are not serious and require no treatment. Mediastinal emphysema, pneumothorax, and air embolism are rare. Abdominal wall bleeding and laceration of blood vessels, organs, or bowel occurs uncommonly but may require surgical management. Biopsy, especially of the liver, accounts for most complications. Tumor implantation at the laparoscopy or biopsy needle insertion site is well described.<sup>67</sup>

## ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

### DIAGNOSTIC ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

The technique of endoscopic retrograde cholangiopancreatography (ERCP) was first reported in 1968 and has been an important diagnostic tool for more than 25 years.<sup>80</sup> The skilled endoscopist working with a cooperative patient can often perform a diagnostic ERCP in less than 20 minutes. Success rates for cannulating the common bile duct and pancreatic duct are well in excess of 90%.

A side-viewing electronic duodenoscope is used to afford excellent visualization of the ampulla of Vater. Cannulization of the biliary and pancreatic ducts is then accomplished, and a contrast agent, such as diatrizoate (Renograffin-60), is injected into the desired duct under fluoroscopic control, and radiologic films of the duct anatomy are subsequently obtained. Duct cytology can be obtained, and biopsy of the ampulla, duodenum, and stomach may also be performed.

Evaluation of the jaundiced patient was one of the more important indications for ERCP. Imaging procedures, such as transabdominal sonography, high-quality CT scans, and magnetic resonance cholangiopancreatography, are replacing diagnostic ERCP ( [Fig. 28-6](#)).<sup>81</sup> Today, therapeutic ERCP is most commonly performed for endoscopic sphincterotomy, removing bile duct gallstones, or placement of an endobiliary stent across the obstructed bile duct segment.

**FIGURE 28-6.** An endoscopic, retrograde cholangiogram demonstrating a short distal common bile duct stricture caused by a primary bile duct cancer.

ERCP may be useful when the patient's symptoms suggest pancreatic cancer and the sonogram or CT scan is not diagnostic. ERCP may be difficult to interpret in the setting of chronic pancreatitis, and cancers can be missed. ERCP is a sensitive and specific diagnostic test for pancreatic cancer. At MSKCC, ERCP had a sensitivity of 92% and a specificity of 97% in the evaluation of 116 patients. In a report by Freeney<sup>82</sup> of 530 patients with pancreatic cancer, normal pancreatograms were seen in only 15 (2.8%). Typical findings include complete occlusion or stenosis of the main pancreatic duct, narrowing or cutoff of the intrapancreatic portion of the common bile duct, and the double-duct sign of stenosis or obstruction of both the main pancreatic duct and the common bile duct. There may also be endoscopic abnormalities, such as a duodenal mass or ulcer that, when subjected to biopsy, document pancreatic cancer.

ERCP is not necessary when the diagnosis appears clear-cut. Frick et al.<sup>83</sup> reported on ERCP used to evaluate 26 patients with indeterminate CT scans and found that ERCP aided the preoperative diagnosis in 25. One pancreatic cancer was missed by ERCP. In an English study<sup>84</sup> of 140 patients with undiagnosed severe chronic abdominal pain, the ERCP was abnormal in 25 (18%). In approximately one-fourth of the patients, diagnoses were made. These diagnoses included gallstones, peptic ulcer disease, pancreatic cancer, and chronic pancreatitis.

### THERAPEUTIC ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

The therapeutic use of ERCP is growing rapidly. The major therapeutic procedures performed are endoscopic sphincterotomy, stone extraction, and placement of endobiliary stents for the palliative nonsurgical treatment of biliary obstruction. Approximately 75% of ERCPs done in our endoscopy unit at MSKCC are therapeutic.

Endoscopic sphincterotomy is performed by inserting into the distal common bile duct through the ampulla a specialized cannula containing an electro-surgical cutting wire. When the electrical current is passed through the exposed wire, a controlled incision is made in the sphincter, opening the distal bile duct to allow the endoscopic removal of bile duct stones or the placement of endobiliary stents. Biopsy of ampullary tumors is facilitated by endoscopic sphincterotomy, and the associated obstructive jaundice may be temporarily relieved by this procedure. Bourgeois et al.<sup>85</sup> obtained the correct histologic diagnosis in all 55 patients with periampullary cancer after endoscopic sphincterotomy but in only one-half before sphincterotomy.

Nonsurgical biliary drainage has become an important tool in the palliative management of patients with malignant biliary obstruction. Endoscopic biliary drainage (EBD) ([Fig. 28-7](#)) and percutaneous transhepatic drainage (PTD) complement each other and are selected on the basis of the level of the biliary obstruction.<sup>86</sup> In a prospective randomized study comparing EBD with PTD in 75 high-risk patients with malignant biliary obstruction, EBD was significantly more successful in relieving jaundice (81% vs. 61%) and had a significantly lower 30-day mortality rate (15% vs. 33%). The complication rate of EBD was 19%, whereas the morbidity of PTD was 67%.<sup>87</sup>

**FIGURE 28-7.** An endoscopically placed biliary stent is seen in the common bile duct across the malignant stricture shown in [Figure 28-6](#).

The location or level of the malignant biliary stricture is very important in determining success and complication rates with nonsurgical biliary drainage. Seventy patients with malignant hilar strictures were stratified by Deviere et al.<sup>88</sup> into three groups. Twenty patients had common hepatic duct lesions (type I), and 50 patients had bifurcation or intrahepatic strictures (types II and III). The type I patients were likely to experience complete drainage, whereas in only approximately 50% of the type II and III patients was drainage adequate. These patients had a higher 30-day mortality, a higher rate of early cholangitis, a higher death rate from sepsis, and a shorter postprocedure survival. Success in adequately draining common bile duct and common hepatic duct strictures should be approximately 90% with large-bore endoprostheses placed during ERCP. The success rate for establishing drainage by ERCP in bifurcation or intrahepatic strictures is much lower. Using an aggressive

approach with multiple attempts and combining EBD with PTD increased the success rate of insertion of two or more stents to only approximately 50% of patients with hilar strictures.<sup>88</sup>

EBD has been prospectively compared to surgical biliary bypass. Fifty-two patients with distal common bile duct obstruction were randomly assigned to either EBD or surgical biliary bypass.<sup>89</sup> Survival data for both groups were similar, as was the 90% success rate in relieving jaundice. Patients treated with EBD had a significantly shorter initial hospital stay (5 vs. 13 days;  $P < .002$ ). Readmissions to the hospital were more frequent in the EBD group, but the total hospital stay in days per patient until death was shorter in the EBD group (8 vs. 13 days;  $P < .01$ ). In patients with pancreatic cancer and jaundice who are not candidates for surgical resection, because of either advanced disease or other medical problems, EBD should be the biliary drainage procedure of choice. Metal endoscopic stents are replacing polyethylene stents, especially in those patients who can reasonably be expected to live more than 6 months. The use of metal endobiliary stents should reduce the number of stent replacements. Although EBD affords good palliation for advanced cancer cholestasis, studies have shown that there is no role for preoperative biliary drainage.<sup>90</sup>

## COMPLICATIONS

The most common complications of ERCP are cholangitis and sepsis. The rate of cholangitis and sepsis varies, depending on the reason for the ERCP and the underlying pathology. For example, therapeutic ERCP done for biliary obstruction may have a sepsis rate as high as 14%.

The level of the biliary obstruction affects the rate of sepsis. In an MSKCC series<sup>91</sup> looking at PTD after failed EBD, the rate of sepsis for patients with intrahepatic and bifurcation strictures was significantly greater than for those with common hepatic or common bile duct lesions (75% vs. 17%;  $P = .04$ ). Another MSKCC study<sup>92</sup> compared the microbiologic data for septic episodes after EBD with septic episodes after PTD. Although enteric gram-negative organisms predominated in both groups, there were significantly more gram-positive organisms noted in the PTD group ( $P < .0005$ ).

Acute pancreatitis is another common complication of ERCP, and it is related to the injection of contrast material into the pancreatic duct. Its frequency varies but generally occurs in fewer than 7% of patients. It is usually self-limited and rarely presents as a serious clinical problem. Clinical trials with such agents as octreotide have not shown a reduction in ERCP-associated pancreatitis.<sup>93</sup>

## SMALL INTESTINAL ENDOSCOPY: ENTEROSCOPY

Evaluation of the small intestine beyond the fourth portion of the duodenum is commonly accomplished by barium studies or angiography. Two endoscopic techniques for studying the small bowel have been developed. Dedicated push enteroscopes (Olympus Corp., SIF-10) often can be passed rapidly to approximately 100 cm distal to the ligament of Treitz. Biopsy, polypectomy, diathermy, and Nd:YAG laser treatment can be performed through this instrument. In a study of 56 patients, the median depth of insertion into the small intestine was 45 cm (range, 15 to 90 cm), and procedure times varied from 10 to 45 minutes.<sup>94</sup> Push enteroscopy has been very useful in the evaluation and treatment of GI bleeding due to occult proximal small intestinal sources and in the evaluation of abnormalities seen on barium small intestinal radiographs.

The sonde-type enteroscope is slender and approximately 2.7 m long. It has an inflatable balloon at its tip that helps in passage through the small intestine. Among the several disadvantages of this instrument are its lack of a biopsy channel, the absence of tip deflection, a limited field of view, the need for fluoroscopy, and the 8 hours required for its use.

In using enteroscopy in the evaluation of obscure GI bleeding, one study of push enteroscopy identified the source of bleeding in 15 of 39 patients (38%).<sup>95</sup> The most common cause found was an arteriovenous malformation. The diagnostic yield in a study of 35 patients with obscure GI bleeding using a sonde-type enteroscope was 26%.<sup>96</sup> A study of 258 patients identified nine malignant and four benign tumors to be the cause of the obscure bleeding (5%).<sup>97</sup>

## PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

Since its original description by Ponsky and Gauderer<sup>98</sup> in 1981, percutaneous endoscopic gastrostomy (PEG) has become a routine procedure, done in an outpatient setting without general anesthesia, in patients either unable to take oral feedings or in whom parenteral nutritional support is not feasible. PEG and percutaneous endoscopic jejunostomy (PEJ) are rapid and safe endoscopic methods for establishing enteral feeding routes and can eliminate the need for long-term nasal feeding tubes. In a study of 42 patients with dysphagia and cancers of the head and neck, successful use of PEG and PEJ was accomplished in 39.<sup>99</sup> No immediate complications occurred. After a mean follow-up of 4.5 months, only one patient developed pneumonia presumed to be due to aspiration. Complication rates for surgical gastrostomies have been reported to be as high as 75%.<sup>100</sup>

When patients have had previous gastric resections, PEJ may be used. In 115 patients, Shike et al.<sup>101,102</sup> had a success rate with PEJ of more than 90%. PEJ was used in gastric outlet and small bowel obstruction, gastroparesis, and anorexia. Only two patients experienced severe complications of bleeding and abscess formation. Significant caloric intake ranging between 900 and 2400 calories per day could be administered.

## BRONCHOSCOPY

Bronchoscopy (Table 28-1) is the single most useful modality for accurately diagnosing lung cancer. With the advent of fiber-optic equipment introduced more than 25 years ago,<sup>103,104</sup> this procedure has been used for diagnosis with increasing frequency

Parameter	Rigid Fiber-Optic Bronchoscopy	Flexible Fiber-Optic Bronchoscopy
Depth	Cervical position	Below epiglottis
Visualization of bronchi	Excellent	Excellent
Visualization of segmental bronchi	Nil (right/left only)	Excellent
Depth of penetration	No	Yes
Anesthesia required	General	Local
Sectioning sections	Excellent	Good
Complication	Pneumonia and bleeding reported	Very unusual
Flexibility of instrument	Rigid	Flexible
Timing to perform examination	Extensive	Minimal
Management of airway obstruction	No	Yes

TABLE 28-1. Comparison of Rigid and Flexible Fiber-Optic Bronchoscopy Technique

## INDICATIONS

The most common oncologic indication for bronchoscopy is to diagnose and assist in staging lung cancer by direct observation and by obtaining material for cytologic and histologic evaluation.<sup>105</sup> In investigating other upper aerodigestive tumors, bronchoscopy rules out extension of laryngeal and esophageal carcinomas to the upper airway. Flexible bronchoscopy has been especially important in localizing occult sites of malignancy when sputum cytology results are positive.

Therapeutically, bronchoscopy has been extensively used to remove retained secretions in the postoperative period, to relieve obstructed airways due to malignancy (in conjunction with laser destruction), and to arrest bleeding. This technique is used to deliver anticancer therapy (cauterization, cryotherapy, photocoagulation, and brachytherapy) in the definitive or palliative treatment of endobronchial malignancies.<sup>106,107</sup> Bronchoscopy is also used to insert intraluminal stents when required to maintain airway patency.

## TECHNIQUE

### **Rigid Bronchoscopy**

The open-tube rigid bronchoscope, although used less frequently for diagnosis, remains a valuable therapeutic tool. It is especially important in controlling airway hemorrhage and is favored by most endoscopists for mechanical removal and laser coagulation of tumors ( [Fig. 28-8](#)). It also has the advantages of a large lumen, allowing suctioning of blood or fumes developing during laser coagulation and obtaining larger biopsies. Although the rigid bronchoscope can be introduced under local anesthesia, the preferred approach is general anesthesia.

**FIGURE 28-8.** Comparison of flexible and rigid equipment and of biopsy potential. This photograph illustrates a flexible esophagoscope, flexible bronchoscope, rigid esophagoscope, rigid bronchoscope, and the biopsy forceps that can be used with each endoscope.

### **Flexible Bronchoscopy**

Flexible bronchoscopy has become the mainstay of endoscopic airway examination. The flexible equipment is small enough to be introduced transnasally or transorally under local anesthesia with or without sedation. Because of its small diameter (6 mm or smaller), the average flexible bronchoscope can enter all segmental orifices of the tracheobronchial tree. Newer instruments (with an external diameter as small as 2.0 mm) can now extend the visible range to the periphery of the lung and have been used for biopsy of peripheral nodules or infiltrates ( [Fig. 28-9](#)).<sup>108</sup> These newer instruments no longer use fiber-optics for visualization: Electronic signals are now transmitted from the tip of the bronchoscope to a television monitor.

**FIGURE 28-9.** The range of the flexible bronchoscope within the tracheobronchial tree. The second order of branchings of the tracheobronchial tree can be inspected and subjected to biopsy.

Most instruments have a 2-mm operating channel for suctioning and to pass brushes and biopsy forceps to obtain pathologic material for examination. Flexible fibers can be passed through the operating channel for Nd:YAG laser treatment and argon beam excitation of hematoporphyrins (PDT) to induce photocoagulation of malignant tissue. The versatility and ease of use of the flexible bronchoscope has allowed this procedure to be performed in an outpatient setting with minimal inconvenience to the patient.

## DIAGNOSTIC BRONCHOSCOPY

Malignant lesions of the tracheobronchial tree and pulmonary parenchyma are most often diagnosed using flexible bronchoscopy. Tumors that involve the proximal airways as distal as subsegmental bronchi can usually be seen at the time of flexible bronchoscopy, and specimens can be obtained for histopathology or exfoliative cytology. Those lesions beyond the range of the flexible equipment can be subjected to biopsy under fluoroscopic control, passing biopsy forceps or brushes into the lesion that has been localized using an image intensifier. Diffuse pulmonary infiltrates requiring diagnosis can be easily sampled using similar radiologic techniques, passing biopsy forceps into the pulmonary parenchyma to obtain representative samples (transbronchial biopsy). Wang et al.<sup>109</sup> have popularized the technique of transbronchial needle aspiration for diagnosing malignancy in mediastinal lymph nodes as well as in submucosal lesions inaccessible to direct biopsy or brushing. More recently, localization of mediastinal lymph nodes has been attempted using bronchoscopic ultrasonography. This has proven to be somewhat difficult because the air-containing airway cannot transmit the ultrasound waves, and obstruction of the airway is required to fill the lumen with a fluid-filled balloon to perform the examination. However, subcarinal lymph nodes can be easily accessed by performing endoesophageal ultrasonography with guided endobronchoscopy.<sup>110</sup>

The success of these techniques is operator-dependent. It is rare for lesions that can be visualized not to yield a diagnosis. Intrapulmonary lesions located more peripherally may be more difficult to diagnose, especially if they are small (<3 cm in diameter) and are probably best diagnosed by percutaneous transthoracic needle aspiration biopsy using radiologic techniques. However, bronchoalveolar lavage with saline and postbronchoscopy sputum samples can provide cytology for examination.

Identification of occult *in situ* malignancies can be enhanced with the use of tumor fluorescence aided by laser light excitation. Injected hematoporphyrin derivatives fluoresce at a specific wavelength (640 nm) emitted by the argon laser beam and, most recently, autofluorescence of tumors using specific wavelengths can identify areas of dysplasia and frank neoplasia (lung imaging fluorescent endoscopy bronchoscopy).<sup>111</sup> This technique is extremely important in identifying occult cancers detected by sputum cytology. This autofluorescence technique is being investigated also as a method of early diagnosis of lung cancer in high-risk individuals (especially patients with previous aerodigestive tumors; [Fig. 28-10](#)).<sup>112</sup>

**FIGURE 28-10.** A lung imaging fluorescent endoscopy bronchoscopic image demonstrating a darkened area of the carina between the anterior and apical segments of the upper right lobe (arrow). This proved to be *in situ* carcinoma on biopsy.

## THERAPEUTIC BRONCHOSCOPY

The most common oncologic indication for therapeutic bronchoscopy is bronchopulmonary toilet after major pulmonary resections for malignancy. This has become an invaluable bedside tool in the postoperative management of thoracic surgical patients since the introduction of flexible instruments. Bronchoscopy has also been used with success in relieving endobronchial obstruction and in dealing with significant airway hemorrhage.

Endobronchial tumors can be mechanically débrided using the tip of the rigid bronchoscope or a large biopsy forceps.<sup>113</sup> Techniques of tumor coagulation and destruction have been introduced that avoid unnecessary or excessive bleeding. These techniques include cryosurgery, electrocautery and, most recently, carbon dioxide, Nd:YAG, or argon laser destruction.<sup>114</sup> These modalities require significant training in the use of lasers and are best applied when visible endobronchial tumors are present. Extrinsic compression by enlarged mediastinal lymph nodes does not respond to this type of treatment. When extrinsic compression is a major problem, endobronchial stents similar to those used for obstructing esophageal lesions can be inserted. A variety of Silastic and self-expanding metallic stents have been devised. The Silastic stents have the disadvantage of frequent migration. Self-expanding metallic stents, once inserted, cannot be removed but rarely migrate. These stents can be coated with Silastic to avoid growth of tumor through the interstices of the stent (Fig. 28-11 and Fig. 28-12). With the expandable metallic stents, instances of tracheoesophageal fistulization have occurred. In properly selected patients, however, these expandable stents are replacing the plastic stents in the management of malignant disease. When either external-beam radiation or internal brachytherapy is added to endobronchial tumor destruction or in conjunction with stents, longer periods of palliation can be achieved, avoiding tumor regrowth and overgrowth.<sup>115</sup> With these techniques, approximately 80% of patients can be relieved of their obstructing symptoms for a median of 3 months.

**FIGURE 28-11.** **A:** An endobronchial stent loaded on the end of a rigid bronchoscope uses a chest tube as an inserter. **B:** Use of an endobronchial stent in extrinsic compression.

**FIGURE 28-12.** A carcinoma *in situ* just at the orifice of the right upper lobe. A standard bronchoscopy (**B**) demonstrates minimal elevation of mucosa. A marked change is apparent in the lung imaging fluorescent endoscopy (LIFE) image (**A**). Note: Black and white production does not reproduce the image that is so well seen at the LIFE bronchoscopy.

PDT has also been used to destroy endobronchial tumors. This technique is used as definitive therapy for *in situ* carcinoma and is effective in totally destroying such tumors in approximately 50% of cases.<sup>4</sup> It is now being used with increasing frequency to destroy inoperable tumors obstructing the airway.<sup>116</sup> Most tumors respond to this therapy, and up to 90% of patients obtain some palliation. With the U.S. Food and Drug Administration release of hematoporphyrins for therapy in North America, significant activity has occurred in investigating this approach for palliation of obstructing tumors and treatment of *in situ* and inoperable stage I proximal tumors. A newer hematoporphyrin, porfimer (Photofrin II), is currently the drug of choice. It is administered 24 to 48 hours before laser illumination of the tumor. This causes an intense and immediate destruction of the tumor, which requires mechanical débridement. In most instances, a second bronchoscopy 24 or 48 hours later completes the débridement. When compared to Nd:YAG laser destruction, it fares very well. Currently, all of these endobronchial-relieving methods are effective, and a combination of two of these (e.g., PDT plus radiotherapy, mechanical or Nd:YAG destruction plus radiotherapy) seems to produce the longest periods of palliation. Metastatic endobronchial tumors are also amenable to these therapies.<sup>117</sup>

## COMPLICATIONS

The complications of diagnostic rigid and flexible bronchoscopy are minimal, with fewer than 1.0% of patients experiencing any significant postprocedure problems. Rigid bronchoscopy has the disadvantage of trauma to the teeth, lips, and mouth as well as the larynx. This is completely avoided by using flexible bronchoscopy. Biopsy of lesions can lead to hemorrhage, although bleeding rarely is excessive.<sup>118</sup> As with any other surgical procedure, care must be taken, before bronchoscopy is performed, to evaluate and correct any coagulation abnormalities. Transbronchial biopsy of lung parenchyma can lead to bleeding and pneumothorax; the latter complication occurs rarely if routine precautions are taken to avoid biopsy at the extreme periphery of the lung. In a series from the Cleveland Clinic,<sup>118</sup> only 58 episodes of bleeding occurred in almost 7000 flexible bronchoscopies. Transbronchial biopsy showed a higher incidence of bleeding, though no deaths ensued. In two other large bronchoscopy series, the death rates were 0.1% and 0.3%, respectively.<sup>119,120</sup> In a series of 4000 patients, major complications (pneumothorax, pulmonary hemorrhage, or respiratory failure) occurred in 0.53% of flexible bronchoscopies. After transbronchial biopsy, however, 6.8% of patients experienced either

hemorrhage (2.8%) or pneumothorax (4%), and there were no deaths.<sup>121</sup>

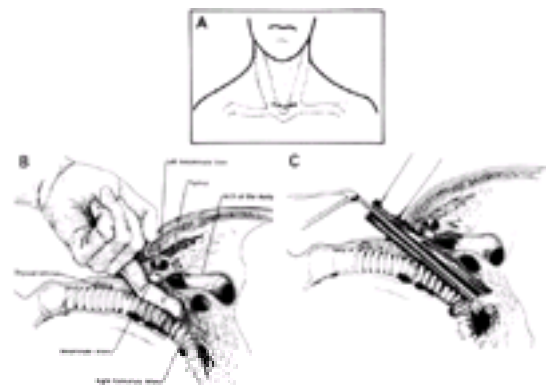

## MEDIASTINOSCOPY

### INDICATIONS

Mediastinoscopy is used most frequently to obtain lymph node samples from the superior mediastinum to assist in the clinical staging of lung cancer. It can be extremely valuable in identifying metastatic malignancy in these lymph nodes, thereby providing histologic evidence of N2 and N3 (stage IIIa and IIIb) disease in patients with lung cancer.<sup>122</sup> Less frequently, this technique is used to diagnose other lesions presenting with mediastinal adenopathy. Lymphomas, primary lung cancers with mediastinal involvement, and a host of benign lesions can be diagnosed using this approach. The procedure can also identify direct mediastinal invasion by a lung tumor and, by extending the mediastinal dissection, can be used for biopsy of lesions in the anterior mediastinum. Either pleural space can be entered through the mediastinum to detect abnormalities, especially in the paramediastinal regions.<sup>123</sup>

### TECHNIQUE

The mediastinoscopy technique (Fig. 28-13) is simple and safe in the hands of well-trained thoracic surgeons. A short suprasternal transverse incision is made, dissecting down to the pretracheal fascia, which is opened. Finger dissection in the pretracheal plane precedes the insertion of the mediastinoscope. Direct visualization of all areas of the superior mediastinum then allows appropriate biopsies of tissue in the various mediastinal nodal stations.

**FIGURE 28-13.** Technique of mediastinoscopy. **A:** Make a 3- to 4-cm incision just above the manubrium. **B:** Use the finger to dissect bluntly the loose fibrofatty tissue in front of the trachea down to the level of the pulmonary artery. **C:** Introduce the endoscope and take biopsies of suspicious tissues. Needle aspiration of structures before biopsy helps to reduce hemorrhagic complications. (Modified from PA Kerschner. Transcervical approach to the superior mediastinum. *Hosp Pract* 1970;5:61.)

Mediastinoscopy is performed under general anesthesia but is usually performed on an outpatient basis. It can also be used just before thoracotomy for final clinical staging in patients suspected of possibly harboring inoperable disease by virtue of mediastinal spread.

### RESULTS

With the ability to biopsy mediastinal lymph nodes directly, the accuracy of mediastinoscopy approaches 90% when assessing the mediastinal involvement of lymph nodes in lung cancer.<sup>124</sup> Virtually no false-positive examination results should occur. Because of the inaccessibility of certain areas of the mediastinum, a 10% false-negative rate can be expected. However, those inaccessible mediastinal lymph nodes are usually resectable at the time of surgery. When mediastinoscopy fails to reveal metastatic disease in patients with otherwise operable lung cancer, the resectability rate of such patients approaches 95%. Mediastinoscopy remains the most accurate method of assessing mediastinal involvement by lung cancer and is usually used when CT scanning suggests enlarged mediastinal lymph nodes (>1 cm) to confirm the presence of metastatic disease to the mediastinum.

Since the introduction of positron emission tomography (PET) scanning, many centers have used this technique of staging the superior mediastinum instead of the invasive technique of mediastinoscopy. There are differences of opinion as to whether PET scanning can be depended on to be accurate. Certainly, "positive" PET scans denoting mediastinal spread of tumor should be confirmed by histologic proof. "Negative" PET scans do not rule out microscopic metastatic disease to the superior mediastinum.<sup>125,126</sup>

In expert hands, mediastinoscopy is safe. One retrospective review from Washington University demonstrates the safety of the technique. In more than 2000 mediastinoscopies, there was one treatment-related death in a patient with very extensive mediastinal disease and very few significant complications: Only three patients required a thoracotomy for bleeding and, in all of those patients, the primary tumor was surgically treated at the time of thoracotomy.<sup>127</sup>

### ANTERIOR MEDIASTINOTOMY (CHAMBERLAIN PROCEDURE)

Tumors situated in the anterior mediastinum (e.g., lymphomas, germ cell tumors, thymomas) are often diagnosed by percutaneous transthoracic needle aspiration biopsy. The most direct approach to the anterior mediastinum, when incisional biopsies are required, is a modification of the technique of anterior mediastinotomy described by MacNeill and Chamberlain.<sup>128</sup> A small transverse incision is made in the second intercostal space or over the second or third costal cartilage. The anterior mediastinum is entered, usually without transgressing the pleura, and a biopsy can be obtained. Frequently, left upper lobe tumors do not metastasize to superior mediastinal lymph nodes but to the lymph nodes in the paraaortic area, most accessible by anterior mediastinotomy.

### THORACOSCOPY

Thoracoscopy (pleuroscopy) is used most frequently to investigate and treat pleural effusions when simple thoracentesis fails. Until recently, open-tube instruments (e.g., mediastinoscopes) were used for inspection and biopsy. However, the use of thoracoscopy has been extended significantly with the introduction of miniaturized video-recording equipment and improved instrument technology (Fig. 28-14). Learning from the experience developed with laparoscopic surgery, video-assisted thoracoscopic surgery has become a burgeoning enterprise.<sup>115,129</sup> Thoracoscopy has now been used not only for diagnosing pleural disease but for assessing mediastinal spread of lung and esophageal cancer and diagnosing lung disease.<sup>130</sup> The diagnosis of indeterminate pulmonary nodules, previously requiring a thoracotomy, can now be accomplished with relatively minimal invasion using video-assisted techniques. This has become especially important in identifying those nodules so frequently seen on CT scan, only a few millimeters in diameter, inaccessible by any other technique short of thoracotomy. Advanced thoracoscopic techniques can allow partial and total lung resection as well as dissection and removal of mediastinal structures (esophagus, thymus gland, mediastinal lymph nodes, etc.). The ultimate indications for video-assisted thoracoscopic surgery in the treatment of oncologic disease await further investigation and long-term follow-up of efficacy.<sup>131</sup>

**FIGURE 28-14.** The video-assisted technique for removing a solitary pulmonary nodule.

## TECHNIQUE

Simple thoracoscopy (pleuroscopy) can be performed using a small incision and inserting an open-tube scope (e.g., mediastinoscope) for removal of fluid and simple biopsy of abnormal lesions on the pleural surface. Video-assisted thoracoscopy usually requires the development of a pneumothorax using one-lung anesthesia, three to four small intercostal incisions, and the insertion of multiple trocars to allow the introduction of a videoscope plus a variety of instruments for surgical dissection. With this technique, the total visceral and parietal pleural surfaces can be examined and subjected to biopsy, the mediastinum can be entered and dissected as well as subjected to biopsy, and portions of the lung can be removed, taking advantage of mechanical stapling and cutting devices designed for the purpose.

With very small lesions, difficult to identify at the time of thoracoscopy, transthoracic needles placed radiologically before thoracoscopy can localize the area for resection, similar to the localization techniques used in performing breast biopsies.

## RESULTS

Thoracoscopy is an excellent tool to diagnose pleural disease definitively and yields almost a 100% success rate. Peripherally placed lesions of the lung can usually be localized and can be resected for diagnosis, avoiding a major thoracotomy and its attendant morbidity. For this reason, hospital stays are shortened, and the use of expensive medical resources is diminished. The long-term results of thoracoscopic resectional surgery for oncologic disease have yet to be determined. When using this technique for cancer treatment, surgeons must be wary of inadequate resections that may result. In reported series, most surgeons limit video-assisted thoracoscopic resections to early-stage (T1 to T2, N0) tumors. In experienced hands, this approach is safe, and adequate oncologic resections can occur. However, as yet, there is no evidence that this approach provides any benefit to the patient with regard to pain, length of stay, or efficacy. Despite its introduction almost 10 years ago, video-assisted thoracoscopic resections for malignancy are practiced by a very small proportion of thoracic surgeons. <sup>132,133 and 134</sup>

## COMPLICATIONS

Video-assisted thoracoscopy usually requires general anesthesia, although in diagnosing pleural disease, local anesthetic techniques can be used. The risks of general anesthesia and one-lung ventilation yield some minor morbidity but rarely, if ever, any mortality. Used judiciously, video-assisted thoracoscopy for diagnosis and staging is an extremely safe technique and may be performed on an outpatient basis. Of great concern is its oncologic application. There have been reports of inadequate resections with high local recurrence rates and tumor implantation in thoracoscopic port sites. However, with appropriate techniques, these problems are avoidable. As yet, there is no real evidence of major cost savings or significant long-term benefit using this approach in treating thoracic malignancies. However, the diagnostic abilities of video-assisted thoracoscopic surgery have allowed firm diagnosis to be established with minimal morbidity.

## INTRODUCTION

Laparoscopy has become an important tool in the diagnosis and treatment of many diseases worldwide since the late 1980s. However, the procedure has been available for nearly 100 years, used mostly by gynecologists, hepatologists, and a few pioneer general surgeons. The first report is from a gynecologic procedure performed by Ott in Russia in 1901.<sup>1</sup> Insufflation was introduced in 1901 by Kelling, in a dog model. The Veress needle was developed in 1938. Older instruments consisted of a metal tube fitted with lenses, which allowed one person at a time to see the hazy images provided. One of the major reasons for the new popularity of laparoscopy is the availability of high-quality images on video monitors, making it easy for a team of surgeons to work together, each with the same view. In addition, the development of long-handled tools that function through ports has rapidly and widely expanded the scope of laparoscopic surgery.<sup>2</sup>

One of the earliest applications of laparoscopy to patients with cancer was by Bagley and coworkers<sup>3</sup> in 1973 who reported 96 cases of peritoneoscopy in the evaluation of lymphoma. Also in 1973, Casirola and colleagues<sup>4</sup> published a series of 38 patients with lymphoma who were evaluated laparoscopically at the University of Pavia. They concluded that laparoscopy should be used routinely in the evaluation of patients with Hodgkin's lymphoma to accurately assess stage. Because of limitations imposed by the available equipment, they were limited to observational staging of the liver surface. Laparoscopy and bone marrow biopsy were advocated as necessary before laparotomy in patients with Hodgkin's disease by several studies as early as 1975.<sup>5,6</sup> The value of laparoscopy in the evaluation of patients with non-Hodgkin's lymphoma (NHL) was further described by Chabner and colleagues<sup>7</sup> from the National Institutes of Health, when they advocated peritoneoscopy as a routine component of a staging procedure. These investigators advocated multiple liver biopsies through the peritoneoscope for patients with negative evaluations for widespread disease, including a history, physical examination, imaging studies, bone marrow biopsies, and a percutaneous liver biopsy. Laparotomy with splenectomy and multiple lymph node biopsies was then recommended for patients with negative peritoneoscopy and liver biopsies.<sup>8</sup>

In 1978, Cuschieri and colleagues<sup>9</sup> reported on the laparoscopic evaluation of 23 patients with pancreatic carcinoma. These pioneers were able to investigate the lesser sac with their primitive instruments and thought that laparoscopy might be used to obviate the need for laparotomy in patients with advanced disease.

Although laparoscopy is applied widely to a large number of surgical conditions and has become the standard surgical approach for cholecystectomy since its introduction to the United States in 1988, its application to patients with cancer remains less well defined. In fact, there are no specific indications for the use of laparoscopy in patients with malignancies. Two principles guide the use of laparoscopy in the care of the cancer patient. First, as with any procedure, laparoscopy should not be performed simply because it can be done. Second, when laparoscopy is used in the care of the cancer patient for diagnosis, staging, treatment, or palliation, the laparoscopic conduct of the operation should compromise neither the nature of the procedure nor the amount or source of the tissue obtained.

Surgeons have been involved in the diagnosis, staging, treatment, and palliation of malignancies for centuries. Laparoscopy is assuming a role in each of these areas. Laparoscopy has a role in establishing the *diagnosis* of cancer in some situations, allowing biopsy of intraperitoneal and retroperitoneal masses and lymph nodes, biopsy of visceral lesions, and the examination of abdominal contents with ultrasound probes. Laparoscopy is useful in the *staging* of established malignancies, such as pancreatic cancer, Hodgkin's lymphoma, and esophageal cancer. Laparoscopy also has a role in the surgical *treatment* of a variety of malignancies, including gastric carcinoma, pancreatic cancer, renal tumors, adrenal tumors, colon cancer, and gynecologic tumors. Laparoscopy may be the appropriate approach for the definitive therapy of these lesions or may be a way to provide a palliative procedure, such as a cholecystojejunostomy, in a patient with unresectable carcinoma of the pancreas. Lastly, laparoscopy can play an important role in the *palliative care* of the cancer patient as a way of performing procedures such as feeding tube placement or intestinal stoma creation with decreased hospitalization and recovery time.

Although many procedures have been performed successfully using laparoscopic technology, the results obtained should be analyzed objectively and critically. There are advantages and disadvantages to both the open and laparoscopic conduct of many procedures. Most important, the technique selected should benefit the patient maximally. This must be viewed from many angles, including patient comfort, tissue obtained, cost-effectiveness, surgical morbidity, and surgical mortality. At the present time, for most laparoscopic procedures applied to the care of the patient with cancer, insufficient data are available to make quantitative judgments about most of these issues. Therefore, only by critically analyzing the existing data can a practitioner begin to make decisions about what techniques to use for a specific patient.

## LAPAROSCOPIC PHYSIOLOGY

### CELLULAR EFFECTS

One of the most notable sequelae of laparoscopic surgery is the generally significant decrease in the amount of pain when compared with open procedures. This may easily be attributed to the use of smaller incisions and the lack of retractors holding these incisions open for hours. However, patients who undergo laparoscopic splenectomy and then require an incision for removal of the intact specimen (see later, [Lymphoma](#)) also note decreased pain in their incisions. West and colleagues<sup>11</sup> investigated the effect of different insufflation gases on murine peritoneal macrophage intracellular pH and correlated these alterations with alterations in lipopolysaccharide stimulated inflammatory cytokine release. Peritoneal macrophages were incubated for 2 hours in air, helium, or carbon dioxide (CO<sub>2</sub>), and the effect on tumor necrosis factor (TNF), interleukin (IL)-1, and cytosolic pH were determined. Macrophages incubated in CO<sub>2</sub> produced significantly less TNF and IL-1 compared with incubation in air or helium. In addition, exposure to CO<sub>2</sub>, but not air or helium, produced a marked cytosolic acidification. These authors conclude that cellular acidification induced by peritoneal CO<sub>2</sub> insufflation contributes to the diminished local inflammatory response seen in laparoscopic surgery.

### EFFECTS ON HEPATIC BLOOD FLOW

Changes in hepatic blood flow can be significant because the liver plays a central role in the removal of a wide variety of substances from the circulation. Changes in hepatic blood flow could significantly alter the biokinetics of anesthetic and other agents. In an effort to investigate the effect of CO<sub>2</sub> pneumoperitoneum, Tuñón and colleagues<sup>10</sup> evaluated the pharmacokinetics of indocyanine green, an anionic dye frequently used to estimate hepatic blood flow in experimental systems. They found a significantly decreased clearance of indocyanine green in the insufflation and laparoscopic surgery groups compared with the open surgery group, corresponding to a significantly decreased hepatic blood flow in these two groups. They concluded that dose adjustments of many agents may be necessary for patients undergoing laparoscopic procedures, especially those with limited hepatic reserve.

### CARDIOPULMONARY EFFECTS

The use of laparoscopy in patients with sepsis may be a significant physiologic challenge. In an effort to assess this experimentally, Greif and Forse<sup>12</sup> studied cardiopulmonary physiologic parameters in a pig model of adult respiratory distress syndrome (ARDS). After inducing ARDS, animals were divided into two groups: One underwent laparoscopy and the other conventional laparotomy. The laparoscopic group demonstrated a significantly decreased pulmonary compliance compared with the laparotomy group, had a higher pCO<sub>2</sub>, and was more acidotic. Animals with ARDS demonstrate further compromise in pulmonary physiologic parameters when undergoing laparoscopy, but overall, cardiorespiratory function was preserved.

In a subsequent study, Greif and Forse<sup>13</sup> used a porcine sepsis model to evaluate interventions to ameliorate the effect of laparoscopy on cardiovascular hemodynamics. Specifically, they found that the adverse effects may be mediated by increased pulmonary vascular resistance, diminished venous return, or both. They found that insufflation with air instead of CO<sub>2</sub> to manipulate arterial pH did not improve cardiovascular hemodynamics. Aggressive fluid administration, and administration of prostacyclin or indomethacin, had positive effects on the hemodynamic effects of pneumoperitoneum.

### LAPAROSCOPY AND THE SYSTEMIC IMMUNE RESPONSE

The effect of laparoscopy on the activation of the systemic immune response has been studied by a number of investigators. Cytokine levels provide us with one method of evaluating the systemic immune response. The cytokines IL-1, IL-6, C-reactive protein, and TNF are known mediators of the acute-phase response.<sup>14</sup> Peak C-reactive protein levels have been shown to be significantly higher after open cholecystectomy compared with laparoscopic cholecystectomy.<sup>14</sup> Furthermore, these investigators found a significantly prolonged elevation in C-reactive protein levels in patients undergoing open cholecystectomy compared with those undergoing laparoscopic cholecystectomy.

Serum IL-6 levels are early and sensitive markers of tissue damage because they increase proportionally to degree of injury. IL-6 levels also have been shown to correlate with the development of significant complications and mortality. Serum IL-6 levels have been shown to be reduced in patients undergoing laparoscopic cholecystectomy compared with those undergoing open cholecystectomy.<sup>15</sup> There remains a distinct lack of consensus about the meaning of the decreased IL-6 response, and further study is indicated.

The immunosuppression induced by open surgery has been studied in the past and has been well described.<sup>16,17</sup> More recent studies have looked at the effect of laparoscopic surgery on the cellular components of the immune system. Previous studies have shown significant decreases in the CD4 and CD8 cell counts in patients undergoing open cholecystectomy.<sup>17</sup> Vallina and Velasco<sup>16</sup> studied peripheral lymphocyte populations in 11 patients undergoing laparoscopic cholecystectomy and found a transient decrease in the CD4 to CD8 ratio, with no difference in absolute CD4 and CD8 cell counts and a return to preoperative ratio within 1 week of surgery. These studies suggest that laparoscopic surgery may impact less on the cellular components of the immune system than open surgery, but further study is necessary to determine the significance of this information.

### PORT-SITE METASTASES

Soon after the laparoscopic treatment of malignancies began throughout the world, a number of reports appeared describing “port-site metastases”—that is, tumor recurrence at the sites of trocar placement<sup>18,19,20,21,22,23,24</sup> and<sup>25</sup> in the postoperative period. A large number of such anecdotal reports were published, which subjectively seemed far more common than wound recurrences after open colon resection. The true extent of the problem was difficult to determine. In a large series of open colon resections, Hughes et al.<sup>26</sup> reported 11 (0.7%) wound recurrences of tumor in 1603 patients. Several investigators began to look for port-site recurrences in a prospective manner. Ramos et al.<sup>27</sup> reported 3 recurrences in a series of 208 laparoscopic colon cancer resections. Of these three patients, two had widespread disease. Between 1993 and 1996, 35 cases of port-site recurrence after laparoscopic colectomy for colorectal carcinoma were reported.<sup>28</sup> These observations led to a number of consequences. First, these reports prompted careful scientific evaluation of the procedure and its application to malignancies. Registries were developed to monitor the occurrence of port-site recurrences. Second, a number of investigators began to examine possible mechanisms for this phenomenon in the laboratory.

A retrospective study of 372 patients who underwent laparoscopic colon resection for malignancy was conducted by Nelson and colleagues.<sup>29</sup> This study had relatively short follow-up, with a mean follow-up of just 23 months. The incidence of port-site metastases was 1.1%, which is similar to published data for open surgical resection of colon cancer. This study also demonstrated a 3-year survival rate that was similar, stage for stage, with open colon resection data. In a large prospective study of 533 patients with a variety of intraabdominal malignancies who underwent laparoscopic investigation, port-site recurrences were identified in just four patients (0.8%).<sup>30</sup> The investigators in this study looked at the extent of disease as well, identifying port-site recurrences in 3 of 71 patients with advanced disease compared with just 1 of 462 without advanced disease ( $P < .003$ ), further supporting the concept that this phenomenon may be an indicator of advanced disease.

A number of investigators have attempted to explain this phenomenon using clinical studies and laboratory models of port-site recurrences, specifically looking at the effects of the insufflation gases. In a clinical study of 15 patients with malignancies by Ikramuddin et al.,<sup>31</sup> the insufflation gas effluent was directed through saline. Malignant cells were found in specimens from only two patients, both of whom had carcinomatosis. These authors concluded that tumor cell aerosolization is unlikely to contribute to port-site metastases. In a study of effluent CO<sub>2</sub>, another group reported very low levels of tumor cells in the gas, but they did find large numbers of tumor cells on trocars and instruments that were used.<sup>32</sup> They suggest that port-site metastases might be reduced with avoidance of mechanical contamination. In another clinical study, labeled red blood cells were injected in the gallbladder bed in two groups of patients, one with standard CO<sub>2</sub> pneumoperitoneum and one with gasless laparoscopy.<sup>33</sup> Radioactivity was observed in the area of trocar insertion in all patients who underwent standard laparoscopy but was rare in patients who underwent gasless laparoscopy. In a rat model of laparoscopy, peritoneal tumor growth was greater after laparotomy than after CO<sub>2</sub> laparoscopy.<sup>34</sup> The investigators in this study also found that insufflation of CO<sub>2</sub> promotes tumor growth at the peritoneal surface and is associated with more abdominal wall metastases than gasless laparoscopy. Others also have shown that CO<sub>2</sub> pneumoperitoneum significantly increases tumor implantation at trocar sites in a hamster model.<sup>35</sup> In a rat study, the influence of the trocar itself was studied, and investigators found an increase in port-site metastases from the act of withdrawing the port and seeding the wound site.<sup>36</sup> Several studies have looked at the role of the gas used for insufflation with contradictory results. In one study, the gas used was not a contributing factor, comparing CO<sub>2</sub>, helium, and air.<sup>37</sup> In another study, helium was associated with reduced tumor growth.<sup>38</sup> Both of these studies suggest the use of gasless laparoscopy

for patients with malignancies.

Other investigators have looked at the influence of tissue trauma on the formation of port-site metastases. In a rat experiment, tissue trauma was induced at the port sites, and a significantly greater amount of tumor grew there after insufflation than at port sites without induced trauma.<sup>39</sup> These authors also identified leakage of insufflating gas as a contributing factor. Other investigators also have looked at the influence of tissue injury and found that peritoneal injury enhances peritoneal implantation of tumor cells.<sup>40</sup> A number of investigators have used laboratory models to compare laparotomy and laparoscopy. In the absence of tumor manipulation, no difference was seen in intraperitoneal tumor growth and spread between laparotomy and laparoscopy in a rat model.<sup>41</sup> The possibility of immune mediation has been investigated by one group.<sup>42,43 and 44</sup> These authors found that tumors were established and grew more readily and larger after laparotomy than after insufflation. In one of their studies, altered levels of TNF were found, suggesting an association.<sup>45</sup> The relative immunosuppression of laparotomy may play a role.

A number of explanations have been put forth to explain the phenomenon of port-site metastases. These are outlined briefly in [Table 29.1-1](#). The potential causes of this problem suggest that technical modifications of the procedure may minimize the likelihood of this problem occurring. Early data clearly suggest that the incidence of port-site recurrences after laparoscopic tumor resection is similar to the wound recurrence rate after open resections for colon cancer. Further clinical and experimental studies are in progress to determine the true extent of this problem. Laparoscopic resection of malignancies performed outside of clinical trials should be undertaken “with circumspection” until the true incidence of this problem is known as a result of prospective randomized trials.<sup>28</sup>

Possible Cause	Intervention to Potentially Minimize This Cause
Dispersion of cells by carbon dioxide gas	Avoid sudden loss of pneumoperitoneum
Tumor spillage from manipulation and instrumentation	Avoid excessive manipulation of the tumor
Tumor spillage at extraction site	Protected tumor extraction (plastic bag)
Immunosuppressive effect of pneumoperitoneum	Irrigation of abdomen with tumoricidal solutions <sup>40</sup>

**TABLE 29.1-1.** Possible Causes of Tumor Cell Dissemination in Laparoscopic Surgery for Cancer

## LAPAROSCOPY IN THE DIAGNOSIS OF MALIGNANCY

### GENERAL CONSIDERATIONS

Patients often present with constitutional symptoms and undergo evaluation by imaging studies in the hopes of identifying an underlying cause. [Figure 29.1-1](#) shows a computed tomography (CT) scan image from a 70-year-old woman who presented with fever and malaise and no evidence of peripheral adenopathy on physical examination. Celiac lymph nodes were sampled laparoscopically ([Fig. 29.1-2](#)), establishing the diagnosis of NHL. In this case, the patient underwent a diagnostic procedure and was discharged home the same day with minimal postoperative pain. The use of diagnostic laparoscopy in the evaluation of abdominal malignancies has been reported. In a series by Easter et al.,<sup>46</sup> of 25 patients with suspected malignancies, 17 (68%) had a positive study for cancer; these investigators concluded that patient management had been altered by the laparoscopic finding in 25 patients (100%).

**FIGURE 29.1-1.** A 70-year-old woman presented with fevers and nonspecific abdominal pain. Workup revealed a negative physical examination, with an enlarged celiac lymph node seen on computed tomography scan. (From ref. 2, with permission.)

**FIGURE 29.1-2.** The celiac node was identified laparoscopically and excised. Histopathologic evaluation revealed non-Hodgkin's lymphoma. (From ref. 109, with permission.)

### BIOPSY OF MASSES

Masses identified on preoperative imaging studies are often amenable to laparoscopic biopsy. Some studies have evaluated the tactile sensation afforded by laparoscopic instruments and have found it to be almost comparable with open palpation.<sup>47</sup> Techniques available for the biopsy of masses under laparoscopic control include<sup>48</sup>

- Percutaneous insertion of a core biopsy needle with direct puncture of the mass; this is easily performed under the direct vision afforded by the laparoscope.
- Wedge biopsy using the electrocautery; this method should be used cautiously to avoid thermal destruction of the specimen.
- Cup forceps biopsy; careful use of these forceps allows removal of adequate tissue for histopathologic examination while avoiding destruction of the specimen. This technique is extremely useful for the biopsy of small lesions such as those present on peritoneal surfaces ([Fig. 29.1-3](#)).

**FIGURE 29.1-3.** Laparoscopic evaluation of the abdomen can sometimes reveal unexpected widespread metastatic disease, as shown here.

### **Liver Biopsy and Evaluation of Liver Tumors**

Laparoscopic investigation of hepatic lesions can include inspection, palpation (with a probe), intraoperative ultrasound (discussed later in [Laparoscopic Intracorporeal Ultrasound](#)), and directed biopsy.<sup>48</sup> Lesions that are located on the thin edge of the liver may be easily biopsied using two applications of the linear stapler to avoid destruction of the tissue as shown in [Figure 29.1-4](#).<sup>50</sup> This method is also useful in obtaining blind liver biopsies requiring larger specimens than those available with a core biopsy needle.

**FIGURE 29.1-4.** The linear stapler can be used to obtain a wedge biopsy of the liver by firing twice at approximately 90-degree angles. The resulting specimen is of adequate size and lacks burn artifact caused by the use of electrocautery to obtain the specimen. (From ref. 50, with permission.)

### **Lymph Node Biopsy**

With careful dissection, laparoscopic access to most lymph node areas can be obtained. Specifically, mesenteric, portal, iliac, pelvic, peri-aortic, and celiac lymph nodes can be biopsied.<sup>51</sup> In cases in which specific lymph nodes are identified preoperatively with imaging studies, it may be helpful to mark the area of dissection with clips and use intraoperative radiographs as a guide as well as to assure that the desired area has been evaluated.

### **LAPAROSCOPIC INTRACORPOREAL ULTRASOUND**

One of the most important developments in the laparoscopic evaluation of malignancies is the laparoscopic intracorporeal ultrasound (LICU) probe.<sup>52</sup> Intraoperative ultrasound was first described in 1958 and, with advancements in the technology, has had significant impact on the intraoperative management of a number of complex problems.<sup>53</sup> The laparoscopic application of these devices is limited by the size and location of the access ports used. The direct contact of the probe to the liver affords superior resolution compared with that obtained with transabdominal ultrasound imaging. When searching for lymphadenopathy, it is critical to adapt the technique to the specific area being studied, assuring good acoustic contact between the probe and the tissue. Saline solution may be instilled to aid in this process.<sup>52</sup> Doppler techniques are useful to identify blood vessels that will aid the identification of lymph nodes.

The ability to examine the biliary tree with LICU has been described.<sup>54</sup> This report establishes the accuracy of this technique compared with cholangiography in determining common duct size and presence of choledocholithiasis. The use of LICU in 176 patients was reported.<sup>55</sup> In this series, 145 patients underwent laparoscopic cholecystectomy, and 31 patients underwent staging laparoscopy with examination of the liver. From these preliminary studies, it appears that LICU has potential in the intraoperative evaluation of patients with malignancies. It is also clear that the value of this procedure is limited by operator skill.

The use of LICU is clearly complementary to laparoscopy alone, particularly in the evaluation of hepatic lesions. In a study of 50 patients with potentially resectable liver tumors, laparoscopy alone demonstrated factors that rendered the patient unresectable in 23 patients (46%).<sup>56</sup> Of the remaining patients, LICU identified nine patients as unresectable. Patients in this study who underwent combined laparoscopic/LICU staging ultimately had a 93% resectability rate, compared with a 58% resectability rate among a historical group who did not have laparoscopic staging. In another study of 420 patients with a wide range of upper gastrointestinal malignancies, laparoscopy/LICU staging precluded laparotomy in 20% of patients deemed resectable by preoperative imaging studies, with an overall sensitivity of 70%.<sup>57</sup> The results of these studies and others demonstrate that effective use of laparoscopy for tumor diagnosis requires the use of LICU as a complementary technique to evaluate the true extent of disease.

### **LAPAROSCOPY IN THE STAGING OF MALIGNANCY**

#### **GENERAL CONSIDERATIONS**

Perhaps the most important benefit of laparoscopic staging is the exclusion of patients with disease that is not resectable for cure from further invasive procedures. It is, however, difficult to assess the utility of this approach. [Table 29.1-1](#) lists the indications for laparoscopic diagnosis and staging at the University of Dundee. This approach was analyzed by a 2-year prospective evaluation, and the parameters assessed were diagnostic yield, management benefit, and management disadvantage.<sup>48</sup> The results of this trial showed a 90% diagnostic yield. The authors concluded that 30% of patients had their management affected by the performance of a laparoscopic staging procedure. Only two cases (4%) in which laparoscopy failed to identify disease that signaled unresectability were reported—a missed hepatic lesion in segment eight, and portal vein involvement by a tumor of the head of the pancreas.

Laparoscopy is extremely accurate for the identification of peritoneal disease, which is often missed by standard noninvasive imaging studies such as CT scanning, ultrasonography, and magnetic resonance imaging.<sup>58</sup> Lesions that are only a few millimeters in size can be biopsied with extreme accuracy. Liver and peritoneal disease are often found in patients with negative CT scans, supporting the use of laparoscopy to identify these lesions.<sup>58</sup> A representative laparoscopic view of such lesions is shown in [Figure 29.1-3](#).

A series of 162 patients with a variety of malignancies, including 98 patients with hepatic lesions and 64 patients with nonhepatic intraabdominal malignancy, underwent laparoscopic staging.<sup>59</sup> All of these patients were believed to be resectable for cure based on a number of preoperative imaging studies. Biopsies were performed in 37% of cases. In 36% of cases, laparoscopy yielded information that prevented unnecessary laparotomy because of the identification of lesions that were unresectable. Conversely, 12% of patients who had laparoscopic findings suggesting resectability were found at laparotomy to be unresectable. Sites missed

included positive lymph nodes, hepatic vein involvement, and missed peritoneal metastases. This study supports the use of laparoscopy to prevent unnecessary laparotomy in those patients who will not benefit from resection.

Laparoscopy is facilitated in patients with tense ascites by repeated paracentesis begun 24 hours before surgery.<sup>60</sup> In a series of 47 patients with ascites, laparoscopy revealed carcinomatosis in 22; ovarian cancer in 11; three patients each with mesothelioma, hepatoma, and hepatic myelofibrosis; two patients with pancreatic cancer; and one patient each with squamous cancer, chronic lymphatic leukemia, breast cancer, and lymphoma.<sup>60</sup> The accuracy of laparoscopy in the evaluation of malignant disease presenting as ascites has been reported in one series as 100%.<sup>60</sup>

## PANCREATIC CANCER

Laparoscopy has been used in the staging of patients with carcinoma of the pancreas for some time. In fact, the first report of laparoscopy in the United States was the evaluation of a patient with carcinoma of the pancreas.<sup>61</sup> The goal of laparoscopy in the staging of patients with carcinoma of the pancreas is to avoid laparotomy in those patients deemed resectable by preoperative imaging studies. An early report describes the experience of 23 patients with pancreatic cancer.<sup>9</sup> This study was carried out before the widespread use of abdominal CT scan and the advent of quality optics for laparoscopy. This report emphasized the utility of biopsy under direct vision.

In a report of 40 patients with carcinoma of the pancreas, Warsaw and coworkers<sup>62</sup> found 26 patients without evidence of metastatic disease and 14 patients with metastatic disease that precluded a curative resection. Laparoscopy was performed as the final study before laparotomy, but only if the imaging studies were negative for metastatic disease. The negative findings at laparoscopy were confirmed in 23 of 26 patients at laparotomy. The positive laparoscopic findings in 14 of 40 patients altered the therapeutic course of all 14 patients. Findings in these patients were single, small (1 to 2 mm) nodules in the liver (n = 6), peritoneal surfaces (n = 7), and omentum (n = 1), all of which were verified histologically. The three instances of false-negative findings were due to incomplete examination of the liver (n = 2) and a central liver lesion (n = 1). The overall accuracy was 93% and, with negative findings, 88%.

Another application of laparoscopy in the staging of patients with carcinoma of the pancreas is the ability to obtain specimens for cytologic examination. In 40 patients with lesions that were resectable according to the results of preoperative imaging studies, peritoneal washings were obtained (27 at laparoscopy and 13 at laparotomy).<sup>63</sup> Malignant cells were found in 12 (30%) of the specimens. Liver metastases were seen in six patients, all of whom had negative cytology. Interestingly, positive cytology was found in six of eight patients who had previously undergone needle biopsy and in 6 of 32 patients who had not, suggesting that intraperitoneal spread may be enhanced by needle biopsy. Laparoscopy is described as an excellent method to obtain cytologic washings, which may be of importance in the evaluation of patients with carcinoma of the pancreas.

The ability of laparoscopy to detect metastatic disease not otherwise identified has been reported by others.<sup>64</sup> The use of laparoscopy and laparoscopic ultrasonography has been described in the evaluation of 40 consecutive patients felt to have a resectable pancreatic lesion.<sup>65</sup> Resectability was confirmed in 12 patients with negative laparoscopic examinations, for a sensitivity of 100%. Occult metastatic disease was identified in 14 patients, including liver lesions (n = 10), disease on peritoneal surfaces (n = 8), and hilar lymphadenopathy (n = 2). Laparoscopy failed to demonstrate metastatic disease in three patients. As for predicting resectability, laparoscopy alone did not identify the 12 patients with locoregional tumor unresectability, with an overall specificity of only 50%. However, the combined use of laparoscopy and laparoscopic ultrasonography resulted in a sensitivity of 92%, a specificity of 88%, and an accuracy of 89%.

The careful exploration of the abdominal cavity was emphasized in a study by Conlon and coworkers.<sup>61</sup> These investigators performed laparoscopy on 115 patients with radiologically resectable lesions. Unresectability was determined by the presence of any of the following: metastatic lesions, extrapancreatic tumor extension, celiac and portal node involvement, and vascular encasement of the celiac or superior mesenteric vessels. Resection was performed in 76% of patients with a negative laparoscopic evaluation, compared with a historical series of radiologic evaluation only with a resectability rate of 35%.

The importance of laparoscopy combined with LICU was emphasized in a report by John et al.<sup>66</sup> that demonstrated that this combined approach was significantly better than CT in predicting resectability (97% vs. 79%,  $P < .005$ ). LICU was considered indispensable for the detection of occult metastases. Furthermore, these investigators found that LICU is a reliable predictor of tumor unresectability. Others also have affirmed the importance of combined laparoscopy and LICU to evaluate extent of disease.<sup>67</sup>

More recently, several investigators have suggested that laparoscopy be used in a highly selective manner in patients with carcinoma of the pancreas rather than as a standard staging modality.<sup>68,69</sup> Of 398 patients who underwent laparotomy for pancreatic or periampullary carcinoma at one center, 172 patients underwent resection, 150 had a palliative bypass, and 76 underwent exploratory laparotomy only.<sup>68</sup> Local signs of unresectability, identifiable only at laparotomy, were found in 47, leaving 29 patients (7%) who did not require palliation and whose signs of unresectability could have been determined by laparoscopy. The authors of this study concluded that laparoscopy (with or without LICU) should be used selectively in patients considered probably unresectable who do not require a palliative surgical procedure. The laparoscopic conduct of palliative bypass procedures may make laparoscopy somewhat more applicable than these data imply, however. In a retrospective study of 148 patients with pancreatic cancer, survival of patients with clinically resectable pancreatic cancer that was deemed unresectable at laparotomy was evaluated to determine the utility of staging laparotomy.<sup>68</sup> The importance of staging laparoscopy is enhanced if one believes that endoscopic stenting is the best palliation. The authors of this study concluded that extensive laparoscopic evaluation is not necessary, because they contend that operative palliation is superior to endoscopic palliation. Staging laparoscopy is useful only to identify those patients with liver or peritoneal metastases who have an expected survival of approximately 6 months and for whom endoscopic palliation is sufficient.

The use of laparoscopy or combined laparoscopy and laparoscopic ultrasonography appears to be helpful in the identification of lesions that suggest unresectability in patients with negative imaging studies.<sup>70</sup> Although some suggest that laparoscopy be used in a fairly routine manner, data suggest that laparoscopy be used more selectively.

## ESOPHAGEAL AND GASTRIC TUMORS

Early laparoscopic studies of the staging of esophageal cancer were usually characterized by little manipulation of the abdominal contents to identify disease and were commonly limited to observation of the parietal peritoneal surfaces. A prospective trial was undertaken to compare the accuracy in diagnosing intraabdominal metastatic disease by scintigraphy, ultrasound scanning, and laparoscopy.<sup>71</sup> Of the 50 patients studied, 23 had esophageal carcinoma, 14 had gastric carcinoma, and 13 had suspected intraabdominal metastatic spread from other lesions. The accuracy of identification of metastatic disease was determined by laparoscopic biopsy, laparotomy, and autopsy. The overall accuracy was 72% for scintigraphy, 75% for ultrasound, and 96% for laparoscopy. Thirteen patients without hepatic metastatic disease had nodal or peritoneal disease diagnosed only by laparoscopy. This study demonstrates the value of laparoscopy and its ability to obviate the need for laparotomy in patients with lesions not resectable for cure.

In another study, 369 patients with carcinoma of the esophagus and cardia of the stomach underwent laparoscopy, revealing single or multiple intraabdominal metastases in 52 patients (14%).<sup>72</sup> This study suggested that intraabdominal metastases become more common as the location of the primary tumor becomes more distal, being greatest in lesions of the cardia. More recent data suggest that abdominal lymph node metastases may be present despite the location of the primary tumor.<sup>73</sup>

The sensitivity, specificity, and accuracy of laparoscopy, ultrasound, and abdominal CT scan were compared in 90 patients with biopsy-proven carcinoma of the esophagus or gastric cardia.<sup>74</sup> Laparoscopy was found to be significantly more sensitive and more accurate ( $P < .05$ ) than either ultrasound or abdominal CT scanning in diagnosing hepatic disease. Peritoneal disease was not identified by ultrasound or CT scan, but laparoscopy identified it in eight (89%) of nine cases. Lymph node metastases were identified most accurately by laparoscopy, although the difference between laparoscopy and CT scanning did not achieve statistical significance. The authors of this study concluded that laparoscopy offers an accurate, reliable, and safe method of preoperative assessment in patients with carcinoma of the esophagus.

Thoracoscopic lymph node staging has been shown to provide accurate pre-resection staging of thoracic node status.<sup>75,76</sup> More recently, laparoscopic lymph node assessment in patients with carcinoma of the esophagus has been combined with thoracoscopic lymph node staging. The use of thoracoscopy in staging accuracy has been validated in a trial comparing thoracoscopy to noninvasive staging techniques that found greater accuracy with thoracoscopic staging.<sup>77</sup> Laparoscopic evaluation of intraabdominal disease was correct in 17 of 18 patients (94%) in a prospective trial.<sup>73</sup> A positive lymph node was not identified in a single patient. Three patients were downstaged as a result of laparoscopic evaluation of intraabdominal lymph nodes. Six of 18 patients (33%) had unsuspected celiac lymph node

involvement. Lymph nodes near the diaphragm may be difficult to evaluate without extensive dissection. Furthermore, the laparoscopic staging procedure can be combined with placement of an enteral feeding tube at the same time.

The value of combined laparoscopy and laparoscopic ultrasound has been demonstrated in a number of other studies. In 56 patients with carcinoma of the esophagus (n = 38) and cardia (n = 18), the preoperative stage of disease was altered by laparoscopy in nine (17%) of the overall group of patients.<sup>78</sup> Of the patients with tumors of the gastric cardia (n = 18), laparoscopy altered the stage in seven (41%), but of patients with esophageal tumors (n = 38), stage was altered in just two (6%). The authors of this study concluded that the approach was better suited to tumors of the gastric cardia than of the esophagus. In this study, no attempt was made to perform thoracoscopic staging for lesions of the esophagus, however, and lymphatic drainage patterns may have precluded their ability to identify intraabdominal metastatic disease in patients with more proximal lesions of the esophagus.

In a study of 71 patients with potentially resectable gastric cancer, laparoscopy identified distant disease in 16 patients (23%).<sup>79</sup> The combination of preoperative CT and laparoscopic evaluation resulted in a 93% resectability rate. These authors advocate staging laparoscopy for all patients with potentially resectable gastric cancer. Future studies may use the combination of laparoscopy and laparoscopic ultrasound to improve the results further.

## HEPATIC TUMORS

The accurate evaluation of the liver is a critical component of tumor staging for many malignancies of interest to the surgeon, because the presence of metastatic disease in the liver often obviates the need for major resections. Radiologic imaging alone is imperfect, and several studies have demonstrated the scope of the problem. In one series, 63 of 150 of patients (42%) with colorectal carcinoma were found to have unresectable hepatic disease at laparotomy after an imaging evaluation demonstrated resectable lesions.<sup>80</sup> In another series, of 132 patients referred to the National Cancer Institute for liver tumor resection, 107 had negative staging evaluations and were brought to laparotomy. Extrahepatic disease was identified in 28 of these 107 patients (26%).<sup>81</sup> These studies demonstrate one of the major potential benefits of laparoscopic staging—the ability to exclude from laparotomy those patients with unresectable lesions in a way that minimizes postoperative pain and hospitalization.

Of interest, one of the early applications of laparoscopy was for the staging of hepatic lesions, which had been reported as early as 1966 and in 1973 was reported in the evaluation of patients with Hodgkin's lymphoma.<sup>3</sup> Before the advent of modern video systems and laparoscopic instrumentation, it was estimated that 80% of the liver surface could be visualized laparoscopically and, of note, performed in the endoscopy clinic.<sup>58</sup> The sensitivity of laparoscopy in the detection of hepatic metastatic disease was estimated at 70% to 90%.

In a study of 29 patients with hepatic malignancies (12 with hepatoma and 17 with metastatic disease), laparoscopy was undertaken before laparotomy to evaluate the resectability of the lesions.<sup>82</sup> Laparoscopy alone demonstrated unresectability in 14 (48%) of 29 patients evaluated. Unsuspected cirrhosis was identified in four, and unresectable or extrahepatic lesions were found in ten. Not surprisingly, these investigators found that patients who underwent laparoscopy had shorter hospital stays than historical controls who underwent laparotomy that identified unresectable disease, and they concluded that laparoscopy should precede laparotomy for planned resection of hepatic malignancies.

The gold standard for evaluation of the liver is intraoperative palpation combined with intraoperative ultrasonography (LICU). In an experimental study to evaluate the effectiveness of laparoscopy and laparoscopic ultrasonography, liver lesions were induced in 18 pigs.<sup>47</sup> Laparoscopic ultrasound identified the lesions in 17 of 18 animals, for a 94% sensitivity. Two false-negatives were obtained, for a specificity of 78%. In a study of 30 patients undergoing planned hepatic resection and 32 patients undergoing resection of a gastrointestinal primary malignancy, intraoperative ultrasonography was compared with CT angiography.<sup>83</sup> Of the 30 patients planned to undergo hepatic resection, the procedure was changed or guided by the ultrasonographic result in 20 cases (67%). Of the 32 patients undergoing resection of their primary tumor, five patients (16%) had the stage of their disease altered by the results of intraoperative ultrasonography.

Having demonstrated the value of laparoscopy and intraoperative ultrasonography, combining the two procedures is a natural extension of the technology. In a study of 50 patients undergoing laparoscopic evaluation of hepatic tumors, laparoscopic ultrasonography was performed in 43 patients.<sup>56</sup> Laparoscopy alone demonstrated that lesions shown resectable by preoperative imaging studies were unresectable in 23 patients (46%). Hepatic lesions not visible by laparoscopic examination alone were identified by laparoscopic ultrasonography in 14 patients. Furthermore, the use of laparoscopic ultrasonography provided staging information in addition to that gained by laparoscopy in 18 patients (42%).

In a study combining laparoscopy with laparoscopic ultrasound, 50 patients were evaluated.<sup>84</sup> Of these, 28 patients were deemed resectable on the basis of the laparoscopic studies. At laparotomy, 26 were ultimately resectable, for a false-negative rate of 4%. Of the 22 patients deemed unresectable after laparoscopy, 11 were identified by laparoscopy alone, but 11 more were deemed unresectable after laparoscopic ultrasound. Nodal involvement and vascular invasion were identified by ultrasound, emphasizing the importance of the combined approach for accurate staging.

A study of 420 patients with upper gastrointestinal malignancies evaluated the utility of combined laparoscopy and laparoscopic ultrasound in staging of these tumors.<sup>57</sup> Patients underwent routine imaging studies and were thought to have resectable disease, then underwent laparoscopy and laparoscopic ultrasound. The use of combined laparoscopic staging avoided laparotomy in 20% of patients, with a sensitivity of 70%. Although it was of little use in esophageal tumors—avoiding laparotomy in just 5% of patients and a 42% sensitivity—it appeared beneficial in patients with proximal bile duct tumors, liver tumors, and pancreatic tumors. This study supports the use of combined laparoscopy and laparoscopic ultrasound in the staging of patients with a variety of upper gastrointestinal malignancies.

Up to 90% of metastatic lesions can be seen on the liver surface using laparoscopy.<sup>85</sup> Furthermore, although CT can reliably detect lesions that are at least 10 mm in size, laparoscopy can detect lesions as small as 1 mm. Laparoscopy also facilitates the identification of lesions in areas often missed by CT scan, such as peritoneal, omental, and mesenteric surfaces. Accurate sampling of hepatic lesions with biopsy instruments is greatly facilitated by the direct vision afforded by laparoscopy, and hemostasis can be assured. Finally, the technical problems caused by loops of bowel are avoided when laparoscopy is used compared with external ultrasonography or CT scanning.<sup>85</sup> Thus, laparoscopy is extremely important in the staging of hepatic malignancies of all types.

## PROSTATE CANCER

The definitive final staging procedure in the evaluation of prostate cancer is now considered to be pelvic lymphadenectomy. In the past, open bilateral pelvic lymphadenectomy was routinely performed, even with its associated significant morbidity, which included a lengthy recovery time. More recently, laparoscopic pelvic lymph node dissection (LPLND) has become standard practice for many urologists, affording their patients the benefits of decreased hospitalization and recovery times. The technique for this procedure has been described, including the extraperitoneal laparoscopic approach.<sup>86,87 and 88</sup>

Laparoscopic detection of positive pelvic lymph nodes may alter the management of patients with prostate cancer. Patients with positive pelvic lymph nodes have been advised to undergo a wide range of therapies, ranging from endocrine treatment to a combination of radical prostatectomy and radiation therapy.<sup>89</sup> An early series of 11 patients found metastatic disease in five, with a resultant change of therapy.<sup>86</sup> This series included one complication, a bladder laceration that was repaired laparoscopically.

The effect of laparoscopic conduct of this procedure on operative morbidity and convalescence has been reported.<sup>90</sup> In a study by Kerbl et al.,<sup>90</sup> the initial 30 patients undergoing LPLND were compared with 16 patients undergoing open node dissections. These authors found that the laparoscopic procedure took longer (mean, 199 minutes) than the open procedure (mean, 102 minutes), but that the blood loss was lower in the laparoscopic group. Furthermore, the laparoscopic group had significantly less postoperative analgesic use, shorter hospital stay, faster return to normal activities, and shorter interval to full recovery compared with the open surgical group. The incidence of complications was higher in the laparoscopic group, but all of these occurred in the first 12 patients of the series. In another series, 54 patients underwent staging laparoscopic pelvic lymphadenectomy for a variety of genitourinary malignancies, with a major complication rate of 17% and a minor complication rate of 18%.<sup>91</sup> Major complications included bleeding requiring transfusion, respiratory failure necessitating intubation, ureteral injury, and small bowel obstruction due to herniation at a trocar site. The ability of CT scan to identify these postoperative complications also has been investigated.<sup>92</sup> Complications were identified in 12 of 85 patients undergoing laparoscopic lymph node dissection, of which eight patients were studied with abdominopelvic CT scans. The CT scan appearance of small bowel herniation, extensive hematomas, urinary ascites, and lymphocele compressing the bladder is described in this review. The CT scan identified the complication in seven of eight patients and is thus an important tool in evaluating the complications of this procedure.

The indications for LPLND have evolved over time, particularly with the advent of widespread prostate-specific antigen (PSA) testing. Before PSA testing, lymph node

dissection was indicated in all prostate cancer patients considered candidates for curative therapy.<sup>87</sup> Many urologists limit the conduct of LPLND to patients at high risk for metastatic disease based on clinical stage, a PSA level of greater than 10 mg/dL, and tumor grade (Gleason score <sup>37</sup>).

## TESTICULAR TUMORS

Patients with early-stage nonseminomatous testicular cancer have a 20% to 30% incidence of retroperitoneal spread of disease to paraaortic nodes at the time of diagnosis.<sup>87</sup> Laparoscopic retroperitoneal lymph node dissection has been described to evaluate these patients.<sup>87</sup> At this time, few cases of this procedure have been reported in the literature. No studies to date have carefully compared this technique with its open counterpart. Therefore, this procedure is appropriate only in patients who have a low likelihood of nodal disease based on clinical risk factors.<sup>87</sup>

## LYMPHOMA

Lymphomas are a diverse group of malignant disorders of the lymphatic system that arise in nodal tissues. Typically, they are categorized by histology into Hodgkin's lymphoma and NHL. The present role of surgery in the management of lymphoma is to establish a tissue diagnosis or to serve as a diagnostic adjunct when noninvasive diagnostic studies do not accurately define the extent of disease. Definitive treatment based on staged disease then follows.

The histologic type and regional extent of the disease are the primary factors used to determine the prognosis and the treatment selection. Histologic type is usually determined by a regional lymph node biopsy. Evaluating or staging the true extent of the disease has proven more elusive by noninvasive modalities. This is especially true in the determination of an intraabdominal component to the spread of lymphoma. The spleen, for example, is involved in approximately one-third of all cases of Hodgkin's lymphoma.<sup>93</sup> Most involved spleens, however, are of normal size or contain malignant foci whose size is beyond the resolution of present imaging technology.<sup>93</sup> Likewise, lymph node size is a poor determinant of involvement by lymphoma. Many involved lymph nodes are of normal size, whereas normal lymph nodes may be enlarged secondary to a reactive response. Because of this lack of sensitivity and specificity of noninvasive modalities, surgical staging still has a key role in the staging of selected patients with lymphoma. This places the lymphoma staging procedure in the unique position of being one of the few major abdominal surgical procedures that is undertaken strictly for diagnostic purposes.

Indications and techniques for the performance of the staging laparotomy, in attempts to influence the associated morbidity and mortality, have undergone considerable evolution. Although previously performed on 85% of all patients with Hodgkin's disease,<sup>94</sup> staging laparotomy is performed in, at most, only 30% of patients.<sup>95</sup> With refinement of noninvasive imaging techniques, and changes in the medical management of the disease, the value of surgical staging of lymphoma has been reevaluated. Consequently, the subset of patients for whom surgical staging appears to be of value has become much smaller. This reduction has resulted in significant decreases in the proportion of splenectomies performed for staging lymphoma. In a study of the frequency of splenectomy for Hodgkin's lymphoma, Marble et al.<sup>96</sup> reported a rate of 44% during the period from 1979 to 1985, compared with only 26% during the period from 1986 to 1991. The role of splenectomy, however, is still in evolution. Some evidence suggests that combined chemoradiation therapy for Hodgkin's lymphoma may be associated with a significantly increased risk of developing a second malignant disease.<sup>93</sup> If this risk proves to hold true, it follows that surgical staging may again provide significant benefits for patients with Hodgkin's lymphoma by reducing their need for combination therapy. Conversely, some centers are treating every patient with Hodgkin's disease using chemotherapy as a first-line modality, obviating the need for surgical staging.

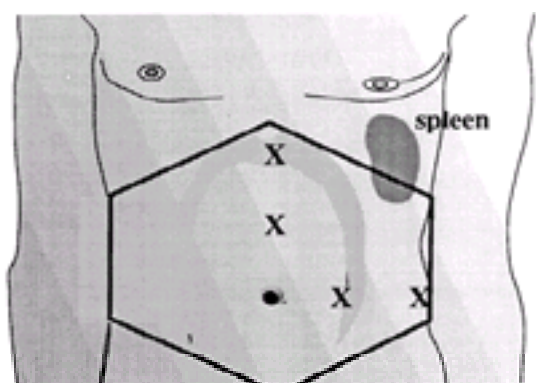

The role of the surgeon in patients with Hodgkin's lymphoma includes lymph node biopsy to establish a diagnosis and staging laparotomy in a very select group of patients, usually limited to those patients with stage IIB disease after imaging evaluation. Patients with obvious stage III or IV disease should rarely be subjected to staging laparotomy because they will be treated with chemotherapy, and patients with stage I disease are usually treated with radiation alone, obviating the need for staging laparotomy. In some centers, chemotherapy is used to treat all patients with Hodgkin's lymphoma, almost entirely eliminating the need for any surgical staging procedure.

Surgical staging of Hodgkin's lymphoma has been reported to change the pathologic stage of the disease in 30% to 40% of patients, resulting in significant alterations in both prognosis and treatment selection.<sup>97,98</sup> Staging laparotomy is associated with 18% morbidity and up to 0.7% mortality.<sup>93,99</sup> Late complications occur in 5% to 15% of patients.<sup>95,100</sup> These include partial small bowel obstruction in 9.8% of patients, requiring lysis of adhesions in 6.8% of these, and overwhelming post-splenectomy sepsis (OPSS) in 6.8% of patients.<sup>100</sup> Horowitz et al.<sup>101</sup> reported a 52% overall morbidity and a 9% mortality rate after splenectomy for hematologic diseases. Splenic size was the only preoperative factor found to be predictive of postoperative complications.

The conventional technique for the surgical staging for lymphoma has been well described.<sup>102,103</sup> With the smaller incisions used in minimal-access surgery, several potential advantages can be offered to patients undergoing laparoscopic staging of abdominal lymphoma. These include less postoperative pain, earlier ambulation, better breathing, and shorter recovery time. These can be translated into fewer postoperative complications and possibly earlier administration of definitive therapy. However, the procedure remains a technically demanding operation with which no single surgeon will probably gain vast experience. With further advances in laparoscopic technology and refinements in techniques, laparoscopic staging of abdominal lymphoma will become an important tool in the surgical armamentarium.

The laparoscopic approach to this procedure follows the same principles as those delineated for the open procedure.<sup>104</sup> There are no true contraindications to laparoscopic staging. Relative contraindications to laparoscopic staging include abdominal wall sepsis, gastrointestinal distention, intraabdominal sepsis, and extensive adhesions.<sup>105</sup> Laparoscopic staging of abdominal lymphoma has been successfully performed by several groups.<sup>104,106,107,108</sup> and <sup>109</sup> A comparison of laparoscopic and open staging of Hodgkin's disease has demonstrated equivalent oncologic results, and functionally superior results with laparoscopic staging.<sup>104</sup> These investigators found a slightly longer operative time (202 vs. 144 minutes), but significantly shortened postoperative ileus and postoperative hospitalization times. These data strongly support the use of laparoscopy for accurate staging of Hodgkin's disease when indicated.

Techniques for the laparoscopic exploration of other abdominal malignancies, with lymph node retrieval, laparoscopic splenectomy,<sup>110</sup> and laparoscopic wedge biopsy of the liver,<sup>50</sup> were developed. When combined, these procedures complete a laparoscopic staging procedure. The ports, or trocars, are positioned as in [Figure 29.1-5](#). All five ports are 12 mm in diameter. Using identical large ports enables the surgeon the versatility to switch instruments between the different anatomic sites required in this procedure. A sixth port may be, but is not always, necessary for access to the iliac nodes.

**FIGURE 29.1-5.** Port placement for laparoscopic splenectomy. The operating ports are on the left side, whereas the two upper midline ports are used for retraction. (From ref. 108, with permission.)

Although several groups have advocated preoperative splenic artery embolization, especially for larger spleens,<sup>111,112</sup> and <sup>113</sup> most patients with Hodgkin's lymphoma have normal-size spleens, and embolization is usually not indicated. The excised but intact spleen is placed into a stout plastic bag and left in the left upper quadrant for the remainder of the procedure, as shown in [Figure 29.1-6](#). Laparoscopic splenectomy has been widely described and is considered to be the gold standard for splenectomy at this time.<sup>114,115,116,117</sup> and <sup>118</sup> The identification and removal of accessory spleens has been shown to be effectively carried out using laparoscopic approaches.<sup>119,120</sup> Not only has it been shown that hospital charges for laparoscopic splenectomy are less than charges for open splenectomy, it also has been shown

that, over time, charges for laparoscopic splenectomy can be decreased by shorter operating times and judicious use of disposable instruments. <sup>121</sup>

**FIGURE 29.1-6.** The spleen is placed in a stout plastic bag after being completely devascularized and the ligaments divided. (From ref. 109, with permission.)

The laparoscopic dissection of lymph nodes can be very challenging because nonpathologic nodes are small and difficult to identify. LPLND is widely used in genitourinary surgery for the staging of prostate cancer and has become well accepted. <sup>87</sup> The magnification afforded by the use of laparoscopic instrumentation has proven to be very helpful. All abnormal nodes on preoperative lymphangiogram should be removed and clips applied as markers. Oophoropexy is then performed in young females by suturing the ovaries to the back of the uterus. The spleen is then removed intact, within the plastic bag, through a small midline incision incorporating the umbilical port site.

The accurate histologic diagnosis of lymphoma requires assessment of the nodal architecture, which requires an intact node capsule. Therefore, whenever possible, one should excise an entire intact lymph node. The use of formalin precludes the assessment by flow cytometry, which has become crucial for complete and accurate classification of lymphoma and on which therapeutic decisions may ultimately be based. Therefore, each lymph node should be sent for examination in saline in a fresh state. As mentioned above, the spleen should be sent to the pathologists intact and, usually, in a fresh state. The liver tissue may be placed in formalin for transport to the pathology department. The planning and conduct of the staging procedure involves close cooperation between surgeon, radiologist, medical oncologist, and pathologist.

The morbidity and mortality associated with staging laparotomy is well established. <sup>93,95,100,101,122</sup> A review of staging laparotomy by Multani and Grossbard <sup>123</sup> demonstrated a mortality of 0.3% to 1.0%, major morbidity of 3% to 18%, and minor morbidity of 6% to 19%. Delays to definitive treatment occurred in 5% to 10% of patients. <sup>123</sup> Jockovitch et al. <sup>100</sup> reported surgical complications in 26% of 133 consecutive patients. Complications included atelectasis in 13%, small bowel obstruction in 10% (requiring reoperation in 7%), subphrenic abscesses in 2%, and wound dehiscence in 1%. <sup>100</sup>

OPSS, which can follow any procedure that removes the spleen, remains a serious potential complication. The incidence of OPSS can be decreased by the preoperative administration of the polyvalent pneumococcal vaccine. <sup>100</sup> In addition, vaccinations for *Haemophilus influenzae* and *Neisseria meningitidis* are often administered. <sup>124</sup> These precautions should provide some protection against the three organisms most commonly responsible for OPSS. The optimal timing of such vaccinations remains difficult to define but should probably be administered as long as possible before operation. <sup>124</sup> Patient education is also vitally important. They should be alerted that a low-grade fever might be a harbinger of a serious infection. Although some recommend prophylactic oral penicillin in children, this practice is somewhat controversial. In general, although some question the value of splenectomy because of the risk of OPSS, patients whose therapy depends on accurate staging should undergo splenectomy. <sup>125</sup>

Causes for conversion to an open procedure during splenectomy include densely adherent adjacent structures, technical errors, and cardiopulmonary instability. <sup>126</sup> The most troubling technical errors are those associated with excessive bleeding that makes delineating anatomic structures very difficult. Conversion rates from 0% to 19% have been reported in series of laparoscopic splenectomy alone. <sup>126</sup> Patients about to undergo laparoscopic staging must be apprised of these data as part of the process of informed consent.

Whereas the use of laparoscopic splenectomy in the treatment of idiopathic thrombocytopenia purpura (ITP) has become the standard, some still question the use of laparoscopic approaches in the staging of Hodgkin's disease. <sup>127</sup> More recent data, such as that reported by Baccharini and coworkers, <sup>104</sup> suggest that the laparoscopic operation is equivalent to the open procedure. They demonstrated equivalent lymph node harvest, and on reasonable postoperative follow-up, they found fewer subdiaphragmatic relapses in the laparoscopy group. Although these data are not prospectively randomized, the results are very compelling in support of laparoscopic staging.

The use of laparoscopy in the management of a variety of abdominal lymphoproliferative diseases has been reported by Silecchia et al. <sup>128</sup> These investigators performed laparoscopic investigation on 64 patients with a number of diseases, including retroperitoneal adenopathy, Hodgkin's disease, and non-Hodgkin's disease. Laparoscopic ultrasound was used extensively. They concluded that the interval between diagnosis and treatment was significantly shortened by using a laparoscopic approach. Although this series does not necessarily provide the final word, it again demonstrates the utility of laparoscopy in the evaluation of these patients and suggests the need for further study.

NHL is a diverse group of diseases with a wide range of biologic behaviors. They may be very aggressive and rapidly fatal or behave as one of the most indolent and well-tolerated malignancies afflicting humans. <sup>129</sup> Because the clinical course is variable, the pattern of spread is also unpredictable. NHL is classified into low, intermediate, and high-grade pathologic groups according to the National Cancer Institute's working formulation. Each of these groups is further subdivided based on cell type (e.g., small cell, large cell). The therapy for these patients is still evolving, and surgical staging is generally reserved for the very small minority of patients with localized disease who receive radiation therapy alone. The role of the surgeon in the care of patients with NHL is usually limited to the biopsy of a single peripheral lymph node to establish a tissue diagnosis. In patients with NHL, the precise definition of disease location, unlike Hodgkin's lymphoma, has less impact on therapeutic decision making. <sup>130</sup> In general, NHLs are systemic diseases at the time of diagnosis and require the use of systemic therapy (e.g., chemotherapy) rather than regional therapy (e.g., radiation) for treatment.

Laparoscopy may play a beneficial role in the diagnosis of NHL in a select subgroup of patients. For example, a 70-year-old woman presented to her primary care physician with general malaise, weight loss, and occasional fevers. In the absence of positive findings on physical examination, she was evaluated with an abdominal CT scan (see Fig. 29.1-1), which demonstrated peri-aortic lymphadenopathy. <sup>131</sup> The diagnosis of NHL was made in this patient by laparoscopic lymph node excision as shown in Figure 29.1-2, performed on an outpatient basis, and systemic chemotherapy was begun.

Staging laparoscopy in patients with NHL is restricted to those few patients with clinically limited disease (stage I and II) who are to be treated with radiation therapy alone with curative intent. <sup>93</sup> In these very unusual cases, a staging procedure similar to that performed for patients with Hodgkin's lymphoma may be undertaken laparoscopically. Splenectomy may be omitted from the surgical staging of abdominal NHL because splenic involvement usually does not affect the therapy used, <sup>130</sup> and its removal increases toxicity to patients given combination chemotherapy. <sup>96,132</sup> Laparoscopy may have a role in the evaluation of treatment efficacy because persistent disease is often overdiagnosed by routine imaging studies. <sup>130</sup>

The gastrointestinal tract is involved in 20% of advanced NHL and represents 1% to 4% of all alimentary tract malignancies. <sup>133</sup> When large or small bowel is involved, the typical presenting signs and symptoms are consistent with a bowel obstruction secondary to external compression or intussusception. The most frequent site of involvement is at the ileocecal valve. Complete, curative resection is generally indicated for localized lesions. If the lymphoma is of a diffuse submucosal pattern where systemic therapy is required, resection should be limited to the correction of the mechanical obstruction. Should the lesion be discovered during a laparoscopic exploration or a laparoscopic staging procedure, laparoscopic resection of the lesion may be feasible if the surgeon has the technical ability and experience.

Laparoscopic localization and laparoscopic-assisted resection of the tumor is another alternative. The entire bowel, however, should be evaluated because skip

lesions may exist.<sup>93,94</sup> Gastric lymphoma, on the other hand, may be diagnosed after esophagogastroduodenoscopy, which is usually performed for upper gastrointestinal bleeding or anemia. If the lesion is localized, then laparoscopic resection may be technically feasible. Most patients with NHL are upstaged by staging laparotomy. This upstaging, however, results in no significant impact on the modality of treatment.<sup>130</sup> Therefore, staging laparotomy for NHL has fallen out of favor except for the small, select group of patients whose treatment would be intensified should the liver be involved. The liver can be involved in 20% of patients with NHL.<sup>105</sup> The role of the surgeon for patients with NHL is generally limited to the minimum procedure needed to establish the diagnosis.

## GYNECOLOGIC MALIGNANCIES

Although gynecologists have used laparoscopic instrumentation for many years, the use of laparoscopy for the management of gynecologic malignancies is more recent. Several reports of laparoscopic staging for apparent early-stage ovarian cancer have been published.<sup>134</sup> However, the follow-up remains short at this time, and the utility of this technique in ovarian cancer remains unproven. A prospective trial sponsored by the Gynecologic Oncology Group is under way to evaluate the utility of laparoscopy in these patients. The utility of the second-look laparotomy in the assessment of patients who have been treated for ovarian cancer is well established. Several reports of second-look laparoscopy with apparently good results have been published.<sup>134</sup> Further evaluation of this application is currently in progress. Laparoscopy also has been used in the staging of advanced ovarian disease. Patients with cervical cancer have undergone laparoscopic-assisted radical vaginal hysterectomy with LPLND. The utility of this procedure remains to be proven with prospective trials. Patients with early endometrial cancer have been staged by combining laparoscopy with vaginal hysterectomy in a procedure that has been named laparoscopic-assisted surgical staging.<sup>134</sup> Laparoscopy provides the ability to assess the peritoneal cavity, obtain peritoneal washings, and guarantee the removal of the adnexae. Lymph node sampling can also be performed laparoscopically when necessary in these patients. Although laparoscopy has been used in the management of ovarian, cervical, and endometrial malignancies, its potential is unconfirmed at this time. Reports of complications and long-term results are not yet available.<sup>134</sup> The results of ongoing clinical trials must be evaluated before this technique is widely applied in the management of gynecologic malignancies.

## LAPAROSCOPY IN THE TREATMENT OF MALIGNANCY

### GENERAL CONSIDERATIONS

Laparoscopic approaches have been used to treat a wide variety of malignancies. Many of these techniques were applied with a curative intent, whereas some were conducted as palliative procedures. At the time of this writing, the use of laparoscopic techniques to treat patients with malignancy remains controversial. In an attempt to afford patients with cancer the same benefits afforded patients with cholelithiasis, many investigators have conducted laparoscopic surgery for cancer with curative intent, particularly for carcinoma of the colon. However, this development may have been somewhat premature. The two major concerns about an operation performed laparoscopically for the treatment of cancer are (1) to be sure that the laparoscopic operation meets the same "oncologic" goals of the open procedure (e.g., margins of resection, lymph node harvest, recurrence rate, evaluation of other intraabdominal organs) and (2) to demonstrate an advantage to the patient for having undergone the procedure laparoscopically (e.g., decreased hospital stay, decreased cost, more rapid return to work). To date, few data convincingly demonstrate the validity of these two principles in the laparoscopic treatment of cancer.

### GASTRIC CANCER

The application of laparoscopic techniques to gastric resection has been made possible by the rapid advances in stapling technology. The first laparoscopic gastric resection using a Billroth II reconstruction performed intraabdominally was reported in 1992.<sup>135</sup> Since that time, the same group has continued to apply laparoscopic surgical techniques to gastric surgery.<sup>136</sup> In a series of 16 patients, all were operated on for benign disease, although two patients had foci of cancer found at the time of histologic examination. These two patients later underwent open lymphadenectomy. Laparoscopic gastric resection remains a technically demanding procedure, with precise identification of anatomic structures essential to its successful completion.

The use of laparoscopic techniques in the treatment of gastric cancer requires careful selection of patients. Early gastric cancer involving the submucosa requires gastrectomy with removal of the greater omentum and level 1 lymph nodes. Techniques for this procedure have been fully described.<sup>137</sup> More advanced tumors, which require further node dissections, are not amenable to laparoscopic resection. Patients with stage IV disease who require palliative gastric resections are good candidates for laparoscopic resection. Gastric lymphoma and gastric polyps requiring resection are also suitable for laparoscopic resection.<sup>137</sup> The inability to perform extensive lymphadenectomy may limit the applicability of laparoscopic gastric resection to malignancies, but it is clear that advances in technology may make this more feasible.

### COLON CANCER

Carcinoma of the colon is a very common disease in the United States, making it an attractive candidate for laparoscopic treatment. Surgical resection of carcinoma of the colon is a well-established procedure. Thus, any surgical approach that can potentially treat this disease with decreased postoperative pain and hospitalization may result in considerable advantages, generating great interest in the laparoscopic resection of colon cancer. It is clear that laparoscopic colon resection is an "advanced" procedure requiring more training, experience, and time than that for procedures such as appendectomy or cholecystectomy.<sup>138</sup> The use of animal models has facilitated the testing of some of these techniques and may be an important educational tool.<sup>139</sup> Intracorporeal anastomotic techniques may be used but remain a greater technical challenge than extracorporeal anastomoses.

Indications for laparoscopic colon resection at this time include segmental resections for diverticular disease, polyps, rectal prolapse, and intestinal volvulus.<sup>140</sup> The role of laparoscopic resections in the management of colonic malignancies remain undefined at this time and should be carried out only in the setting of a prospective trial.<sup>28,140,141,142</sup> and <sup>143</sup> It is reasonable to laparoscopically resect colonic malignancies with synchronous hepatic or pulmonary metastases as a palliative procedure. When performed appropriately, laparoscopic colon resection for cancer should include the following components, just as in open surgical resections: (1) resection of tumor in the bowel wall and adjacent soft tissues, (2) resection of an adequate margin of normal bowel, and (3) an adequate lymph node resection with associated vascular pedicle.<sup>144</sup>

The preoperative factors affecting suitability for laparoscopic colonic surgery are similar to those important in other laparoscopic procedures. The lack of ability to use palpation in the abdominal cavity prompts some to perform a more thorough preoperative evaluation with colonoscopy and CT scan.<sup>144</sup> In general, the surgeon and assistant stand on the side opposite the bowel to be resected. Some prefer the dorsolithotomy position,<sup>144</sup> and others prefer the patient in the supine position.<sup>138</sup> The use of the dorsolithotomy position has two potential advantages. First, intraoperative colonoscopy, facilitated by the use of low stirrups, may be necessary for localizing the lesion in the operating room. Second, one technique demonstrates the utility of the colonoscope in dissecting the hepatic and splenic flexures.<sup>145</sup> The zero-degree laparoscope is used for these procedures.

In general, for a right hemicolectomy, two left-sided and one right-sided port are used in addition to the umbilical camera port ( Fig. 29.1-7). The abdomen is explored thoroughly, with special attention paid to the liver, just as is performed with open surgical approaches. Ports are best placed as they are needed, which allows for flexibility, rather than using a static pattern placing all ports synchronously.<sup>139,141</sup> The bowel is then mobilized and the vascular pedicle to the sigmoid colon divided using a stapler. The bowel is then exteriorized and an extracorporeal anastomosis fashioned.<sup>146</sup>

colon resection.<sup>164</sup> The problem with many of the anecdotal reports in the literature is that the overall denominator is not known, and only through a prospective trial can these issues be adequately studied. The 1-year port-site recurrence rate has been reported at less than 1% in the first 252 patients in the registry of the American Society of Colon and Rectal Surgeons.<sup>27</sup> In this series, all of the recurrences were in patients with node-positive disease. Sugarbaker<sup>165</sup> has advocated the use of intraperitoneal chemotherapy based on his work with disseminated gastrointestinal malignancies.

Although laparoscopic surgery has the potential to save hospitalization time and recovery time, such savings must not be made at the expense of overall survival. The prospective trial currently under way at many centers throughout the United States and funded by the National Institutes of Health should address the issues of cancer control, costs, and quality of life.<sup>142</sup> The surgical community is awaiting the results of this trial. This carefully designed prospective trial will answer the significant questions regarding laparoscopic resection of colon cancer. The approach of waiting for the results of this study has been endorsed by a number of authors.<sup>141,142,166,167</sup>

## GALLBLADDER CANCER

Although it is rare, the presence of a gallbladder malignancy is a possibility that must always be in the mind of the laparoscopic surgeon while performing a routine laparoscopic cholecystectomy. This disease, most common in older women, is the fifth most common malignancy of the gastrointestinal tract and is associated with a dismal prognosis.<sup>168</sup> It is estimated that carcinoma is present in 1% of all cholecystectomy specimens.<sup>168</sup> Laparoscopic cholecystectomy is the procedure of choice for patients with symptomatic cholelithiasis, but the presence of gallbladder carcinoma remains a contraindication to the laparoscopic conduct of this procedure.<sup>169,170</sup> Preoperative diagnosis of this disease is difficult, because the sensitivity for ultrasonography in early cases is only approximately 20%. In view of the difficulty with which preoperative diagnosis can be made, it is not surprising that the diagnosis is often made only after histologic examination of the surgical specimen.

The optimal treatment for this rare disease remains elusive. In a large retrospective study of 724 patients from a number of European centers, only 4% of patients presented with Tis lesions, but these were the only patients with any hope of long-term survival.<sup>171</sup> Prognosis in stage T1 and T2 was markedly worse, although no data support the use of extended surgical resections in these patients. Furthermore, others have shown that, at the present time, the use of adjuvant chemotherapy or radiation therapy does not significantly affect survival.<sup>172</sup>

The treatment of patients suspected of having carcinoma of the gallbladder preoperatively should include a definitive procedure performed through conventional open surgical techniques as the initial procedure. Clinical data from ten patients with laparoscopically discovered gallbladder carcinoma have been reported.<sup>173</sup> All ten patients were believed to have resectable disease based on preoperative studies and intraoperative findings. The interval to exploration at the referral center was 14 to 74 days, with a median of 30 days. Gross intraperitoneal dissemination was found in four patients. The investigators concluded that patients in whom gallbladder carcinoma is suspected on visual examination of the gallbladder during attempted laparoscopic cholecystectomy should be converted immediately to an open procedure or the procedure terminated and the patient referred for definitive therapy. During the conduct of a laparoscopic cholecystectomy, any evidence for the presence of a carcinoma is cause for conversion to an open procedure.<sup>174</sup> Routine examination of the specimen with frozen section if suspicious areas are present should also be carried out, with conversion to an open procedure if positive for malignancy.<sup>170</sup>

In summary, any patient with a lesion that is preoperatively suspect for malignancy should undergo cholecystectomy by conventional open cholecystectomy.<sup>175</sup> If the diagnosis is suspected during a laparoscopic cholecystectomy based on the appearance of the gallbladder, frozen section should be obtained and the procedure converted to an open cholecystectomy if the histology demonstrates malignancy. If the diagnosis is made only after laparoscopic cholecystectomy is completed, then port sites should be excised at a second procedure.<sup>176</sup> Further surgical or adjuvant therapy may also be indicated.

## HEPATIC TUMORS

Whereas the use of laparoscopy in the staging of hepatic lesions, either primary or metastatic, has become fairly widespread, laparoscopic treatment of hepatic malignancies is rarely performed. This is because of the technical difficulty of this procedure as well as the scarcity of patients with lesions amenable to laparoscopic resection. The laparoscopic treatment of hepatic lesions has been reported. A benign liver cyst was fenestrated under laparoscopic guidance and provided effective therapy for a benign condition while avoiding the potential morbidity of a laparotomy.<sup>177</sup> A large series of 43 patients with benign solid and cystic lesions treated laparoscopically has been reported by Katkhouda et al.<sup>178</sup> These authors concluded that laparoscopic surgery is indicated for patients with giant solitary hepatic cysts and select patients with small, benign solid tumors located in anterior liver segments.

A number of techniques can be performed laparoscopically, including wedge excisions using a stapling device<sup>50</sup> or even laparoscopic hepatic segmentectomy. The anterolateral areas of the segments in the Couinaud classification are amenable to laparoscopic resection because of their accessibility.<sup>178</sup>

Although a number of techniques are available for liver resection, the ultrasonic dissector is preferred by some. A randomized prospective trial has shown that a laparoscopic version of this device is effective in laparoscopic cholecystectomy.<sup>179</sup> It is natural that this device may be used for hepatic resection. An animal trial has been reported, demonstrating hepatic resection on pigs using the ultrasonic dissector.<sup>180</sup> The ultrasonic dissector was effective in dissecting the intraparenchymal structures, including vascular structures. A single case of a left lateral segmentectomy in a human performed laparoscopically has been reported.<sup>181</sup> With improved instrumentation becoming available, perhaps more hepatic resections will be performed laparoscopically.

Another application of laparoscopic technology to the treatment of liver lesions is cryotherapy. Cryosurgery has been shown to be effective in the treatment of some hepatic malignancies.<sup>182</sup> Ultrasound monitoring of this procedure is essential. With the advent of laparoscopic ultrasound probes and cryotherapy probes, it is possible to perform cryotherapy of hepatic lesions. However, anatomic limitations may prevent the use of this technology because of limited exposure of certain lesions.

More recently, radio frequency ablation of tumors has been performed for metastatic and primary lesions of the liver.<sup>183,184</sup> This technique is often performed percutaneously, but situations exist in which a lesion is accessible only by using laparoscopic techniques to position the treatment probe accurately. Of 30 patients who underwent radio frequency ablation for primary and metastatic lesions of the liver in one series, 12 were treated laparoscopically, 12 at laparotomy, and six percutaneously.<sup>184</sup>

As laparoscopic technology improves and new modalities are applied to the treatment of hepatic lesions, more applications of minimally invasive surgery may be found for these patients. The role of laparoscopy in the management of malignant lesions of the liver remains undefined.

## PANCREATIC CANCER

Resection with the intent for cure is possible in only approximately 10% to 20% of patients who present with carcinoma of the pancreas, and 5-year survival rates of all patients presenting with the disease are only approximately 3%.<sup>185</sup> However, several more recent series have reported 5-year survival rates as high as 20% to 25% for patients who undergo resection for cure. Patients with pathologically negative lymph nodes have an even higher survival rate.<sup>186</sup> Many of the patients who are not resectable for cure often require surgical palliation. Laparoscopic surgery has the potential to provide this palliation while minimizing postoperative pain and length of hospital stay, both especially important considerations in patients with limited life expectancy.

The laparoscopic resection of pancreatic tumors is technically feasible but unlikely to become widely practiced. Gagner and Pomp<sup>187</sup> reported having performed a pylorus-preserving pancreaticoduodenectomy in a patient with chronic pancreatitis and pancreas divisum. Reconstruction was performed with a gastrojejunostomy, hepaticojejunostomy, and pancreaticojejunostomy. The patient's postoperative course was complicated by delayed gastric emptying, and he was discharged on the 30th postoperative day.

Laparoscopic distal pancreatectomy, with or without splenic salvage, has been well described.<sup>188</sup> It is often combined with splenectomy, as described by Cuschieri and colleagues,<sup>189</sup> who reported a series of five patients who underwent laparoscopic distal pancreatectomy and splenectomy using a five-port technique. This procedure is indicated for benign tumors in which the splenic vein cannot be separated from the pancreatic lesion, or in palliative resections of the distal pancreas for lesions such as cystadenoma, neuroendocrine tumors, cysts, and adenocarcinoma of the tail of the pancreas. It is unlikely that minimally invasive surgery will play a large role in the curative resection of malignancies of the head of the pancreas in the near future.

## RENAL CELL CARCINOMA

The use of laparoscopic surgical approaches for patients with renal cell carcinoma has been described,<sup>190,191 and 192</sup> with investigators demonstrating that nephrectomy can be safely performed using existing laparoscopic instrumentation. In this early series, the procedure took a mean of 5.6 hours to complete, and patients had an average hospital stay of 4.6 days.<sup>190</sup> The kidney is morcellated with an electric morcellator placed through a 10-mm port and extracted using a sturdy bag.

In some cases, preservation of renal parenchyma may be indicated. The laparoscopic enucleation of a renal cell carcinoma also has been described.<sup>193</sup> These investigators concluded that this procedure is relatively easy to perform compared with nephrectomy and, when indicated, may be preferable to perform by a laparoscopic approach.

## SPLEEN

Although the spleen rarely harbors primary or secondary tumors in humans, the surgical oncologist is often called on to perform a splenectomy for hematologic diseases. The spleen is well within the reach of the laparoscopic surgeon, and by applying laparoscopic techniques, the patient is afforded the benefits of laparoscopic surgery, including shortened hospitalization and decreased postoperative pain. A number of series in the literature report laparoscopic removal of the spleen.<sup>108,107,110,111 and 112,114,121,194,195 and 196</sup> These procedures have been performed for a number of indications including staging of Hodgkin's lymphoma, ITP, thrombotic thrombocytopenia purpura, acquired immunodeficiency syndrome–related thrombocytopenia, hereditary spherocytosis, autoimmune hemolytic anemia, leukemia, and splenic abscess. There may be particular subsets of patients for whom laparoscopic splenectomy is particularly beneficial. A case report of successful laparoscopic splenectomy on a patient who is human immunodeficiency virus–positive, a devout Jehovah's witness refusing transfusion, and with a preoperative hematocrit of 8.8% highlights the attractiveness of this technique.<sup>197</sup> In general, laparoscopic splenectomy represents the gold standard for removal of the spleen.<sup>115</sup>

Splenectomy was commonly performed for the staging of lymphomas in the past, and in one series demonstrated a significant increase in the period 1963–1982 compared with 1946–1962.<sup>96</sup> However, more recent trends show that splenectomies are now being performed more often for cytopenic and anemic diseases and less often for Hodgkin's disease.<sup>198</sup> The consequences of splenectomy are poorly understood at an immunologic level, but it is clear that the spleen plays a major role in a wide range of immune responses.<sup>199</sup> Patients should receive a pneumococcal vaccine preoperatively to help avoid the infectious complications of the asplenic state.<sup>125,199</sup> The patient can be positioned in several ways for this procedure, with some groups preferring a right decubitus position.<sup>200</sup>

In one large series, 43 patients were brought to the operating room for laparoscopic splenectomy, and 35 (81%) were successfully completed.<sup>114</sup> The remaining 19% underwent conversion to open splenectomy, usually for bleeding. Laparoscopic splenectomy has become the standard method for splenectomy in some centers. Conversion rates in other series have been reported as 2 (9%) of 22 cases,<sup>195</sup> 2 (12%) of 17,<sup>111</sup> and 3 (19%) of 13.<sup>194</sup> The details of the technique have been adequately described by Flowers et al.<sup>114</sup>

It is important to make a thorough search for accessory splenic tissue, identified in 10% of the patients in one series.<sup>114</sup> Accessory spleens are identified in up to 18% of patients undergoing splenectomy.<sup>201</sup> The magnification afforded by the laparoscope may aid in this task. In a series of 100 patients undergoing open splenectomy for ITP, 13 patients had a poor response to splenectomy, five of which required accessory splenectomy.<sup>202</sup> In one large series of laparoscopic splenectomies for ITP, a positive response was observed in 18 (82%) of 22 patients with ITP.<sup>114</sup> It is difficult to predict who will respond to splenectomy, with no predictive factors being identified, even in large series of patients with ITP.<sup>202</sup>

In a prospective study of operative outcomes, laparoscopic splenectomy using the lateral approach was performed on 147 patients and open splenectomy performed on 63 matched patients at three teaching centers.<sup>194</sup> Laparoscopic splenectomy resulted in longer operative times (145 minutes vs. 77 minutes), reduced blood loss (162 mL vs. 380 mL), shorter postoperative stay (2.4 days vs. 9.2 days), and fewer complications compared with the open procedure. The authors of this study also reported that the mean weighted cost of laparoscopic splenectomy was lower than the open procedure (\$3311 vs. \$3861). The conversion rate in this series was 2.7%.

Although laparoscopic splenectomy is a technically demanding procedure, it offers the patient the potential for decreased postoperative pain and hospitalization with more rapid return to normal activities of living. Further prospective data are needed to confirm these observations. Surgical alternatives to splenectomy, such as partial splenectomy, have been offered as a way to reduce the incidence of postoperative infections.<sup>203</sup> These techniques may also be approachable with laparoscopic techniques in the future.

## ADRENAL TUMORS

Laparoscopic techniques have been used for the resection of adrenal lesions.<sup>204,205,206,207,208 and 209</sup> Although the anterior transabdominal approach is considered by some to be a source of postoperative morbidity, the laparoscopic approach may offer some advantages. Adrenal tumors are fairly common, having been found in 2% of patients in autopsy series.<sup>210</sup> Small, asymptomatic tumors are reported in as many as 0.6% of abdominal ultrasound and CT examinations. Those discovered that are less than 4 cm in diameter and in the absence of endocrine syndromes can be observed after a careful evaluation.<sup>210</sup> However, a fair proportion of these lesions may require extirpation, a procedure that has been performed laparoscopically with the apparent advantages of decreased pain and more rapid return to full activity.

Furthermore, a number of laparoscopic approaches have been described. The anterior laparoscopic approach requires mobilization of the colon and, occasionally, other intraabdominal organs. A retroperitoneal laparoscopic approach also has been described, which may be more attractive. One study has compared the two approaches and found no difference in operative time, analgesia requirements, hospital time, recovery time, or complication rate.<sup>205</sup> The retroperitoneal laparoscopic approach may ameliorate some of the negative effects of pneumoperitoneum on the cardiovascular hemodynamics of the patient. However, most surgeons prefer the anterior approach at this time.

In one series of four patients, three patients had unilateral tumors and one had a bilateral pheochromocytoma.<sup>205</sup> Single right adrenalectomy was performed in 2.0 to 2.5 hours, whereas bilateral adrenalectomy lasted 5.5 hours. The hospital stay was 3 to 4 days postoperatively.

Over a 14-month period, Takeda and coworkers<sup>204</sup> removed seven left adrenal glands and three right adrenal glands from ten patients in operations ranging from 165 to 572 minutes (mean, 295 minutes). Conversion to open adrenalectomy was reported in one case (10%). They concluded that laparoscopic adrenalectomy is applicable to cases of primary hyperaldosteronism, but application to other lesions requires further study.

Twenty-five consecutive laparoscopic adrenalectomies performed on 22 patients in a 1-year period were reported by Gagner et al.<sup>206</sup> These surgeries were performed through a lateral decubitus flank approach and four 11-mm trocars and included 12 right and 13 left adrenal glands. The mean operative time for single adrenalectomy was 2.3 hours and for bilateral adrenalectomy was 5.3 hours. Diseases in this series included nonfunctional adenoma, pheochromocytoma, Cushing's disease, Cushing's adenoma, primary aldosteronism, angiomyolipoma, and medullary cyst. Lesions ranged in size from 1 to 15 cm, with a mean of 4.1 cm. Conversion to open laparotomy was required in one patient for lack of exposure, resulting in completion of the procedure in 96% of patients. The median postoperative stay was 4 days. Gagner et al.<sup>206</sup> concluded that laparoscopic adrenalectomy results in less postoperative pain and more rapid return to normal activity compared with open adrenalectomy.

A study compared laparoscopic adrenalectomy with a historical group of posterior adrenalectomies.<sup>207</sup> The two groups were comparable for patient demographics. The median time for posterior adrenalectomy was 120 minutes versus a median of 160 minutes for laparoscopic adrenalectomy. Patients who underwent laparoscopic adrenalectomy had a mean hospital stay of 3 days, a shorter time to return to work, and a lower blood loss than those patients who underwent posterior adrenalectomy with a mean hospital stay of 5 days. The authors of this study concluded that laparoscopic adrenalectomy is the procedure of choice.

One study reported the results of a case-controlled study of 40 laparoscopic and 40 open adrenalectomies.<sup>208</sup> Statistically significant differences were found (laparoscopic vs. open) in operative blood loss (40 mL vs. 172 mL), operating time (147 minutes vs. 79 minutes), hospital stay (12 days vs. 18 days), and late morbidity (0% vs. 48%). The authors of this study found no statistically significant differences in time to oral intake, total cost, and early morbidity. The late morbidity in the open group consisted of wound complications that were absent in the laparoscopic group. The authors concluded that the laparoscopic approach is the method of

choice for adrenal masses less than 6 cm in diameter.

A series from the National Cancer Institute reported the learning curve for laparoscopic adrenalectomy. In the first five patients, median operating time was 255 minutes, which dropped to 207 minutes in the second group of five patients and to 143 minutes in the third group of five patients. <sup>209</sup>

The use of minimally invasive surgery for adrenal malignancies remains controversial. *The SAGES Manual* states that laparoscopy is not to be used in the treatment of patients with malignant lesions. Other contraindications to laparoscopic adrenalectomy include masses larger than 10 cm, untreated coagulopathies, and surgeon inexperience. <sup>211</sup> Further study of this technique is clearly needed.

## GYNECOLOGIC MALIGNANCIES

The use of laparoscopy in the treatment of gynecologic malignancies has begun relatively recently, particularly in the treatment of endometrial and cervical cancer with the laparoscopic-assisted surgical staging and laparoscopic-assisted radical vaginal hysterectomy trials (described earlier in [Gynecologic Malignancies under Laparoscopy in the Staging of Malignancy](#)). At this time, the utility of laparoscopy in the treatment of gynecologic malignancies is unclear, and the results of ongoing prospective trials are awaited. <sup>134</sup>

## LAPAROSCOPY IN THE PALLIATION OF MALIGNANCY

### PANCREATIC CANCER

The use of laparoscopy in the staging of patients with carcinoma of the pancreas is discussed earlier in [Pancreatic Cancer under Laparoscopy in the Staging of Malignancy](#). In addition, laparoscopic techniques may be useful for palliative surgical procedures. Unfortunately, palliative therapy is all that is indicated for many patients with this disease. It is possible to palliate the three symptoms of this disease—biliary obstruction, gastrointestinal obstruction, and pain—using laparoscopic techniques. As many as 57% of patients who present with this disease undergo palliative surgery. <sup>212</sup> A particularly attractive concept is to stage patients using laparoscopic techniques, and then perform palliative bypass surgery at the same time using a laparoscopic approach in patients found to have unresectable disease. <sup>213,214</sup> Nonoperative palliation of obstructive jaundice using an endoscopically placed stent has been shown effective when compared with surgical palliation, and it also is associated with lower complication rates than surgical palliation. <sup>186</sup>

Palliation for obstructive jaundice may be performed nonoperatively using an endoprosthesis, or it may be carried out using a number of bypass procedures that can be performed laparoscopically. The simplest technique is cholecystojejunostomy, which has been described using both sutured and stapled techniques. <sup>215</sup> Choledochoduodenal or choledochojunal anastomoses may also be fashioned laparoscopically. <sup>215</sup> The biliary bypass is then combined with a gastroenterostomy, which is performed at the surgeon's discretion. Similarly, the celiac plexus may be injected under laparoscopic guidance to provide pain relief. <sup>216</sup> Such a combined approach was used by Mouiel <sup>215</sup> in 12 patients with excellent results.

### FEEDING TUBE PLACEMENT

Enteral feedings are preferable to parenteral feedings in patients who can tolerate them, yet not all patients with cancer are able to take in enough calories by mouth, thereby necessitating placement of a feeding tube. Open surgical gastrostomy is most often performed in the United States by the method of Stamm. <sup>217</sup> This was the only method available until 1980, with the development of the percutaneous endoscopic gastrostomy (PEG). <sup>218</sup> However, placement of a PEG requires upper endoscopy, which is not possible in all patients. Furthermore, the use of a PEG tube, necessitating pulling the tube through the tumor-bearing area, has been reported to result in implantation of the tumor at the PEG site in three cases. <sup>219</sup> In select patients, including patients with head and neck tumors, Zenker's diverticula, and large hiatal hernias, open surgical gastrostomy remains the preferred method of enteral access.

The technique for laparoscopic gastrostomy has been described. <sup>220</sup> Importantly, although formal laparotomy is not needed, the stomach is directly visualized using this technique. A retrospective review established the usefulness of this technique. <sup>218</sup> In this study, 32 patients who underwent laparoscopic gastrostomy and 37 patients who underwent open gastrostomy were reviewed. The underlying illnesses and contraindications to PEG placement were similar in both groups. Operative time was significantly greater in the open gastrostomy group (62 ± 19 minutes) compared with the laparoscopic gastrostomy group (38 ± 7 minutes). Complication rates were 11% in the open group and 6% in the laparoscopic group. The investigators concluded that laparoscopic gastrostomy is a safe and effective alternative procedure in patients unable to undergo placement of a PEG. Laparoscopic placement of jejunostomy tubes also has been described. <sup>221</sup>

### LAPAROSCOPIC STOMA CREATION

Decompression of the intestinal tract may be an important procedure in the cancer patient, especially in those with carcinomatosis and resulting intestinal obstruction. The importance of colonic decompression in patients with obstructing carcinomas of the colon has been described. <sup>222</sup> The initial presentation of carcinoma of the colon is obstruction in 15% to 21% of patients, most commonly in the left colon. The 5-year survival rate in these patients is significantly less than that in patients without obstruction. This common situation underscores the importance of palliative procedures that may decrease postoperative pain, incidence of ileus, and recovery time.

Laparoscopic creation of a loop colostomy has been described. <sup>223</sup> In this technique, after the sigmoid colon is mobilized, a drain is passed through its mesentery and is then used to extract the colon through a special 3.5-cm trocar placed in the left lower quadrant. This procedure was modified and described with an associated decrease in postoperative pain and ileus with a rapid recovery. <sup>224</sup>

The use of small laparotomy incisions may be used for the creation of intestinal stomas; however, the presence of metastatic disease or peritoneal implants may make such procedures difficult to perform. The use of a laparoscopic approach makes possible the inspection of the abdominal cavity for other lesions and results in discharge from the hospital within 24 to 48 hours of surgery. In one study, 17 (89%) of 19 patients were successfully diverted using laparoscopic techniques. <sup>225</sup> The remaining two patients had extensive adhesive disease that could not be managed laparoscopically and required conversion to open laparotomy. Other procedures, such as laparoscopic gastrostomy, may also be carried out as needed.

## THE FUTURE OF LAPAROSCOPY IN THE CARE OF THE PATIENT WITH CANCER

Exciting technology for laparoscopic surgery now under development will soon be in operating rooms. Cuschieri <sup>226</sup> has pointed out that we need to “see better, feel better, increase the precision of maneuverability and handling, reduce contamination, facilitate specimen extraction and bring order to the present ergonomic chaos in our operating rooms.” New developments in the technology of imaging are being applied to laparoscopic surgery. Although head-mounted displays have been tested, they are probably less than optimal for the laparoscopic surgeon because of the isolation created by these devices. Current three-dimensional imaging systems are not without their limitations, but new systems may provide a true improvement in tissue visualization. Continued improvements in instrumentation will certainly be an important part of the evolution of laparoscopic surgery. New methods of tissue extraction include a sleeve system and an extracorporeal pneumoperitoneal access bubble. <sup>226</sup> Both of these systems have potential advantages, especially for the removal of large tumor specimens.

Training of surgeons in these newly emerging techniques remains a complicated problem. Because hospitals decide what procedures may be performed by surgeons, criteria for training and furnishing credentials must be developed. <sup>227</sup> The Society of American Gastrointestinal Endoscopic Surgeons (SAGES) has suggested criteria for training and awarding credentials. It remains to be shown whether some advanced laparoscopic procedures result in a true cost savings when the increased cost of instrumentation and operating room time are factored into the total expenses incurred.

The surgeon has traditionally been involved in the diagnosis, staging, treatment, and palliation of patients with malignancies. Laparoscopy is rapidly becoming an important tool in each of these areas of cancer patient care. The ultimate application of laparoscopic techniques depends on the imagination of surgical investigators and on careful analyses of risks and benefits. Over time, it may be discovered that certain uses for this technology are not ultimately advantageous to the patient compared with traditional open surgical techniques. Only by the conduct of carefully controlled studies, however, will the facts be elucidated, allowing this methodology to be used when it will benefit the patient and avoided when it will not.

#### INTRODUCTION

The complex management of the cancer patient frequently relies on the ability to deliver a variety of intravenous or intraarterial agents over a prolonged period. Chemotherapy, anesthesia, analgesics, and total parenteral nutrition may be required alone or in combination. Certain drug delivery systems may be more appropriate than others, depending on the particular situation. Since their introduction in the early 1970s, significant changes and improvements have been made in indwelling catheters and infusion devices.<sup>1,2</sup> All physicians who are involved in caring for cancer patients should have a basic understanding of the uses and limitations of these devices. An understanding of the issues involved in catheter selection, techniques of insertion, routine maintenance, and treatment for catheter-related complications, allows the physician and the patient to optimize the use of these devices.

#### CATHETER TYPES

A variety of catheter types are available, each with its own intrinsic advantages and disadvantages. The choice of which one to use is based on a variety of factors, including type of agent to be infused, length of time the catheter is to be used, number of concurrent therapies requiring intravascular routes, need for blood draws, desirability of continuous infusion, and patient (or physician) preference. Given the number of available systems, it is convenient to divide catheters into two broad categories. The first group are those catheters having an external component, represented by devices such as the Hickman, Groshong, or Broviac (Bard Access Systems, Salt Lake City, UT). The second group are devices that can be completely internalized or implanted, such as Portacaths and infusion pumps. (Sims Deltec, Inc., St. Paul, MN).

#### EXTERNAL DEVICES

The simplest and most straightforward central venous access catheter is a single-lumen 16-gauge catheter positioned in either the subclavian, internal jugular, or femoral vein. When inserted using sterile technique, these catheters can generally remain in place for 7 to 10 days, and they allow for the acute infusion of a variety of agents. The catheter is not tunneled, and therefore it is at risk for both infection and migration. Although a simple central line can be very useful, these catheters are not appropriate for long-term or outpatient intravenous therapy.

The Hickman- or Broviac-type catheters are made of barium impregnated silicone rubber (Silastic, Dow Corning Corporation, Midland, MI) and are available as single- or double-lumen devices in both pediatric and adult sizes. These catheters can be tunneled under the skin and have a Dacron cuff, which is implanted in the subcutaneous tissue just above the exit site. This cuff is intended to promote fibrous ingrowth and scarring, which serves to lessen the likelihood of catheter migration and infection. Although some early suggestion was made that silver ion impregnation of the cuff might further reduce the incidence of catheter-related bacteremia,<sup>3,4</sup> prospective randomized studies have not supported any benefit of silver ion impregnation.<sup>5,6</sup> It appears that the mechanical barrier provided by the fibrous reaction to the cuff is sufficient. The Groshong-type catheter is similar to the Hickman and Broviac designs in all respects except for the tip. The Groshong tip is modified with a slit valve to prevent the passive reflux of blood into the lumen (Fig. 29.2-1). The valve only opens when positive or negative pressure is applied to it, such as during infusion or withdrawal of fluid, thereby reducing the frequency with which the catheter must be flushed. These catheters can normally be flushed with saline alone. However, Mayo et al. have shown that the addition of a weekly heparinized saline flush decreased the presence of intraluminal adherent clots and improved the catheter function.<sup>7</sup> This study also demonstrated that the slit valve is frequently incompetent.

FIGURE 29.2-1. The slit valve along the side of the Groshong catheter tip is designed to prevent passive reflux of blood into the lumen.

Considerable interest has been focused on peripherally inserted central catheters (PICC lines).<sup>8,9,10,11</sup> and <sup>12</sup> These lines can be inserted in a peripheral vein in the arm using a Seldinger technique or a “through the needle” technique and threaded into the subclavian vein. Advantages include ease of insertion and the low risk of serious complication. Skilled nurses trained in the insertion technique can perform the procedure at the bedside with results similar to those obtained by interventional radiologists.<sup>11</sup> For initial insertions, this approach has proven very cost-effective. If maintained properly, these lines can last for as long as 1 year and can be used for chemotherapy<sup>12</sup> or total parenteral nutrition.<sup>13</sup>

#### IMPLANTED DEVICES

Since their introduction, implantable ports have become popular with patients and clinicians alike.<sup>14</sup> These devices are constructed from a variety of materials, including titanium and plastic, and can be made compatible with magnetic resonance imaging (MRI) and computed tomography (CT). The general design includes a compressed silicone diaphragm, which can withstand repeated punctures with a Huber needle. A comparison of a typical external catheter device with an implantable port is shown in Figure 29.2-2. The device shown is a single-lumen port; however, dual-lumen models are also available. These ports are typically inserted in the operating room. The technique used for the insertion of the catheter itself is identical to that used for external catheters and is described in detail in the section Insertion Technique. The port housing is placed in a subcutaneous pocket on the chest wall. Care needs to be taken to make sure that the diaphragm of the port can be palpated through the overlying tissue to allow for access to the device. The port housing is anchored to the underlying fascia by several interrupted sutures. Unlike external catheters, removal of a port generally requires a repeat trip to the operating room to perform a cutdown over the port and a removal of the device from the

subcutaneous pocket. If the device is removed because of infection, the pocket should be left open to close by secondary intention to prevent the formation of an abscess.

**FIGURE 29.2-2. A:** Dual-lumen 10 Fr. Hickman catheter showing the Dacron cuff. **B:** Implantable venous access device. A noncoring Huber needle is also shown. The housing of the port can be made of titanium (pictured) or plastic.

Comparisons have been made between external catheters and implanted ports with respect to infection rates, patency, and long-term complications such as vessel thrombosis.<sup>15,16,17,18,19,20 and 21</sup> Most studies have demonstrated comparable rates of infection between external and implanted devices, with the implanted devices having a longer durability of usage.<sup>19</sup> Overall, the majority of studies have not demonstrated one system to be overwhelmingly superior to the other. The main determinants of catheter survival, regardless of whether the device is external or implanted, are still careful placement and careful maintenance.

Improvements in port design have allowed for the construction of very low profile, small devices that can be implanted in the subcutaneous tissue of the arm with the catheter threaded in a similar fashion as a PICC line. These devices, referred to by their trade name as *Pasports* (Sims Deltec, Inc., St. Paul, MN), can be inserted in the operating room or imaging suite using local anesthesia. Comparisons between these devices, standard Portacaths, and external catheters have shown that both the Portacath and Pasport have a reduced incidence of infectious complications when compared to external catheters.<sup>22</sup>

### **Implantable Infusion Pumps**

Although the implantable ports have been an advance in convenience and comfort for patients, they still must be connected to an external infusion system. This is true whether the port is placed for intravenous or intraarterial access. The reliance on the external pump has been partially supplanted by completely implanted subcutaneous infusion pumps.

The implantable devices are larger, but they resemble infusion ports in many respects ( [Fig. 29.2-3](#)). The earliest devices were used to deliver long-term heparin therapy for patients with thrombotic complications.<sup>23</sup> Using such a system, patients were able to receive long-term continuous intravenous therapy for periods of up to 1 year.<sup>24</sup>

**FIGURE 29.2-3. A:** The implantable infusion pump (Arrow International, Reading, PA), which comes in various sizes. The smaller pump is used for the infusion of narcotic analgesics either intravenously or via an intraspinal route. **B:** A schematic representation of how the pump system works. Body heat causes the propellant to shift from a liquid to a gaseous phase, which compresses the bellows and allows for the drug to be dispensed. When the drug reservoir is refilled, the propellant is compressed and shifts back into a liquid phase.

The first implantable pump to be introduced was manufactured by Infusaid and was known by the same name (it is now produced by Arrow International (Reading, PA)).<sup>14</sup> This system weighed slightly less than 200 g when it was empty and was positioned in the subcutaneous tissues of the abdominal wall. The pump delivers a constant rate, determined by internal flow resistors, and is powered by the pressure generated from the expansion of a liquid fluorocarbon to the gaseous phase at body temperature. As the drug reservoir is filled percutaneously through a septum, the surrounding fluorocarbon chamber is recharged as gas is compressed and condensed into the liquid phase. The newest models have a side-access septum that bypasses the infusion system and allows for direct delivery of a flush or bolus of medication.

Although its main use has been in the delivery of intraarterial chemotherapy via the gastroduodenal artery for the regional treatment of liver metastases,<sup>25,26,27 and 28</sup> the Infusaid pump has been used to deliver insulin intravenously,<sup>29</sup> as well as morphine for intractable pain.<sup>30</sup> The current models are smaller than their predecessors, resulting in improved patient comfort (see [Fig. 29.2-3](#)). Other implantable systems using battery-powered peristaltic or solenoid pump mechanisms are also available. A telemetry system transmits or receives signals from the totally implanted device, which can turn the pump on or off, adjust the delivery rate, and determine battery voltage.<sup>31</sup> Although these implantable pumps can save patients the inconvenience of carrying an external device and free them from the need to be attached to an intravenous line, they can be expensive. As the number of uses for these devices increases, however, the costs will undoubtedly decline.

### **INSERTION TECHNIQUE**

The single most important aspect of catheter insertion is to strictly adhere to sterile technique. To do this, it is important to have adequate light and space to perform the procedure. Therefore, the preferred setting for the insertion of long-term indwelling catheters is the operating room or interventional radiology suite. The availability of real-time fluoroscopy is also extremely helpful for confirming catheter position. In a patient who is not cognitively impaired and who is able to follow direction, local anesthesia is all that is required. Monitored sedation can be used in certain cases and with pediatric patients.

The most common insertion technique used today is the one described by Seldinger, using a percutaneous approach over a guidewire. This technique has been shown to be superior to open cutdown approaches.<sup>20,32</sup> This technique can be used to insert a catheter into any vein; however, the preferred locations are the subclavian or internal jugular veins. The approach to the subclavian vein is described in greater detail.

The precordium is prepared sterilely, and a local anesthetic is infiltrated infraclavicularly. The patient is placed in Trendelenburg's position, and a shoulder roll positioned longitudinally between the shoulder blades will sometimes facilitate insertion. A finder needle attached to a 5-cc syringe is advanced into the vein under the clavicle with the bevel of the needle facing up. Gentle aspiration is applied until blood freely flows into the syringe. If there is any question as to whether the needle is

in an artery or a vein, a central venous pressure line can be connected to confirm a venous insertion.

Once the needle is in the vein, it is rotated 90 degrees and the syringe is disconnected, taking care not to allow air into the vein through the needle. A flexible guidewire is then advanced into the needle. If advancement of the guidewire meets with any resistance, it is not intraluminal and the wire should be removed. The needle should then be repositioned and aspiration of venous blood reconfirmed.

Once the wire has been successfully inserted, its position can be confirmed with fluoroscopy. At this point, a site on the precordium is selected for the catheter exit site (Fig. 29.2-4). After infiltrating the tissues with local anesthetic, a small incision is made at the exit site as well as adjacent to where the wire enters the skin. The catheter is then tunneled under the skin subcutaneously until the Dacron cuff is situated approximately 1 cm from the exit site. A peel-away sheath dilator is then advanced over the wire into the vessel by intermittently advancing the sheath and withdrawing the wire to check for resistance (see Fig. 29.2-4 inset). It is possible for the sheath dilator to bend the wire and result in the dilator penetrating the wall of the vessel. This can result in fatal hemorrhage.

**FIGURE 29.2-4.** Insertion of a long-term indwelling central venous catheter via a subclavian approach using a percutaneous technique. **A:** After insertion of the guidewire, the catheter is tunneled from the chosen exit site to the venous cannulation site. **B:** The Dacron cuff is placed subcutaneously 1 cm above the exit site. **Inset:** As the sheath/dilator is advanced over the guidewire, care is taken to ensure that the dilator is advancing along the course of the wire by intermittently moving the wire back and advancing the dilator. After trimming the catheter to the proper length, it is advanced through the peel-away sheath.

Once the dilator is in place, the catheter is inserted into the lumen of the dilator and the catheter is advanced as the dilator is peeled apart (see Fig. 29.2-4 inset). The ideal catheter tip position is just inside the right atrium. The surgeon must keep in mind that, when the patient is upright, the catheter tip migrates back from 1 to 3 cm. A high rate of catheter failure can occur from thrombotic complications if the tip is in the subclavian vein rather than in the right atrium.<sup>33</sup> To avoid this, the catheter is cut to its estimated desired length, which is determined from external bony landmarks. Typically, the right superior vena cava/right atrial junction lies approximately 4 to 6 cm inferior to the angle of Louis (Fig. 29.2-5). The final position of the catheter tip can be confirmed with fluoroscopy. After the procedure is completed, the patient should have an upright chest x-ray to confirm position and to rule out a pneumothorax. The incidence of pneumothorax after percutaneous placement of a central venous catheter by either a subclavian or jugular approach has been shown to be less than 1%.<sup>34</sup>

**FIGURE 29.2-5.** The length of the catheter can be estimated by simulating its course through the subclavian vein and superior vena cava along the clavicle and right border of the sternum. If the catheter is cut 6 cm inferior to the angle of Louis, it approximates a final position at the superior vena caval and atrial junction. Tip position should be confirmed using fluoroscopy.

In certain situations the subclavian vein may not be suitable for catheter insertion. In such an instance, the internal jugular vein is the preferred location. This vein can be accessed percutaneously in a similar fashion by using the bellies of the sternocleidomastoid muscle as landmarks. The vessel can also be isolated through a cutdown procedure. In some patients with occlusions of the subclavian and jugular veins, other sites must be used. The femoral vein may be used with a relatively low complication rate.<sup>35</sup> This site, however, is less desirable given its anatomic position and difficulty in keeping the area aseptic. Other insertion sites have included the saphenous vein, gonadal vein, intercostal vein, or azygous vein, or direct placement into the inferior vena cava.<sup>35,36,37,38 and 39</sup>

After the successful placement of a long-term indwelling central venous catheter, certain routine postoperative maintenance procedures should be performed to increase the durability of the catheter. Careful attention should be paid to the maintenance of catheter patency and to the catheter exit site to ensure it is kept clean. Although there is some discrepancy among catheter manufacturers, external catheters are typically flushed daily or every other day with a heparin solution or saline when they are not in use.

## SELECTING THE APPROPRIATE CATHETER

The selection of the right catheter for a particular patient must be based on an assessment of a number of factors. Consideration must be given to the intended use of the catheter and how long the catheter will be needed. For example, a patient who needs 2 weeks of intravenous antibiotics as an outpatient will probably be best served by having a single-lumen external catheter placed, which can be more easily removed when the course of therapy is completed. Some evidence suggests that single-lumen catheters pose less of an infection risk than dual-lumen devices.<sup>40</sup> In contrast, a patient expected to receive several courses of chemotherapy over the next 3 months, who will also require frequent blood draws, may be best served by the placement of a double-lumen implantable Portacath.

At the National Institutes of Health, a team approach is used in the selection, insertion, and maintenance of intravenous access devices. The team is made up of surgeons, interventional radiologists, intensivists, and specially trained access nurses. When a physician requests a consult for a line placement, information about the patient and planned uses is obtained. The most important issues, in addition to type of agent to be infused and duration of planned use, are history of previous indwelling catheters, patency of central veins (duplex Doppler examinations are obtained if necessary), the patient's ability to maintain the catheter, age of the patient, size of the patient, and need for blood draws. All of these issues are factored into the selection of the appropriate device. The Vascular Access Device (VAD) Service then assists in patient teaching both before and after the device is inserted. Once the device is in place, the VAD Service then tracks information regarding outcome. Programs such as this have been shown to enable the patient and the physician to derive the longest possible benefit from the vascular access device and to minimize complications.<sup>41</sup>

## CATHETER-RELATED COMPLICATIONS

## CATHETER MALFUNCTION

Catheters leak or break because of defective construction or because they are pinched between the clavicle and first rib when the patient is upright. <sup>42,43</sup> More commonly, infusion through a VAD may be difficult because of a kink in the catheter, a forgotten suture holding it in place, or precipitates of salts or medications obstructing the lumen. The latter can sometimes be removed with instillation of 0.1 N HCl or 70% ethanol. <sup>44,45</sup>

The most common type of VAD malfunction, however, is the inability to withdraw blood from the catheter without difficulty infusing through it. Withdrawal occlusion not only prevents use of the VAD for blood sampling, but also is a sign that fluid injected through the catheter may not be entering freely flowing blood in the superior vena cava. Continuously bathing a small vein with a nonphysiologic solution may lead to chemical phlebitis. <sup>46,47</sup> Withdrawal occlusion is caused by an obstruction at the catheter tip that acts as a one-way valve. It occurs when aspiration pulls the wall of a vein against the catheter orifice. This is especially likely if the catheter tip is in a vein smaller than the superior vena cava. Even if the VAD has been properly placed initially, the catheter tip can migrate into the contralateral innominate or a jugular vein as a result of postural changes. <sup>46,47</sup> More commonly, it can be pulled back into the ipsilateral innominate vein by traction applied by the chest wall, or partially retracted so that the tip is held perpendicular to the superior vena cava wall. <sup>48</sup>

Malpositioning of a catheter can often be identified by a chest x-ray. The problem can be relieved, at least temporarily, by having the patient stand, raise his or her arms, or use Valsalva's maneuver to move the catheter tip. Interventional radiologists can sometimes return a migrant catheter to the superior vena cava with a snare. <sup>42</sup> In the long run, however, poor catheter position is typically associated with recurrent malfunction and ultimately requires replacement of the VAD.

Catheter tips that rub against the vein may stimulate local thrombosis, which can also cause withdrawal occlusion and sometimes anchor the tip to the venous wall. Even in good position, however, catheters virtually always accumulate a coat of fibrin. <sup>49,50</sup> If this "sheath" extends to the catheter orifice, it can act as a one-way valve to obstruct withdrawal. <sup>50</sup> In extreme cases, these fibrin sheaths can extend from the tip of the catheter to the point where it enters the vein. This not only creates withdrawal occlusion but provides a channel for infusates to backtrack and possibly extravasate. <sup>51</sup> Withdrawal occlusion that is not relieved by changing the patient's position, therefore, suggests the possibility that the obstruction is actually due to a fibrin sheath.

An effort can be made to dissolve the obstructing fibrin by instilling a thrombolytic agent through the obstructed catheter into the suspected sheath, where it is left to dwell for 1 to 2 hours before re-attempting withdrawal. Although the traditional thrombolytic agent for this indication has been urokinase, this drug is now unavailable and has been replaced by instillations of recombinant tissue plasminogen activator (rtPA) in a concentration of 1 mg/mL. <sup>52,53</sup> Usually 2 to 3 mL are infused and left for 2 hours before withdrawal is attempted.

If this treatment is not successful, the cause of the withdrawal occlusion should be investigated further. If a chest x-ray has not already been taken, one should be performed to confirm that the catheter tip is properly positioned in the superior vena cava. Then x-ray contrast material should be injected through the obstructed lumen to look for a fibrin sheath, which is detected as a tubular structure filled with contrast encasing the catheter. <sup>51,54</sup> If the presence of a fibrin sheath is confirmed, repeat instillations of rtPA can be tried. In the past, regimens of continuously infused urokinase were often successful in relieving obstructions refractory to routine instillations of the drug. <sup>54</sup> Experience using rtPA in a similar manner, however, is quite limited.

Open-ended catheters have traditionally been flushed with low-dose heparin on a regular schedule to reduce the risk of thrombotic obstruction of the catheter. However, the value of this technique has not been proven, except perhaps with dosing schedules that are not practical on a long-term outpatient basis. <sup>55,56</sup> A reason not to use heparin flushes is the risk, albeit a low one, of heparin-induced thrombocytopenia and thrombosis. <sup>57,58</sup> and <sup>59</sup> In addition, coagulation tests cannot be reliably performed with blood drawn through heparinized VADs, even with a large discard volume. <sup>60</sup>

## VENOUS THROMBOSIS

Thrombi usually originate at the point where a catheter enters the vein or at any point where it chronically rubs against the venous wall. Symptomatic thrombosis of the catheterized vein develops in 5% to 10% of patients with VADs. <sup>61,62</sup> Most VAD-related venous thrombosis, however, is asymptomatic, occurring in approximately 30% to 70% of patients. <sup>61,62</sup> Thrombi develop soon after the catheter is placed and usually remain clinically silent because abundant collateral veins relieve the pressure as the primary vein becomes obstructed. <sup>62</sup> It is important to be aware of asymptomatic thrombosis as a potential nidus of infection as well as a source of pulmonary emboli. <sup>60,63</sup> Furthermore, because thrombosis may leave the vein permanently obstructed, it may create a problem for an unsuspecting surgeon who attempts to re-catheterize the vein at a later time. <sup>61</sup>

The management of symptomatic VAD-related thrombosis must be individualized. The catheter rarely must be removed immediately and does not necessarily have to be removed until the need for it has passed. <sup>64</sup> Prompt relief of symptoms is often achieved by simply elevating the affected arm overnight. Most patients also receive systemic anticoagulation in the form of heparin, followed by warfarin for several months, with the rationale that this prevents the thrombus from extending. <sup>64,65</sup> and <sup>66</sup> However, the risk of extension is unknown. Anticoagulation also is recommended to prevent pulmonary emboli, which are reported to occur in 10% to 15% of patients with upper extremity deep venous thrombosis and can be fatal. <sup>63,67,68</sup> Small emboli, however, frequently occur when the catheters are removed, but the minimal morbidity from these does not justify routine evaluation or therapeutic intervention before explantation. <sup>69</sup> The more threatening emboli appear to be much less commonly associated with the modern silicone and polyurethane catheters. <sup>67</sup> The risk of chronic venous insufficiency due to thrombosis in the axillary-subclavian vein may also be a consideration. On the other hand, the most important issues are often the need for long-term venous access and the risks of antithrombotic treatment.

With the introduction of low-molecular-weight heparin, hospitalization is no longer necessary for initial anticoagulation. <sup>70</sup> Subcutaneous low-molecular-weight heparin and oral warfarin can be started together and the heparin continued for at least 5 days and until the patient's international normalized ratio has been between 2 and 3 for 2 days. The necessary duration of warfarin therapy is unknown. It can be argued that warfarin should be continued as long as the VAD is in place but that 4 to 6 weeks of warfarin is sufficient if the VAD is removed after the thrombus is discovered. <sup>64,65</sup> However, no clinical trials have tested this recommendation, and extenuating circumstances often dictate the anticoagulant regime for an individual patient.

Thrombolytic therapy of VAD-related thrombosis may be reasonable when salvaging the vein is a high priority because anticoagulation alone will probably not leave the vein patent enough to be used for subsequent VADs (Fig. 29.2-6). A regimen using relatively low doses of rtPA has been published. <sup>71,72</sup> Long-term patency, however, generally requires that the catheter be removed while anticoagulation is continued for several weeks or months. <sup>71</sup>

**FIGURE 29.2-6. A:** Catheter-related subclavian vein thrombosis documented by venogram, which shows complete obstruction and collateral venous flow. The patient was treated with urokinase infusion through an ipsilateral forearm vein and, after 16 hours **(B)** and 39 hours **(C)** of urokinase infusion, showed progressive resolution of the thrombosis.

Of course, effective prophylaxis would eliminate the problem of VAD-related thrombosis. This reportedly can be achieved with very low-dose warfarin (1 mg/day) or with low-molecular-weight heparin.<sup>73,74</sup> and <sup>75</sup> However, the benefit of these regimens was demonstrated in patients with an unusually high incidence of symptomatic thrombosis, and therefore it is not clear how easily these results can be generalized. The value of prophylactic warfarin was not apparent in a population of less hypercoagulable patients.<sup>76</sup>

## INFECTIONS

Infection is the most common complication of VADs and the most common reason that they are removed prematurely.<sup>77,78</sup> and <sup>79</sup> Short-term (i.e., less than 1 month), nontunneled central venous catheters carry the greatest risk of infection, although bonding the catheter material with antimicrobial agents reduces this risk significantly.<sup>80</sup> Among long-term, tunneled VADs the infection rate varies considerably, and in some series, infections are much more common (e.g., approximately 40%) with externalized catheters than for subcutaneous ports (approximately 5% to 10%), with the risk of infection decreasing over time from catheterization.<sup>20,79</sup>

The organisms infecting VADs are most commonly derived from the patient's skin flora or from the hands of health care workers.<sup>81</sup> They migrate along the internal (introduced by accessing the hub) and external (from the skin wound) surfaces of the catheter, secreting a biofilm that protects them from the host's immune system as well as from antibiotics.<sup>82,83</sup> and <sup>84</sup> Before the skin is well healed, percutaneous infections are most common, in the form of cellulitis at the insertion site ("exit-site" infections) or deeper in the subcutaneous track of the catheter ("tunnel" infections).<sup>81,85</sup>

Exit-site infections occur at the skin wound, which is the catheter insertion site, or in the case of subcutaneous ports, the needle access site. They present with tenderness and erythema and purulent discharge and are most commonly caused by *Staphylococcus epidermidis*. The site should be cultured and treated with topical antibiotic ointment. The VAD can usually be left in place unless the infection is due to *Pseudomonas* species or atypical mycobacteria.<sup>86,87</sup> If fever or other systemic signs develop, however, blood cultures should be obtained and antibiotics started. If the cultures are negative, an oral cephalosporin may be adequate.<sup>85</sup>

Very serious infections can also develop in the subcutaneous tunnel of the catheter or in the pouch where a port resides. These are usually quite tender and swollen and may be fluctuant. Bacteremia associated with a deep-seated infection requires at least 4 weeks of antibiotics. If fever or bacteremia persists after 3 days of antibiotics, however, catheter removal is usually necessary, particularly when the organism is *Staphylococcus aureus*.<sup>81,88</sup>

Diagnosing catheter-related bacteremia requires obtaining quantitative blood cultures both through the catheter itself and from a peripheral vein. If the number of colonies growing in the catheter-derived culture is more than tenfold greater than the number in the peripheral blood culture, the VAD is implicated as the source of the bacteremia.<sup>81,85</sup> If the catheter is no longer necessary for the patient's care, it should be immediately removed and antibiotics given for 72 hours. However, if retaining the VAD is a priority, it may be left in place and the antibiotics administered through it. If the catheter has several lumens, the antibiotics should be rotated among them. Blood cultures from the catheter should be repeated after 2 to 3 days. If they are sterile, antibiotics should be continued for an additional 7 to 14 days, and the cultures should be repeated 24 to 48 hours after the antibiotics have been discontinued.<sup>85</sup> The most common organism, coagulase-negative staphylococci, can usually be eradicated with vancomycin.

If, however, the patient continues to have positive cultures or does not show prompt symptomatic improvement after antibiotics are started, serious consideration must be given to removing the VAD. An alternative is a trial of local thrombolytic therapy. Skin flora migrating through the catheter to the blood stream tend to adhere to the fibrin sleeve that inevitably coats the catheter surface.<sup>50</sup> Some species add their own secreted proteins to this sleeve.<sup>84</sup> In this matrix, the organisms are relatively protected from phagocytes and antibodies, as well as from antibiotics. Instillations of rtPA into the catheter have been shown to improve the outcome in cases refractory to antibiotics alone.<sup>89,90</sup> rtPA would be expected to provide the same benefit and should be given in the same manner as for treating withdrawal occlusion associated with a fibrin sheath.<sup>53</sup> Another consideration in assessing antibiotic-resistant bacteremia is whether the patient has an infected venous thrombus. A venogram is necessary to evaluate this possibility. If thrombosis is found, the catheter must be removed and antibiotics continued for 4 to 6 weeks. In some cases, the infected clot may require surgical resection.<sup>91</sup>

#### INTRODUCTION

Vascular isolation and perfusion of a cancer-bearing organ or region (i.e., extremity) using a recirculating extracorporeal perfusion circuit has been in clinical use for almost 50 years. It was originally applied to the limb by Creech et al. in the 1950s for patients with high-grade unresectable extremity sarcoma or in-transit melanoma.<sup>1</sup> In the early 1960s additional experience with isolated perfusion of the limb or liver was reported by a small number of centers.<sup>2,3</sup> and<sup>4</sup> More recently, the technique has been actively under clinical evaluation for patients with these conditions and has also been used in isolation perfusion of the lung and kidney.<sup>5,6</sup>

Isolation perfusion was initially applied under normothermic conditions using chemotherapeutics alone and subsequently mild to moderate hyperthermia (38.5°C to 42°C) became a routine component of treatment.<sup>7</sup> Over the past 6 years there has been considerable interest in the use of tumor necrosis factor (TNF) used in combination with melphalan and hyperthermia in isolation perfusion.<sup>8,9,10</sup> and<sup>11</sup> This chapter reviews the principles and technique of isolation perfusion and the current status of this treatment modality in clinical practice. The role of the various components of therapy that are routinely used on efficacy and toxicity are reviewed.

#### PRINCIPLES OF ISOLATION PERFUSION

Isolation perfusion is a specialized surgical technique administered under a general anesthetic and usually for an interval of 60 to 90 minutes. Initially, the vascular supply of a cancer-bearing organ or region such as liver or extremity is identified and isolated and all collateral blood flow to the area is controlled to avoid any leak of perfusate into the systemic circulation or leak of systemic blood into the perfusion circuit. Once the vessels are cannulated they are connected to inflow and outflow lines of an extracorporeal bypass circuit, which consists of an oxygenator, reservoir, heat exchanger, and roller pump. The heat exchanger, which warms the perfusate, is connected to a closed water-recirculating circuit (Fig. 29.3-1). It has become routine practice during isolation perfusion to confirm that complete vascular isolation has been achieved using a continuous intraoperative leak monitoring technique with either radiolabeled <sup>131</sup>I human serum albumin or technetium 99–labeled red blood cells.<sup>12,13,14</sup> and<sup>15</sup> Once the perfusion is complete, the vascular bed of the treated region is flushed with several liters of saline and colloid solution to remove any residual intravascular therapeutic agents. Finally, the native vascular blood flow is reestablished to the site and therapy is completed. Because of the need to place indwelling vascular catheters during treatment, the patient must be systemically anticoagulated usually using heparin during perfusion. However, the anticoagulation effects can be effectively reversed with protamine sulfate and thawed fresh frozen plasma.

**FIGURE 29.3-1.** General components of isolated organ perfusion circuit showing the venous reservoir, oxygenator heat exchanger, and roller pump. Blood flow from the perfused site is collected in a venous reservoir by passage drainage. The roller pump on the arterial side of the circuit can be adjusted to increase or decrease flow rates as appropriate. The oxygenator and heat exchanger are in-line components of this circuit, and the latter can effectively heat the perfusate so that tissue hyperthermia can be routinely achieved.

There are several advantages of isolation perfusion as a treatment technique. In practice, complete separation of the regional and systemic circulation can be achieved in most circumstances. This is particularly true for isolation perfusion of the liver<sup>16</sup> and in patients undergoing isolated limb perfusion (ILP) for in-transit melanoma for high-grade unresectable sarcoma of the extremity.<sup>12</sup> Small, less than 1%, leaks of perfusate into the systemic circulation can be detected using a leak-monitoring system. Klaase and coworkers<sup>12</sup> reported the frequency of perfusate leak in 383 patients who underwent 438 ILPs using a standardized technique. The cumulative overall leak rate was 0.9%. A leak rate of greater than 5% was encountered in 6.2% of ILPs and a leak rate of greater than 10% was observed in only 1.4%. During ILP, leak of perfusate can usually be controlled with various maneuvers such as adjustments in flow rate or tightening of the extremity tourniquet.<sup>17</sup> Because treatment is confined to an organ or region of the body, systemic exposure and toxicity secondary to the therapeutic agents can be eliminated or significantly limited.<sup>18</sup> In addition, dose escalation of the therapeutic agents is limited largely by the tissue tolerance of the perfused organ or the extremity.<sup>19</sup> Finally, isolation perfusion allows one to deliver clinically significant levels of hyperthermia, which has direct cytotoxic<sup>3,20</sup> and synergistic antitumor effects with various chemotherapeutic and biologic agents.<sup>21,23</sup> and<sup>24</sup>

#### ISOLATED LIMB PERFUSION

ILP of the lower extremity is most commonly performed via cannulation of the external iliac vessels and in the arm via the axillary vessels. However, in the lower extremity ILP can be performed via the femoral or popliteal vessels and in the arm via the brachial vessels under certain clinical situations. For the approach to the iliac vessels, a lower abdominal *transplant* incision and a retroperitoneal approach is made. The external iliac artery and vein are carefully dissected from their origin down to the inguinal ligament and small arterial branches and venous tributaries and ligated and divided. This is particularly important in the region of the inguinal ligament to prevent leak of perfusate into the systemic circulation. The hypogastric vein is ligated *in situ* and the hypogastric artery is temporarily occluded with a vascular occluding clamp. If possible, some of the branches of the hypogastric artery in the pelvis should be identified and ligated to prevent collateral flow across the pelvis. These vessels include the vesicular, pudendal, and obturator arteries. A Steinmann pin is anchored into the anterior superior iliac spine and the external iliac vessels are cannulated with the catheter tips positioned just below the inguinal ligament. An Esmarch tourniquet is snugly wrapped at the root of the extremity and the

cannulae are connected to the extracorporeal bypass circuit ( [Fig. 29.3-2](#)).

**FIGURE 29.3-2.** Intraoperative photograph showing an isolated limb perfusion circuit in a patient with in-transit extremity melanoma. Note the leg is wrapped in warming blankets to facilitate tissue warming, and the leak-monitoring gamma detection camera is positioned over the patient's precordium and connected to a strip chart recorder. The extracorporeal bypass circuit (not shown) is positioned by the patient's side during therapy.

## ISOLATED HEPATIC PERFUSION

Isolated hepatic perfusion (IHP) is a more complex treatment to administer and has not gained as widespread or consistent a clinical evaluation because of the major nature of the operative procedure, the associated morbidity associated with the treatment, and the fact that initial clinical studies did not clearly document efficacy of the therapy. The unique vascular anatomy of the liver, however, does make it an ideally suitable organ for isolated perfusion. The procedure starts with a right subcostal incision and once it has been determined that there are no contraindications to proceeding with IHP, the incision is extended and the liver is extensively mobilized. This includes division of the diaphragmatic attachments of the left and right hepatic lobes and complete dissection of the retrohepatic vena cava from the level of the renal veins to the diaphragm to prevent any leak of perfusate from the retrohepatic inferior vena cava ( [Fig. 29.3-3](#)). A cholecystectomy is performed and the portahepatis structures are completely dissected and isolated. This includes complete dissection and division of the surrounding connective tissue and lymphatics, which can serve as a leak of perfusate into the systemic circulation during therapy. Cannulation for inflow to the liver is typically via the gastroduodenal artery alone or the gastroduodenal artery and portal vein.<sup>8</sup> Splanchnic venous flow is shunted to the right atrium using a second veno-veno bypass circuit similar to that used in hepatic transplantation procedures with an inflow cannula positioned in the axillary vein. The venous effluent of the liver is collected from a cannula positioned in an isolated segment of retrohepatic inferior vena cava and, therefore, during treatment the inferior vena cava flow must also be shunted (see [Fig. 29.3-3](#)). Originally reports of IHP described the use of a passive double-lumen internal shunt system that may not have provided adequate venous return from the inferior vena cava and the portal vein to the heart.<sup>25</sup> The external veno-veno bypass circuit results in flow rates of approximately 2 L/min and stable cardiac parameters during treatment.<sup>16</sup>

**FIGURE 29.3-3.** Schematic illustration of the isolated limb perfusion circuit. The arterial inflow is via the gastroduodenal artery, and venous outflow is collected from a cannula positioned in an isolated segment of retrohepatic vena cava. The inflow and outflow cannulae are connected to a perfusion circuit as shown in Figure 29.3-1. On the patient's left is the veno-veno bypass circuit that shunts portal splanchnic and inferior vena caval blood flow back to the systemic circulation during therapy. IVC, inferior vena cava.

## PERFUSION PARAMETERS

The extracorporeal perfusion circuit typically contains 1 L of perfusate, which consists of 700 mL of a balanced salt solution, 1 U of type-matched packed red blood cells, and 1500 U of heparin. The resultant hematocrit of approximately 25% provides adequate tissue oxygen retention and perfusates containing higher hematocrits and provide no additional benefit in preventing regional toxicity.<sup>26</sup> Generally, flow rates in the range of 400 to 800 mL/min are achievable and adjusted depending on line pressure, changes in reservoir volume, or the presence of a systemic perfusate leak based on intraoperative monitoring.

Continuous intraoperative leak monitoring to assess for the presence of leak of the perfusate into the systemic circulation is being used more routinely and is an important component of isolation perfusion therapy when one considers that the perfusate often contains doses of therapeutic agents that are at least tenfold greater than maximally tolerated systemic doses. Careful monitoring of leak can reduce the severity of systemic complications and may improve response rates.<sup>15,18</sup> Standard leak-monitoring techniques using <sup>131</sup>I radiolabeled albumin or technetium 99–labeled red blood cells have been described for continuous intraoperative monitoring.<sup>12,13</sup> and <sup>14</sup> A gamma detection camera is positioned either over the precordium of the heart for patients undergoing ILP or over the pump housing of the veno-venous bypass circuit for patients undergoing IHP, both of which serve as a stable reservoir of blood to measure radioactivity (see [Fig. 29.3-2](#)). The detection system provides continuous assessment of leak rates and can discriminate leaks less than 1%.<sup>12</sup> Once the gamma detection camera has been positioned, a small dose of radionuclide is given systemically and a baseline level of radioactive counts is measured on a strip chart recorder. Then a tenfold higher dose is administered into the perfusion circuit. Therefore, if a 10% leak of perfusate into the systemic circulation occurs, there will be a doubling of the amount of radioactivity compared with baseline. Leak rates using this system have been shown to correlate with measured leak rates with TNF or melphalan from the perfusate into the systemic circulation.<sup>12,18</sup>

Despite careful preoperative preparation, during ILP the surgeon may encounter several situations that require adjustment in perfusion parameters to minimize a leak of perfusate out of or blood into the perfusion circuit. Flow rates that indirectly affect arterial line pressure, reservoir volume, and leak of perfusate are continuously monitored. If there is leak of systemic blood into the perfusion circuit this is reflected by an increase in the reservoir volume in the circuit and can be remedied by increasing flow rates to increase line pressure, tightening the extremity tourniquet, or increasing venous pressure in the circuit by placing a partial occluding clamp on the venous outflow line. If there is a perfusate leak into the systemic circulation this is manifested by an increase in radioactive counts detected by the gamma camera and the strip chart recorder. In addition, one may see a decrease in reservoir volume in the perfusion circuit, although this is a relatively late manifestation of a perfusate leak. Under these circumstances, one may decrease flow rates to lower the line pressure or tighten the tourniquet to stop systemic leak. Rarely, a two-way leak occurs that is evidenced by changes in reservoir volume (generally a gain) as well as an increase in radioactivity on the strip chart recorder. This can be a particularly difficult and tricky condition to adequately control, and typical steps would include decreasing flow rates to stop any systemic leak of perfusate, tightening the tourniquet, and then placing the partial occluding clamp on the venous outflow line of the perfusion circuit.

## RESULTS OF ISOLATION PERFUSION

There are many perfusion and treatment-related factors that may affect efficacy and toxicity of isolation perfusion. The majority of clinical experience with isolation

perfusion has been with ILP using chemotherapeutics for in-transit melanoma or sarcoma of the extremity ( [Table 29.3-1](#)). The early clinical trials of ILP using hyperthermia or chemotherapy for sarcoma were difficult to interpret because of the variability in treatment conditions and patient selection. [27,28](#) and [29](#) Two early studies of adjuvant ILP using melphalan for patients with melanoma undergoing initial excision of all disease did show a significant reduction in local recurrences with ILP compared with excision alone but suffered from including high- and low-risk patients. [30,31](#) and [32](#) A large multicenter trial of prophylactic ILP following excision of primary melanoma greater than 1.5 mm in depth showed a decrease in local recurrence with ILP from 6.6% to 3.3% compared with excision alone with no benefit for survival. [33](#) Based on these results prophylactic ILP has been largely abandoned. There are other components of isolation perfusion that may have substantial effects on outcome including hyperthermia and biologic agents, most notably TNF.

Author	Year	Diagnosis	Number	Treatment	Setting	Outcome	Comments
Liénard <sup>30</sup>	1968	Sarcoma	21	Hyperthermia + TNF	Outpatient	11/21 had complete response, 10/21 had partial response, 0/21 had no response	1-patient died of hyperthermia, 1-patient died of TNF toxicity
Klein <sup>31</sup>	1968	Sarcoma	19	Hyperthermia + TNF	Outpatient	10/19 had complete response, 9/19 had partial response, 0/19 had no response	1-patient died of hyperthermia, 1-patient died of TNF toxicity
Klein <sup>32</sup>	1968	Sarcoma	21	Hyperthermia + TNF	Outpatient	10/21 had complete response, 11/21 had partial response, 0/21 had no response	1-patient died of hyperthermia, 1-patient died of TNF toxicity
Chambers <sup>33</sup>	1988	Melanoma	107	Melphalan + hyperthermia	Phase III adjuvant	Local recurrence: 3.3% (ILP) vs 6.6% (excision)	18% overall group high (30%)
Heldner <sup>34</sup>	1991	Melanoma	10	Melphalan + hyperthermia	Phase III adjuvant	Local recurrence: 3.0% (ILP) vs 6.6% (excision)	No difference in survival
Klein <sup>35</sup>	1988	Melanoma	13	Melphalan + hyperthermia	Phase II adjuvant	10/13 had complete response, 3/13 had partial response, 0/13 had no response	30% the overall
Klein <sup>36</sup>	1988	Melanoma	102	Melphalan + hyperthermia	Phase III adjuvant	Local recurrence: 3.0% (ILP) vs 6.6% (excision)	No difference in survival

**TABLE 29.3-1.** Results of Selected Trials of Isolated Limb Perfusion for Melanoma or Sarcoma

## HYPERTHERMIA

Hyperthermia has been used in isolation perfusion alone or in combination with chemotherapeutics and TNF. In experimental models it has direct cytotoxicity against tumor lines<sup>3,20</sup> and has established synergy with various chemotherapeutics and TNF. [21,22](#) and [23,34,35,36](#) and [37](#) This later feature is presumed to be the main contribution of hyperthermia in isolation perfusion. Under hyperthermic conditions tumor neovasculature responds differently than native blood vessels. At temperatures up to 46°C normal microvessels dilate and blood flow increases up to sixfold as a compensatory mechanism to diffuse local heat accumulation. [38](#) In contrast, tumor-associated microvessels have a diminished capacity to vasodilate and at comparable temperatures there is stasis and diminution of blood flow, [38](#) indicating a differential sensitivity between tumor-associated and normal microvasculature.

Following the original report of normothermic ILP using chemotherapeutics in 1957 by Creech et al., [1](#) most investigators subsequently incorporated some degree of hyperthermia as closed circuit water-recirculating heat exchangers became available to replace the use of inefficient warm moist towels and infrared lamps to warm perfusate fluid. [2](#) Stehlin et al. reported results of ILP in 50 patients in 1969 [2](#) and a follow-up report in 1975 of 165 patients [35](#) with extremity sarcoma or melanoma in whom significant hyperthermia was delivered to the perfused limb. In the initial series the perfusate was warmed to 46°C and average tissue temperatures of 42°C resulted in severe regional toxicity including pain, edema, blistering, and weakness observed in 70% of patients. When tissue temperatures were reduced to 40°C or less, regional complications were minimal. [39](#) In 1967 Cavaliere and coworkers [3](#) reported results of hyperthermia alone ILP with tissue temperatures ranging from 42°C to 44°C. The combination of this degree of hyperthermia, perfusion lasting more than 8 hours, and the lack of a proximal tourniquet resulted in severe regional toxicity and an unacceptable 28% mortality. Stehlin reported that compared with historic controls treated identically at one institution, the addition of hyperthermia during ILP with melphalan in patients with extremity melanoma resulted in an increase in response rates from 35% to 80%. [39](#) Klaase and coworkers [40](#) reported an analysis of factors associated with toxicity following ILP for melanoma in 425 patients. Tissue temperature greater than 40°C was the most significant factor associated with increased regional toxicity. In addition, female gender and a decrease in perfusate pH were also associated with worse regional toxicity.

Skibba et al. have reported data on eight patients with unresectable cancer confined to liver and treated with a 4-hour IHP using hyperthermia alone to 42.5°C. [41,42](#) Toxicity associated with this therapy was substantial; all patients had marked elevation in post-IHP hepatic transaminases and bilirubin and two of eight died in the early postoperative period. There was evidence of some transient antitumor activity by central tumor necrosis on computed tomography scans obtained, in what appears to be, to improve the efficacy chemotherapeutics given via isolation perfusion of the limb or liver. It has marginal, if any, independent antitumor effects, and temperatures higher than 40°C to 41°C are associated with unacceptable toxicity.

## TUMOR NECROSIS FACTOR

In 1975 Carswell et al. demonstrated that a circulating factor present in the sera of endotoxin-treated mice caused dramatic hemorrhagic necrosis of tumors when administered to tumor-bearing mice. [43](#) This factor was termed *TNF*, and after it became available in recombinant form in the mid-1980s it was evaluated in multiple clinical trials via various methods of administration. [44](#) However, it was found that humans are very sensitive to the toxic effects of TNF, and, at the maximum tolerated doses administered, it had little antitumor activity. Although interest in TNF as a systemically administered antitumor agent waned, enthusiasm for its administration via isolation perfusion grew remarkably in the early 1990s when Liénard et al. reported initial results in 29 patients treated with a combination of TNF, melphalan, and hyperthermia for in-transit melanoma or high-grade sarcoma of the extremity. [45](#) The overall response rate in that initial trial was 100%, with 89% of patients having a complete response to treatment.

TNF is ideally suited for administration via isolation perfusion and is thought to exert its antitumor activity via effects on the tumor-associated neovasculature. TNF has significant known procoagulant activity [46,47](#) and increases vascular permeability. [48](#) In addition, several authors have published data showing selective obliteration of tumor neovasculature following ILP with TNF hyperthermia and melphalan for patients with high-grade unresectable extremity sarcoma ( [Fig. 29.3-4](#)). [49,50](#) However, there are few clinical data available using TNF alone via isolation perfusion. Three patients with high-grade extremity sarcoma were treated at our institution with hyperthermic ILP and TNF. [51](#) One patient had angiographically documented obliteration of tumor-associated neovasculature following ILP; however, he experienced clinical and radiographic tumor progression within 6 weeks, suggesting that the vascular obliteration observed after TNF may not be sufficient for subsequent tumor regression. Posner et al. reported results of ILP with TNF alone in six patients with in-transit melanoma. [52](#) One had a complete response of 7 months' durations and two others had brief, less than 1 month, partial responses. TNF administered alone via IHP has little antitumor activity. Fraker reported a 20% transient response rate following IHP with escalating doses of TNF. [53](#) Interestingly, the responses were seen only at the lowest doses of TNF and once perfusate pH was corrected with sodium bicarbonate during treatment, no further responses were seen despite dose escalation of TNF to 2 mg.

**FIGURE 29.3-4.** Preperfusion and postperfusion magnetic resonance angiograms showing neovascularity in a large multiply recurrent Ewing's sarcoma arising on the dorsum of a forearm. The patient had small volume pulmonary metastases and was treated with palliative 90-minute hyperthermic isolated limb perfusion using tumor necrosis factor and melphalan. He had a significant regression ( *top panel*) that lasted for 2 years until death from systemic disease progression. Three days posttherapy complete obliteration of the tumor neovasculature was observed with no effect of perfusion on the native blood vessels in the extremity ( *bottom panel*).

ILP, isolated limb perfusion; MRA, magnetic resonance angiography.

When TNF is used in ILP with melphalan it is associated with a rapid time course of response in tumors compared with ILP with melphalan alone, and large tumors form eschar reminiscent of the findings in murine models (Fig. 29.3-5). Because TNF causes increased endothelial permeability<sup>48</sup> and has selective procoagulant effects on tumor-associated vasculature, it has been postulated that during ILP TNF may augment delivery of chemotherapeutics to the tumor by increasing vascular permeability. However, a study reported by Alexander and coworkers<sup>54</sup> evaluated vascular permeability in tumor and unaffected liver tissue obtained from patients undergoing IHP with melphalan alone or TNF and melphalan. After IHP there was a significant increase in permeability in tumor vasculature compared with liver. However, the increase in permeability was similar in those treated with or without TNF, suggesting that the augmentation in permeability occurred via TNF-independent mechanisms.

**FIGURE 29.3-5.** Photographs of a patient treated with isolated limb perfusion using tumor necrosis factor and melphalan for in-transit extremity melanoma. **A:** In-transit site of disease before and **(B)** 5 days after isolated limb perfusion. Note the rapid eschar formation over tumor with sparing of overlying and adjacent normal skin, which is characteristic of the effect of tumor necrosis factor.

### CURRENT STATUS OF ISOLATED LIMB PERFUSION

The role of TNF in isolation perfusion is still under clinical evaluation and has no conclusively demonstrated benefit in properly designed and conducted prospective random assignment trials. In the initial report from Liénard and Lejeune, results from 29 patients treated with ILP using a combination of TNF, melphalan, and hyperthermia for in-transit melanoma or high-grade sarcoma of the extremity were presented.<sup>45</sup> The overall response rate in that initial trial was 100%, with 89% of patients having a complete response to treatment. In subsequent reports from various institutions, including a follow-up report from Liénard and Lejeune of a larger series of patients, the complete response rates were lower and ranged between 70% and 79% (Table 29.3-2).<sup>18,55,56</sup> A prospective random assignment trial was initiated at the National Cancer Institute and subsequently expanded to a multiinstitutional study but was closed prematurely in 1997 due to the lack of available clinical-grade TNF in the United States. The results of that trial showed no difference in overall or complete response rates between the groups.<sup>57</sup> It is also noteworthy that in several trials of ILP using melphalan alone, complete response rates between 56% and 82% have been reported.<sup>58,59,60</sup> and <sup>61</sup> A prospective random assignment trial comparing melphalan and TNF with melphalan alone administered via ILP for in-transit melanoma of the extremity was closed in Europe because of low accrual, suggesting a bias that TNF for most patients with this histology does not substantially contribute to efficacy compared with melphalan alone.

ILP has been used for patients with unresectable high-grade extremity sarcoma for palliation, for potential cure in cases of multifocal disease, and as a neoadjuvant therapy to convert an unresectable lesion to a resectable one. Most data reported on ILP using chemotherapeutics alone indicate limited antitumor activity against this histology.<sup>28,62</sup> After the initial reports by Liénard and Lejeune using the combination of TNF, melphalan, and hyperthermia as a neoadjuvant treatment for high-grade unresectable sarcoma, a multiinstitutional trial using this regimen for patients with condition was conducted in Europe and the results reported in two papers by Eggermont and coworkers.<sup>50,63</sup> In more than 219 patients, the overall clinical and pathologic response rate was more than 80% and the limb salvage rate was 84%. Based on these results TNF is now licensed for administration via ILP for high-grade sarcoma in Europe, but no trials are currently being conducted in the United States.

### CURRENT STATUS OF ISOLATED HEPATIC PERFUSION

Following the initial experience with TNF and melphalan in ILP several centers have reported results with this regimen used in IHP for patients with unresectable primary or metastatic cancers confined to liver (see Table 29.3-2).<sup>16,64,65</sup> and <sup>66</sup> De Vries and coworkers reported results in eight patients treated with melphalan and TNF and one patient treated with TNF alone for 1 hour at 41°C.<sup>66</sup> IHP was associated with a 33% mortality in the series but five of six evaluable patients treated with melphalan and TNF had radiographic evidence of antitumor efficacy. Hafström and coworkers reported results in 11 patients using melphalan and TNF and also reported a high morbidity and mortality of 45% and 18%, respectively.<sup>64</sup> Three patients experienced a radiographic partial response to therapy. A German group reported results in six patients treated with a 60-minute IHP using melphalan and TNF at 40°C to 41°C and had no mortality in this series.<sup>65</sup> Three of six patients had radiographic evidence of significant tumor regression. The largest series reported using TNF and melphalan via IHP comes from the National Cancer Institute; 34 patients underwent IHP with doses of melphalan and TNF that were derived from previously conducted phase I studies and were higher than those used at higher institutions.<sup>16</sup> The treatment lasted for 1 hour and hyperthermia between 39.5°C and 40°C was used in all circumstances. The treatment-related mortality was 4% and the investigators observed an overall radiographic response rate of 75%. The group has presented follow-up data on 44 patients with metastatic unresectable colorectal cancer to the liver.<sup>67</sup> The cohort of patients who had advanced and largely refractory disease had a median number of hepatic lesions of eight, the median diameter of the greatest lesion was 8.5 cm, and one-fourth of patients had more than 50% hepatic replacement by tumor. Furthermore, approximately 45% of patients had failed prior systemic 5-fluorouracil-based chemotherapy. In the 32 patients treated with IHP using TNF and melphalan there was a 74% radiographic partial response rate. The time to liver progression was 8.5 months, and median survival was 16.5 months. In a second cohort of patients, IHP with melphalan alone was administered followed by hepatic artery infusional therapy using floxuridine and leucovorin. The radiographic partial response rate was 90%, with 9 of 11 responses ongoing in the liver at a median follow-up of 11 months.

Author	Tumor Type	Agents	Assessable	Complete Response (%)	Partial Response (%)	Overall (%)
Liénard <sup>45</sup>	Phase I ILP Melanoma/sarcoma	Aggrenin 1 Melphalan, 10-15 mg/L TNF, 2.5 mg	29	29	29	100
Liénard <sup>55</sup>	Phase II ILP Melanoma	Aggrenin 1 Melphalan, 10-15 mg/L TNF, 2.5 mg	21	21	21	100
De Vries <sup>66</sup>	Phase I ILP Sarcoma	Aggrenin 1 Melphalan, 10-15 mg/L	9	9	9	100
Eggermont <sup>50</sup>	Phase II ILP Sarcoma	Aggrenin 1 Melphalan, 10-15 mg/L	100	100	100	100
Hafström <sup>64</sup>	Phase II ILP Sarcoma	Melphalan, 10-15 mg/L TNF, 2.5 mg	11	11	11	100
Albrecht <sup>65</sup>	Phase II ILP Sarcoma	Melphalan, 10-15 mg/L TNF, 2.5 mg	6	6	6	100
Witt <sup>67</sup>	Phase II ILP Sarcoma	Melphalan, 10-15 mg/L TNF, 2.5 mg	34	34	34	100

**TABLE 29.3-2.** Selected Series of Isolation Perfusion Using Tumor Necrosis Factor and Melphalan

Although the morbidity and treatment mortality in some of these series are high, the data, for the most part, represent initial institutional experience with a highly

technical procedure using agents that have known regional and systemic toxicity. With continued refinement and experience the morbidity and mortality associated with the therapy should decrease. Additional refinements in the technique of IHP, and when combined with potentially effective therapies tailored for specific histologies, the treatment may become a more widely used option for patients with unresectable hepatic malignancies from a variety of histologies (see [Chapter 52.3](#)).

## STATUS OF ISOLATION PERFUSION OF OTHER SITES

There are few data regarding the application of isolation perfusion to other organs. Pass and coworkers from the National Cancer Institute reported results of a phase I isolation lung perfusion with escalating dose TNF for patients with unresectable pulmonary metastases.<sup>6</sup> Twenty patients were treated with unilateral isolated lung perfusion, with TNF doses ranging from 0.3 to 6.0 mg. An oxygenated circuit was used analogous to that in other isolation perfusion settings, and tissue hyperthermia between 38°C and 39.5°C was used. There were no deaths on study, and short-term regression of metastatic nodules was noted in three patients. Walther and coworkers, also from the National Cancer Institute, published a case report of an isolated kidney perfusion with TNF in an individual with localized multifocal renal cell carcinoma for whom renal parenchymal-sparing surgery would normally have been advocated.<sup>5</sup> The patient tolerated the procedure well, but there were no data presented with respect to any antitumor efficacy.

## CONCLUSIONS

Isolated perfusion of various organs or the extremity using chemotherapeutics with or without TNF has been shown to have substantial antitumor activity against a variety of histologies. Following the initial studies using TNF there was considerable enthusiasm for its routine use in organ perfusion for the treatment of in-transit melanoma and high-grade extremity sarcoma. Although the data support its importance in treatment of high-grade extremity sarcoma, the benefit of TNF in combination with melphalan against in-transit melanoma has not been conclusively demonstrated. Because of the potential associated toxicity with TNF, its routine use outside of a clinical research trial cannot be advocated. IHP is a promising regional modality for unresectable malignancies confined to the liver, but continued investigation in a clinical research setting is clearly necessary to determine the optimal clinical setting in which to offer this form of therapy. Hyperthermia appears to be an important component of treatment and appears to act primarily by enhancing the tumoricidal effects of melphalan. TNF has no substantial antitumor activity when administered via isolated organ perfusion alone but may enhance the antitumor effects of melphalan against the extremity tumors such as sarcoma.

## INTRODUCTION

In radiotherapy, the sum of experimental and clinical data indicates that the probabilities of local tumor control and normal tissue complications are dose dependent, and that the corresponding dose-response curves are sigmoidal in shape. For some disease sites the curves for local control are at lower dose levels relative to those for associated normal tissue toxicity, underpinning the success of radiotherapy in those cancers. For other sites, where these curves are closer to each other, or when the tumor control curve is less steep (the effect of population averaging due to heterogeneous radiosensitivity among individual tumors), the high doses required for tumor cure may cause unacceptable complications. In the last two decades, the development of three-dimensional conformal radiotherapy (3D-CRT), which substantially reduces the volume of critical organs irradiated to high doses, has partly addressed this issue.<sup>1</sup> In 3D-CRT, patient immobilization, image-guided treatment planning, and computer-controlled treatment delivery have combined to conform the radiation dose to the tumor, while maximally excluding the adjacent normal organs. This approach has permitted the increase of tumor dose without concomitant increase in normal tissue complications. At Memorial Sloan-Kettering Cancer Center (MSKCC), a clinical trial in cancer of the prostate has accrued more than 1100 patients, and the prescription dose has been escalated to 81 Gy with 3D-CRT, and to 86.4 Gy using intensity-modulated radiotherapy (IMRT), with promising results.<sup>2,3</sup>

3D-CRT involves the delineation of target and nontarget structures from patient-specific 3D image data sets [primarily computed tomography (CT), sometimes supplemented with magnetic resonance imaging, positron emission tomography, and so forth], the design of treatment portals using *beam's eye view* (BEV), the calculation and display of dose distributions, the analysis and evaluation of structure-specific dose-volume data [dose-volume histogram (DVH)], radiation delivery with computer-controlled multileaf collimators (MLC), and treatment verification with electronic portal images. However, the dose-distribution conformality achieved with 3D-CRT can be further improved by the use of computer-optimized intensity modulation. In addition, the treatment design phase of 3D-CRT involves several iterative steps and can be time-consuming, particularly when the anatomic geometry is complex. Thus, with the advance in computer technology, there has been much investigation on computer-aided treatment plan optimization.

IMRT is an advanced form of 3D-CRT with two key enhancements: (1) computerized iterative treatment plan optimization, and (2) the use of intensity-modulated radiation beams.<sup>4</sup> Although the overall process of IMRT and 3D-CRT is quite similar, these two ingredients have implications in some aspects of treatment planning and implementation. In this chapter, we describe the process of IMRT as compared with 3D-CRT, identify how they differ, emphasize those features and benefits unique to IMRT, and point to current and future development. At present, there are two primary methods of IMRT delivery: (1) intensity-modulated radiation fields at fixed gantry angles delivered with MLCs,<sup>5</sup> and (2) tomotherapy using beams from 360 degrees and modulated by a slit MLC.<sup>6</sup> Most of our discussion focuses on the former approach.

## PROCESS OF INTENSITY-MODULATED RADIOTHERAPY

The process of IMRT, as implemented at MSKCC, is schematically illustrated in [Figure 29.4-1](#). The following is a discussion on each of the steps in the process, and in addition, other information that is pertinent to the development and application of IMRT.

**FIGURE 29.4-1.** A schematic illustrating step by step the intensity-modulated radiation therapy process. CT, computed tomography; EPID, electronic portal imaging device; MLC, multileaf collimators.

## PATIENT SETUP, IMMOBILIZATION, AND IMAGE ACQUISITION

The minimization of patient setup uncertainty is more important in 3D-CRT relative to conventional radiotherapy due to the improved conformality of the dose distribution, and this is even more critical in IMRT, as discussed here. Thus, immobilization devices and precise positioning procedures should be used throughout the

process of image acquisition, simulation, and treatment.

The use of simulators may be decreasing in 3D-CRT and IMRT, relative to its use in conventional radiotherapy. If a simulator is used, an initial (pre-CT) simulation may be carried out in conjunction with patient immobilization to establish fiducial skin marks, define the tentative treatment isocenter, and obtain anteroposterior and lateral radiographic films. A second simulation may be performed, after the treatment plan has been accepted, to position the patient at the established isocenter and acquire reference radiographs of each field for comparison with the corresponding BEV digitally reconstructed radiographs and subsequently, the verification portal films.

A complete 3D CT image set is usually obtained with the patient in the treatment position on a flat couch. The number of CT slices and the interslice spacing are according to protocols, depending on the size, shape, and location of the target and the treatment technique. However, to produce high-resolution digitally reconstructed radiographs, the slices are contiguous with interslice spacing of 3 to 5 mm. For certain sites, magnetic resonance imaging and positron emission tomography are complementary to CT and helpful in defining the extent of disease, especially when used with image-correlation software.

The advent of CT simulation may make the process more efficient, by combining the simulation and CT imaging sessions into one. The CT simulator combines the capabilities of spiral (or helical) scanners for volumetric data acquisition and high-speed workstations for rapid image reconstruction and display. This permits the so-called virtual simulation, carried out on a computer workstation using the 3D CT data set (the virtual patient).<sup>7</sup> In this process, a complete 3D CT data set is first obtained with the patient in the treatment position using 3- to 5-mm slice thickness. Then, corresponding to the specific treatment set-up parameters, patient anatomy is reconstructed from the CT data and displayed in BEV, and simulation fluoroscopic and radiographic images are digitally generated for viewing, decision-making, and documentation.

Aside from the improved efficiency, CT simulation eliminates or minimizes systematic uncertainties in the registration of simulation films to CT data sets, and in set-up errors when transferring the patient from one mechanical coordinate system to another. The disadvantage is the degraded image quality of reconstructed radiographs as compared with a conventional simulation film.

## DELINEATION OF TREATMENT VOLUME AND SELECTION OF TREATMENT BEAMS

Treatment volumes are derived from the CT images according to the ICRU Report 50 nomenclature,<sup>8</sup> with clinical target volume (CTV) being the visualized tumor plus the regions at risk, and planning target volume (PTV) to include setup and other uncertainties. The manual delineation of these and their adjacent critical organs are time consuming and would benefit from new and improved tools. However, human intervention will likely remain a necessary and important component for defining the CTV and PTV. Other contours needed for treatment planning and dose-distribution calculation such as the outer skin, bone, lungs, and air cavities can be outlined automatically with existing edge detection algorithms.

In 3D-CRT, to facilitate the selection of beam angles and field shapes, various display methods have been developed to represent the PTV and the adjacent critical organs in 3D perspectives. These objects are often displayed as wireframes or solid structures, using colors to differentiate between them and intensity to indicate depth. The treatment geometry is best visualized in the BEV, in which the anatomy is viewed from the perspective of the radiation source.<sup>9,10</sup> Once the beam orientations are chosen, their shapes (apertures) can be determined, again facilitated by the BEV display.

3D image display is probably less critical in IMRT than in 3D-CRT. We believe that as long as there are a sufficient number of radiation fields (five to seven or more), the number of beams and their orientations are less important. This is because the many degrees of freedom in intensity modulation can effectively compensate the less optimal beam direction. Also, field size and shape can be completely defined by the assignment of intensity pattern in the optimization process (see [Computer-Aided Plan Optimization in Intensity-Modulated Radiotherapy](#), later in this chapter). This is true at least for the treatment of cancers of the prostate and of head and neck at MSKCC and likely applies to other disease sites as well. Whether significant improvements in IMRT can be achieved via the use of noncoplanar beams is yet to be demonstrated, although this may likely prove advantageous for brain tumors and possibly other sites.

## COMPUTER-AIDED PLAN OPTIMIZATION IN INTENSITY-MODULATED RADIOTHERAPY

The most distinguishing feature in IMRT planning is the use of intensity modulation to improve the dose distribution. An iterative process is invariably used, alternately adjusting the intensity pattern of the beams and assessing the resulting dose distribution until an acceptable plan is devised. The iterative process could be computer automated or could involve significant manual intervention. In general, computer automation is needed in the so-called inverse planning, while user experience and involvement are more important in the forward planning of IMRT. As widespread enthusiasm is primarily for the inverse method, we shall only briefly describe the forward process.

In forward planning, the starting point is a number of open beams and their field shapes. Based on the resultant dose distribution, the user adjusts the intensities in parts of some of the beams and recalculates the dose distribution. This is repeated until an optimal dose distribution is obtained. This approach is sensitive to the experience of the planner and may be restrictive in terms of the number of intensity levels and the complexity of the intensity-modulation pattern.<sup>11</sup>

The inverse method of treatment planning was first proposed by Brahme in 1988.<sup>4</sup> In this approach, the user specifies the number and orientations of the beams, and the desired objectives for the PTV and the critical organs. The computer algorithm divides each beam into individual rays and iteratively alters the ray weights until the composite 3D dose distribution conforms to the specified objectives. The beams derived by this method are intensity modulated (i.e., the pattern of radiation varies within each beam). It is easy to see why the field shapes need not be prespecified; the optimization process determines the edges as well as the intensity patterns within.

Central to the success of computer optimization is the specification of some quantitative measure of the *goodness* of a treatment plan. In inverse planning, the criteria are stated mathematically as objective functions that the optimization algorithm attempts to minimize. At present, most algorithms (including ours) are dose or dose-volume based (i.e., constraints are defined as doses to the target and normal tissues, or to volumes of interest).<sup>12,13</sup> The use of biologically weighted objective functions is in principle more relevant, but is currently limited by the lack of validated biophysical models on tumor control and organ toxicity. The inverse planning method developed by Spirou and Chui at MSKCC is briefly summarized in the section [Clinical Experience with the Use of Optimization Criteria](#), later in this chapter.<sup>13</sup>

The starting point is the specification of the number of beams and their directions, and then the algorithm optimizes the intensities in the different parts of each of the beams. Suppose a patient is treated with three beams as shown in [Figure 29.4-2](#), the computer program first calculates the doses to a matrix of points within the target and the normal organs from each individual rays of the three beams. If the point in question is in the target with a prescribed dose  $p_i$ , the goodness of the current set of ray weights is given by the square of the difference between  $p_i$  and the current dose. This square of the difference is then summed over all the target points to determine the objective function that describes the goodness of the present set of beam weights. The weights of the individual rays and of each beam are then changed one at a time, with the change accepted if the objective function is reduced. The iterative process continues until the optimal plan is obtained, that is when the objective function is at its minimum.

**FIGURE 29.4-2.** In this illustration of the inverse planning method, the user begins by specifying three beams and their directions. The planning algorithm optimizes the intensities of the different rays ( $x_j$ ) of each of the beams so that the dose to each point  $i$  within the target and the critical organ conform to the user's criteria. The

resulting beams are intensity modulated (as shown by the profile of the vertical beam).

Constraints for critical organs can be incorporated as added term in the objective function. Dose-volume considerations are typically stated as “no more than  $q\%$  of the particular organ may receive a dose greater than  $d_{dv}$ .” To impose such a constraint, at each iteration, the cumulative volume of the organ receiving doses greater than  $d_{dv}$  is compared with  $q$ . If it exceeds  $q$ , a penalty in the form of constraint is added to the objective function, but only for those points that cause the constraint to be violated (i.e., the points beyond the volume  $q$ ).

Several objective functions are illustrated graphically in [Figure 29.4-3](#). For the treatment target, the graph illustrates the concept of the *allowable inhomogeneity* (i.e., if the dose is between a lower limit  $P_l$  and an upper limit  $P_u$ , penalty is not assessed). Also, a larger weight can be assigned to penalize underdose as opposed to overdose. For the normal organ, penalty can be applied if dose exceeds a certain critical value ( $D_c$ ) or based on dose-volume considerations, as discussed previously.

**FIGURE 29.4-3.** Examples of possible objective functions, illustrated graphically. For the treatment target, doses within the allowable inhomogeneity are permitted, with different penalties ( $w$ ) assessed for underdose as opposed to overdose. For the normal organ, penalty can be applied if dose exceeds a certain critical value ( $D_c$ ) or based on dose-volume considerations.  $D$ , dose;  $V$ , volume.

## CLINICAL EXPERIENCE WITH THE USE OF OPTIMIZATION CRITERIA

The iterative adjustment of beam modulation by the optimization algorithm is supposed to minimize the user-specified objective function so that the resultant plan would satisfy the specified criteria. However, in our initial experience the resultant plan was often unsatisfactory. There are several reasons for this. First, the initial sets of optimization criteria may not have been realistic. Second, the relationship between the objective function parameters and the resulting dose distribution is complex. Thus, through a trial-and-error process we have developed preliminary criteria templates that are disease-site specific. We have also learned that the optimization criteria must be more stringent than the desired clinical result because no penalty is applied unless the constraint is violated.

The relationship between optimization criteria and desired clinical result is further confounded by patient-to-patient variability in the geometric relationship between the target and normal structures. Although site-specific constraint templates can serve as starting points for inverse planning, the constraints must often be refined for individual patients in order to achieve uniform clinical results. In general, sites with a high degree of variability in the position, size, or shape of the target require more individualized modification of constraints. Another trick in inverse planning is to control the spatial distribution of dose by structure definition. By defining subsections within a target, normal tissues, or both, and constraining them separately for optimization, one can alter the doses in various regions (e.g., to move a high-dose region away from a nearby critical structure). At the present stage of IMRT development, the specification of structures and criteria for optimization are still being studied for the different disease sites, and exactly how patient specificity of such criteria will affect the optimization process needs to be better understood.

## TREATMENT PLAN EVALUATION

The process of treatment plan evaluation is continuing to evolve, particularly for IMRT with inverse planning. The tools by which plans are evaluated are largely the same for 3D-CRT and IMRT: two-dimensional (2D) dose distributions superimposed on CT images, 3D volumetric rendering of dose distribution and the PTV (and critical organs), structure-specific DVH, and biologic indices as a rough guide. Additionally, for IMRT plans, inspection of the intensity profiles either from an *observer view* (like a relief map) or by the projection of isointensity lines on a BEV is often useful in evaluating an individual beam's contribution to the dose distribution. Even though the evaluation tools for 3D and IMRT plans are quite similar, the approach and action are quite different.

In the forward process of 3D-CRT or IMRT, the planner and the physician evaluate the initial treatment design(s) with a view to improve on it by altering some of the beam parameters (e.g., directions, weights, shapes, wedges, and so forth). The identification of deficiencies and the devising of remedies rely on the experience and intuition of the planner. The effort-intensive nature of this approach limits the practical number of iterations of evaluation and alteration. On the other hand, the application of class solutions to some disease sites minimizes the alterations needed and facilitates convergence to an acceptable solution within a few cycles.

In the inverse process of IMRT, to exploit the benefits of the increased degrees of freedom with modulated individual ray weights, a significant number of iterations (typically five to ten) are both needed and carried out. As the goal of the iterative adjustment of beam modulation by the optimization algorithm is to minimize the user-specified objective function, the resultant plan should satisfy the clinical criteria of acceptance. Thus, ideally the evaluation process should be primarily checking and approval. However, as discussed previously, this is usually not the case, at least in the developmental phase of IMRT.

Corrective action for an unacceptable IMRT plan would involve alteration of the parameters of the objective functions (instead of the beam parameters in a 3D-CRT plan). As alluded to previously, our observation is that such adjustments are not always consistent with our intuition or past experience in conventional or 3D-CRT treatment planning. One major difference is the lack of control in making coordinate-specific adjustment (i.e., it is difficult to alter the dose level to specific regions in the 3D space by changing the objective function parameters). At present, a trial and error (and time-consuming) approach is used to alter the input parameters and improve the IMRT. However, with improvement in software features and with experience in IMRT planning, we believe that this situation will improve.

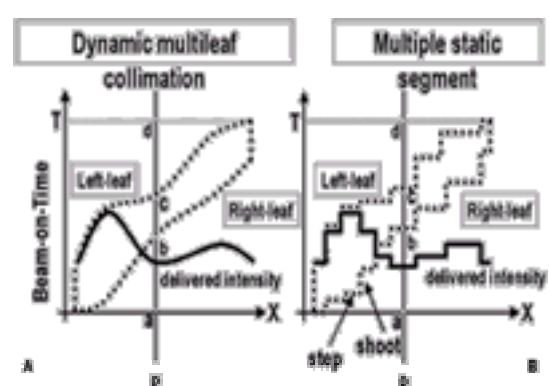

## DELIVERY OF INTENSITY-MODULATED FIELD WITH DYNAMIC MULTILEAF COLLIMATOR

The intensity-modulated field can be delivered with an MLC. [14,15](#) and [16](#) The 2D intensity distribution is divided into one-dimensional intensity profiles, with each profile delivered by one pair of leaves. In the dynamic MLC (DMLC or sliding-window) method, the leaves are in continuous motion during radiation delivery. In [Figure 29.4-4](#), the trajectory (the dotted lines) of the left and right leaves of one leaf pair is plotted as a function of beam-on time during radiation delivery, from their initial (instance a) to their final positions (instance d). As the beam is turned on (instance a), both leaves move, with different speeds, from left to right. The point P begins to receive radiation at instance b when the right leaf edge moves past it. It continues to receive radiation until instance c, when the left leaf begins to block the beam from P. By controlling the movement of the leaves and therefore the *exposure* duration (in this case, between b and c), one can deliver any desired intensity to point P, or any other point under this leaf pair. Extending this concept to multiple pairs of leaves, any desired intensity modulation can be produced with designed sequences of leaves positions.

**FIGURE 29.4-4.** This graph depicts radiation delivery by the dynamic multileaf collimation (sliding window) method. The dotted lines are the positions of a leaf pair (x-axis) as a function of beam-on time (y-axis). As the beam is turned on (point a), both leaves move, with different speeds, from left to right. The point P begins to receive radiation when the right leaf edge moves pass over it (point b). It receives radiation until the left leaf blocks the beam (point c). By controlling the movement of the leaves and therefore the beam-on-time duration between b and c, one can deliver any desired intensity to point P, or any other point under this leaf pair.

The leaves' paths illustrated in [Figure 29.4-4](#) (replotted in [Figure 29.4-5A](#) as dotted lines) are planned to produce the intensity profile indicated by the solid line in [Figure 29.4-5A](#). In practice, a separate computer program (different from the inverse planning algorithm), sometimes called the *leaf sequencer*, is used to translate the intensity profiles of the intensity-modulated beam into the so-called DMLC file, that contains the data of the leaf position sequence as a function of monitor units (MU).<sup>16</sup> In practice, not all desired intensity profiles are (exactly) achievable because of the constraints on leaf motion imposed by the design of the MLC and the clinical dose rate of the machine. The MLC manufactured by Varian Medical Systems, for example, is constrained by the maximum leaf speed ( $v^{\max}$  of 2.5 cm/s) and a maximum DMLC field of 14.5 cm (unless movement of the carriage is allowed). Beam delivery systems from other manufacturers may have similar or different limitations and constraints. Some leaf motion patterns may require a large number of MUs to deliver the desired dose (typically two to three times that for static beam conformal therapy), which increases the importance of scatter and leakage dose. Transmissions through the leaves and the rounded leaf ends (see [Dose Distribution Calculation](#), later in this chapter) typically contribute 10% to 15% of the total dose and are compensated for in the leaf sequence translation.

**FIGURE 29.4-5. A:** Illustrating the intensity profile delivered by the leaves' paths shown in [Figure 29.4-4](#) (replotted here as dotted lines). In practice, a leaf-sequencing algorithm is used to translate the desired intensity profiles into computer data file of the leaf positions as a function of monitor units. **B:** Another method using the multileaf collimators to deliver intensity-modulated beams is by multiple static segment (the so-called step-and-shoot method). In the step phase, multileaf collimator travels to discrete positions, then beam-on in the shoot phase (i.e., alternate multileaf collimator movement and radiation delivery). The result is discrete intensity levels, the number of which depends on the step number.

The MLC can also be used to deliver intensity-modulated beams in the multiple static segment (MSS, or the so-called step-and-shoot) mode. In this mode, the MLC travels in a stepwise manner to discrete positions, with the beam turned off during the stepwise movement. As illustrated in [Figure 29.4-5B](#), the leaf paths can be approximated by alternate horizontal *step* and vertical *shoot* segments, representing stepwise and alternate MLC movement and radiation delivery. As a result, the delivered intensity profile comprises discrete levels, with its number depending on the number of steps. In either mode, the total beam-on time for this leaf pair is T, and the MU needed for an intensity-modulated field is the largest T among all leaf pairs. It should be noted that there are other methods of MSS leaf sequencing to produce intensity-modulated beams.<sup>17,18</sup>

## OTHER METHODS OF DELIVERY OF INTENSITY-MODULATED FIELD

A large number of IMRT treatments have been delivered using the MIMiC collimator from NOMOS.<sup>6</sup> In this schema, a slit beam is used, typically 2-by-20 cm, and intensity modulation is achieved via 20 pairs of leaves. Each of the 40 leaves defines a pencil beam of 1 by 1 cm<sup>2</sup> that is either on or off at any given gantry position. As the gantry rotates through its 360-degree arc, all 40 leaves open and close (in a binary manner, either fully open or fully closed) according to the leaf motion pattern determined during treatment planning. Thus, each gantry arc treats a 2-cm long longitudinal strip of tissue. Treatment fields longer than 2 cm can be delivered by longitudinally translating the patient (with the treatment couch) between multiple arcs. Of extreme importance is the accuracy and stability of patient positioning as the treatment progresses from one axial slice to the next.

Yu proposed the intensity-modulated arc therapy method of IMRT delivery.<sup>19</sup> In this method, the 2D intensity-modulated beams at many equally spaced gantry angles are approximated by a superposition of multiple-shaped radiation fields with uniform intensity. The increments of intensity level are delivered by individual arcs, with the leaf positions changing with gantry angle to produce the shaped fields. As has been pointed out, there are a large number of possible permutations of decomposition patterns for the 2D beams, and therefore the design of the most efficient MLC position sequence in the arc therapy is a challenging problem.

## DOSE DISTRIBUTION CALCULATION

To fully account for the intricacies of IMRT dose delivery, the calculation model must accurately predict the incident energy fluence and use a dose kernel that describes the transport of photons and electrons and energy spread in an inhomogeneous medium. One accurate method of dose calculation involves the convolution of pencil beams. In our current dose model, inhomogeneity is accounted for by the traditional equivalent path length method, and pencil beam convolution is used only as a correction factor to account for the variation of intensity as opposed to a flat, uniform field.<sup>20</sup> However, in a highly heterogeneous media such as the lung, the accuracy of this calculation method needs improvement, for which development is in progress. The Monte Carlo method can provide the most accurate dose calculation, but because of the lengthy computation time, its routine use awaits faster computer speed. Nevertheless, the Monte Carlo method is relied on to derive accurate pencil beam kernel and the source function (which predicts the incident intensity pattern), with detailed accounting of the finite source size, extrafocal radiation (from the flattening filters, primary and secondary collimators), beam spectrum, and so forth. For both the DMLC and the MSS methods of IMRT treatment delivery, because small aperture sizes are frequently used, accurate prediction of output factor is important.<sup>21</sup>

Beam-on time calculation for IMRT treatment at MSKCC is an adaptation from our empirical-based method in which the dose D at a point (x,y,z) is given as  $D(x,y,z) = MU \times F$ , where MU is the monitor unit of radiation beam, and F is a product of several factors, including the field size or output factor, the tissue maximum ratio, the off-center ratio, the inverse-square factor, and so forth. For IMRT, we modify the equation using a factor that accounts for the intensity modulation.

In delivering the intensity-modulated field with an MLC, only a portion of the entire field is exposed at a given time. As a result, the total MU required is usually longer than that normally required. There is no simple relationship between the maximum beam intensity and MU. In practice, the total beam-on time MU is calculated by a computer program, taking into account effects such as leaf transmission, rounded leaf ends, tongue and groove, distributed source, maximum leaf speed, and dose

rate. In general, the more complex the intensity modulation, the larger the MU.

For conventional treatment, the independent MU check is typically calculated by hand. For IMRT, however, the intensity distribution is sufficiently complex that hand calculation is not feasible. At MSKCC, the independent check was initially provided by ionization chamber measurement, and subsequently by another computer program. Measurement is a direct assessment of the delivered dose, particularly valuable for new treatment techniques, but extremely time consuming as a routine check. Our computer MU check software was programmed by an independent team. The program first constructs the delivered intensity distribution from the leaf-sequencing files and the beam-on time. Doses to points or to planes at depth in a phantom are then calculated and compared with those of the original plan.

## COMMISSIONING AND QUALITY ASSURANCE PROGRAM

Both mechanical and dosimetric measurements are required in the commissioning of IMRT delivery using DMLC.<sup>22,23</sup> and <sup>24</sup> Because the dose delivered using DMLC is directly related to the gap widths between pairs of opposing leaves, precise leaf position is much more important in this approach than in treatments using static MLC. Mechanical calibration of the leaf positions can be accomplished using the recommended procedure and software supplied by the manufacturer. We have determined that a precision of 0.2 mm in leaf position is necessary, and that the Varian Mark II MLC satisfies this requirement. Dosimetric characterization of the MLC, using film, ion chambers, or both, includes measurements of radiation transmission through the leaves and their rounded ends, and the determination of head scatter. The dosimetric contribution of these factors, which can amount to as much as 15% of the dose, are accounted for in the leaf sequencer algorithm of the treatment planning system.

Another important consideration of DMLC is the monitoring of the performance of the MLC during treatment. While the beam is on, the Varian MLC control computer checks all leaf positions every 55 msec, compares them to the planned leaf positions in the DMLC file, and records them in a DMLC log file. If any leaf deviates from its planned position beyond a preset tolerance, the control computer invokes a *beam holdoff*, and radiation delivery is withheld until all the leaves are within tolerance again. Deviations that invoke beam holdoff should occur infrequently as the leaf sequencer algorithm, in generating the DMLC file, has duly considered the maximum MLC leaf speed and the nominal dose rate. Tests using clinical fields indicate that deviations of greater than 1 mm occur less than 1% of the time. For the initial group of patients, we tested the delivery of each field before treatment and examined the log files to ensure that there was no deviation that would significantly affect the dose. Based on those studies, a preset tolerance level of 2 mm was selected that mainly serves to insure against a potential hardware failure (e.g., a stuck leaf).

In addition, a comprehensive program to evaluate the routine performance of DMLC needs to be in place. This includes a quality assurance procedure and periodic dosimetric verification of intensity-modulated fields. Image patterns of predesigned fields are produced on radiographic films twice a week by radiotherapists to provide a quick visual assessment that the DMLC is functioning properly.<sup>9</sup> Ion chamber and diode array measurements at different gantry and collimator angles are performed monthly by a physicist to ensure constancy of the DMLC output and to track long-term stability. Ion chamber measurements in solid phantom for patient fields provide a straightforward check on the MU calculations. Film dosimetry, with sufficient spatial resolution for the intensity-modulated patterns, efficiently compares the delivered and the planned dose distributions. It is also used intensively during the testing of new software and new treatment sites for IMRT, as well as for periodic spot checks. The general procedure is to irradiate the film in a homogeneous plastic phantom and to digitize the exposed film with a laser scanner.

## TREATMENT DELIVERY WITH DYNAMIC MULTILEAF COLLIMATOR

For treatment implementation, the DMLC files of the intensity-modulated fields are transferred either via a floppy disk or electronically to the MLC control computer of the treatment machine. Also transmitted for each intensity-modulated beam is its fluence aperture, defined as the area with greater than 1% of the maximum intensity, or approximately the MLC aperture with the leading leaves and the trailing leaves at their respective final and initial positions. This fluence aperture is used for acquiring portal image (see [Consideration of Treatment Uncertainties](#), later in this chapter) and for recording and verification purposes by that system.

Before the first treatment, portal localization electronic portal imaging device (EPID) images are taken of each intensity-modulated field with its fluence aperture. The portal localization films are then compared with the corresponding digitally reconstructed radiographs overlaid with the maximal DMLC apertures. This verifies that the radiation is directed properly, relative to the bony anatomy of the patient. During the treatment course, weekly portals are obtained for each field using the EPID. Using the EPID in combination with the MLC allows machine setup and image acquisition to occur without the therapist reentering the room between fields, thereby improving efficiency.

Before the dose delivery in patient treatment, the record and verify computer checks the initial leaf settings and the other machine parameters: the gantry angle, collimator angle, jaw positions, and MU setting. During radiation delivery, the MLC control computer monitors the leaf positions every 55 msec, compares them with the planned positions, and records the result in a DMLC log-file. On completion of the first DMLC field, the record and verify system records the MU delivered and the final positions of the MLC. Without reentering the room, the radiotherapists rotate the gantry to the next orientation, program the accelerator and the MLC for the next intensity-modulated field, and then deliver the radiation. The process is repeated for each of the fields.

## CLINICAL EXPERIENCE

### CANCER OF THE PROSTATE

Since 1986 we have treated more than 1000 patients with cancers of the prostate using 3D-CRT. An analysis of 743 of these patients showed a significant effect of increased dose (from 64.8 Gy to 81.0 Gy) on response.<sup>3</sup> With the capability of IMRT, we have further escalated the dose and have treated approximately 40 patients to 86.4 Gy. At the same time, a five-field IMRT treatment with a prescription dose of 81.0 Gy has become the standard of care for prostate of the cancer at MSKCC. This summary describes this experience and our preliminary clinical results.

Patients are immobilized in the prone position, simulated, and imaged on a CT simulator. With the CT data transferred electronically to the MSKCC planning system,<sup>30</sup> the PTV, bladder, rectum, bowel, femurs, and pelvis are contoured. IMRT planning is performed with the inverse method using a five-field technique (0, 75, 135, 225, and 285 degrees) as detailed previously.<sup>23</sup> The present criteria for optimization are dose uniformity (within 12%) to the PTV, less than 34% of the rectal wall at 75 Gy, and less than 58% of the bladder wall at 81 Gy. The overlap region between the PTV and the rectal wall is separately constrained during optimization to exert greater control over the spatial dose distribution in that region. On approval of the optimized plan, BEV digitally reconstructed radiographs and the fluence apertures are generated, and the DMLC files transmitted to the MLC controller for treatment delivery using DMLC.<sup>16</sup>

We reported the preliminary results of 171 IMRT patients, in comparison with those of 61 3D-CRT patients treated to the same 81 Gy.<sup>25</sup> Comparison of the dose distributions of the five-field IMRT plan and the 3D-CRT plan (six-field primary to 72.0 Gy, plus a 9-Gy boost with the rectum blocked) indicated that IMRT improved the conformality of the 81-Gy isodose line relative to the PTV and decreased the dose to the surrounding normal tissues. A systematic analysis (using the Wilcoxon assigned rank test) of the two types of plans on 20 randomly selected patients demonstrated that significantly higher percentage of the CTV received 81 Gy with IMRT relative to 3D-CRT ( $98 \pm 2\%$  vs.  $95 \pm 2\%$ ,  $P < .01$ ).<sup>25</sup> Concomitantly, the percentages of the rectal wall and bladder wall volumes carried to 75 Gy were significantly decreased with IMRT ( $P < .01$ ). These data support the notion that IMRT significantly improves the conformality of the radiation treatment in prostate cancer.

[Figure 29.4-6](#) is an example of the dose distribution, in a color wash representation, achieved for an IMRT prostate treatment to 81 Gy with five intensity-modulated beams. The dose distributions in the transverse and midsagittal planes are shown, with the PTV (green) and rectum (yellow) outlined. The dose distribution conforms to the PTV and restricts the rectum volume irradiated to high doses. The cumulative DVHs for this plan ([Fig. 29.4-7](#)) reinforce this point. Approximately 95% of the PTV receives the prescription dose and the level of dose inhomogeneity is reasonable. DVHs for the rectal and bladder walls are also compliant to acceptable criteria derived from previous 3D-CRT clinical experience. [Figure 29.4-8](#) illustrates the intensity profile of the posterior beam, in the isocentric plane, from the 81-Gy IMRT plan illustrated in [Figure 29.4-6](#).

**FIGURE 29.4-6.** An example of the dose distribution, in a color wash representation, for intensity-modulated radiation therapy prostate treatment to 81 Gy with 5 intensity-modulated beams. The dose distributions in the (A) transverse and (B) midsagittal planes are shown, with the planning target volume (PTV) (green) and rectum (yellow) outlined.

**FIGURE 29.4-7.** The cumulative dose volume histograms for the 81-Gy intensity-modulated radiation therapy plan illustrated in Figure 29.4-6. The dose-volume histograms for the planning target volume, rectal wall, and bladder wall are shown.

**FIGURE 29.4-8.** The intensity profile of the posterior beam, in the isocentric plane, from the 81-Gy intensity-modulated radiation therapy plan illustrated in Figure 29.4-6.

In terms of clinical outcome, the combined rates of acute grade 1 and 2 rectal toxicity for IMRT were significantly less (45%) than that of 3D-CRT (61%) using the Radiation Therapy Oncology Group morbidity grading scale ( $P = .05$ ).<sup>28</sup> Similarly, there was a highly significant decrease in late grade 2 rectal bleeding to 0.5% with IMRT as compared with 13% for conventional 3D-CRT ( $P < .001$ ). There was one grade 3 rectal toxicity (bleeding requiring laser cauterization) in each treatment group. Based on this experience, we have escalated the dose to 86.4 Gy and have successfully treated 40 patients using IMRT. We now await follow-up data on late reactions before additional patient accrual at this dose level.

Compared with our previous method of 3D-CRT planning for the 81-Gy treatment, IMRT planning is less labor intensive. The 81-Gy 3D-CRT plan was performed in two phases, a standard six-field plan to 72 Gy and a second one for the 9-Gy boost. In contrast, a single IMRT plan for both the 81-Gy or 86.4-Gy treatment course was judged acceptable for both tumor coverage and normal tissue sparing. Thus, the treatment planning effort has been reduced by a factor of two.

In terms of implementation, on average the length of treatment sessions was comparable for the five-field IMRT and the six-field 3D-CRT plans, even though the MUs of IMRT were approximately 2.5-fold higher. The average session for 138 patients treated (April 1995 to March 1996) with 3D-CRT to 75.6 Gy was  $17.7 \pm 0.1$  minutes, compared with  $16.5 \pm 0.1$  minutes for 140 IMRT patients treated (April 1997 to March 1998) to 81 Gy on the same machine, inclusive of the time for setup and weekly portal imaging.

## HEAD AND NECK CANCER

Radiotherapy of head and neck cancers is often complex due to target doses of 70 Gy or higher and the close proximity of the spinal cord, brain stem, parotid glands, and optic pathway structures with tolerance doses of 45 to 55 Gy or less. Traditional treatments, consisting of parallel opposed photon fields (with blocks added to shield the spinal cord at 45 Gy) and electron fields to augment the dose to the cervical lymph nodes, are often inadequate in target coverage and in normal tissue sparing. We have previously used a multifield 3D-CRT approach, but since May 1998 have adopted IMRT and DMLC to deliver a uniform target dose with steep dose gradients at target-normal structure interfaces and reduced doses over normal tissues. Approximately one-half of 20 patients have received treatment for primary nasopharynx cancer, with 70 Gy to the gross disease and 54 Gy to the presumed microscopic disease.

Subsequent to CT simulation and image (3-mm increments) acquisition of the immobilized patient, the PTV (the gross disease and adjacent lymph nodes) and the normal structures (spinal cord, brain stem, optic nerves, chiasm, mandible, larynx, and parotid glands) are delineated. The beam arrangement, consisting of seven equally spaced beams directed from the posterior and lateral directions, attempts to create a concave dose distribution that encompasses the nasopharynx, skull base, and regional lymph nodes but encircles and spares the spinal cord and brain stem. When implemented with 3D-CRT, the technique is limited by excessive dose nonuniformity within the PTV (up to 140%) and by both planning and treatment complexities. These limitations are easily overcome with IMRT.

The dose-based criteria for optimization are for the nasopharynx and nodal target volumes to receive the prescription dose with a maximum of 120%, and dose constraints on the normal structures as follows: spinal cord, 40 Gy; brain stem, 50 Gy; optic structures, 50 Gy; and larynx, 45 Gy. The penalties for the spinal cord and brain stem are generally four to five times greater than the penalties for the PTV and other normal tissues. The derived IMRT plan, as assessed by dose distribution and DVH for the PTV and normal structures, demonstrates significant improvements over the traditional approach of parallel opposed primary plus 3D-CRT boost. The dose distributions are highly conformal and constrain the maximum spinal cord and brain stem doses to less than 40 and 50 Gy, respectively, well below maximum acceptable doses. Although there is no specific attempt to decrease the dose to the parotid glands for fear of underdosing nearby lymph nodes, the distribution of dose within the parotid gland is substantially different from that obtained with traditional opposed fields. With traditional parallel opposed beams, nearly the entire parotid gland volume would receive a dose of 70 Gy or more. With IMRT, approximately one-half the gland receives less than 50 Gy. Dose to the mandible is also substantially improved. Although the maximum mandible dose is still approximately 75 Gy, only 10% of the mandible receives more than 60 Gy. [Figure 29.4-9](#)

Superimposed are the outer skin surface (purple) and wireframe representation of the planning target volume (yellow), parotids (green), and spinal cord (red). The left lateral (A) and cranial (B) views are presented.

## BREAST CANCER

Radiation therapy after lumpectomy remains a primary method of treatment for primary breast cancer. Excellent local control is achieved in early-stage disease along with generally good cosmetic results and low toxicity. Nonetheless, improvements are needed, particularly for large-breasted patients with left-sided disease for whom cosmesis and potential cardiac toxicity remain significant issues. Since April 1999, we have treated selected patients with disease in the left breast and with large chest wall diameters with intensity modulation using a standard tangential beam arrangement. All patients undergo CT simulation during which the direction and size of the tangential beams are determined. The PTV is defined to be all tissue encompassed within 0.5 cm of the tangent field borders. The ipsilateral lung and coronary artery regions are defined by the physician using the CT.

The IMRT plan must deliver a uniform dose distribution in the PTV to within 10% of the prescription. Typically, this is achieved by setting an even tighter dose uniformity constraint for the target (of 5%) during optimization. The dose to the coronary artery region is minimized to the extent possible without sacrificing target coverage. Generally, a maximum dose constraint of 95% is used for this structure during optimization. Dose to the apex of the breast is controlled by separately contouring and constraining this region.

The advantages of tangential fields include treatment and setup simplicity and the ability to totally exclude critical structures such as the opposite breast from the treatment fields. Despite the limits imposed by this simple beam geometry, target dose uniformity and normal tissue doses have improved with IMRT. In a study comparing intensity modulation with conventional wedged tangents, an average improvement in target dose homogeneity of 5% was observed with IMRT. The mean dose to the coronary artery region and opposite breast decreased by more than 30% and 35%, respectively. The average volume of ipsilateral lung receiving doses in excess of the prescription decreased by 35%.

## CONSIDERATION OF TREATMENT UNCERTAINTIES

To account for treatment uncertainties, arising from patient set-up variation and organ motion, a margin is added to the target in radiotherapy planning.<sup>26</sup> As the dose distributions become more conformal in 3D-CRT and even more so in IMRT, the outcome of the treatment may become more sensitive to these uncertainties. Thus, it is important to quantify them, develop corrective methods to minimize them, and account for the residual component in treatment planning.

Ideally, patient-specific treatment uncertainty data should be used, but practically it would be difficult. Thus, approaches have been developed to quantify treatment uncertainties of a patient population. Set-up errors have been measured for several disease sites using serial portal images and interfraction organ motion by repeated CT scans.<sup>27,28</sup> and <sup>29</sup> Based on such data, analysis can be performed to assess the potential effect of treatment uncertainties on treatment outcome using statistical sampling technique.

The previously mentioned population average uncertainty data can also be useful for the calculation of the dose distribution in treatment planning. Specifically, the frequency distribution of treatment uncertainties can be incorporated into the pencil beam kernel, which is equivalent to a convolution of the idealized dose distribution with the frequency distribution of treatment uncertainties. This yields an average dose distribution representing the effects of random, or daily, errors occurring over a treatment course.

## DEVELOPMENT AND RESEARCH ISSUES

IMRT is in a developmental phase and there has been limited experience in the use of inverse planning in the radiotherapy community. Although we have had some experience of its use in the treatment of the prostate, each application to a new disease site (head and neck and breast) represented a new challenge, requiring adaptation or new custom features. For example, in the treatment of the breast, an extension of each intensity-modulated field to include a skin flash is needed. Given that our optimization algorithm is developed at MSKCC, we are able to modify the software to meet the unanticipated clinical requirement. We surmise that users of the emerging inverse planning systems may encounter similar experiences and will seek incremental improvement of their algorithms. The situation will likely be system specific and may vary widely among them due to the large number of variables in such systems and in the inverse process. In addition, better understanding in the use of optimization criteria is needed for the efficacious use of the inverse planning technique, and we have approached this by trial and error. Such criteria are certainly disease site specific and probably algorithm specific as well.

There are investigations on the use of biologic models of tumor tissue response as criteria for plan optimization.<sup>30,31</sup> In general, biology-based score functions typically consist of some weighted combination of biologic indices. Two under current study are the normal tissue complication probabilities<sup>32</sup> and tumor control probabilities.<sup>33</sup> These indices condense structure-specific dose-distribution data to yield relative figures of merit for the respective objects of interest. However, both of these indices are at present based on rather rudimentary models with simplistic assumptions. Importantly, clinical data for validating the models and deriving the model parameters are lacking. Nevertheless, the advent of 3D treatment planning and the accrual of patients treated with this modality are beginning to provide clinical outcome data for which dose volume information are available. For example, analysis has been performed on clinical complication data of the lung, liver, and optic pathways.<sup>34,35</sup> and <sup>36</sup> Such studies promise to improve the present biologic models, provide better estimates for the model parameters, or both. It is hoped that the iterative process of generating clinical data and refinement and validation of the models will incrementally improve the predictive power of the biologic indices and facilitate the quantitative evaluation of 3D treatment plans.

Certain technical aspects of inverse planning will continue to be investigated. For example, the advantages and disadvantages of gradient-based optimization as compared with simulated annealing.<sup>37,38</sup> and <sup>39</sup> The latter method, though much slower computationally, is more likely to yield the global minimum (or the most optimal solution), but this theoretical advantage has not been demonstrated to be clinically important. Another often discussed issue pertains to the optimal number of intensity-modulated beams and their orientations. Again, our view is that given a sufficient number of equally spaced beams (five to seven or more) and the intensity-modulation capability, near optimal plans can be generated.<sup>40</sup>

There is significant interest in developing methods to verify the delivery of intensity-modulated beams. These efforts are benefiting from the gradual maturation of the EPID technology, particularly using amorphous silicon detectors. The ability to verify directly the intensity pattern of the delivered intensity-modulated beams will greatly enhance the confidence in the use of IMRT and lead to wider acceptance of this modality. At present, the electromechanical monitoring of leaf positions during radiation delivery provides similar assurance, albeit indirectly and without providing measured data.

The ability of IMRT to deliver nonuniform dose patterns by design brings to fore the question of how to *dose paint* and *dose sculpt*, leading to the suggestion that *biologic* images may be of assistance.<sup>41</sup> In contrast to the conventional radiologic images that primarily provide anatomic information, biologic images reveal metabolic, functional, physiologic, genotypic, and phenotypic data. Important for radiotherapy, the new and noninvasive imaging methods may yield 3D radiobiologic information. Studies are urgently needed to identify genotypes and phenotypes that affect radiosensitivity and to devise methods to image them noninvasively. Incremental to the concept of gross target volume, CTV, and PTV, we suggest the concept of *biologic target volume* and hypothesize that biologic target volume can be derived from biologic images and that their use may incrementally improve target delineation and dose delivery.<sup>41</sup> We emphasize, however, that much basic research and clinical studies are needed before this potential can be realized.

In conclusion, IMRT is a powerful technique that provides extra degrees of freedom in customizing the dose distribution for photon radiotherapy. With the development of the computer-controlled treatment machines equipped with DMLC, it is now possible to deliver these treatments reliably. The clinical implementation of inverse planning and treatment delivery with DMLC is extremely complex and involves a substantial developmental effort. However, once accomplished, the process is efficient and capable of providing the dual benefits of improved dose distribution and cost savings. It is likely that this new modality will become widely accepted and applied in the future.

#### INTRODUCTION

Cancer is a complex genetic disease derived from the accumulation of various genetic changes. These genetic alterations include activation of protooncogenes and inactivation of tumor suppressor genes. Moreover, inactivation of tumor suppressor gene function requires inactivation of both parental alleles, usually by point mutation and a chromosomal deletion. The correlation of these specific genetic changes with the various lesions depicted in the histopathologic progression of colorectal cancer has led to the development of a molecular progression model for this disease.<sup>1</sup> This molecular model now serves as a paradigm for the molecular progression of many other solid neoplasms.

A number of specific genetic events have been identified in the progression of head and neck squamous cell carcinoma (HNSCC). Primary tumor DNA can now be isolated and assessed directly for the presence of chromosomal deletions and amplification, as well as direct characterization of candidate oncogenes. Identification of the critical genetic changes that drive the neoplastic process has provided a preliminary progression model for head and neck cancer. This model now delineates appropriate genetic targets for novel diagnostic, prognostic, and therapeutic strategies.

#### GENETIC SUSCEPTIBILITY

It has been estimated that up to 10% of all cancers have a strong hereditary component. Generally, familiar clustering of cancer has suggested the possibility of genetic predisposing factors. A clustering of oral cancer has been seen in certain ethnic groups, and an increased risk of cancer has been noted among relatives of patients with one head and neck cancer.<sup>2,3</sup> Several studies have suggested a threefold higher risk of developing an oropharyngeal cancer in populations that have a first-degree relative with HNSCC.<sup>4</sup> There also has been some suggestion of a remarkable increase in the relative risk of cancer in relatives of individuals with multiple primary tumors. Except for the finding of head and neck cancer in some rare cancer syndromes, the basis of this genetic susceptibility has yet to be determined.<sup>5</sup>

An emerging area of study centers on the prevalence of specific polymorphisms in enzymes that are involved in the detoxification of several tobacco smoke-derived carcinogens. One larger study of 162 patients with head and neck cancer and 315 healthy controls suggested that certain glutathione S-transferase (GST) genotypes represented independent risk factors for head and neck cancer.<sup>6</sup> Some studies also have shown a two- to threefold risk for the GST M1 and GST T1 null genotypes, whereas others have shown no increase in HNSCC risk.<sup>7,8,9,10,11</sup> and <sup>12</sup> In all these studies, it is difficult to exclude other important risk factors, such as smoking, yet there appears to be a consistent susceptibility based on certain metabolic genotypes. Others also have found that the repair capacity of peripheral lymphocytes or their ability to repair carcinogen-induced chromosomal breaks may also define a certain risk for head and neck cancer.<sup>13,14</sup> and <sup>15</sup> A more precise contribution of these polymorphisms and other risk factors to the development of head and neck cancer will need to be elucidated in larger studies.

#### CYTOGENETIC ALTERATIONS

Statistical analysis based on the age-specific incidence of head and neck cancer suggests that HNSCC tumors arise after the accumulation of six to ten independent genetic events.<sup>16</sup> Cytogenetic approaches have given us some insights into potential areas of deletion and amplification involved in the progression of head and neck cancer. Previously, karyotypic studies concentrated on established cell lines with complex chromosomal abnormalities. Unfortunately, different cell culture conditions added substantial variation to these observed chromosomal alterations.<sup>17</sup> Moreover, cultured cells from the primary tumor may represent only a small clone derived from *in vitro* selection pressure that is not representative of the entire cell population. Short-term cultures of primary tumors have proven more reliable for the assessment of complex chromosome abnormalities and rearrangements. These studies have already demonstrated consistent chromosomal abnormalities and the presence of important alterations.<sup>18</sup> Loss of chromosomes 3p, 5q, 8p, 9p, 18q, and 21q has been commonly identified. Preliminary data also suggest that loss of 18q may indicate the presence of a tumor with a poor prognosis.<sup>18</sup> Additionally, multiple chromosomal breakpoints including those on 1p22, 3p21, 8p11, and distal 14q have correlated with decreased radiosensitivity.<sup>19</sup> Fluorescence *in situ* hybridization potentially represents a more sensitive approach for recognizing both chromosomal deletions and amplifications.<sup>20</sup> For example, genomic amplification at the 11q13 region can be detected in preneoplastic lesions and should allow its placement directly into a molecular progression model.

More recently, comparative genomic hybridization has emerged as a comprehensive method for genome-wide evaluation to detect deletions or amplification. In this approach, tumor-normal DNA is mixed and hybridized to metaphase spreads from normal cells. Labeling of tumor-normal DNA by different fluorescent colors allows direct visualization of increased or decreased chromosomal material in neoplastic tissue by fluorescence detection. This approach is complementary to other methods for assessment of both tissue culture and primary tumor material. In addition to the chromosomal areas previously noted, comparative genomic hybridization has demonstrated amplification of 3q, 5p, 11q13, and 19q.<sup>21</sup>

#### PROTOONCOGENES

Protooncogenes were initially identified as activated cellular genes specifically altered in some human neoplasms.<sup>22</sup> Despite the cloning of dozens of putative protooncogenes involved in the development of human neoplasms, few were found to be altered directly in the progression of primary tumors and cell lines. In addition to activation of oncogenes such as *ras* by point mutation, amplification is also a mechanism for activation of a protooncogene locus. Definitive studies suggested that the 11q13 amplification was associated with amplification of a critical protooncogene termed *cyclin D1* (PRAD1; CCND1). Although other genes were also coamplified in the same region, only cyclin D1 was consistently amplified in approximately 30% of HNSCC and most other neoplasms.<sup>23,24</sup> Moreover, amplification of this region correlated with increased expression of the cyclin D1 gene and may indicate a likelihood of progression in primary HNSCC.<sup>25</sup>

As previously noted, amplification of 3q has been noted in many squamous cell carcinomas, including head and neck cancer. A p53 homologue (p40/p51/p63) has been cloned and localized to the distal arm of 3q.<sup>26</sup> Although homologous to p53, this genetic locus was found to be amplified in a high frequency of squamous cell cancers (ais), and this amplification correlated with increased expression at the RNA and protein level.<sup>27</sup> Although there has been no evidence of activating point mutations in squamous cell cancers, functional evidence suggests that AIS may in fact be a true oncogene in squamous cell cancers.<sup>27</sup> Interestingly, dominant negative mutations are responsible for a specific hereditary syndrome called *ectrodactyly-ectodermal dysplasia-clefting syndrome*.<sup>28</sup> Knockout mice display a lack of epithelial development consistent with the role of this gene in epithelial renewal.<sup>29</sup> Further studies should establish the role of ais in the genetic progression of head and neck cancers.

The role of cyclin D1 in the progression of human cancer is now well established.<sup>30</sup> Other tumor suppressor genes, including Rb and p16, are negative regulators of the cyclin D1 pathway and often are inactivated in human neoplasms. In head and neck cancer, p16 appears to be a major target of inactivation. Thus, abnormal cycling through this critical G<sub>1</sub>/S checkpoint may be a consistent genetic alteration in a majority of primary HNSCC. Although p16 and Rb inactivation are almost

always exclusive, cyclin D1 amplification is independent of p16 inactivation in head and neck cancers. <sup>31</sup>

Like other epithelial neoplasms, the role of other protooncogenes has been much less definitive. Few mutations in ras have been identified in primary head and neck tumors. Although epidermal growth factor receptor (EGFR) has been an interesting candidate, increased levels of the receptor at the RNA or protein level rarely correlate with primary DNA amplification. <sup>32</sup> New evidence suggests that activation of signaling through Stat-3 leads to EGFR-mediated cell growth and that antisense suppression of EGFR protein leads to apoptosis (programmed cell death). <sup>33,34</sup> The protein eukaryotic initiation factor (eIF4E) binds to messenger RNA during initial protein synthesis, and its overexpression can result in the up-regulation of proteins essential for cell growth and division. Overexpression of eIF4E has been found in HNSCC, and there has been some evidence of gene amplification and protein overexpression in these tumors. <sup>35,36</sup> Overexpression of the protein in cells can lead to oncogenic transformation and may facilitate the synthesis of angiogenic factors such as vascular epidermal growth factor by enhancing their translation. In at least one study, there was a correlation between increasing eIF4E and vascular epidermal growth factor levels, suggesting its possible role in angiogenesis. <sup>37</sup>

Additionally, several other genes or gene products have been found to be overexpressed in head and neck tumors. High levels of cyclooxygenase (COX)-2, have been seen in squamous cell carcinomas by a competitive reverse transcription assay. <sup>38</sup> GST P1 messenger RNA levels are found to be high in most moderately and poorly differentiated tumors, <sup>39</sup> but only a fraction of these had specific gene amplification. Newer cytogenetic techniques may lead to the identification of important protooncogenes more commonly involved in the progression of HNSCC.

## SUPPRESSIVE GROWTH REGULATION

In addition to growth factors with "positive" regulation and augmentation of tumor growth, other growth factor pathways may suppress cell growth. Transforming growth factor- $\beta$  (TGF- $\beta$ ) is among these growth factors that have been implicated almost universally with suppression of tumor growth. Alterations of the type II TGF- $\beta$  receptor, one target of TGF- $\beta$ , were noted in primary colorectal cancers potentially involved in abrogation of this negative regulatory pathway. <sup>40</sup> Initially, some head and neck cancer cell lines were also found to harbor TGF- $\beta$  receptor mutations, and mutations in the conserved serine/threonine kinase domain were found in 6 of 28 primary tumors. <sup>41,42</sup> The interaction of TGF- $\beta$  with this critical receptor normally leads to an increase of negative regulators of the cell cycle (e.g., p15, INK4B) and G<sub>1</sub>/S arrest; thus, normal negative regulation may be abrogated by mutations in the type II TGF- $\beta$  receptor.

Through a different mechanism, retinoic acid receptors (RARs) have been implicated in the negative growth regulation of HNSCC. This negative regulation has been the cornerstone of successful chemopreventive approaches to diminish the incidence of second primary tumors by administration of *cis*-retinoic acid to patients with a primary HNSCC tumor. <sup>43</sup> Well-designed studies have demonstrated a significant reduction in the occurrence of second primary tumors in patients who receive retinoic acid. Although the regulation of retinoids is complex, one critical end point may be down-regulation of RAR- $\beta$ . Studies in patients with premalignant disease (leukoplakia) have suggested that RAR- $\beta$  levels are closely associated with response to retinoic acid. <sup>44</sup> In particular, those patients with tumors demonstrating low RAR- $\beta$  levels did not respond to retinoic acid. Further functional studies into the role of retinoic acid and RAR- $\beta$  may yield important information regarding the role of this pathway in the progression of HNSCC and successful treatment of premalignant lesions.

## TUMOR SUPPRESSOR GENES

Molecular analysis has now revolutionized the ability to look at primary neoplasms. Methods that required large amounts of DNA (e.g., Southern blot analysis) have now been supplemented by polymerase chain reaction (PCR)-based approaches that allow access to limited DNA samples. Minute primary specimens from paraffin can be evaluated by rapid and accurate techniques. DNA extracted from these samples can be amplified by PCR to reveal the presence of allelic losses. In practice, maternal and paternal alleles can be distinguished by testing highly polymorphic markers that occur naturally among DNA sequences. <sup>45</sup>

It is now generally believed that these allelic losses (or chromosomal deletions) are markers for inactivation of critical tumor suppressor genes contained within the regions of loss. <sup>46</sup> Testing of highly polymorphic microsatellite markers (small 2- to 4-base pair repeats) from a specific chromosomal region allows rapid assessment of allelic loss by comparing the alleles in tumor DNA to normal DNA. Perhaps the best example of this association is derived from loss of chromosome 17p. These losses led to characterization of p53 as a candidate gene within the deleted area and subsequent identification of point mutations within the remaining allele. Inactivation of p53 now represents the best described and most common genetic change in all of human cancer. <sup>47</sup> Approximately 50% of all primary HNSCCs harbor p53 mutations in the conserved regions (exons 5 to 9). <sup>48,49</sup>

A comprehensive allotype of head and neck cancer has now been completed and refined. <sup>50,51</sup> The most commonly deleted region in head and neck cancer is located at chromosome 9p21-22. <sup>50,51</sup> Loss of chromosome 9p21 occurs in the majority of invasive tumors and is also present at a high frequency in the earliest definable lesions, including dysplasia and carcinoma *in situ*. <sup>52</sup> Furthermore, homozygous deletions in this region are frequent in HNSCC and represent one of the most common genetic changes identified in all human neoplasms. p16 ( *CDKN2*) is contained within this critically deleted region and is a potent inhibitor of cyclin D1/ *CDK4* complexes. Thus, p16 has emerged as an excellent candidate tumor suppressor gene within the deleted area. <sup>53</sup> Indeed, germline point mutations of p16 predispose to familial melanoma, <sup>54</sup> and loss of p16 may be necessary for immortalization of keratinocytes. <sup>55</sup>

Although initial enthusiasm for p16 as a target gene in head and neck cancer was diminished when sequence analysis revealed rare point mutation (approximately 10% to 15% of HNSCC tumors), <sup>56,57</sup> alternative mechanisms of inactivation were identified suggesting that abrogation of p16 function may be a common occurrence in head and neck cancer. Homozygous deletion (deletion of both gene copies) and methylation of the 5' CpG region of p16 have been identified, each detected in approximately one-fourth of primary head and neck cancers. <sup>58,59</sup> This methylation is associated with complete block of p16 transcription and appears to be a common mechanism for p16 inactivation. The notion that p16 inactivation is directly involved in the progression of primary tumors has been strengthened. Lack of p16 protein was detected by immunostaining in most primary invasive lesions, and tumors with absent p16 protein contained a homozygous deletion, methylation, or point mutation of p16. <sup>60</sup> Loss of p16 protein has been observed in most advanced premalignant lesions. <sup>61</sup>

It is also possible that a second critical tumor suppressor gene resides at 9p21. We and others have identified an alternative RNA transcript for p16 termed p16 beta. <sup>62</sup> This unique transcript originates from an upstream initiating site in a novel exon 1 and codes for a protein through an alternative reading frame (ARF). Interestingly, introduction of p16 or p16 beta into head and neck cancer cell lines results in potent growth suppression. <sup>63</sup> Although the human transcript is somewhat shorter than the murine protein, functional studies have suggested that ARF binds to MDM2, leading to a decrease in p53 degradation and a subsequent increase in p53 levels. <sup>64,65</sup> Moreover, a knockout ARF mouse develops certain tumors at an increased frequency. <sup>66</sup> In human tumors, homozygous deletion of the p16 locus concomitantly leads to knockout of p16 beta, and thus approximately 30% of HNSCCs have no ARF protein. Evidence in squamous cell carcinoma of the lung suggests that p53 mutations and p16 inactivation are not exclusive, suggesting that, at least at the genetic level, they do not function in the same pathway. <sup>67</sup> Ultimately, further studies will have to be done in primary tumors and human models to establish the precise role of p16 beta inactivation in squamous cell carcinoma.

A second commonly deleted locus occurs on chromosome 3p. Several studies have suggested that this region of loss is complex in head and neck cancer and may in fact be composed of three distinct suppressor regions juxtaposed to one another. <sup>68,69</sup> As for 9p21, analysis of 3p21 losses in HNSCC has revealed frequent loss in early lesions. The 3p21 region is also frequently lost in lung cancer and has been the target of an intensive search for the critical tumor suppressor gene. The *FHIT* gene was found in a critical area of homozygous deletion and was evaluated as possible tumor suppressor gene in many cancers. Although altered transcripts have been detected in primary tumors and cell lines, specific inactivating mutations of the second allele have not been forthcoming. <sup>70,71</sup> Thus, although many candidate genes have been isolated, none has been demonstrated to be the critical inactivated tumor suppressor gene at 3p involved in the progression of these cancers.

Loss of chromosome 17p is a frequent occurrence in most human cancers, and head and neck cancer is no exception (occurring in 60% of invasive lesions). <sup>48</sup> Although p53 inactivation correlates closely with loss of 17p in invasive lesions, p53 mutations are quite rare in early lesions that contain 17p loss. Some evidence from cell lines also suggests that a distal breakpoint to p53 occurs in head and neck cancer. Together, these data suggest that a second tumor suppressor gene on 17p may be involved early in the progression of this neoplasm. p53 mutations, as in most tumors, generally rise in frequency between the preinvasive to the invasive state. This is consistent with a critical function for p53 in response to DNA damage. <sup>72</sup> p53 mutant tumors are also less likely to respond to local radiation therapy. <sup>73</sup> This model is certain to become more complex, but offers an important insight into the role of p53 in the progression of head and neck cancer and many other tumors.

Loss of chromosomal arm 10q is not uncommon in HNSCC and lung cancer. The *PTEN* gene was cloned and found to be homozygously deleted and inactivated in a variety of different cancers. Homozygous deletion and rare point mutation inactivation have been seen in HNSCC. <sup>74,75</sup> Although only 10% of these cancers have

inactivated gene, it seems to be more common in advanced tumors and may harbor a poor prognosis.<sup>74,76</sup>

Loss of 13q also occurs in approximately 60% of primary tumors and the minimal area of loss includes the tumor suppressor gene Rb. However, immunohistochemical analysis of Rb (which detects most Rb alterations) revealed inactivation of Rb in only small percentages of tumors with loss of 13q.<sup>77</sup> Again, as in many other chromosomal regions, there appears to be another tumor suppressor gene near Rb, putatively inactivated in the progression of head and neck cancer.

More recent work has suggested that there may be one or more regions of specific loss on the short arm of chromosome 8 and on 7q31.<sup>78,79,80</sup> and<sup>81</sup> Loss of 18q has been seen, and one of these minimally deleted regions harbors two tumor suppressor genes.<sup>82,83</sup> Homozygous deletions of both *DCC* and *DPC4* have been noted in cell lines but have been rarely seen in primary tumors.<sup>84</sup> Many other areas of chromosomal loss have been seen in head and neck cancer consistent with the occurrence of multiple genetic events in the progression of these neoplasms. Except for those previously noted, critical tumor suppressor genes have not been identified from these loci and remain to be isolated and characterized. Further fine mapping of these deletions, amplifications, and translocations with characterization of critical genes within these areas may provide important information about the biology and clinical behavior of these neoplasms.

We have tested the ten most common allelic loss events in a large number of primary preinvasive lesions and invasive HNSCC to develop a molecular progression model.<sup>85</sup> As seen in [Figure 30.1-1](#), the progression of head and neck cancer involves inactivation of many putative suppressor gene loci. Chromosomes 9p and 3p appear to be lost early, closely followed by loss of 17p. p53 mutations are seen in the progression of the preinvasive to invasive lesions, and many other genetic events occur later in progression. Other specific genetic events, such as amplification of cyclin D1 and inactivation of p16, have been tested predominantly in invasive lesions, and their precise order in the model cannot yet be determined. As noted in the molecular model for colorectal cancer, it is the accumulation and not necessarily the precise order of these genetic events that determine histopathologic progression. This is best exemplified by some early lesions that demonstrated a "late" event as the sole genetic alteration.

**FIGURE 30.1-1.** Preliminary progression model for head and neck squamous cell carcinoma. Genetic alterations have been ordered by testing a variety of preinvasive and invasive lesions and determining the frequency of these events at each stage in progression. Inactivation of p16 (chromosome 9p21) and amplification of cyclin D1 (chromosome 11q13q) have not been directly tested in preinvasive lesions. It is the accumulation and not necessarily the order of these genetic changes that determines progression.

To test this model directly, we were able to analyze lesions that demonstrated histologic progression from one area to another. In each of the cases, we confirmed that 9p and 3p loss were early events, with other genetic changes occurring in the more advanced histopathologic lesion. Moreover, lesions biopsied in the same area over time in a few critical patients also demonstrated the same general order of these events. Molecular progression models such as this one allow direct characterization of early genetic events that might be important in diagnostic strategies. Critical events that occur in the progression from the preinvasive state to the invasive state (e.g., p53 mutations) may be useful as prognostic indicators in primary lesions. Losses occurring later in progression, such as 11q, 13q, 14q, and 18q, and loss of p27 protein (another cyclin-dependent kinase inhibitor) have been found to correlate with a decrease in survival.<sup>83,84,85,86,87,88,89</sup> and<sup>90</sup> Early losses at 3p14 and 9p21 may persist in premalignant lesions exposed to chemoprevention agents and may predict those likely to relapse despite apparent histologic remissions.<sup>91,92</sup> All of these genetic events may one day serve as appropriate targets for novel therapeutic approaches. This model also has given some interesting insights into the well-known phenomenon of field cancerization.

## FIELD CANCERIZATION

Patients with head and neck cancer often present with second metachronous and synchronous tumors of the aerodigestive tract. Moreover, patients with primary lesions often have skip areas that are characterized by preinvasive lesions throughout the field. Slaughter<sup>93</sup> originally coined the term *field cancerization* and attributed this to a field defect that allowed independent transformation of epithelial cells at a number of sites. Previous studies in bladder cancer demonstrated that multiple tumors arising in a single patient were derived from the uncontrolled spread of a single transformed cell.<sup>94</sup> These tumors then grew independently with variable subsequent genetic alterations. For head and neck cancer, our working progression model allowed direct assessment of the genetic changes in surrounding areas of histopathologic abnormality. In every case, surrounding lesions appeared to share the same genetic events (e.g., critical breakpoints at chromosomes 9p21 and 3p21) present in the primary tumor, suggesting that a single transformed cell gave rise to the independent and apparently geographically distinct skip areas seen in these patients. Thus, Slaughter's original observations can be explained as follows: A cell is transformed by a critical genetic event and begins to migrate through the mucosa. Additional genetic events in one critical lesion eventually give rise to the clinical tumor that is seen on presentation. However, direct molecular assessment of surrounding regions confirms the presence of clonal cell populations that are not yet fully transformed. Given time, these lesions then arise as other preinvasive or invasive lesions in the same patient.

Although investigators have reported a confirmation of this field cancerization effect in head and neck cancer by detection of discordant p53 mutations in multiple tumors,<sup>95</sup> our working model suggests that this conclusion may be premature. Other genetic events, including loss of 9p and 3p, precede inactivation of p53. Thus, one of these early events probably leads to initial cell transformation and replacement of surrounding mucosa, whereas subsequent genetic events including p53 appear to arise independently. Thus, these investigators identified the diversity of subsequent genetic events rather than established the distinct clonal origin of these clinically independent lesions. By examining the pattern of X chromosome inactivation and loss of chromosome 9p21 in multiple tumors from female patients, we demonstrated a common clonal origin in most of these cases.<sup>96</sup> In support of this result, cytogenetic evidence in at least one patient identified the presence of a specific chromosomal marker in both primary neoplasms.<sup>97</sup> More recently, apparent second primary tumors of the lung and even rare esophageal tumors were found to be clonally related to the initial primary HNSCC.<sup>98,99</sup>

If minimally abnormal or benign-appearing premalignant lesions show clonal genetic changes adjacent to a primary HNSCC, it is conceivable that normal-appearing mucosal areas could harbor an occult neoplasm. Clinically detectable cervical lymph node metastases without identification of the primary tumor were assessed by molecular analysis of multiple surveillance biopsies. We investigated whether the site of origin of the primary tumor could be localized by detection of specific losses on some of the key chromosomes described in the molecular progression model.<sup>100</sup> In 10 of 18 patients, at least one pathologically benign biopsy demonstrated a pattern of genetic alterations identical to that present in cervical lymph node metastases. Three of these patients went on to develop primary tumors in the identical or adjacent mucosal region between 1 to 13 years later.<sup>100</sup> These data further support the notion that histopathologically benign mucosa may harbor patches of clonal preneoplastic cells that are genetically related to the metastatic HNSCC and that such mucosal sites are the sites of origin of unknown primary HNSCC.

## MOLECULAR EPIDEMIOLOGY

The pattern of specific mutations within a given gene sequence may provide important information concerning the etiology (e.g., effect of a carcinogen) of that particular cancer.<sup>101</sup> The p53 gene can be inactivated by a large variety of distinct mutations and is frequently inactivated in many human cancers, providing an excellent candidate for this type of survey. Analysis of the pattern of the p53 gene mutation in 129 HNSCC patients has demonstrated that the incidence of p53 mutations is much higher among patients exposed to tobacco and alcohol than among those patients who abstained from both.<sup>49</sup> Moreover, we found that the alcohol appeared to augment the effect of smoking, consistent with models in which alcohol is not a carcinogen per se, but might lead to an increase in the absorbance of carcinogens contained within cigarette smoke. Furthermore, we found that CpG mutations are rare among mutations patients who smoke cigarettes, whereas they

constituted most of the mutations found in nonsmokers and nondrinkers. C to T mutations at these CpG sites are important because, through methylation and deamination, they are thought to represent potential sites of “endogenous” mutations. These data thus support a growing body of epidemiologic evidence that abstinence from cigarette smoke may help decrease the overall incidence of head and neck cancer.

## HUMAN PAPILLOMAVIRUS

Human papillomavirus (HPV) has long been thought to play a role in some head and neck cancers. One study of more than 250 patients used PCR followed by definitive techniques such as sequencing and *in situ* hybridization to search for the presence of HPV in head and neck tumors.<sup>102</sup> HPV was detected in approximately 25% of the lesions and virtually all were “high-risk” oncogenic types (HPV 16). Remarkably, most HPV-positive tumors were in the oropharynx. For these HPV-positive oropharyngeal cancers, they were less likely to occur among heavy smokers and drinkers, less likely to harbor a p53 mutation, and had an improved disease-specific survival. Another group suggested that HPV-positive tumors may also inactivate Rb and harbor a better prognosis.<sup>103</sup> These new data are consistent with previous studies with a smaller number of patients<sup>104</sup> or those that used less definitive determine techniques. It appears that HPV-positive oropharyngeal tumors compose a distinct clinical and pathologic disease entity causally associated with HPV.

## DIAGNOSTICS

Clonal genetic alterations can be identified in clinical samples including bodily fluids. These clonal genetic alterations are generally considered to represent specific markers for the presence of neoplastic cells. In many clinical samples, however, the number of neoplastic cells are greatly outnumbered by normal cells within the same specimen. Therefore, we and others have developed very sensitive and specific techniques to detect these rare clonal genetic alterations among many “normal” or wild-type DNA molecules. Clonal ras gene mutations have been detected in the stool of patients with colorectal cancer and p53 mutations in the urine of patients with bladder cancer.<sup>105,106</sup> Moreover, both ras and p53 oncogene mutations were used as targets to detect neoplastic cells in the sputum of patients with lung cancer. In one case, the same clonal cell population containing the identical mutation eventually identified in the primary tumor was detected 1 year before clinical diagnosis in a patient with lung cancer.<sup>107</sup> Analysis of p53 mutations also has confirmed the ability to detect neoplastic clones in the saliva of patients with head and neck cancer.<sup>108</sup>

Telomerase is a ribonuclear protein that maintains telomere length, and reactivation of its activity is associated with escape from cellular senescence. Using a modified PCR-based assay for telomerase activity, 80% to 100% of primary head and neck cancers were found to display telomerase activity.<sup>109,110</sup> Some authors have suggested that most dysplastic lesions and preneoplastic lesions also display telomerase activation.<sup>110</sup> Interestingly, 14 out of 44 (32%) of oral rinses from HNSCC patients were found to harbor telomerase activity, but a small percentage of normal controls also exhibited this telomerase activity.<sup>109</sup> Using a panel of 21 microsatellite markers, clonal genetic changes (loss of heterozygosity or microsatellite instability) were detected in 80% of the saliva samples from the patients with head and neck cancer.<sup>111</sup> Moreover, exfoliative cell samples were subjected to microsatellite analysis and found to contain the identical changes observed in the primary tumors.<sup>112</sup> It is still unknown if these changes can be identified in early lesions or if they can detect recurrence, as has been seen in bladder cancer through urinalysis. Clearly, the continued identification of molecular markers will lead to improved diagnostic techniques for squamous cell carcinoma.

A more pressing problem in HNSCC is the high incidence of local-regional recurrence despite aggressive surgical therapy. We used a similar molecular approach as previously described to probe surgical margins and lymph nodes from patients with primary head and neck cancer after surgical resection.<sup>113</sup> A segment of the p53 gene is amplified by PCR from DNA extracted from the clinical sample. The PCR products are then cloned into phage, transferred to nylon membranes, and probed with a specific oligomer (small DNA strand) able to recognize the same mutation initially identified in the primary tumor. Thus, a unique DNA probe was synthesized and used to test the resected surgical margins and lymph nodes from affected patients. Perhaps not surprisingly, many of the apparently normal margins and lymph nodes by light microscopy were found to contain infiltrating tumor cells by this sensitive molecular analysis ( Fig. 30.1-2).

**FIGURE 30.1-2.** Schematic representation of molecular staging. DNA is extracted from primary clinical (e.g., margin) material and then tested for the presence of infiltrating tumor cells that harbor the identical p53 mutations detected in the primary tumor. This polymerase chain reaction–based approach is much more sensitive than morphologic analysis by standard light microscopy. Patients positive by molecular analysis are at high risk for local regional recurrence.

In an initial pilot trial that contained 30 patients, the results were quite interesting. Although all patients were thought to be completely negative by light microscopy, final pathology revealed at least one positive margin in five patients.<sup>113</sup> These five patients had markedly positive margins by molecular analysis and were further excluded from this study. There were 25 remaining patients who were still completely negative by light microscopy. Of these, 13 were positive by molecular analysis and five have recurred within 2 years (average, 9 to 12 months). Of the 12 patients who were completely negative by molecular assessment, none has recurred at 2-year follow-up. As expected, there is a significant improvement in survival for those patients initially negative by molecular analysis ( Fig. 30.1-3). Other markers have been used to assess possible recurrence in tumor-free margins. e14FE (previously described) is associated with increasing overexpression in the progression of head and neck cancer and also has been detected in apparently tumor-free margins.

**FIGURE 30.1-3.** Probability of having no local recurrence, according to the results of the molecular assay. Kaplan-Meier curves are shown for the probability of having no local recurrence in the 25 study patients with surgical margins that were negative by light microscopy but were reevaluated with molecular probes. The probability of having no local recurrence in patients with positive margins by the molecular assessment was significantly lower than that in patients with negative margins (  $P = .02$  by the log-rank test).

Although the previous results must be confirmed by a larger prospective trial, the results are already intriguing. Perhaps patients with negative molecular assessment may be spared adjuvant radiation therapy. Moreover, patients with positive margins will benefit from more aggressive chemotherapeutic approaches and perhaps

novel approaches, including gene therapy. Because staging is so critical for many types of cancer, this approach may be important for other tumors in addition to head and neck cancer.

The identification of new genes and other molecular markers will help in the early detection of head and neck cancer and may already provide useful prognostic information regarding clinical tumor behavior. As we further understand critical pathways in the genesis of these tumors, chemotherapeutic, pharmacologic, and genetic approaches may all be useful in either reestablishing or abrogating newly established pathways that lead to tumor growth. These discoveries will eventually lead to improved surgical techniques, chemoprevention strategies, and novel therapeutic approaches.

## INTRODUCTION

The analysis of cancers within the upper aerodigestive tract reveals a heterogeneity of neoplastic processes. Each bears its own unique set of epidemiologic, anatomic, pathologic, and treatment considerations. This chapter reviews such considerations based on four anatomically defined regions: the nasal cavity and paranasal sinuses; nasopharynx; oral cavity; and oropharynx.

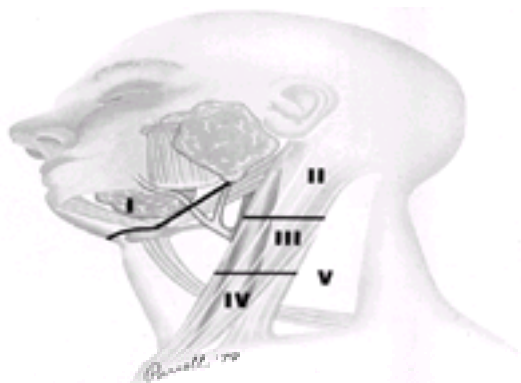

However, there exist general principles regarding these cancers that may be considered here. Such principles involve anatomy (i.e., primarily the anatomy of regional lymph nodes within the head and neck), pathology, staging, and screening, as well as general principles of treatment involving either single modality or multimodality therapy, which are relevant to all sites.

## ANATOMY

An understanding of the regional lymph node anatomy is critical to the care of head and neck cancer patients. There are several major lymphatic chains in the neck containing nearly 200 lymph nodes that run parallel to the jugular veins, spinal accessory nerve, and facial artery and into the submandibular triangle ( [Fig. 30.2-1](#)). To facilitate communication regarding cervical lymph node anatomy, the regions of the neck have been characterized by levels ( [Fig. 30.2-2](#)).<sup>1,2 and 3</sup>

**FIGURE 30.2-1.** Superficial and deep cervical lymph nodes of the head and neck. (From Shah JP. *A color atlas of head and neck surgery*. Orlando: Grune & Stratton, 1987, with permission.)

**FIGURE 30.2-2.** Level classification of regional cervical lymph nodes (see text for description). (From Shah JP. *A color atlas of head and neck surgery*. Orlando: Grune & Stratton, 1987, with permission.)

Level I includes nodes within the submental triangle and the submandibular triangle. The submental triangle extends from the midline anteriorly to the anterior belly of the digastric muscle posteriorly. Its third border is formed by the hyoid bone inferiorly. The submandibular triangle is bounded by the mandible superiorly. The anterior and the posterior belly of the digastric muscle complete the triangle.

Level II includes the jugular nodes extending from the subdigastic area down to the carotid bifurcation and the nodes surrounding the spinal accessory nerve from the jugular foramen to the posterior border of the sternocleidomastoid muscle. It includes the lymph nodes in the upper posterior cervical triangle above the entrance of the spinal accessory nerve into this triangle.

Level III represents the nodal area principally along the jugular vein between the carotid and its bifurcation, the posterior border of the sternocleidomastoid muscle, and the omohyoid muscle.

Level IV constitutes nodal areas below the omohyoid muscle above the level of the clavicle and between the carotid vessels anteriorly and the omohyoid muscle posteriorly.

Level V represents nodes in the posterior cervical triangle. Its borders are formed by the posterior edge of the sternocleidomastoid muscle, the level of the entrance of the spinal accessory nerve, the trapezius muscle, and the posterior belly of the omohyoid muscle.

Specific sites within the aerodigestive tract have a predetermined drainage pattern. A knowledge of this pattern aids in diagnosis. It also affects therapy. Drainage patterns are addressed in each of the anatomic subsites detailed in this chapter.

## PATHOLOGY

The predominant lesion within these anatomically defined regions is squamous cell carcinoma. Squamous cell carcinoma can be categorized into three classic differentiations. Well-differentiated disease shows greater than 75% keratinization; moderately differentiated disease contributes to the bulk of squamous cell carcinoma and is characterized by 25% to 75% keratinization; and poorly differentiated disease demonstrates less than 25% keratinization. Other variants of squamous cell carcinoma include verrucous carcinoma, sarcomatoid squamous cell carcinoma, and lymphoepithelioma. Additional pathologic criteria of squamous cell carcinoma that is believed to be clinically relevant were developed by Jacobsson and others.<sup>4,5,6 and 7</sup> This includes the number of mitoses, presence of vascular invasion, size of nuclei, degree of inflammatory infiltrate, and pushing or infiltrating borders ( [Table 30.2-1](#)).

Classification	Score
<b>TUMOR CELL CHARACTERISTICS</b>	
Degree of keratinization	1-4
Nuclear pleomorphism	1-4
Number of mitoses	1-4
<b>TUMOR-HOST RELATIONS</b>	
Mode of invasion	1-4
Leukocyte infiltration	1-4
<b>TOTAL MALIGNANCY SCORE*</b>	
The sum of scores of features	1-5

\*All features are registered in the most anaplastic areas of invasive sites of the tumors.  
\*A high malignancy score indicates a poorly differentiated tumor.  
(Modified from ref. 6.)

**TABLE 30.2-1.** Jacobsson Classification System<sup>a</sup>

## PREMALIGNANCY

A series of pathologic changes from premalignant disease to frank malignancy can occur in the oral cavity. Among the premalignant diseases are leukoplakia, erythroplakia, hyperplasia, and dysplasia. Each of these types has a propensity for malignant transformation.<sup>8</sup> Histopathologic assessment of leukoplakia reveals hyperparakeratosis, which is variably associated with an underlying epithelial hyperplasia. Leukoplakia without underlying dysplastic changes is rarely associated with progression to malignancy (i.e., less than 5% probability of malignant changes).<sup>9,10</sup> Erythroplakia is a condition within the oral cavity and pharynx characterized by red superficial patches adjacent to normal mucosa. Distinct from leukoplakic lesions as identified previously, erythroplakia is commonly associated with underlying epithelial dysplasia. Likewise, it can be associated with carcinoma *in situ* to frank malignancy in nearly 40% of lesions.<sup>9,11</sup>

*Dysplasia* as compared with the previously mentioned two clinical descriptives is a true histopathologic term that is characterized by several morphologic changes, including the presence of mitoses, pleomorphism, and prominent nucleoli. When dysplasia involves the entire thickness of the mucosa, it is commonly referred to as *carcinomain situ*. Dysplasia has been associated with a subsequent risk of progression to frank malignancy ranging from 15% to 30% of cases.<sup>12,13</sup>

## STAGING AND SCREENING

### STAGING

The role and current status of staging for head and neck cancer is undergoing continuous analysis.<sup>14,15,16,17 and 18</sup> Although standard staging has been defined, there is a growing debate as to what the primary function of staging should be. The American Joint Committee on Cancer Staging (AJCC), however, has described the principal goal of staging as a means of defining the natural history of disease. Additional goals include the ability to judge therapeutic results between various centers as well as a means of defining patient prognosis. Revisions to standard staging have continually been offered,<sup>15,16</sup> but today it is based on the TNM classification. T stage represents extent of primary disease. N represents the extent of regional lymph node metastasis and M is a measure of distant metastasis. The AJCC staging system, used for classifying TNM status, is periodically revised.<sup>14</sup>

The current clinical staging system, although based principally on physical examination, has also incorporated specific radiographic observations of disease status. Thus, invasion *through* cortical bone by an oral cavity tumor up-stages a T2 or T3 lesion to T4 (i.e., from stage II or III to stage IV).

Radiographic assessment of cervical lymph node metastases has not been integrated into clinical staging. The benefits of these diagnostic techniques beyond that provided by standard physical examination are under investigation.<sup>17,18,19,20,21 and 22</sup> Most would consider the combination of radiographic and clinical assessment to be more accurate than either one alone. Furthermore, growing emphasis is being placed on the advantages of one imaging technique versus another [i.e., the relative merit of magnetic resonance imaging (MRI) vs. computed tomography (CT)].<sup>17</sup> [Table 30.2-2](#) summarizes the relative value of these two techniques in head and neck imaging.

<b>CT SCANNING</b>	
Fast acquisition time/less motion artifact (especially true for patients with bulky tumors that cause them to continually swallow)	
Increased sensitivity to bony destruction?	
For patients who cannot tolerate MRI because of claustrophobia, or patients who are not MRI candidates (pacemakers, aneurysm clips)	
Cost	
Currently CT is better than MRI for evaluating metastatic adenopathy	
<b>MRI</b>	
No iodinated contrast (contrast allergy renal failure)	
No irradiation	
Multiphasic capability	
No dental amalgam artifact	
Superior soft tissue contrast	
May be better than CT for primary tumor staging	
CT, computed tomography; MRI, magnetic resonance imaging. (From ref. 22, with permission.)	

**TABLE 30.2-2.** Advantages of Computed Tomographic Scanning and Magnetic Resonance Imaging in the Evaluation of Head and Neck Cancers

The criteria for T staging within the upper aerodigestive tract differs depending on the primary site. N staging and M staging, however, are uniform and therefore are considered in [Table 30.2-3](#). [Table 30.2-4](#) represents the most current stage classification as defined by the AJCC.<sup>14</sup>

<b>REGIONAL LYMPH NODES (N)</b>	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3	Metastasis in a lymph node more than 6 cm in greatest dimension
<b>DISTANT METASTASIS (M)</b>	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

**TABLE 30.2-3.** Staging within the Upper Aerodigestive Tract

Stage	Classification		
	T	N	M
0	Tis	N0	M0
I	T1	N0	M0
II	T2	N0	M0
III	T3	N0	M0
	T1	N1	M0
	T2	N1	M0
IV	T3	N1	M0
	T4	N0	M0

**TABLE 30.2-4.** Stage Grouping Based on American Joint Committee on Cancer Staging Criteria

Additional data continue to accrue regarding the effect of comorbidities in prognostication. Data suggest that these host-related factors provide information beyond standard AJCC criteria alone. Host factors include the presence of significant heart disease, liver disease, and severe cerebrovascular disease. Survival rates are significantly reduced if comorbidities exist and are improved with their absence.<sup>23,24</sup> and<sup>25</sup> In a study by Singh et al., for instance, involving 70 patients with squamous cell carcinoma of the upper aerodigestive tract, patients with Kaplan-Feinstein comorbidity index grades 2 and 3 had a significantly decreased disease-free survival as compared with those with comorbidity index of grade of 0 to 1.<sup>23</sup> Stage distribution between the two groups was similar.

### SCREENING FOR PRIMARY CANCERS

It is intuitive that detection of disease at its earliest stages would improve cancer mortality. Given the degree to which the oral cavity and upper aerodigestive tract can be easily examined, it would also seem that screening for head and neck cancers would be a readily accomplishable goal. Diminished mortality would be readily achievable. The significance of screening as a potentially significant modality is emphasized by a review by Smart, who reported that 94% of head and neck cancer patients had seen a physician at least 1 year before diagnosis.<sup>24</sup> Each patient reported an average of 11 physician visits within a 3-year period before diagnosis. Smart's review emphasizes that with appropriate training and practice of systematic screening habits by examining physicians, head and neck cancer may be diagnosed considerably earlier. In that regard, a study by Prout et al. assessed the value of educational programs for health care providers in the Boston area and provided information that would reinforce that notion.<sup>25</sup> These latter authors noted that health care providers schooled in the oral cancer educational program were significantly more likely to perform systematic oral screening in subsequent years. These studies emphasize the important role of the physician in the early detection of head and neck cancer and that such individuals, if properly motivated, are more likely to perform such screening than those less aware of the significance of oral cancer.

Despite the intuitive benefit that would come with more effective screening, confounding factors may limit success. First, head and neck cancer is a relatively sporadic disease. Mass screening procedures would detect cancer in only limited instances. Second, individuals at risk tend to be less health conscious. Compliance with health care advice such as avoidance of substance abuse, good nutritional habits, and regular physical evaluation is not readily achieved in this population. Third, head and neck cancer patients can often be characterized by diminished social support systems. Access to medical care is hindered, making routine follow-up by a health care provider difficult. Finally, although it is often stated that a readily identifiable premalignant condition exists (i.e., leukoplakia or erythroplakia), few head and neck cancer cases can be shown to progress through this premalignant clinical stage. Although head and neck cancers tend to occur late in life, these same cancers can occur at any time within a 20-year interval. Knowing which patient and when that patient will develop disease remains a conundrum. Furthermore, whether or not the identification of disease changes its natural history is not clear. We cannot state with certainty the interval required for a tumor to achieve its initially diagnosed stage. We do not know whether the biologic potential of a head and neck cancer follows the same time course within every individual. Ultimate tumor aggressiveness may be determined early in its natural history. The window of opportunity to detect the most lethal cancers may be small. No studies have yet demonstrated that systematic screening diminishes head and neck cancer mortality. Indeed, the Task Force for the Guide to Preventive Services has concluded that routine screening for oral cancer cannot be recommended.<sup>26</sup>

It is not surprising, therefore, that various mass screening programs for head and neck cancer have demonstrated mostly negative results. Jullien et al. and others have made it apparent that the identification of head and neck cancer is only one part of the process.<sup>27,28,29</sup> and<sup>30</sup> In the assessment of nearly 1000 patients as reported by Jullien et al., only 67% of the 12 patients noted to have potentially malignant disease were compliant with follow-up recommendations.<sup>27</sup> The experience in Cuba, likewise, showed similar discouraging results.<sup>28</sup> Annual oral examination had been considered mandatory for all individuals over 15 years of age in Cuba since 1984. The proportion of early-stage disease was noted to increase during this period of more intensive screening. However, overall oral cancer mortality was not altered. As in the study by Jullien et al., a major problem was patient compliance in follow-up examinations once the disease has been diagnosed. The investigators of these large population-based studies conclude that systematic mass screening for head and neck cancer is not a cost-effective process and has little effect on overall cancer mortality.

Perhaps more significant than the screening process itself and in light of the development of more effective behavioral modification approaches, Cowan et al. have demonstrated that screening strategies are valuable in identifying the health care beliefs of the provider.<sup>30</sup> Primary care dentists participating in this study were noted to routinely assess the oral cavity for evidence of disease.<sup>30</sup> However, a minority of dentists routinely recorded information about tobacco and alcohol abuse. The implication of Cowan's study was that screening was already adopted. What should be developed in the primary care setting is a clearer understanding of the benefits of health promotion involving substance abuse modification.

There are, however, novel strategies under development that may enhance screening effectiveness.<sup>31,32,33,34,35,36,37,38</sup> and<sup>39</sup> We have previously noted in this brief review that epidemiologic investigations continue to refine risk estimates. Current computer technology may allow for translating previous risk factor assessments into clinical strategies that enhance screening efforts. An example involves the use of neural networks. The Oral Cancer Screening Group in England has demonstrated its potential utility.<sup>31</sup> The performance of the network to identify individuals at increased risk was compared with the results of oral screening by health care specialists. Over 2000 adults were entered into the study and were asked to fill out a questionnaire that identified ten input variables. The overall sensitivity and specificity of the screeners as compared with the neural network were comparable. The use of neural networks could be performed, however, at a fraction of the cost.

Other screening techniques under investigation include the use of genetic markers of increased risk, molecular cytology, serum tumor markers, as well as newer technologies involving optical engineering and the computer sciences.<sup>31,32,33,34,35,36,37</sup> and<sup>38</sup>

### SCREENING FOR SECOND PRIMARY CANCERS

Head and neck cancer patients are characterized by their high risk of developing second primary malignancies. The majority of these cancers occur within tobacco-exposed tissue, including the esophagus, lung, and remaining upper aerodigestive tract. This risk has been well characterized and is known to occur at a rate of 4% per year.<sup>39</sup> Given the high rate of second malignancies within these individuals, numerous screening strategies have been described. Available screening modalities include laryngoscopy, esophagoscopy, contrast studies of the esophagus, chest radiography, sputum cytology, and bronchoscopy. Newer modalities are under investigation including the use of molecular assessments of cells within saliva and sputum.<sup>40</sup> Despite this effort, no agreement exists as to the optimal screening means, including the timing and duration of follow-up. Perhaps the greatest controversy revolves around the role of panendoscopy at the time the patient presents for treatment of the index cancer. Proponents of this procedure, which includes laryngoscopy, esophagoscopy, and bronchoscopy, cite the high rate of identified second cancers, reported in one prospective study to occur in 10% of patients.<sup>41</sup> Disease found in this setting is presumed to be of an earlier stage and more responsive to treatment. Opponents of routine panendoscopy cite the relatively low yield and questionable value in actually altering disease course and survival.<sup>42,43</sup> and<sup>44</sup> A

prospective study by Benninger et al. provided compelling evidence to support the use of screening procedures based principally on symptomatology (i.e., so-called symptom-directed selective endoscopy).<sup>43</sup> A careful history and physical examination of all newly diagnosed head and neck cancer patients represents the most effective screening method. Although routine panendoscopy cannot be advocated, in certain individuals its use may be more beneficial. This, in our experience, includes patients whose index cancer resides within the pharynx and who admit to a long history of tobacco and alcohol abuse. Special attention should be given to the assessment of the esophagus in these individuals as well as the remaining upper aerodigestive tract.

## TREATMENT

### PRETREATMENT CONSIDERATIONS

The comprehensive care of the head and neck cancer patient begins with pretreatment considerations including the assessment of general medical conditions, nutritional status, dental health, and the appropriate choice of medical therapies designed to minimize treatment-related complications. It is beyond the scope of this chapter to detail the numerous associated medical illnesses that are typically identified in the head and neck cancer patient. Given the prolonged history of tobacco and alcohol abuse that can be typically identified, diseases involving the pulmonary, cardiovascular, and digestive systems are common. There remain, however, important considerations that should be stressed. This includes the significance of pretreatment dental care, nutritional support, the effect of therapy on the elderly patient, and the choice of preoperative medications (i.e., antibiotics for the patient about to undergo major surgical procedures).

The standard of care today for the head and neck cancer patient is the reduction of oral diseases before initiation of treatment.<sup>45,46 and 47</sup> Periodontal diseases, infections, and caries are common in this patient population. This can lead to loss of integrity of the gingival-crevicular tissues. Left unchecked, significant morbidity can result to structural elements of the oral cavity in the face of aggressive therapy. Following initial evaluation by the oncologic team, dentulous patients should be referred to dental colleagues for appropriate oral hygiene. Pretreatment radiographic dental surveys should identify caries and periapical lesions. Other factors that should be considered include defective restorations, ill-fitting prostheses, and impacted molars. It is generally considered prudent to perform necessary dental rehabilitation, including extractions, approximately 2 weeks before the initiation of any radiotherapy. This allows for the appropriate healing of extraction sites and mucosal coverage of exposed bone. In order to minimize delays in the initiation of radiation, dental care can be performed at the time of surgical resection in a patient who is to undergo multimodality therapy.

The assessment of nutritional status and the choice of pretreatment nutritional regimens is more controversial. Several authors report the common finding of malnutrition in the head and neck cancer patient.<sup>48,49 and 50</sup> Severe malnutrition has been identified in over 25% of the patients.<sup>48</sup> Furthermore, the presence of severe malnutrition was associated with increased operative morbidity.<sup>50</sup> This has led to efforts to appropriately quantitate nutritional status through the use of documentation of pretreatment weight loss, the measurement of triceps skin fold thickness, and the inclusion of various laboratory measures such as plasma protein levels and the creatinine and height index. To date there has been no conclusive randomized trial of pretherapy nutritional restoration in order to minimize treatment morbidity. However, Goodwin and Byers have stressed that in the severely malnourished patient, attention should be given to a 2-week pretreatment course of nutritional support.<sup>48</sup> Such attempts can most often be achieved through enteral means with the placement of either a nasogastric tube or a percutaneously placed gastrostomy tube.

The care of the elderly patient represents a commonly occurring dilemma.<sup>51,52,53 and 54</sup> The tendency to deny a patient optimal treatment because of the patient's advanced years should be avoided. In a study by McGuirt and Davis, operative mortality was 4% in 217 patients greater than 65 years of age and not significantly different than those less than 65 years.<sup>52</sup> In a subset of patients over the age of 75 and with stage III or IV disease, however, the mortality increased to 6%. A prospective case-control study by Kowalski et al. on elderly patients undergoing head and neck surgery failed to identify any increased frequency of postoperative complications or mortality as compared with younger patients.<sup>51</sup> The choice of treatment should not be predicated on the age of the patient. Rather, it is the patient's general medical condition that remains the most critical consideration, regardless of age. In a more recent article by Clayman, 43 patients who were 80 years of age or older were noted to have no increased postoperative complications than a stage- and site-matched population aged 65 years or less.<sup>54</sup> Of note, the older population was more likely to have a lesser surgical procedure, more likely to have positive pathologic margins, and less likely to receive postoperative radiation therapy (RT). Disease-free survival was also decreased in the older population. The perception of an increased risk of treatment-induced complications may compromise appropriate therapy.

Increasing attention recently has been given to the significance of continued tobacco use in the head and neck cancer population. The data would support the notion that continued tobacco use following diagnosis of the index cancer leads to an adverse patient outcome. This relates to not only the more obvious problem of progressive cardiopulmonary disease, but considerations related to head and neck cancer progression as well. Day et al. and others have provided more information regarding the risk of second primary malignancies in patients who continue to smoke following treatment of their index cancer.<sup>55,56</sup> The risk of second primary malignancies was significantly higher in the smoking population as compared with those who achieved smoking cessation. This difference was apparent only after 5 years following initial treatment.<sup>55</sup> In another study by Browman et al., continued tobacco use was associated with a decreased likelihood to respond to primary therapy.<sup>57</sup> This latter study represents an initial report and is limited by its small population size. It does, however, raise an important consideration in the overall care of these patients, namely, the systematic approach toward achieving smoking cessation. In that regard, several studies have identified characteristics of patients who are likely to continue smoking habits.<sup>59,61,62 and 63</sup> Interestingly, Ostroff et al. have reported that it is the patients with the best outlook who seem to be the most recalcitrant.<sup>60</sup> Patients with early-stage disease continued to use tobacco at higher rates than patients with higher stage disease. Strategies are being explored in order to effectively support the patient through this critical period.<sup>58</sup> The hallmark of any approach should include surgeon-delivered advice as well as the judicious use of nicotine replacement.

Finally, head and neck surgical oncologists should critically assess the need for supportive therapies in the patient who is to undergo operative procedures. This has principally related to the choice of perioperative antibiotics. The use of prophylactic antibiotics can only be supported for those individuals undergoing clean-contaminated surgery (i.e., when it is anticipated that the aerodigestive tract is to be entered) or in those circumstances in which there is frank contamination. Postoperative infectious complications may occur in up to 30% of the patients. Several studies have addressed risk factors for infectious complications and found duration of the operative procedure, blood loss, and complexity of the reconstructive procedure to be high-risk variables.<sup>61,62 and 63</sup> Common microorganisms isolated from infected wounds include both aerobes and anaerobes with *Bacteroides fragilis*, *Escherichia coli*, b-hemolytic streptococcus, *Staphylococcus*, and *Pseudomonas* being frequently identified. Perioperative antibiotics should be started before the operative procedure and should be continued for 72 hours postoperatively depending on the likelihood of infection. Antibiotic regimens should allow for broad coverage. Regimens include combination sulbactam and ampicillin, metronidazole combined with a cephalosporin, or clindamycin alone. Comparative studies regarding the appropriate antibiotic regimen may be confounded by the definition of infection and rigor in wound assessment. Regardless of the antibiotic regimen one may choose, however, postoperative infection rates should average less than 15%.<sup>64</sup>

### GENERAL PRINCIPLES OF SURGERY

In the execution of effective surgical management, the single most significant principle is the adequate preoperative assessment of disease extent. Precise and methodic physical examination of the patient is paramount. Such examination allows for the assessment of adequate extent of surgical excision, which remains for most cancers the fundamental tenet for achieving cure.

An extension of adequate preoperative assessment is optimal intraoperative exposure of disease. The surgeon should consider appropriate means to achieve operative exposure. The choice of incision and the ability to mobilize surrounding anatomic structures to achieve exposure is considered later in the text for each anatomic subsite. Additionally, exposure is facilitated by careful hemostasis. Besides allowing for better operative exposure, minimizing blood loss prevents potential sequelae associated with blood transfusion. Weber et al. reported expected blood loss for various surgical procedures involving cancers of the upper aerodigestive tract.<sup>65</sup> Electrocautery dissection had been used by Weber and colleagues, which may explain the relatively infrequent need for blood transfusion. Electrocautery dissection has been adopted by many experienced surgeons as the preferred extirpative technique.

Additional methods of surgical excision have included the use of the Moh's technique and laser ablation.<sup>66,67 and 68</sup> These techniques, however, cannot be considered standard surgical procedure at this time.

#### ***Surgical Management of the Cervical Lymph Nodes***

General principles of surgery exist involving regional lymph nodes as well. The standard in the surgical control of cervical metastases by which various procedures

are judged is the radical neck dissection. The radical neck dissection involves complete removal of the lymphatic pathways within the neck. To ensure complete extirpation, anatomic structures including the sternocleidomastoid muscle, spinal accessory nerve, and jugular vein are routinely sacrificed.

Developments in the management of cervical lymph node disease involve more conservative surgical procedures.<sup>3,69,70</sup> and<sup>71</sup> These procedures differ from the classic radical neck dissection principally in the sparing of specific anatomic structures (i.e., principally the spinal accessory nerve and the sternocleidomastoid muscle). [Table 30.2-5](#) provides a classification of currently used selective neck dissection and details removed lymph node regions.

Classification	Level of Lymph Node Removed
I. Standard radical neck dissection	I, II, III, IV, V
II. Modified radical neck dissection	I, II, III, IV, V
III. Selective neck dissection	
A. Supraomohyoid	I, II, III
B. Lateral type	II, III, IV
C. Posterolateral type	II, III, IV, V
D. Anterior compartment type	VI
IV. Extended neck dissection	

(From Robbins KT. Classification of neck dissection: current concepts and future considerations of neck dissection. *Otolaryngol Clin North Am* 1998;51:509, with permission.)

**TABLE 30.2-5.** Classification of Neck Dissections

### **Surgical Management of Disease in the Neck: N0 Neck**

Multiple studies have determined that cancers of the upper aerodigestive tract are associated with an approximately 20% to 30% incidence of occult cervical lymph node metastases, despite clinically negative examination.<sup>72,73</sup> and<sup>74</sup> The overall incidence of occult primary disease is influenced by multiple factors including size and location of the primary cancer within the upper aerodigestive tract, depth of invasion, and tumor differentiation.<sup>75</sup> These observations have led to the generally accepted need for elective lymph node neck dissection as part of standard surgical management. Support for this approach has been provided by Spiro et al.<sup>76</sup> Those patients who did not undergo elective dissection were more likely to present with more advanced neck disease when disease recurred as compared with those individuals who underwent prophylactic dissection.<sup>76</sup> It should be emphasized, however, that randomized clinical trials that conclusively support the role of elective cervical lymph node dissection have been limited. Indeed, a study by Vandenbrouck and colleagues failed to find a survival benefit in oral cavity cancer patients randomized to receive elective dissection.<sup>77</sup> This study was limited by the small number of patients entered.

A debate exists as to the type of elective neck dissection that should be performed. The standard radical neck dissection that encompasses lymph node basins I through V as well as the spinal accessory nerve, internal jugular vein, and sternocleidomastoid muscle is not indicated in the treatment of occult disease, principally because of its associated shoulder dysfunction. The debate still exists as to whether to perform modified radical neck dissection versus a more limited selective procedure. Leemans et al., citing a metaanalysis, report a lower incidence of neck recurrence in those patients treated by a modified neck dissection.<sup>78</sup> Others argue that a supraomohyoid neck dissection for cancers of the oral cavity is adequate given the limited likelihood of level V metastases and the limited likelihood of disease recurrence in level V region. In a randomized study conducted by the Brazilian Head and Neck Cancer Study Group, overall survival was the same in patients who underwent a supraomohyoid neck dissection as compared with patients who underwent a standard modified radical neck dissection.<sup>79</sup> This is despite the observation that 50% more lymph nodes were identified in the surgical specimen from the population undergoing modified radical neck dissection. The standard supraomohyoid neck dissection does not, however, encompass level IV nodes. *Skip metastases* may occur in level IV nodes and disease recurrence in this level has been identified. These latter two observations suggest that a selective lymph node dissection in oral cancer patients who are clinically N0 should include levels I to IV.

The value of elective neck dissection is further justified by its low risk ratio. When performed by an experienced head and neck surgeon, the procedure does not require excessively prolonged operative time and can be performed with minimal morbidity. The caveat should be the performance of careful dissection along the spinal accessory nerve. Indeed, advances in the performance of elective neck dissection have been reported by Kraus et al.<sup>80</sup> The authors investigated the probability of metastases in the lymph nodes superior to the spinal accessory nerve in patients who were clinically N0. In 44 patients analyzed, only one individual had disease in this region.

### **Surgical Management of Disease in the Neck: N+ Neck**

The presence of cervical metastases dictates in most instances the use of combination surgery and RT. Surgery alone has been reserved for those situations in which only a single lymph node is involved with disease and in which there is no extension of disease beyond the lymph node capsule. For patients with evidence of disease within cervical lymph nodes the most commonly accepted surgical management involves radical neck dissection. A trend, however, is evolving toward a more oncologically conservative approach designed to preserve shoulder function. Traynor et al. reported on the use of selective neck dissection in the management of the node-positive neck.<sup>81</sup> Twenty-nine patients were retrospectively reviewed in whom 16 had N2 disease or higher. Only one patient developed recurrence. Again, however, experience has been limited by the lack of controlled clinical trials designed to answer the question as to the optimal surgical procedure. Pellitari et al. reviewed their experience with selective neck dissection in 34 patients with multiple pathologically positive lymph nodes who underwent a selective neck dissection.<sup>82</sup> Regional recurrence rates approximated 12%, indicating the adequacy of the surgical resection when used judiciously with postoperative radiation.<sup>83</sup>

A major debate in the management of disease in the neck revolves around the handling of the carotid artery. This includes (1) indications for removal of the carotid as a part of an oncologic procedure and (2) indications and means of carotid artery reconstruction including preoperative assessment determination of cerebral blood flow reserve. There are those who advocate a less aggressive approach to the carotid, indicating that in the majority of circumstances, actual invasion of the carotid wall is rare and with careful dissection disease can be dissected away from the vessel without compromising cancer control. Furthermore, in those situations in which cancer invasion of the carotid artery actually exists, long-term disease control is limited, patients typically die from regional, distant, or both regional and distant metastatic disease. Finally, and most significantly, a conservative approach to the carotid artery minimizes significant incidence of cerebral vascular morbidity. Carew and Spiro reported experience with carotid artery resection at Memorial Sloan-Kettering Cancer Center.<sup>84</sup> In their review of extended neck dissections, the authors noted that in only 3 instances in over 2500 cervical lymph node dissections performed in a 10-year period was carotid artery resection required. Regional disease control in this population of individuals with predominantly N3 cervical lymph node disease was 71% and comparable with those reports in which carotid artery resection is more liberally used. None of the three patients who underwent carotid resection was alive at 2 years. The approach at Memorial Sloan-Kettering Cancer Center also includes the use of brachytherapy implants on the carotid artery in those circumstances in which the surgical peel potentially left macroscopic or microscopic disease. Others use an intermediate approach for disease encasing the carotid. Adams et al., for instance, reserve resection for instances in which there is 70% encasement of the vessel.<sup>85</sup> In those situations in which the patient was noted to tolerate preoperative balloon occlusion, survival was 30% at 2 years. Snyderman et al. have performed a metaanalysis of the reported experience with carotid artery resection in patients with metastatic head and neck cancer.<sup>86</sup> The overall (disease-free) survival for the group of patients reported was 22% and was similar between those who underwent carotid resection versus those who did not. Interestingly, survival has not changed in this group of patients over the last 20 years. The authors emphasize the high complication rate, with major cerebral vascular accidents occurring in 26% of the patients undergoing carotid artery resection. The rate of cerebrovascular accidents was 17% and no difference was seen between the two groups.

There are an increasing number of reports, however, that demonstrate that carotid artery resection in selected circumstances can be performed safely when preceded by appropriate presurgical assessment of collateral blood flow from the opposite cerebral hemisphere through the circle of Willis. This approach is justified by a classic pathologic report by Huvos et al., who showed that metastatic squamous cell carcinoma can be microscopically identified invading the carotid adventitia in up to 30% of cases in which disease is adjacent to the vessel.<sup>87</sup> Vascular surgeons have used pressure flow studies that assess the patency of collateral blood flow, mostly contributed through the circle of Willis, to determine the safety of carotid occlusion. Hays et al. reported that back flow pressure of 50 mm Hg was safe for temporary occlusion and/or ligation.<sup>88</sup> The current protocol of Adams et al. is to perform angiography to demonstrate nonstenotic patent carotid arteries, spontaneous crossover, and an intact circle of Willis. Patients also undergo an angiogram with controlled balloon inflation for 30 minutes. If tolerated, a xenon CT scan to assess

the likelihood of successful outcome follows.<sup>85</sup>

## GENERAL PRINCIPLES OF RADIATION THERAPY

For early-stage disease, both radiation and surgery are frequently curative and can produce similar rates of cure. Selection of treatment must be individualized to each patient and must consider issues such as cosmetic and functional outcome, quality of life, speed with which treatment can be completed, sequelae of each modality, patient reliability, risk of subsequent cancers, and capacity of salvage therapy should there be a recurrence.

For advanced-stage disease, surgery and radiotherapy are often combined (for resectable cases). When this is done, radiation is usually delivered postoperatively. Peters et al. reported a prospective randomized trial evaluating various dose levels for postoperative radiation in locoregionally advanced head and neck cancer.<sup>89</sup> They found that a dose of 57.6 Gy in daily fractions of 1.8 Gy were superior to doses of 54 Gy. For patients with extracapsular spread in the lymph nodes in the neck, doses of 63 Gy were superior to 57.6 Gy. Doses above 63 Gy did not appear warranted. Typical indications for postoperative radiation include T3 to T4 primary, close or involved margins for any primary, the presence of nodal metastases, especially extracapsular extension, and factors such as perineural invasion, soft tissue extension, and so forth. Ang updated this experience, assessing the effect of a variety of risk factors and total treatment time (surgery plus radiation) on outcome.<sup>90</sup> High-risk features included extracapsular extension, oral cavity primary, positive mucosal margins, nerve invasion, more than one node involved, more than one nodal station involved, node size greater than 3 cm, and greater than a 6-week interval between surgery and radiation. Patients with none of these features did not receive RT. Those with one adverse feature in addition to extracapsular extension were considered intermediate risk, and those with more than one feature plus extracapsular extension were considered high risk. Locoregional control for low-risk patients (no RT) and intermediate-risk patients (57.6 Gy) was greater than 90%, compared with 68% for high-risk (63 Gy) patients ( $P = .004$ ). Actuarial 4-year survival by risk was 83%, 66%, and 43%, respectively. Those who began radiation more than 6 weeks after surgery and whose total therapy time extended beyond 12 to 13 weeks also had worse outcomes.

There are other groups of patients with advanced disease that are treated differently, and these subjects are covered in this chapter. Those with small primary lesions and neck metastases can be treated with definitive RT to the primary and neck, plus a neck dissection. This is especially true for pharyngeal wall, oropharynx, and larynx cancers. Patients who have resectable larynx cancer but who would require total laryngectomy are often treated with organ-preserving therapy combining chemotherapy and radiotherapy. Either that approach or radiation alone (neck dissection) is often used for base of tongue and tonsil lesions, for the purpose of preserving organ function.

A variety of fractionation programs have been used by different groups.<sup>91</sup> The Radiation Therapy Oncology Group (RTOG) reported a prospective trial looking at four different schedules: conventional fractionation (70 Gy/35 fractions/7 weeks) versus hyperfractionation (81.6 Gy/68 fractions/7 weeks) versus accelerated fractionation with split (67.2 Gy/42 fractions/6 weeks including 2 weeks rest after 38.4 Gy) versus accelerated fractionation with concomitant boost (72 Gy/42 fractions/6 weeks), which used a twice a day concomitant boost during the last 12 treatment days.<sup>92</sup> The latter schedule provided better 2-year locoregional control than standard fractionation, and will be the standard treatment in future RTOG trials for locally advanced squamous cell carcinoma of the head and neck.

For unresectable disease, combined chemotherapy and radiotherapy has become the standard of care. Many of these trials are reviewed in this chapter. Interestingly, a combined modality experience using cisplatin and RT has been reported, using a concomitant boost schedule not dissimilar to the RTOG experience. Harrison et al. have reported long-term results of a program using 70 Gy/6 weeks using a concomitant boost during weeks 5 and 6, as well as cisplatin, 100 mg/m<sup>2</sup> on days 1 and 22.<sup>93,94</sup> and <sup>95</sup> Three-year local control for unresectable paranasal sinus cancers, T4 nasopharynx cancers, unresectable oropharynx cancers, and unresectable larynx and hypopharynx cancers were 78%, 78%, 64%, and 100%, although there were only six patients in the latter category. Unresectable oral cavity cancers fared poorly.

Merlano et al. reported a prospective, randomized trial comparing radiation alone with an alternating chemotherapy and radiation approach. This trial is reviewed later in this chapter, in Combination Chemotherapy and Radiotherapy, but revealed an improved outcome in the chemotherapy and radiation group.<sup>96</sup>

Side effects of RT are usually separated into acute and late effects. Acute effects generally are related to inflammatory reactions in the tissues within the radiation field (i.e., epidermitis and mucositis). Irradiation of the taste buds can cause loss or diminution of taste, irradiation of the salivary glands causes xerostomia, irradiation of the lacrimal glands can cause dryness in the eye, and epilation can result from irradiating hair-bearing skin. Whether these effects are temporary or permanent are usually dose related and site related. Because RT to the salivary glands and oral cavity can have a significant effect on dentition, all patients receiving this treatment should be seen by a dentist before RT. Any required dental work should be done before the initiation of radiation, and patients should be placed on dental prophylaxis with fluoride applications. It has been clearly shown that fluoride application significantly reduces dental sequela after RT.<sup>97</sup> It has also been clearly shown that dental extractions in an irradiated mandible can lead to osteonecrosis.<sup>98</sup>

Advances in radiotherapy techniques have had a significant effect on head and neck patients. For external-beam treatments, three-dimensional conformal radiation and stereotactic radiotherapy are particularly exciting new areas ( Fig. 30.2-3). This allows the physician to plan RT based on three-dimensional reconstruction of the target area, and three-dimensional planning of the radiation beams. As a result, it is frequently possible to lower the dose to surrounding normal tissue while potentially escalating the dose to the tumor.<sup>99</sup> Efforts to use this technique in nasopharyngeal cancer have been particularly interesting and are discussed in that section (see [Nasopharynx](#), later in this chapter). The development of multileaf collimators and on-line portal imaging techniques should make the delivery of three-dimensional RT more efficient. Intensity-modulated radiation is also being developed.

**FIGURE 30.2-3.** Dose distribution for a stereotactic radiotherapy plan for a boost for a patient with an unresectable squamous cell carcinoma of the frontal sinus. The microleaf collimator conforms nicely to the target. The optic chiasm is well protected, as is the contralateral orbit.

Finally, there are biologic and treatment-related factors that have been emerging as clinically relevant. Anemia has been shown to have a significantly adverse effect on local control<sup>100</sup> and is discussed in greater detail throughout [Chapters 30.1, 30.3, 30.4, and 30.5](#). Attempts to overcome tumor hypoxia with hypoxic cell sensitizers concomitant with RT (mitomycin C) have also shown success, all suggestions that tumor oxygenation has significant importance in the success of radiotherapy.<sup>101,102</sup> Also, with respect to reducing the side effects of radiotherapy, Brizel et al. have reported a clinical trial that shows that the daily administration of amifostine with radiotherapy reduced the incidence of acute and chronic xerostomia. This is an area under active investigation.<sup>103</sup>

## PRINCIPLES OF CHEMOTHERAPY: RECURRENT AND METASTATIC DISEASE

The median survival for patients with recurrent squamous cell carcinoma of the head and neck is 6 months and the 1-year survival rate is 20%. These statistics have not been affected by the use of chemotherapy. Consequently, patients with recurrent squamous cell carcinoma of the head and neck are candidates for phase I and II trials of experimental therapeutics.

### SINGLE-AGENT CHEMOTHERAPY

The activity of older single agents commonly incorporated into combination regimens and newer drugs are listed in [Table](#)

30,2-6,<sup>104,105,106,107,108,109,110,111,112,113,114,115,116,117,118,119,120,121,122,123,124,125,126,127,128,129,130,131,132,133,134,135,136,137,138</sup> and <sup>139</sup> The older drugs include methotrexate, bleomycin, cisplatin, carboplatin, ifosfamide, and 5-fluorouracil (5-FU). The details of these phase II studies may be found in older reviews, <sup>111,112</sup> and <sup>113</sup> whereas the activity of newer agents such as the taxanes, vinorelbine, gemcitabine, and topotecan are covered in more recent reviews. <sup>140,141</sup>

Chemotherapy	No. of Patients	Response Rate	References
Methotrexate	988	51	104-110
Bleomycin	547	21	111-115
Cisplatin	398	28	111-116
Carboplatin	169	22	111-115, 117
5-Fluorouracil	114	15	111-115
Ifosfamide	120	23	118-124
Paclitaxel (mg/m <sup>2</sup> )			
250 (24-h)	73	40	125-127
175 (24-h)	41	20	128
175 (3-h)	60	15	128,129
Docetaxel (mg/m <sup>2</sup> )			
100 (1-h)	80	53	130-132
60 (1-h)	25	30	133
Vinorelbine	102	18	134-136
Gemcitabine	34	13	137
Topotecan	45	14	138,139

**TABLE 30.2-6.** Activity of Single Agents in Recurrent and Metastatic Head and Neck Squamous Cell Carcinoma

Methotrexate is the standard palliative therapy for recurrent squamous cell carcinoma of the head and neck. The standard dose for initiation is 40 mg/m<sup>2</sup>/week to be escalated weekly by 10 mg/m<sup>2</sup> increments to 60 mg/m<sup>2</sup>/week or until dose-limiting toxicity or an objective response is reached. Therapy with this drug is relatively nontoxic, inexpensive, and convenient. Higher doses of methotrexate in single-arm studies were shown to produce higher response rates. <sup>104,105,106</sup> and <sup>107</sup> Five randomized trials have shown no significant difference in survival rates between higher doses of methotrexate with leucovorin (as much as 5000 mg) and standard-dose methotrexate. <sup>108,109</sup> and <sup>110</sup>

The methotrexate analogues trimetrexate,<sup>142</sup> edatrexate,<sup>143</sup> and piritrexim<sup>144,145</sup> and <sup>146</sup> have all been tested in small numbers of patients and seem to be active, but have no particular advantage over methotrexate. In a randomized comparison of methotrexate and edatrexate, activity was similar but edatrexate was more toxic. <sup>143</sup>

Bleomycin has been studied extensively as a single agent and in combination in recurrent and metastatic squamous cell carcinoma of the head and neck. Response rates as a single agent vary from 6% to 45%, with a pooled average of 21%. <sup>111,112</sup> It has largely been replaced by continuous infusion 5-FU, which is synergistic and more active in combination with cisplatin.

Cisplatin is perhaps the most important chemotherapeutic agent for treating squamous cell carcinoma of the head and neck. Most of the studies have used a dose of 80 to 100 mg/m<sup>2</sup> every 3 to 4 weeks. Response rates have ranged from 14% to 41%, with a pooled average of 28%. <sup>111,112</sup> and <sup>113</sup> Whether there is a dose-response relationship is not yet proven. Single-agent cisplatin in doses of up to 200 mg/m<sup>2</sup> produced higher response rates in pilot trials, <sup>114,115</sup> but a randomized trial comparing 60 mg/m<sup>2</sup> doses with 120 mg/m<sup>2</sup> doses found no difference in response or survival. <sup>116</sup>

Carboplatin has significantly less renal, otologic, neurologic, and gastrointestinal toxicity than does cisplatin, but response rates are lower, in the range of 14% to 30%, with an average of 22%. <sup>111,112,117</sup> Carboplatin should be reserved for treatment of patients with peripheral neuropathy or renal dysfunction that prohibits use of cisplatin. Of the other platinum analogues, iproplatin trials have yielded much lower response rates and major toxicity in phase II trials. <sup>147,148</sup> Oxaliplatin is under investigation in gastrointestinal and ovarian malignancies and nedaplatin is in early investigations in Japan. <sup>149</sup> Each drug has its own toxicity profile; the relative advantage over cisplatin and carboplatin will need to be determined in appropriately designed trials in head and neck cancer patients. 5-FU was studied initially using intravenous daily bolus dosing for 5 days or weekly in recurrent squamous cell carcinoma of the head and neck as second- or third-line chemotherapy. Response rates ranged from 0% to 33%, with an average of only 15%. <sup>111,112</sup> The dose-limiting toxicity of this method of administration was myelosuppression. Subsequent studies of 5-FU as a prolonged infusion for 96 to 120 hours at a dose of 1000 mg/m<sup>2</sup>/d showed mucositis to be dose-limiting, and antitumor activity was increased. 5-FU was synergistic with cisplatin, leading to the establishment of the now standard combination regimen of cisplatin plus infusional 5-FU. <sup>113</sup>

Ifosfamide, a synthetic analogue of cyclophosphamide, was limited in early clinical trials by the occurrence of hemorrhagic cystitis. With the use of MESNA, a thiol compound that inactivates the urotoxic metabolites, standard doses (less than 10 g) and high doses (17.5 g) have been tested in patients with head and neck cancer. Response rates reported from phase II trials vary widely but average 23%. <sup>118,119,120,121,122,123</sup> and <sup>124</sup> An example are the two most recent reports of single-agent phase II trials conducted in chemotherapy-naïve patients. Huber and associates from the M. D. Anderson Cancer Center reported a 26% response rate in 31 patients, <sup>121</sup> whereas the Hoosier Oncology Group reported only a 10% response rate in 21 patients <sup>124</sup> using similar regimens. As with most chemotherapy trials for head and neck cancer, response rates appear to correlate with extent of prior treatment, the antitumor activity is modest, and an advantage for very high doses has not been demonstrated.

The taxanes, paclitaxel and docetaxel, bind to the P subunit of tubulin, induce the formation of stable microtubule bundles, and inhibit microtubule depolymerization. *In vitro*, docetaxel is the more potent analogue. Docetaxel appears to be schedule independent, whereas paclitaxel appears to be more effective with prolonged exposure. <sup>150,151</sup>

Initial paclitaxel trials tested 24-hour infusion paclitaxel repeated every 3 weeks. Three phase II trials evaluating 250 mg/m<sup>2</sup> dose with granulocyte colony-stimulating factor (G-CSF) support in chemotherapy-naïve patients with recurrent or metastatic disease and excellent performance status [Eastern Cooperative Oncology Group (ECOG) 0 to 1] reported complete and partial response in 36% to 43% of patients. <sup>125,126</sup> and <sup>127</sup> The trial conducted by the ECOG observed a 9-month median survival time and 33% survival rate at 1 year, suggesting a highly active new agent. <sup>125</sup> The European Organization for Research and Treatment of Cancer (EORTC) Head and Neck Cancer Cooperative Group conducted a three-arm randomized phase II trial of single-agent methotrexate, 40 mg/m<sup>2</sup>/week with dose escalation up to 60 mg/m<sup>2</sup>; paclitaxel, 175 mg/m<sup>2</sup> by 3-hour infusion; and paclitaxel, 175 mg/m<sup>2</sup> by 24-hour infusion. <sup>128</sup> Dose escalation to 200 and 225 mg/m<sup>2</sup> was allowed for the two paclitaxel arms. Eligibility differed from other paclitaxel trials by the inclusion of patients with performance status 2. In contrast to the promising results reported by others, of the 123 evaluable randomized patients, complete and partial response rates were 9.5% for methotrexate, 12.5% for 3-hour infusion paclitaxel, and 19.5% for 24-hour infusion paclitaxel. Median progression-free survival was 2.0, 2.0, and 2.7 months, respectively, and the median survival ranged from 5.4 to 6.3 months. Serious toxic events such as febrile neutropenia, hypersensitivity reaction, or treatment-related death were observed in 34% of 24-hour infusion paclitaxel compared with less than 10% of patients in the other two treatment groups. The authors concluded that the 24-hour infusion schedule was too toxic for further study, and the antitumor activity of 3-hour infusion paclitaxel was no better than standard weekly methotrexate. One other trial tested paclitaxel, 175 mg/m<sup>2</sup> by 3-hour infusion, in 20 patients and reported a 20% response rate. <sup>129</sup>

The optimal infusion schedule for paclitaxel has not been established. It is known that at doses of 135 mg/m<sup>2</sup>, adequate plasma concentrations of paclitaxel can be achieved to induce polymerization of microtubules. Studies are in progress evaluating other infusion schedules: 1-hour weekly infusions in doses of 60 to 100 mg/m<sup>2</sup>, 3-hour infusions of doses ranging from 175 to 225 mg/m<sup>2</sup> every 3 weeks, and 96-hour infusions of 110 to 150 mg/m<sup>2</sup> every 3 weeks. Toxicities associated with paclitaxel that vary with the infusion schedule include myelosuppression (primarily leukopenia), sensory neuropathy, cardiac conduction disturbances causing bradycardia or arrhythmias, and anaphylaxis that requires premedication with corticosteroids. At present, only the 3-hour infusion schedule every 3 weeks can be recommended.

Phase II trials of docetaxel have been conducted in the United States and Europe. Response rates of 21%, <sup>130</sup> 31%,<sup>131</sup> and 42%<sup>132</sup> were reported in three small trials evaluating 100 mg/m<sup>2</sup> every 3 weeks. A 30% response rate was reported from a fourth study of 60 mg/m<sup>2</sup> every 3 weeks.<sup>133</sup> In addition to myelosuppression, the toxicity profile for docetaxel includes peripheral neuropathy, fluid retention, asthenia, and skin toxicity. Trials using 100 mg/m<sup>2</sup> have been limited to patients with excellent performance status. Lower doses (60 to 75 mg/m<sup>2</sup>) are better tolerated and recommended. As with paclitaxel, a weekly dosing schedule of 30 to 40 mg/m<sup>2</sup> is under investigation.

Three other relatively recent drugs with activity in lung cancer and other solid tumors are the semisynthetic vinca alkaloid vinorelbine, [134,135](#) and [136](#) the pyrimidine antimetabolite gemcitabine, [137](#) and the topoisomerase I inhibitor topotecan. [138,139](#) These drugs appear to have only marginal activity in head and neck cancer with response rates under 20%.

Drugs with an uncertain level of activity because they were studied in broad phase I and II trials before uniform response criteria were established include doxorubicin, cyclophosphamide, and hydroxyurea. Response rates of less than 10% have been reported from phase II trials of the plant alkaloids vinblastine and etoposide. [152,153](#)

## COMBINATION CHEMOTHERAPY

Over the last two decades numerous phase II trials of cisplatin-based regimens have been published and detailed in reviews. [111,112](#) and [113,140,141](#) Most contain small numbers of patients and often the results suggest greater efficacy than would be expected with single-agent cisplatin or methotrexate. In the early 1980s, researchers at Wayne State reported a response rate of 70% and a complete response rate of 27% using cisplatin, 100 mg/m<sup>2</sup> day 1, and 5-FU, 1000 mg/m<sup>2</sup>/d for 96 hours repeated every 3 weeks. [154](#) The compiled results of 12 trials including 365 patients with recurrent or metastatic squamous cell carcinoma show an average response rate of 50% and complete response rate of 16%. [155](#)

Three large multicenter trials reported by Jacobs et al., [156](#) Forastiere et al., [157](#) and Clavel et al. [158](#) compared cisplatin and infusional 5-FU to the single agents cisplatin, 5-FU, or methotrexate. The results of the three trials were remarkably similar. The response rate to cisplatin plus 5-FU was 32% in two of the trials and 31% in the third; all studies demonstrated a significantly higher response rate for cisplatin plus 5-FU compared with the single agents. However, there were no differences in median survival rates (5 to 6 months) or 1-year survival (20%) for any of the treatment arms. These response and survival results serve as the benchmark for comparison of regimens incorporating new agents.

Attempts to improve on the cisplatin plus 5-FU regimen include the addition of leucovorin, continuous infusion bleomycin, [159,160](#) and [161](#) bleomycin and methotrexate, [162](#) interleukin-2, [163](#) and interferon. [164](#) These three- and four-drug combinations result in enhanced toxicity without indications of survival benefit. More recently, two- and three-drug combinations incorporating paclitaxel or docetaxel have been reported in phase II trials.

[Table 30.2-7](#) and [Table 30.2-8](#) list the results of uncontrolled trials of combination chemotherapy regimens that include paclitaxel or docetaxel. Many consist of preliminary findings presented in abstract form at oncology meetings. Some studies include only patients with recurrent or metastatic disease undergoing palliative treatment, whereas others include varying proportions of patients with locally advanced, untreated disease who received two to four cycles before proceeding to radiotherapy, surgery, or both. Nearly all studies were limited to patients with good performance status who had not received prior chemotherapy for treatment of recurrent disease. All paclitaxel studies used the 3-hour infusion schedule and docetaxel was infused over 1 hour.

Author (Year)	Paclitaxel (mg/m <sup>2</sup> )	Combination Drug(s) (mg/m <sup>2</sup> )	Schedule	No. Evaluable Patients (Percent)	Response Rate (% Complete Response)

**TABLE 30.2-8.** Phase II Trials of Docetaxel Combination Regimens

Trials testing paclitaxel in combination with either cisplatin or carboplatin in recurrent and metastatic disease patients (see [Table 30.2-7](#)) demonstrate response in 32% to 39% of patients and complete response rates of less than 10%. [165,166,167](#) and [168](#) In contrast, a phase I and II trial of escalating doses of paclitaxel and cisplatin, 75 mg/m<sup>2</sup>, reported by Hitt and associates in locally advanced, untreated patients resulted in a 78% overall response rate and 46% clinical complete response rate. [169](#) Similarly, Dunphy and associates evaluated paclitaxel in doses of 150 to 265 mg/m<sup>2</sup> combined with carboplatin at area under the concentration-time curve (AUC) 7.5 in 33 locally advanced, untreated patients and observed a 54% overall response and 27% complete response rate. [170](#) The results were quite similar, adding paclitaxel to cisplatin and 5-FU: 38% in recurrent disease patients [171](#) and 81% in locally advanced, untreated patients evaluated for primary site response before definitive local therapy. [172](#)

Two successive trials adding ifosfamide to paclitaxel and either cisplatin or carboplatin (TIP or TIC regimens) have been reported by Shin and associates from the M. D. Anderson Cancer Center for the treatment of recurrent disease. [173,174](#) Both studies combined 175 mg/m<sup>2</sup> of paclitaxel and 1000 mg/m<sup>2</sup> of ifosfamide daily for 3 days with cisplatin, 60 mg/m<sup>2</sup>, or carboplatin, AUC 6, repeated at 3- to 4-week intervals. The overall response rate of 55% to 58% and complete response rates of 17% to 18% were encouraging.

Despite the low single-agent activity observed for gemcitabine in head and neck cancer, a 41% response rate was reported by Fountzilias et al. when it was combined with paclitaxel using a day 1 and 8 schedule every 3 weeks. [175](#)

While the amount of life-threatening toxicity varies with each particular regimen, the data do not suggest that taxane-based regimens are less toxic than older regimens. Myelosuppression and neuropathy are common, particularly with 3-hour infusion paclitaxel combined with cisplatin while the substitution of carboplatin has the potential to augment myelotoxicity. All of the combination regimens should be reserved for patients with good performance status, while patients with poor performance status should be considered for either single-agent chemotherapy or supportive care. The results of these phase I and II series suggest response rates that are similar to what is reported for cisplatin plus 5-FU and certainly no better, for either untreated patients or for patients with recurrent disease. The only exception is the response data from the TIP and TIC regimens [173,174](#) for patients with recurrent disease that needs to be evaluated further in a larger multiinstitutional trial setting. A randomized trial directly comparing cisplatin plus 5-FU as the standard regimen to paclitaxel plus cisplatin completed accrual in January 2000 in the

ECOG. This trial will provide important comparative data on response, duration of response, survival, toxicity, and cost.

Phase II trials of docetaxel in combination with other cytotoxic drugs are shown in Table 30.2-8. Similar to the studies in Table 30.2-7 for paclitaxel, many include patients with locally advanced untreated disease for which the overall response rates and complete response are proportionately higher. Only one trial was designed to test docetaxel and cisplatin specifically in patients with recurrent and metastatic disease.<sup>176</sup> A total of 33 patients were enrolled from Johns Hopkins, Vanderbilt, and M. D. Anderson, of whom 5 were previously untreated, presenting with far advanced locoregional disease or metastatic disease. The overall response rate was 52% including a 9% complete response. Toxicity was typical of docetaxel and cisplatin combination regimens with grade 3 to 4 neutropenia observed in 79% of patients, asthenia in 21%, and grade 3 peripheral neuropathy in 9%. Four other small phase II trials with previously untreated patients constituting one-half to all patients enrolled reported overall response in 46% to 73% of patients and complete response in 15% to 30%.<sup>177,178,179 and 180</sup>

In separate trials, docetaxel has been combined with 5-day infusional 5-FU<sup>181</sup> and with vinorelbine<sup>182</sup> with response outcomes similar to that achievable with cisplatin plus 5-FU.

Two studies have evaluated the three-drug combination of docetaxel, cisplatin, and 5-FU with or without G-CSF support primarily in patients with locally advanced inoperable disease before treatment with radiotherapy.<sup>183,184</sup> Each study enrolled under 30 patients and reported overall response of 75% and 80% after several cycles of chemotherapy. Whether or not this level of response is superior to cisplatin plus 5-FU in a comparable population of advanced head and neck cancer patients is unknown. The addition of docetaxel clearly leads to a substantial increase in life-threatening toxicities of neutropenia and infection. A large multicenter randomized trial is under way to address this question.

**RANDOMIZED TRIALS OF SINGLE AND COMBINATION CHEMOTHERAPY REGIMENS**

Randomized trials comparing combination regimens with either single-agent methotrexate or cisplatin are shown in Table 30.2-9.<sup>156,157 and 158,185,186,187,188,189,190,191 and 192</sup> Survival benefit was reported in three trials.<sup>188,191,193</sup> Morton et al. reported median survivals of 4.2 and 4.0 months for patients treated with cisplatin or cisplatin plus bleomycin, respectively, compared with a 2-month median survival for a no-treatment control group.<sup>188</sup> Campbell et al. reported a significant improvement in survival of patients treated with cisplatin (8.7 months) compared with those treated with methotrexate (2.7 months).<sup>191</sup> The Liverpool Head and Neck Oncology Group randomized 200 patients to receive cisplatin alone, methotrexate alone, cisplatin and infusional 5-FU, or cisplatin and methotrexate.<sup>193</sup> Although there were no differences in response rate, survival was significantly better in the three cisplatin-containing arms. In contrast, the three large multicenter trials reported by Jacobs et al.,<sup>156</sup> Forastiere et al.,<sup>157</sup> and Clavel et al.<sup>158</sup> comparing cisplatin plus 5-FU with single agents all showed a significantly increased response rate for combination chemotherapy but no benefit in median or 1-year survival rate. No other trials comparing combination regimens with single agents have been reported since 1994.

Author (Year)	Combination Regimen	Response Rate (%)	Median Survival (mo)
Jacobs (1986)	Cisplatin	53	4.2
Jacobs (1986)	Cisplatin + Bleomycin	53	4.0
Jacobs (1986)	Control	0	2.0
Forastiere (1987)	Cisplatin	53	4.2
Forastiere (1987)	Cisplatin + 5-FU	53	4.0
Forastiere (1987)	Methotrexate	27	2.7
Campbell (1988)	Cisplatin	53	8.7
Campbell (1988)	Methotrexate	27	2.7
Campbell (1988)	Control	0	2.0
Morton (1988)	Cisplatin	53	4.2
Morton (1988)	Cisplatin + Bleomycin	53	4.0
Morton (1988)	Control	0	2.0
Clavel (1988)	Cisplatin + 5-FU	53	4.2
Clavel (1988)	Cisplatin	53	4.0

**TABLE 30.2-9.** Phase III Trials of Combination Regimens versus Single-Agent Cisplatin or Methotrexate in Recurrent and Metastatic Squamous Cell Carcinoma of the Head and Neck

Randomized trials comparing combination regimens are shown in Table 30.2-10.<sup>161,194,195,196,197,198 and 199</sup> Kish et al. compared cisplatin plus infusional 5-FU versus cisplatin plus bolus 5-FU.<sup>194</sup> The response rate was significantly higher for infusional 5-FU, but median survivals were 6.7 and 5.0 months, respectively. Response rates were also significantly higher for the methotrexate plus bleomycin plus vincristine plus cisplatin regimen compared with methotrexate, bleomycin, and vincristine reported by Clavel et al.,<sup>195</sup> but survival was similar.

Author (Year)	Regimen	No. of Patients	Response (%)	Response Duration (mo)	Median Survival (mo)
Kish (1994)	IF (bolus)	30	30	—	5.0
Kish (1994)	IF (infusional)	30	70	—	6.7
Clavel (1995)	MBVP	75	20*	4.5	5.5
Clavel (1995)	MBVP + Cisplatin	75	52*	4.8	5.5
Brown (1996)	MB (bolus)	30	45	—	—
Brown (1996)	MB (infusional)	30	47	—	—
Neuwirth (1997)	IF	30	45	—	6.0
Neuwirth (1997)	IF + 5-FU	30	55	—	6.0
Forastiere (1998)	IF	45	45	5.5	—
Forastiere (1998)	IF + 5-FU	45	55	6.7*	5.8
Clavel (1998)	IF	30	45	—	6.5
Clavel (1998)	IF + 5-FU	30	55	—	6.5

**TABLE 30.2-10.** Phase III Trials Comparing Combination Regimens in Recurrent and Metastatic Squamous Cell Carcinoma of the Head and Neck

To gain perspective on the many trials that have been reported for palliation of patients with recurrent and metastatic squamous cell carcinoma of the head and neck, Browman and Cronin<sup>113</sup> performed a metaanalysis of randomized trials published between 1980 and 1992. Based on this pooled analysis of response and survival data, they concluded that single-agent cisplatin was more efficacious than single-agent methotrexate; the combination of cisplatin and 5-FU was more efficacious than treatment with single agents; and cisplatin and 5-FU was more efficacious than other combinations.

Since then, two additional randomized trials have been reported. The ECOG addressed the questions of dose response and antitumor activity of the combination of paclitaxel and cisplatin in patients with recurrent and metastatic squamous cell carcinoma.<sup>198</sup> A total of 210 patients were randomized to receive either high-dose paclitaxel (200 mg/m<sup>2</sup> over 24 hours) plus cisplatin, 75 mg/m<sup>2</sup>, plus G-CSF or low-dose paclitaxel (135 mg/m<sup>2</sup> over 24 hours) plus cisplatin, 75 mg/m<sup>2</sup>. No differences were observed in overall response rate, event-free survival, and median and 1-year survival rates. The response rate was 35% for patients in the high-dose paclitaxel arm and 36% for the low-dose paclitaxel group. The median survival of all patients was 7.3 months and 29% of patients were alive at 1 year, suggesting a possible small advantage over the cisplatin plus 5-FU regimen. Myelosuppression was the most frequently encountered toxicity, grade 3 to 4 neutropenia occurring in 70% of patients on the high-dose arm receiving G-CSF support and in 78% of patients on the low-dose arm. These results showed no advantage for the high-dose paclitaxel plus cisplatin regimen, and the toxicities associated with the 24-hour infusion schedule proved excessive for this patient population because of the prevalence of comorbid disease.

The other randomized trial was conducted by Head and Neck Interferon Cooperative Study Group and addressed the question of whether or not the activity of cisplatin and 5-FU could be modulated by interferon-α<sub>2b</sub> as shown in preclinical experiments.<sup>199</sup> A total of 244 patients with recurrent or metastatic disease were randomized to receive the standard cisplatin (100 mg/m<sup>2</sup>) and 5-FU (1000 mg/m<sup>2</sup>/d × 4) regimen with or without interferon, 3 million U subcutaneously, days 1 to 5 of

each chemotherapy cycle, repeated every 3 weeks. There was no significant difference in response or survival rates between treatment groups.

In summary, cisplatin-based combination chemotherapy is more effective than single agents. Response to cisplatin plus infusional 5-FU occurs in approximately one-third of patients, with complete response in 5% to 15%. An advantage for choosing combination chemotherapy seems to be limited to patients with excellent performance status, no prior chemotherapy for treatment of recurrent disease, and minimal tumor burden. Durable complete responses and prolonged survival are possible in this small subset of patients. Randomized trials directly comparing docetaxel and paclitaxel combination regimens with cisplatin plus 5-FU are in progress. However, it is unlikely that the addition of the taxanes to other conventional cytotoxics will produce substantial gains in survival, reduce toxicity, or otherwise improve patient quality of life. This underscores the need for new therapies to treat this population.

## BIOLOGIC TARGETED THERAPIES

An understanding of the molecular and cellular pathways involved in normal and unregulated cell growth is leading to the development of biologically targeted therapies. These novel agents in early clinical trials affect signal transduction, cell-cycle traversal, programmed cell death, transcription regulation, matrix invasion, and angiogenesis. Three targeted therapies in head and neck cancer clinical trials with promising preliminary results are the epidermal growth factor receptor (EGFr) antagonists, cyclin-dependent kinase (cdk) inhibitors, and replication competent adenoviruses.

The EGFr is a transmembrane glycoprotein that is a member of the tyrosine kinase growth factor receptor family encoded by *c-erb-B*. Activation of the protooncogene results in overexpression of the receptor, which has been demonstrated to occur in over 90% of squamous cell head and neck cancers. Transforming growth factor- $\alpha$ , EGF, and other growth factors bind to the extracellular domain of the EGFr-stimulating tumor growth through autocrine and paracrine pathways. <sup>200,201</sup> Agents that block ligand binding could inhibit cell proliferation. Several monoclonal antibodies against the EGFr are in clinical development. <sup>202,203</sup> and <sup>204</sup> The chimeric IgG antibody C225 developed by Mendelsohn has binding affinity that is equal to the natural ligand effectively blocking EGF/transforming growth factor- $\alpha$  binding when administered using a weekly intravenous dosing schedule. Enhanced cytotoxicity is observed in combination with a number of chemotherapeutic agents including cisplatin and paclitaxel, and in combination with radiotherapy. <sup>205</sup> The major toxicity is a follicular rash. Phase I and II trials of C225 with cisplatin are in progress in patients with recurrent disease and in combination with radiotherapy for patients with locally advanced disease. <sup>204,206</sup> The preliminary response rates suggest enhanced antitumor activity, which has prompted the initiation of multicenter double-blind placebo-controlled trials in patients with advanced disease.

Another novel compound in clinical trials that affects signal transduction is the cdk inhibitor flavopiridol. <sup>207,208</sup> Cdks phosphorylate key substances that regulate transition from one cell-cycle phase to the next. *In vitro*, inhibitors of cdks 1, 2, and 4 block cell-cycle progression at G<sub>1</sub>/S and G<sub>2</sub>/M boundaries. In preclinical testing, flavopiridol induces cell-cycle arrest and p53-independent apoptosis. Flavopiridol is a particularly suitable candidate drug for study in tumors in which cyclin D is overexpressed or in which p16, the endogenous inhibitor of cdk4, is deleted. <sup>209</sup> The most commonly deleted chromosomal region in head and neck cancer is 9p21-22, the locus of p16, and p16 is commonly absent. A phase I trial has been completed by investigators at the National Cancer Institutes, and a phase II trial in head and neck cancer is under way. <sup>210</sup>

A third area of promising clinical research for head and neck cancers involves replication competent viruses. Mutant adenoviruses have been developed that selectively replicate in and cause lysis of cells deficient in p53-suppressor activity. <sup>211</sup> This takes advantage of the high rate (approximately 45%) of p53 mutations in squamous head and neck cancers. Phase I and II clinical studies of intralesional injection of the E1B-deleted adenovirus ONYX-015 have shown tumor cell necrosis and improvement in tumor-related symptoms. <sup>212</sup> There appears to be enhanced antitumor efficacy in studies of systemic chemotherapy combined with ONYX-015 and perhaps more durable responses at the injected tumor sites. <sup>213,214</sup> The status of other novel investigational bioresponse modifiers and gene therapies directly administered to local or regional tumor is discussed in reviews. <sup>215</sup>

## PRINCIPLES OF CHEMOTHERAPY: PREVIOUSLY UNTREATED DISEASE

### INDUCTION CHEMOTHERAPY

Initial trials of cisplatin-based combination chemotherapy given to newly diagnosed patients before receiving local therapies showed dramatic tumor reduction in 70% to 80% of patients. This observation suggested that sequencing therapies so that chemotherapy was administered before the tumor vasculature was disrupted might improve locoregional control and affect survival. Now, more than two decades since the first randomized trial evaluated induction cisplatin and bleomycin before surgery, <sup>216</sup> we can conclude from many such trials that the induction strategy confers no survival advantage. A role in preservation of the larynx for patients with locally advanced cancers of the larynx or hypopharynx who would otherwise undergo total laryngectomy has emerged and is discussed in [Chapter 30.3](#). Down-staging of the primary and regional node disease with three cycles of cisplatin plus 5-FU chemotherapy has successfully allowed for larynx preservation and a reduction in the rate of development of distant metastases. <sup>217,218</sup>

### NONRANDOMIZED TRIALS OF INDUCTION CHEMOTHERAPY

In the early 1980s, Wayne State University investigators reported high response rates with the regimen cisplatin and infusional 5-FU <sup>219,220</sup> administered before local treatment. They achieved a response rate of 88% (complete response 19%) <sup>219</sup> with two courses and 93% (complete response 54%) with three courses of the same regimen. <sup>220</sup> Over the past two decades, thousands of patients have received this regimen (cisplatin, 100 to 120 mg/m<sup>2</sup> day 1, and 5-FU, 1000 mg/m<sup>2</sup>/d infused over 96 to 120 hours) in clinical research trials and in community practice. Response occurs in 85% of patients, on average, with complete response in approximately 40%. Two-thirds of clinical complete responses are pathologically confirmed in biopsy or resection specimens. Response varies by site, with the larynx and nasopharynx being most responsive and the oral cavity less responsive. Cisplatin and infusional 5-FU remains the most active regimen in previously untreated patients. <sup>221,222</sup>

Modifications of this regimen to increase the complete response rate have been tested. <sup>223,224,225,226,227,228,229</sup> and <sup>230</sup> This includes trials of cisplatin, 5-FU, and leucovorin, <sup>223,224</sup> and <sup>225</sup> demonstrating overall and complete response rates ranging from 59% to 95% and 24% to 65%, respectively. The initial reports by Vokes et al., <sup>223</sup> using oral leucovorin, and Dreyfuss et al., <sup>224</sup> using continuous infusion leucovorin appeared promising; however, long-term follow-up did not demonstrate any striking improvement in survival over cisplatin plus 5-FU. Severe myelosuppression, diarrhea, and mucositis occurred frequently, necessitating dose reductions in most patients.

Cisplatin-based combination regimens that include paclitaxel or docetaxel are being tested in patients with locally advanced, unresectable disease before receiving radiotherapy. The preliminary results of those small phase II studies are listed in [Table 30.2-7](#) and [Table 30.2-8](#). <sup>169,170,172,177,178</sup> and <sup>179,184</sup> Colevas and associates from the Dana Farber Cancer Institute have published the results of an intensive induction regimen containing docetaxel for patients with stage III or IV squamous cell carcinoma receiving nonsurgical management. <sup>226,227</sup> In a phase I and II trial, the maximum tolerated dose of docetaxel in combination with cisplatin (25 mg/m<sup>2</sup> days 1 to 5), 5-FU (700 mg/m<sup>2</sup> days 2 to 5) and leucovorin was 60 mg/m<sup>2</sup>. <sup>226</sup> This regimen required postchemotherapy home infusion of fluids, antibiotics, and G-CSF. In 23 patients, a response rate of 100%, including 61% complete response, was documented after three cycles of chemotherapy. Frequently occurring severe toxicities in addition to myelosuppression included nausea, mucositis, diarrhea, peripheral neuropathy, and sodium-wasting nephropathy. This regimen is of interest because of the remarkably high response rate, but the toxicity is prohibitive for general use. A regimen with more manageable toxicity is being evaluated in a multicenter trial. <sup>228</sup> The preliminary results of docetaxel, 75 mg/m<sup>2</sup>, plus cisplatin, 75 mg/m<sup>2</sup> (group A) or cisplatin, 100 mg/m<sup>2</sup> (group B) on day 1, plus 5-FU, 1000 mg/m<sup>2</sup>/d, days 1 to 4, were reported by Posner. The response rate for 13 patients in group A was 84%, 23% complete and 61% partial; while all 17 patients in group B responded (47% complete and 53% partial responses). Based on this experience, a phase III trial of taxotere, cisplatin, and 5-FU versus cisplatin plus 5-FU is being initiated.

### RANDOMIZED TRIALS OF INDUCTION CHEMOTHERAPY

Many randomized trials have been conducted to determine if the addition of chemotherapy improves survival, and these are detailed in several reviews. <sup>221,231,232</sup> and <sup>233</sup> A listing of 14 randomized trials published since 1990 are shown in [Table 30.2-11](#). <sup>234,235,236,237,238,239,240,241,242,243,244,245</sup> and <sup>246</sup> These trials compared induction chemotherapy followed by definitive local therapy, as dictated by initial resectability status, versus immediate surgery, radiotherapy, or both. Improved survival through a decrease in local and regional failure and distant metastatic rates was the primary goal. Studies designed in the latter half of the 1980s up to 2000 (not included in [Table 30.2-7](#)) have focused on organ preservation specifically for primaries in the larynx and hypopharynx. <sup>217,218</sup> The results of these randomized trials are consistent and fail to demonstrate a survival advantage with the addition of induction chemotherapy.

Author (Reference)	Year	No. of Patients	Chemotherapy	Overall Survival

**TABLE 30.2-11.** Recent Randomized Trials of Induction Chemotherapy followed by Locoregional Treatment versus Locoregional Treatment Alone

Although many trials have been criticized for methodologic flaws, five used full doses of cisplatin and 5-FU for three to five courses and had adequate power to reach statistical conclusions.<sup>234,241,243,244</sup> and <sup>245</sup> Only one of these trials found a significant improvement in survival for chemotherapy-treated patients and that was limited to a subset with unresectable disease.<sup>245</sup> Several studies, however, have found a significant reduction in distant metastases,<sup>216,242,243</sup> but in the absence of improvement in locoregional control this has failed to affect survival. It is noteworthy that both distant metastases and locoregional failure were reduced in the inoperable subset of patients achieving a survival advantage reported by Paccagnella et al.<sup>243</sup>

The following conclusions can be drawn from two decades of experience with induction chemotherapy:

- Induction chemotherapy results in major response rates in 60% to 90% and complete response in 20% to 50% of patients with locally advanced squamous cell carcinoma of the head and neck.
- Pathologic complete response is documented in approximately two-thirds of complete responders determined by clinical assessment, and these patients appear to have a survival advantage.
- Response to induction chemotherapy is predictive of response to subsequent radiotherapy.
- There is no increase in morbidity from surgery or radiotherapy in patients who have received induction chemotherapy.
- Although cancers from all head and neck sites are lumped together in almost all the studies, there is evidence that biologic behavior differs with primary site.
- No significant difference in overall survival has been demonstrated with the use of induction chemotherapy compared with surgery or radiation alone.
- Organ preservation and improved quality of life can result from induction chemotherapy (see [Chapter 30.3](#)).

## POSTOPERATIVE ADJUVANT TREATMENT

### ADJUVANT CHEMOTHERAPY

Chemotherapy administered after a patient has been rendered disease free with surgery, radiation, or both has been evaluated in three large multicenter randomized trials.<sup>247,248</sup> and <sup>249</sup> The rationale for this approach was threefold. First, definitive surgery is not delayed. Second, tumor margins may become blurred after response to induction chemotherapy, leaving the extent of required surgery uncertain. Third, up to 20% of patients receiving induction chemotherapy refused surgery once response was achieved and their symptoms abated.

The sequence of surgery followed by adjuvant chemotherapy and then radiation was a strategy developed to avoid these potential disadvantages of induction chemotherapy. The Head and Neck Intergroup tested this strategy using three cycles of cisplatin and infusional 5-FU as adjuvant chemotherapy.<sup>247</sup> From 1985 to 1990, 499 patients with stage III and IV resected squamous cell carcinoma of the oral cavity, oropharynx, hypopharynx, and larynx were stratified into high- and low-risk groups; high-risk was defined as close surgical margins less than 5 mm, cancer *in situ* at margins, or extracapsular nodal extension. Randomization was to immediate radiation or adjuvant chemotherapy followed by radiation. Although the overall comparison of the two treatments showed no significant differences in survival, disease-free survival, or time to locoregional failure, an analysis of treatment effect on high-risk patients suggested benefit. Improved survival and decreased locoregional failure that approached statistical significance was observed for the high-risk subset of patients who received adjuvant chemotherapy compared with those receiving radiation alone. No benefit for adjuvant chemotherapy could be detected for the low-risk patients. Had this trial been limited to high-risk patients, a significant positive outcome may have resulted.

The RTOG<sup>250</sup> retrospectively analyzed survival and locoregional failure rates in three patient cohorts enrolled in RTOG clinical trials: those considered low risk, those at intermediate risk because of two or more involved regional lymph nodes or extracapsular extension of tumor, and those at highest risk because of a positive surgical margin with or without other risk factors. At 3 years, the locoregional recurrence rate was 14% for the low-risk group, 27% for those at intermediate risk, and 49% for the highest risk group. Median survival rates were 5.6 years, 2.6 years, and 1.5 years, respectively, for the three groups.

Two other large randomized trials have been performed by head and neck cancer study groups in Japan and France.<sup>248,249</sup> Japanese investigators evaluated a combination of tegafur and uracil known as *UFT*, 300 mg/d, for 1 year.<sup>248</sup> Three groups of patients were randomized to observation or adjuvant UFT: 424 patients with stage II to IV cancers treated surgically, 111 patients with stage II disease treated with definitive radiotherapy, and 25 patients with nasopharyngeal cancer treated with radiotherapy. Three-year survival results of surgically treated patients showed no significant difference in survival or relapse-free survival, but adjuvant UFT patients had a significantly lower rate of distant metastases (7.9% vs. 14.6%,  $P = .034$ ). No benefit could be shown in the patients treated with primary radiotherapy.

Reported only in preliminary abstract form, French investigators randomized 287 patients with extracapsular nodal extension to receive postoperative radiation alone or adjuvant cisplatin, bleomycin, and methotrexate after completion of RT.<sup>249</sup> Chemotherapy-treated patients had significantly worse overall survival and an increased rate of distant metastases, but better local regional control.

Several randomized trials that use both induction and adjuvant chemotherapy have been conducted in an attempt to further intensify therapy.<sup>216,251,252</sup> The Head and Neck Contracts Program, a three-arm trial, compared surgery and postoperative radiation to neoadjuvant cisplatin and bleomycin and to treatment with induction chemotherapy plus adjuvant cisplatin for 6 months after surgery and radiation.<sup>216</sup> No differences in overall survival were observed, but a significant decrease in distant metastases was reported for the adjuvant group.

Ervin et al. treated 114 patients with neoadjuvant cisplatin, bleomycin, methotrexate, and leucovorin.<sup>251</sup> After definitive local treatment, patients were randomized to observation or three cycles of adjuvant chemotherapy. The 3-year disease-free survival rates were 55% and 88%, respectively; partial responders to induction chemotherapy showed the greatest benefit. The Southwest Oncology Group conducted a feasibility trial of postoperative radiotherapy and three cycles of concurrent cisplatin followed by three cycles of adjuvant cisplatin plus 5-FU. Compliance was poor, with only 37% of 72 patients completing all six chemotherapy cycles.<sup>252</sup>

In summary, there is no role for adjuvant chemotherapy in low-risk patients (negative margins of resection, neck disease staged N0 or N1 without extracapsular extension). Patients with positive or close margins of resection, two or more involved regional nodes, or extracapsular extension of disease are at increased risk for both locoregional recurrence and distant metastases. It now seems clear from several studies that at least the rate of development of distant metastases can be reduced with systemic chemotherapy, but an effect on overall survival has not been shown perhaps because of the lack of large enough randomized trials enrolling only high-risk patients.

### ADJUVANT CHEMORADIOTHERAPY

Improvement in locoregional control through the use of concomitant chemotherapy and radiotherapy may be most feasible in the patient with locally advanced but *resectable* disease. Locoregional recurrence is the most frequent site of failure after surgery and postoperative radiation. Extracapsular extension of tumor in cervical

node metastases is well established as an adverse prognostic factor for recurrence. [253,254](#) and [255](#)

The rationale and potential role of chemotherapy to enhance radiation effects is well known and the clinical experience in head and neck cancer is extensive. [256,257,258](#) and [259](#) Before 1999, this experience was almost exclusively limited to patients with bulky unresectable disease. The RTOG conducted a small feasibility study treating 51 patients with resected stage IV disease, positive margins, or both, with postoperative RT and concurrent cisplatin, 100 mg/m<sup>2</sup> every 3 weeks for three cycles. [260](#) Locoregional control was significantly better compared with matched historic controls. This pilot trial and the positive results of a randomized trial by Bachaud et al. [261](#) led to a Head and Neck Intergroup Phase III trial now in progress. Resected patients with positive margins, metastases to multiple regional nodes, and the presence of extracapsular spread of disease are randomized to receive postoperative RT with or without concurrent cisplatin (100 mg/m<sup>2</sup> days 1, 22, and 43).

Four randomized trials of postoperative chemoradiation have been published. [261,262,263](#) and [264](#) Bachaud et al. randomized 88 patients with extracapsular spread of disease in regional neck node metastases to receive postoperative RT alone or postoperative RT plus cisplatin, 50 mg intravenously weekly. [261](#) After a minimum follow-up of 5 years, the median survival (22 months vs. 40 months) and 5-year survival (13% vs. 36%) were significantly better for the chemoradiotherapy group. Radiation-treated patients had a higher locoregional failure rate compared with the chemoradiotherapy group, while no differences were observed in the incidence of distant metastases. Randomized trials reported by Weissberg et al. [262](#) and Haffty et al. [263](#) evaluated mitomycin C and postoperative RT versus RT alone. Both investigators reported improvement in locoregional control but not survival. A third small trial conducted by Weissler et al. found no benefit for cisplatin and 5-FU plus RT compared with RT alone. [264](#) These last three trials were not targeted to high-risk patients but included all resected patients with stage III and IV disease.

All postoperative chemoradiotherapy studies reported increased acute toxicity, primarily mucositis, and weight loss with combined therapy. Careful monitoring of patients receiving combined chemoradiotherapy along with psychosocial and nutritional support is essential for these therapies to be successful and to have a high level of patient compliance. Completion of the current Head and Neck Intergroup Trial is crucial to confirm the improved survival reported by Bachaud and to change standard of care.

## CONCURRENT CHEMORADIOTHERAPY

The purpose of administering chemotherapy and radiotherapy together is to take advantage of the radiosensitizing capability of many of the active drugs for this disease and effect a substantial enough increase in locoregional control to significantly improve survival. The postulated mechanisms for enhanced cell kill with concurrent chemoradiation strategies have been described for decades and include interference with repair processes after sublethal or potentially lethal damage or with tumor cell synchronization. [257,258](#) In addition, administering both modalities together may prevent or decrease the emergence of radioresistant or drug-resistant clonogens.

## RESULTS FROM METAANALYSES

Since 1992, four metaanalyses evaluating the effect of chemotherapy on survival from randomized trials of induction, adjuvant, and concurrent chemotherapy compared with definitive local therapy alone have been published. [265,266,267](#) and [268](#) These analyses covered the period of publication up to 1993; three were literature based, [265,266](#) and [267](#) while the largest and most comprehensive used updated individual patient data from 63 trials including 10,741 patients. [268](#) The results of all four analyses were consistent in finding a small survival benefit favoring chemotherapy: 2.8%, [265](#) 4.0%, [267](#) 4.0%, [268](#) and 6.5%. [266](#) The reduction in risk of death was statistically significant in three of the metaanalyses. [266,267](#) and [268](#) The survival benefit observed in all of the studies was associated primarily with the patient group receiving concurrent chemoradiation. In the Meta-Analysis of Chemotherapy in Head and Neck Cancer (MACH-NC) analysis based on individual patient data, the absolute survival benefit at 5 years from chemoradiation was 8%. [268](#) It should be emphasized that the most impressive gains in locoregional control, disease-free survival, and overall survival have been reported since 1995 in large, multicenter randomized trials employing cisplatin-based chemotherapy and concurrent radiotherapy, either standard or altered fractionation.

## SINGLE-AGENT CHEMOTHERAPY AND RADIOOTHERAPY

Many randomized trials have been published combining the single agents hydroxyurea, methotrexate, bleomycin, 5-FU, mitomycin-C, and cisplatin with radiotherapy compared with radiotherapy alone. These older trials were limited to patients with extensive, locally advanced disease not considered resectable. The results of selected trials with adequate power to demonstrate outcome differences are shown in [Table 30.2-12](#). [269,270,271,272,273,274,275,276,277,278,279](#) and [280](#) Gupta and associates at the Christie Hospital and Holt Radium Institute in Manchester randomized over 300 patients to concurrent methotrexate or radiotherapy alone. [270](#) There was a highly significant improvement in local control ( $P = .0019$ ) and survival ( $P = .0089$ ) for patients with oropharyngeal cancers in the methotrexate arm, while survival benefit did not reach statistical significance ( $P = .075$ ) in the overall analysis.

Author (Ref)	No. of Patients	Chemotherapy	Significance Benefit			
			Complete Response	Local Control	Progression-Free Survival	Survival
Shanta (270)	138	MTX		Yes	Yes	Yes
Gupta (270)	303	MTX	Yes	Yes	Yes	Yes
Wang (271)	136	Bleomycin	Yes	Yes	Yes	Yes
Wang (271)	136	Bleomycin	Yes	Yes	Yes	Yes
Fu (272)	144	Bleomycin	Yes	Yes	Yes	Yes

Arborelius (277)	147	Cisplatin	Yes	Yes	Yes	Yes

Abb. Mitomycin, 5-FU, 5-fluorouracil; MTX, methotrexate; MFC, mitomycin C; MFC, methotrexate.  
 Significant benefit for all parameters: Yes/Yes/Yes/Yes.  
 Significant benefit for at least one parameter: Yes/Yes/Yes/No, Yes/Yes/No/Yes, Yes/No/Yes/Yes, Yes/No/No/Yes, Yes/Yes/No/No, Yes/No/No/No.  
 No significant benefit: No/No/No/No, No/No/Yes/No, No/Yes/Yes/No, No/Yes/No/No, No/No/Yes/No, No/No/No/No.

**TABLE 30.2-12.** Selected Randomized Trials of Concurrent Single-Agent Chemotherapy and Radiotherapy versus Radiotherapy Alone

The results of four trials with bleomycin and radiotherapy are conflicting. [271,272,273](#) and [274](#) Only the trial reported by Shanta and Krishnamurthi in patients with T3 to T4, N0 to N2 squamous cell carcinoma of the buccal mucosa showed a significant beneficial effect of bleomycin on local control, disease-free survival, and overall survival. [271](#) Local control and progression-free survival were improved in the Northern California Oncology Group trial reported by Fu et al., [273](#) while large trials from the EORTC [274](#) and the Norwegian Radium Hospital [272](#) did not observe benefit for any outcome parameter.

Many studies have used 5-FU with concurrent RT. In the study by Lo and associates, local control and 5-year survival were superior in the combined treatment group, but only in patients with oral cavity cancers was the difference significant. [275](#) Browman and associates of the National Cancer Institute Canada evaluated infusional 5-FU and radiotherapy. [276](#) The complete response rate was significantly better with combined treatment, but only a trend for improved progression-free and overall survival was observed. Investigators in Barcelona randomized 859 patients with T3 to T4, N0 to N3 cancers to three treatment groups: radiotherapy, 60 Gy in 30 fractions; radiotherapy, 70.4 Gy in 64 fractions; or radiotherapy, 60 Gy in 30 fractions, plus concurrent 5-FU, 250 mg/m<sup>2</sup> every 2 days. [277](#) The complete response rate and survival were significantly better for the 5-FU-treated group compared with the control group receiving 60-Gy radiotherapy alone, but there was no difference when compared with patients receiving 70.4-Gy radiotherapy. Mitomycin C has been shown in trials conducted at Yale to improve progression-free survival but not overall survival. [278](#)

Cisplatin has been combined with RT because mucositis is not a primary toxicity and experimental data support its effectiveness as a radiosensitizer. [259](#) As a single agent, cisplatin has been administered using two schedules in head and neck cancer: weekly low doses (20 mg/m<sup>2</sup>) or intermittent high doses (100 mg/m<sup>2</sup> every 3 weeks) concomitant with RT. The results of an intergroup randomized trial comparing low-dose weekly cisplatin (20 mg/m<sup>2</sup>) during radiation with conventional radiation were reported by Haselow et al. [279](#) The overall response rate was significantly higher for the cisplatin-treated patients (73% vs. 59%,  $P = .007$ ), but there was no difference in complete response rate (34% vs. 30%) or survival. The lack of benefit may be attributable to the low total dose of cisplatin received (120 to 140 mg/m<sup>2</sup>) over the 6 to 8 weeks of radiotherapy. The higher dose of cisplatin (100 mg/m<sup>2</sup> every 3 weeks) during radiotherapy resulted in significant survival benefit for

.02) at 3 years for patients with stage III and IV oropharyngeal cancer. In addition, it is noteworthy that most of patients included in the other positive trials had oropharyngeal primaries. Adelstein et al. using cisplatin and 5-FU on days 1 and 22 of radiotherapy, 66 to 72 Gy, in patients with resectable cancers reported a complete response rate at the primary site in 90% with chemoradiotherapy compared with 66% ( $P = .03$ ) after radiotherapy alone.<sup>301,302</sup> Recurrence-free interval, local control, and survival with primary site preservation were all significantly better with chemoradiotherapy although overall survival, including salvage surgery for primary site failure, was equivalent in the two treatment groups. What has not been adequately addressed in any trials in patients with resectable disease is speech and swallowing *function*. Preservation of the organ does not equate with preservation of function. Intensive chemoradiotherapy regimens may result in late toxic effects of soft tissue fibrosis that leave patients unable to swallow and thus dependent on gastrostomy tubes. The outcomes of function and quality of life need to be addressed in future trials in addition to survival and local control.<sup>308</sup>

In contrast to the favorable results of chemoradiotherapy achieved with oropharyngeal cancers, oral cavity primaries continue to be managed by a surgical approach. Resection produces less relative organ dysfunction, and these cancers appear somewhat less responsive to cytotoxic therapy. Site-specific trials have not been performed.

The positive results in unresectable patients in five trials<sup>300,304,305,306</sup> and<sup>307</sup> support the use of chemoradiotherapy as the standard of care provided that patients have adequate performance status and psychosocial supports to undergo this more toxic and complex treatment.<sup>308</sup> The large German trial reported by Wendt and associates<sup>306</sup> combining cisplatin, 5-FU, leucovorin, and twice a day radiotherapy compared with the same radiotherapy alone showed significant improvements in locoregional control (36% vs. 17%,  $P < .004$ ) and survival at 3 years (48% vs. 24%,  $P < .0003$ ).

The preliminary results of a three-arm intergroup trial, E1392, show significant survival benefit for cisplatin, 100 mg/m<sup>2</sup> on days 1, 22, and 34, during radiotherapy compared with radiotherapy alone in patients with advanced unresectable disease.<sup>305</sup> This trial compared the cisplatin and radiotherapy regimen previously tested in the RTOG<sup>309</sup> and the regimen of cisplatin and 5-FU and split-course radiotherapy tested by Adelstein in the ECOG<sup>310</sup> with standard radiotherapy alone. A total of 295 patients were randomized, and the two investigational therapies were separately compared with the control arm. At a median follow-up of 25 months, there is a significant difference in 2- and 3-year projected survivals for patients in the cisplatin and radiotherapy arm compared with radiotherapy alone, but not for the cisplatin and 5-FU split-course radiotherapy arm. Median survivals were 12.6 months, 19.1 months, and 14 months, respectively, for RT, RT plus cisplatin, and RT plus cisplatin and 5-FU.<sup>304</sup>

In a smaller trial of mitomycin C combined with bleomycin and 66- to 70-Gy radiotherapy compared with the same radiotherapy was reported by Zakotnik and associates.<sup>300</sup> A total of 64 patients with inoperable carcinoma, the majority from oropharyngeal sites, were randomized. The study was closed early because of a significant benefit in complete response (75% vs. 29%,  $P = .007$ ), disease-free survival at median follow-up of 42 months (48% vs. 10%,  $P = .001$ ), and overall survival (38% vs. 10%,  $P = .019$ ) observed for patients with unresectable oropharyngeal cancer in the combined treatment group.

What is apparent in all of these trials is the substantial and significant improvement in local regional control that is of a magnitude (20 to 30 percentage points on average) sufficiently large to affect survival.<sup>308</sup> This is in contrast to the modest increase in local regional control observed in the RTOG radiotherapy trial comparing altered fractionation with concomitant boost or hyperfractionation with standard radiotherapy in over 1200 patients.<sup>311</sup> Local regional control increased from 45% with standard fractionation to 54% with altered fractionation and concomitant boost, but survival was not affected.

Of the various regimens tested in these positive trials, cisplatin, 100 mg/m<sup>2</sup>, administered with vigorous hydration and diuretics on days 1, 22, and 43 of standard fractionation radiotherapy (70 Gy) would be a reasonable recommendation for treating unresectable patients. Grade 3 or worse toxicities, particularly mucocutaneous toxicity, can be expected in approximately 75% of patients and thus aggressive support is required with analgesics, oral care, and gastrostomy tube for nutritional support. Patients with poor performance status, complicating comorbid disease, or who lack the psychosocial resources to undergo these complex therapies should be managed with radiotherapy alone.

## PRINCIPLES OF CHEMOPREVENTION

Patients at increased risk for developing upper aerodigestive tract cancer may be identified by a history of previous head and neck cancer or exposure to risk factors such as alcohol and tobacco. Because alcohol and tobacco are avoidable risks, there has been considerable interest in developing effective prevention strategies for these patients. One approach currently being tested is chemoprevention, which is the administration of natural or synthetic agents to reverse or suppress carcinogenesis before the development of an invasive cancer. Chemoprevention trials in the upper aerodigestive tract, guided by epidemiologic studies, have often evaluated dietary constituents, such as b-carotene and retinol. The retinoids, natural and synthetic analogues of vitamin A, have been studied extensively as chemopreventive agents. Retinoids can modulate the growth and differentiation of normal, premalignant, and malignant epithelial cells in culture and can suppress carcinogenesis *in vivo* in various human epithelial tissues.<sup>312,313</sup> and<sup>314</sup>

Aerodigestive tract epithelial carcinogenesis is an extremely complex, multistep process. The process begins with genetic alterations and proceeds to altered expression of regulatory gene products and dysregulated tissue growth or proliferation and dysregulated differentiation. Gross histologic and clinical markers of this process are observable but not until late in the process. Molecular techniques have revealed specific genetic alterations in the process of epithelial carcinogenesis in which losses of genes on chromosomes 3p, 9p, 11q, 13q, and 17p are common.<sup>315,316</sup> This step-wise process is an accumulation of genetic events that may be reversed or suppressed at any of various points. Advances in the biology of carcinogenesis are leading to the development of reliable intermediate biomarkers that can be quantitatively measured to assess modulation by chemopreventive agents.<sup>317</sup>

## CHEMOPREVENTION OF ORAL PREMALIGNANCY

The first chemoprevention studies in oral premalignancy began in the mid-1950s and used high doses of topical and systemic natural vitamin A derivatives.<sup>318,319</sup> and<sup>320</sup> These early studies reported clinical and histologic activity and response, relapse, and toxicity patterns that are still relevant currently for the reversal of oral leukoplakia. Agents that have been studied in oral premalignancy chemoprevention trials include selenium, a-tocopherol, b-carotene, and six retinoids.<sup>317,321,322,323,324,325,326,327</sup> and<sup>328</sup> To date, five randomized trials in oral leukoplakia have been reported.<sup>322,323,324,325</sup> and<sup>326</sup>

Hong et al. reported the first randomized study in 1986 in which 44 patients were entered into a 3-month placebo-controlled trial of 13- *cis* retinoic acid (isotretinoin), 2 mg/m<sup>2</sup>/d.<sup>322</sup> Differences observed in clinical response rate (67% vs. 10%,  $P = .0002$ ) and histopathologic reversal of dysplasia (54% vs. 10%,  $P = .01$ ) were highly significant between treated and placebo patients, respectively. Toxicity, however, was unacceptable in those patients receiving 2 mg/kg. Cheilitis, facial erythema, and skin dryness and peeling occurred in 88% and conjunctivitis in 76% of patients. Although reversal of the leukoplakic lesions was demonstrated, a relapse rate of higher than 50% occurred within 3 months of stopping the drug.

Hong and coworkers designed a second study to prolong remission with less toxic maintenance therapy. After a 3-month induction phase with high-dose 13- *cis* retinoic acid (1.5 mg/kg/d), responding or stable patients were randomized to a 9-month maintenance program with low-dose 13- *cis* retinoic acid (0.5 mg/kg/d) or b-carotene (30 mg/d).<sup>323</sup> Low-dose 13-*cis* retinoic acid was significantly more effective than b-carotene in maintaining clinicopathologic remission. Only 8% of patients in the 13-*cis* retinoic acid group had progression of their leukoplakia during maintenance, compared with 55% in the b-carotene group ( $P < .001$ ). In addition, the low-dose 13-*cis* retinoic acid regimen was well tolerated, causing only mild and reversible toxicities. The long-term results of this study at a median follow-up of 66 months showed that 17 of 70 patients (24%) developed cancer with an annual rate of 5.8%.<sup>329</sup> The rate of development of cancer in the two treatment groups was not different, 23% for 13-*cis* retinoic acid and 27% for b-carotene.

Four other randomized trials also demonstrated positive results. Stich et al. observed significant activity with natural vitamin A in Asian patients with leukoplakia chewing betel nuts and enrolled in a 6-month placebo-controlled trial: 57.1% complete remission with vitamin A versus 30% for controls ( $P < .01$ ).<sup>330</sup> Benefit was also seen in a second trial from this group comparing b-carotene plus retinol with placebo.<sup>330</sup> Han et al. also noted positive results with a synthetic Retinamide taken for 4 months in a placebo-controlled trial for oral leukoplakia.<sup>325</sup> The most recently completed trial is a randomized maintenance study of the retinoid fenretinide after laser resection of oral premalignant lesions.<sup>326</sup> After 12 months of fenretinide, the relapse rate in 39 treated patients was 8% compared with 29% in 41 control patients. These results are similar to that observed with low-dose 13- *cis* retinoic acid maintenance therapy.

Current research efforts are focusing on the biochemoprevention therapies such as the combination of high-dose 13- *cis* retinoic acid, a-tocopherol, and interferon- $\alpha$  for the treatment of patients with advanced premalignant lesions defined as moderate to severe dysplasia.<sup>331,332</sup> and<sup>333</sup> A striking difference in response was noted in

favor of laryngeal lesions as compared with oral lesions, suggesting that this may be a promising approach for laryngeal dysplasia.

### Chemoprevention of Second Primary Tumors

Regardless of their initial treatment, head and neck cancer patients remain at significantly increased risk for second primary tumor (SPT) development. SPTs occur after treatment for all stages of head and neck cancer, but their effect is most striking in patients treated for early disease.<sup>317,334</sup> SPTs, either synchronous or metachronous, develop conservatively at a constant yearly rate of 2% to 5% in previously treated patients. The long-term risk of developing additional aerodigestive tract malignancies is 10% to 40%.

Investigators at the M. D. Anderson Cancer Center evaluated the role of *cis*-retinoic acid in preventing SPTs.<sup>335,336</sup> Following surgery, radiotherapy, or both, 103 patients with stage I through IV (M0) squamous cell carcinoma of the head and neck were randomized in a double-blind fashion to receive 13- *cis* retinoic acid (100 mg/m<sup>2</sup>/d) or placebo for 12 months. After a median follow-up of 32 months, there was a significant difference in the development of SPTs (24% vs. 4%, *P* = .005), respectively, for placebo and treated patients.<sup>335</sup> At a median follow-up of 55 months, the retinoid-treated patients continued to have fewer SPTs, within the upper aerodigestive tract (7% vs. 33%, *P* = .008), although the difference in incidence for all SPTs had diminished (14% vs. 31%, *P* = .004).<sup>336</sup> Although these results are impressive, no survival advantage was seen. This may be due to the small sample size and the nature of the study population: One-half of patients had advanced disease.

Bolla and colleagues evaluated etretinate in a placebo-controlled trial to prevent SPTs in patients with squamous cell carcinoma of the oral cavity or oropharynx following local therapy.<sup>337</sup> After a median follow-up of 41 months, the rates of primary disease recurrence and SPTs were the same for both treatment groups.

Two National Cancer Institute–sponsored multicenter placebo-controlled randomized trials evaluating 13- *cis* retinoic acid for the prevention of SPTs were initiated in the early 1990s. Both trials are for patients with stage I or stage II squamous cell carcinoma of the oral cavity, pharynx, or larynx who have been rendered disease free with surgery or radiation. The trial, conducted jointly by M. D. Anderson Cancer Center and the RTOG, randomizes patients between placebo and low-dose 13- *cis* retinoic acid, 30 mg/d (approximately 0.5 mg/kg/d) for 3 years. The trial has completed accrual and is under analysis. The second intergroup trial (ECOG, NCCTG) evaluates very low-dose 13-*cis* retinoic acid, 0.15 mg/kg/d, versus placebo for 2 years. Until these trials are analyzed, there is no role for retinoids in daily practice.

## POSTTREATMENT REHABILITATION

Increasing emphasis on the posttreatment rehabilitation of the head and neck cancer patient has taken place over the last decade. No doubt as we see the limitations of current therapeutic strategies to improve on mortality for advanced disease, quality-of-life issues will become increasingly important. Specific approaches to the rehabilitation of the head and neck cancer patient have now been defined.<sup>338,339,340,341,342,343,344,345</sup> and <sup>346</sup> The majority of these approaches are based on quantitative assessment of various speech and swallowing parameters ([Table 30.2-15](#)).

Function	Measure
Food intake	—
Oral competence	Water-holding test
Mastication	Food consistency capacity
Tongue mobility	Protrusion To upper teeth To buccal mucosa
Swallowing	Time interval Degree of aspiration Pocketing in soft
Occlusion	Degree of malocclusion
Quality of bolus	Extent of comminution
Speech intelligibility	Diadochokinesis
Trismus	Oral commissure diameter
Laryngeal elevation	Barium swallow

**TABLE 30.2-15.** Assessment of Swallowing Capacity after Oral Cavity and Oropharyngeal Surgery

Optimal rehabilitation approaches for the head and neck patient begin before the initiation of treatment. We have discussed the role of dental examination and hygiene. Another pretreatment assessment should be performed by a speech and swallowing therapist, especially in those circumstances in which resection of critical organs is anticipated, such as the tongue, palate, and pharyngeal wall. Posttreatment rehabilitation should generally be considered within 3 days after treatment depending on the healing and integrity of surgical wounds. Each site within the upper aerodigestive tract must be considered separately.

Appropriate rehabilitation of the oral cavity begins with choice of reconstruction. Resections contribute to intraoral sensory loss, which impairs the initial phases of deglutition. The optimal reconstruction in most circumstances involves primary closure, thereby minimizing large insensate contact surfaces. Teichgraber et al., however, raised the important consideration of tongue mobility.<sup>343</sup> The degree of swallowing dysfunction correlates with the extent of tongue resection. In certain circumstances, approximation of the residual tongue to lateral soft tissue may serve to further restrict tongue movement. In this setting the use of a split-thickness skin graft to cover the surgical defect may prevent this restricted function. Teichgraber et al. noted that patients reconstructed with a split-thickness graft had improved articulation and improved swallowing.<sup>343</sup> Resections involving the base of tongue and pharyngeal wall may contribute to velopharyngeal dysfunction (i.e., the inability to build adequate intraoral pressure), which contributes to dysfunction of the pharyngeal phase of swallowing. Reduced capacity for generating normal food bolus propulsion results. Rehabilitation in such circumstances may require several means. The placement of an intraoral prosthesis obturates the defect. The obturator also serves to lower the palate to allow for appropriate contact with the remaining tongue base. Logemann notes that patients with 50% or more of the tongue base resected are likely to benefit from prosthetic rehabilitation.<sup>338</sup> Other rehabilitation approaches to be initiated by the speech and swallowing therapist include the use of exercise programs to improve tongue-base motion. Barium swallow studies should be performed before and following rehabilitation efforts to document both the degree of dysfunction and the extent of improvement.

## NASAL CAVITY AND PARANASAL SINUSES

### EPIDEMIOLOGY

Cancers of the nasal cavity and paranasal sinuses are relatively infrequent cancers with an incidence of 0.75 per 100,000 individuals in the United States.<sup>347</sup> Lesions of the maxillary antrum are twice as frequent as those of the nasal cavity. Cancers of the ethmoid and sphenoid sinuses are the least frequently observed. Disease occurs more frequently in male than in female subjects (2:1 ratio) and primarily involves individuals in the sixth decade of life. It is noted that cancer of the paranasal sinuses is more frequently observed in other regions of the world including Japan and South Africa.<sup>348</sup>

Etiologic factors involved in disease development are multifold. Exposure to nickel has been attributed to cancer development in the nasal cavity.<sup>348,349</sup> Occupations associated with a high incidence of nasal cavity cancers also include those within the furniture, textile, as well as boot and shoe industries.<sup>350,351</sup> and <sup>352</sup> Other workers considered at risk include those involved with production of chromium, mustard gas, isopropyl alcohol, and radium.<sup>347</sup> When considering cancers of the paranasal sinuses, the most frequently cited agent has been Thorotrast.<sup>353</sup> Some have attributed maxillary sinus carcinoma to chronic sinusitis.

### ANATOMY

The nasal cavity comprises the nasal vestibule, nasal antrum, and turbinates. The paired nasal cavities are separated by septal cartilage. The nasal vestibule is the triangular region of the nasal cavity bounded by the palatine processes of the maxilla inferiorly, the nasal septum medially, and laterally by the fibrofatty tissue called the *nasal ala*. The nasal vestibule represents that portion of the nasal cavity composed of skin (i.e., bearing hair follicles and sweat glands). Its posterior border is demarcated by transition from skin to mucosa.

The nasal antrum represents the remaining portion of the nasal cavity and contains the inferior, middle, and superior turbinates. The superior and middle turbinates are composed of highly vascular tissue overlying fragile bony projections that inset onto the ethmoid air cell bony framework. The inferior turbinate is composed of a separate bone.

The paranasal sinuses include the maxillary, ethmoid, sphenoid, and frontal sinus. More detailed anatomy of this region is provided. <sup>354</sup>

Primary lymphatic drainage of the maxillary sinuses is into the submandibular nodal basin. The ethmoid sinuses drain into the submandibular as well as retropharyngeal nodes. The nasal cavity drains into these regions as well as along the course of the facial blood vessels into the submandibular triangle and to periparotid nodes.

## PATHOLOGY

The majority of tumors of the nasal cavity and paranasal sinus are squamous cell carcinomas. Distinct from other sites within the upper aerodigestive tract, however, squamous cell carcinoma is less predominant. A vast variety of histopathologically distinct cancers occur in this region. Tumors found in the superior portion of the nasal cavity include adenocarcinoma and esthesioneuroblastoma. In the paranasal sinuses, additional neoplasms include tumors of minor salivary gland origin including adenocarcinoma, adenoid cystic carcinoma, and mucoepidermoid carcinoma. Rare tumors of this region are lymphoma, mucosal melanoma, teratocarcinomas, angiosarcomas, and various odontogenic and bone tumors.

## NATURAL HISTORY

The most common cancers (i.e., squamous cell carcinomas) are usually well differentiated and slow-growing, and the tendency to metastasize is infrequent. Common presenting symptoms include a nonhealing ulcer, occasional bleeding, and unilateral nasal obstruction.

Given the anatomic limitations in making early diagnosis, disease is usually far advanced at time of initial presentation. Other symptoms may reflect growth into the oral cavity causing dental pain, loose teeth, or ill-fitting dentures, or into the orbit leading to ocular symptoms such as diplopia, proptosis, and epiphora. Severe pain and trismus may occur with extension into the pterygoid fossa. Tumors in the superior nasal antrum and paranasal sinuses may invade the cribriform plate and extend into the anterior cranial fossa, causing anosmia or headache.

The regional lymph nodes most frequently involved with metastatic disease are nodes within the periparotid region or within the submandibular triangle. The propensity for spread to regional lymph nodes is dependent on the subsite in which primary disease may occur. <sup>355,356</sup> and <sup>357</sup> Approximately 20% of patients with cancers of the nasal vestibule develop clinically evident lymph node disease. Nearly 15% of these patients have bilateral disease. Regional lymph node spread is less frequently seen from tumors of the ethmoid and maxillary sinus, approaching 10% to 15% of patients. The probability of lymph node spread increases with extension of tumors outside the normal confines of the nasal and paranasal cavities, especially with extension into the oral cavity.

Prognoses from nasal cavity lesions are directly proportional to size of the lesion and overall approximate 60% at 5 years. <sup>357,358</sup> The principal determinant of survival is the presence of local recurrence, which is the most frequent site of disease failure. Prognosis for paranasal sinus cancers likewise depends on extent of primary disease at presentation and approximates 30% for advanced T4 lesions. <sup>355,359,360</sup>

## STAGING AND SCREENING

Given the infrequency in which primary cancers occur in this region, AJCC classification has been adopted only within the maxillary sinus. For the maxillary sinus, the definition of the TNM system is presented in [Table 30.2-16](#). The regional lymph node (N) and distant metastases (M) staging are identical to other sites within the upper aerodigestive tract and are as stated previously (see [Staging](#), earlier in this chapter).

TX	Primary tumor cannot be assessed
T0	No existence of primary tumor
Tis	Carcinoma in situ
T1	Tumor limited to antral mucosa with no erosion or destruction of bone
T2	Tumor with erosion of the infrastructure including the hard palate, middle nasal meatus, or both
T3	Tumor invades any of the following: skin of cheek, posterior wall of maxillary sinus, floor or medial wall of orbit, anterior ethmoid sinus
T4	Tumor invades orbital contents, any of the following, or both: cribriform plate, posterior ethmoid or sphenoid sinuses, nasopharynx, soft palate, pterygomaxillary or temporal fossae, or base of skull

**TABLE 30.2-16.** Staging for Cancer of the Maxillary Sinus

Careful examination of patients presenting with symptoms referable to the midface may minimize delay in diagnosis of these cancers. Likewise, considerable progress has occurred in the use of diagnostic radiology in the preoperative assessment of tumors of this region. Kraus et al. described how the judicious use of CT, MRI, or both may help to delineate the extent of disease. <sup>361</sup> These authors and others show that CT scan may be optimal for the definition of tumor infiltration of bony architecture ([Fig. 30.2-4](#)). MRI, on the other hand, aids in the assessment of tumor invasion of soft tissue structures including orbit, dura brain, and cavernous sinus ([Fig. 30.2-5](#)). <sup>361,362</sup> Gadolinium-enhanced MRI is an additional tool to aid the therapist in the pretreatment of patients with paranasal sinus cancers by helping to distinguish inflammatory disease from neoplastic extension.

**FIGURE 30.2-4.** Coronal computed tomographic scan demonstrating bony involvement of the lamina papyracea (*curved arrow*) and intracranial extension (*double arrow*). (From ref. 361, with permission.)

**FIGURE 30.2-5.** T1-weighted sagittal magnetic resonance image showing dural invasion ( *arrows*) within the same patient as in Figure 30.2-4. (From ref. 361, with permission.)

## TREATMENT

### *Treatment of Tumors of the Nasal Cavity*

For tumors of the nasal cavity, the appropriate surgical procedure depends on location of the primary disease. Tumors of the nasal septum can be approached through a lateral rhinotomy or by a midface degloving technique.<sup>363</sup> Cancers of the superior or lateral nasal cavity can be resected by a medial maxillectomy and an *en bloc* ethmoidectomy.<sup>364</sup>

Early tumors of the nasal cavity do not require elective treatment of regional lymph nodes as regional spread of disease is relatively infrequent.

RT and surgical resection yield roughly equivalent results for early lesions. Wong and Cummings have pointed out that most patients presented with lesions that are less than or equal to 5 cm, and less than 10% present with lymph node metastases.<sup>365</sup> When RT is used, treatment can be given by either external-beam techniques, interstitial implants, or a combination of both.

The difficulty with advanced tumors is in obtaining adequate surgical margins. Given the high propensity for local recurrence, combined modality therapy consisting of surgery and radiation should be used in most circumstances.

### *Treatment of Paranasal Sinus Cancers*

For cancers of the maxillary sinus, maxillectomy is the procedure of choice and generally is combined with postoperative radiation. For most lesions, maxillectomy entails a standard Weber-Fergusson incision through skin of the anterior face. The bone cuts used depend on the decision to preserve or resect the orbital floor and orbital contents. It should be recognized that multiple procedures are encompassed by the term *maxillectomy* dependent on the extent or resection of the bony framework (i.e., inferior, medial, anterior, and lateral walls). Spiro et al. have suggested classification schemes indicating limited, subtotal, and total maxillectomy.<sup>366</sup>

Debate in the management of paranasal sinus cancers centers on extent of surgical resection as well as what constitutes resectability. Furthermore, the management of the eye in patients with paranasal sinus cancer remains controversial. For T1 or T2 lesions of the maxilla, the eye can be preserved. Surgeons would advocate resection of orbital contents in patients whose tumors transgress the orbital floor and infiltrate orbital contents. In certain circumstances, however, invasion of orbital floor by maxillary sinus cancers cannot be determined preoperatively.<sup>367</sup>

Should disease involve orbital floor and yet not extend into the orbit, resection of the bony floor may be entertained with preservation of globe. However, ocular motion may be impaired and diplopia can result from such a procedure secondary to loss of structural support of orbital contents. This complication has led to numerous procedures for reconstructing the resected orbital floor including median galeal pericranial flaps.<sup>368</sup> The value of one surgical approach versus another is limited by the relative infrequency of these tumors. Tiwari et al. have provided additional insight as to the management of orbital contents in patients whose tumors involves periorbital.<sup>367</sup> The authors, in a careful analysis of anatomic contents of the orbit, note that the periorbital is not the final barrier to tumor invasion, rather, a thin fascia around the periocular fat. This fascial plane is rarely involved in their series, even in the presence of periorbital involvement. The authors note radiographic assessment cannot discriminate involvement of this fascial plane. The authors go on to note that ocular function with preservation of this fascial plane, even when combined with postoperative radiation, is good. Diplopia is not a complicating factor.

With advances in surgical technique and cumulative experience, factors that classically are considered to preclude surgical excision are continually evolving.<sup>369,370</sup> and <sup>371</sup> Lund et al., for instance, presented results of craniofacial resection in over 200 patients with a wide variety of tumors of the paranasal sinuses.<sup>371</sup> Actuarial survival in this population was 44%. Lund et al. describe acceptable survival results with acceptable morbidity in patients who underwent skull base resection. Disease involving dura, although associated with an adverse outcome, in selected instances can be controlled surgically. Similar results were noted by McCaffrey et al.<sup>370</sup> Results, however, are significantly influenced by histology. Survival of patients with olfactory neuroblastoma is far superior to those with adenocarcinoma. Involvement of brain parenchyma and extensive involvement of the infratemporal fossa from tumors of the maxillary sinus has not been considered amenable to surgical resection for cure. Each of the decisions regarding resectability should be tempered by the skill of the primary surgeon and availability of neurosurgical and reconstructive expertise.

A major decision in the treatment of paranasal sinus involves reconstruction of the surgical defects. Multiple methods of reconstruction have been advocated including temporal muscle slings, skin grafts, and even composite flaps containing bone.

In general, elective treatment of regional lymph nodes in patients without clinical evidence of lymph node metastases is not indicated.

RT alone is not commonly used for these lesions although it can be used when surgery is not feasible. Roa et al. have reported results of three-dimensional conformal RT for advanced paranasal sinus cancer.<sup>372</sup> For unresectable lesions treated by radiation alone, local control was 32% at 3 years. For patients who had a grossly incomplete resection, local control was only 20%. The group of patients who had a grossly complete operation, leaving only microscopic residual, enjoyed 79% local control. These data suggest that there is considerable room for improvement. In fact, newer programs that combine this type of sophisticated RT with chemotherapy, either sequential or concomitant, have been promising.

### *Results of Treatment*

**NASAL CAVITY.** Spiro et al. have reviewed the results of therapy for 27 patients with squamous cell carcinoma of the nasal cavity.<sup>373</sup> Surgery alone was the treatment in 21 instances. Five-year determinate cure for nasal cavity lesions were 43%. Local failure remains the most frequent site of failure in the treated surgery, occurring at rates ranging from 10% to more than 40%, emphasizing the need for effective multimodality therapy.<sup>357,358,373,374</sup>

Levendag and Pomp have reported a series of 63 consecutive patients with squamous cell carcinoma of the nasal vestibule who were managed with RT, principally with interstitial implantation.<sup>375</sup> A mean dose of 62 Gy for T1 and 64 Gy for T2 lesions was used. Patients were grouped according to the classification system proposed by Wang.<sup>376,377</sup> Local control was obtained in 97% of T1N0 patients, and 79% of T2N0 patients. Similar results have been observed by others.<sup>365,374</sup> Factors associated with an adverse outcome to primary RT include the presence of nodal metastases and local tumor extension into surrounding anatomic structures such as skin, lip, cartilage, or bone.

**PARANASAL SINUS.** Results of surgical resection of paranasal sinus cancer have demonstrated local control rates ranging from 10% to 90%, depending on disease stage.<sup>372,373</sup> Surgical series likewise demonstrated that limits of surgical resection could be extended into the anterior as well as the middle cranial fossa with 5-year

survival rates approaching 50%.<sup>370,371,378,379,380 and 381)</sup>

Parsons et al. have reported on the success of radiation therapy against malignant tumors of the nasal cavity, ethmoid sinus, or sphenoid sinus.<sup>382</sup> The 10- and 15-year actuarial local control for all patients except the adenoid cystic histologies was 52% and 42%, respectively. A 10-year actuarial local control rate for stage I (seven patients) was 100%. The 10-year actuarial local control rate for stage II was 53%, and for stage III it was 30%. Results were dependent on histology, with only a 17% local control in patients with adenoid cystic carcinoma. Although these data support using radiation alone for the occasional stage I patient, the results with more advanced stages are clearly suboptimal. Treatment with surgery and postoperative radiation would be preferred.<sup>382,383,384,385 and 386</sup>

Other adverse prognostic factors may relate to site of disease within the paranasal sinuses. Suprastructure lesions in the maxillary antrum, for instance, appear more readily controlled with RT than infrastructure lesions.<sup>384</sup>

Yu-Hua et al. compared preoperative and postoperative RT in a cohort of patients with maxillary sinus carcinoma.<sup>385</sup> They reported 64% 5-year survival in the preoperative group, as opposed to 26% in the postoperative group. The surgical complication rate was higher (29% vs. 14%) in the preoperative versus the postoperative groups, but the authors concluded that preoperative radiation was better. Nowadays, however, preoperative RT is seldom used in resectable lesions. Zaharia et al. reported 149 patients treated with surgery and postoperative radiotherapy for cancer of the maxillary sinus.<sup>386</sup> Patients were treated at 180 to 200 cGy/d, 5 days per week, to a total dose in the 5500 to 6000 cGy range. Megavoltage equipment was used. Only two patients had T1 lesions, 12 patients had T2 lesions, 117 had T3 lesions, and 198 had T4 lesions. The 5-year actuarial survival, corrected for death not due to cancer, was 42%. Clinical stage was an important prognostic feature, with survival being 75%, 36%, and 11% for stage II, III, and IV, respectively.

It is clear that the reported local control rates for paranasal sinus tumors are suboptimal. Future results may be improved through the use of CT-based treatment planning. [Figure 30.2-6](#) demonstrates a typical radiation technique for paranasal sinus tumors. A more detailed discussion of treatment planning is available elsewhere.<sup>387</sup>

**FIGURE 30.2-6.** A patient with squamous cell carcinoma of the right maxillary antrum, with disease extension toward the medial portion of the right eye. He underwent a complete resection with close margin near the globe. He was treated with postoperative radiation therapy. The plan is shown here. **A:** A representative cut through the level of the orbit. The plan calls for an anteroposterior field and a left lateral field. The anterior field is weighted over the lateral field 1.6 to 1. The target volume is seen, and the isodose curve shows that the isodose line covers the target volume well. The anterior field has a block for the lateral aspect of the orbit, thereby protecting the lacrimal gland. The medial aspect of the eye is in the target volume well. The left lateral field has blocking for the spinal cord, optic chiasm, and left eye. The dose to the left orbit is less than 10%. A total of 6300 cGy was given, prescribed to the 90% line. This keeps the dose to the optic chiasm well within tolerance. **B:** The same patient, with a cut through a level below the orbits but through the maxillary antrum. The target volume and isodose curves are seen.

### **Chemotherapy for Cancer of the Paranasal Sinuses**

Information on the role of chemotherapy in treating paranasal sinus cancer is limited because these patients are usually reported as a subset of a larger series of head and neck cancer patients. For carcinomas of squamous cell histology, there are no data to suggest that the response rate to standard intravenous chemotherapy such as cisplatin and 5-FU is any different from that achievable at other primary sites.

One form of chemotherapy that is specific to paranasal sinus cancer is intraarterial drug delivery. Intraarterial chemotherapy has been studied for almost three decades. The rationale is based on the steep dose-response curve exhibited by most cytotoxic drugs.<sup>388</sup> Regional or intraarterial drug delivery has the potential to increase tumor drug exposure while reducing systemic toxicity. The rationale for using this method of drug delivery for maxillary sinus cancers in particular is to increase local control and to preserve the orbit.

Most of the literature is from trials performed in the 1970s and 1980s using intraarterial bleomycin or 5-FU.<sup>389,390,391,392,393,394 and 395</sup> As an example, Japanese investigators reported cannulating the superficial temporal artery in 68 patients with paranasal sinus cancer and treating with intraarterial 5-FU and RT.<sup>389</sup> In 57 patients, 38 showed disappearance of tumor, and among these, 22 required no further treatment. In 19 cases of residual tumor after therapy, partial resection of the maxilla and intracavitary irradiation were effective in eradicating the tumor. The 2-year survival was 57% compared with 41% in the historic controls treated with surgery and postoperative RT. Similar results were reported by others with intraarterial 5-FU, bleomycin, or methotrexate and RT.<sup>390,391,392 and 393</sup> Many patients avoided radical surgery, which resulted in better cosmesis. In question, however, as cisplatin-based combination chemotherapy regimens evolved, was whether the intraarterial route afforded any advantage over intravenous administration.

More recent trials used intraarterial cisplatin alone or combined with other agents in sequence or simultaneously with radiotherapy. In one trial, intraarterial cisplatin, bleomycin, and intravenous 5-FU infusion were used as an induction regimen.<sup>394</sup> Of a total of 28 evaluable patients, 6 complete and 13 partial responses were observed. After chemotherapy, 13 patients had RT alone and 11 had surgery followed by RT. Overall, 21 patients were rendered free of disease. Of 18 patients who were initially judged to need orbital exenteration, only 7 required it. The median disease-free survival was 42 months. Mortimer et al. employed external carotid artery catheterization to treat 25 patients with intraarterial cisplatin, 100 mg/m<sup>2</sup> every 7 to 14 days for three cycles. The complete response rate was 32% and partial response rate was 50%, which is comparable with that reported for combination chemotherapy administered intravenously.<sup>395</sup>

Wayne State reported its 10-year experience with intravenous cisplatin-based chemotherapy in 24 patients.<sup>396</sup> The response rate was 82% (complete response, 44%; partial response, 38%) for previously untreated patients and 88% (complete response, 38%; partial response, 50%) for patients with recurrent disease. The median survival of untreated patients who achieved complete response was 21 months; for those achieving partial response it was 13 months, and for those achieving no response it was 3 months. For patients treated for recurrent disease who achieved a complete response, the median survival was 16 months; for those who achieved a partial response it was 13.5 months; and for those who achieved no response it was 5 months.

Lee and colleagues from the University of Chicago Hospitals published the results of treatment of 19 consecutive patients with stage III and IV paranasal sinus cancer with multimodality protocols over a 12-year period.<sup>397</sup> Patients received cisplatin-based induction chemotherapy, followed by resection and then concomitant radiotherapy and hydroxyurea and 5-FU. The disease-free survival rate at 5 and 10 years was 66.6% and local control was 76%. Regional and distant control rates were 93% and 95.5%, respectively. These results compared favorably with a 40% survival rate for historic controls treated with surgery and radiotherapy.

Harrison and associates reported the results of a prospective study evaluating concomitant chemotherapy with RT for advanced unresectable head and neck cancer.<sup>398</sup> Eight of the ten patients with unresectable paranasal sinus tumors had a complete response to the combined chemotherapy with RT treatment program. None of the complete responders have had a local recurrence, although median follow-up is only 1 year. These encouraging results for unresectable paranasal sinus cancer raise the issue as to whether this combined modality approach could be successful in earlier stage disease. Larger numbers of patients and longer follow-up are needed before this could be considered an alternative to standard treatment with surgery and RT.

Interesting results have come from Robbins and colleagues using their *Rad-Plat* protocol of 150 to 200 mg/m<sup>2</sup> of cisplatin weekly for up to four doses through a microcatheter placed angiographically to selectively encompass the dominant tumor supply.<sup>399</sup> Concurrent with the intraarterial cisplatin, intravenous bolus sodium thiosulfate was administered to neutralize the systemic effects of cisplatin. The response rate in 22 patients in a phase I trial was 62%. This intraarterial regimen is continuing to be studied by this group in patients with locally advanced head and neck cancer, and high complete response rates have been achieved.<sup>399,400 and 401</sup>

Based on the information published to date, it seems that intraarterial chemotherapy with radiation in locally advanced maxillary sinus tumors may achieve results similar to surgery and RT without the effects of major surgery. For patients with paranasal sinus cancer who need orbital exenteration or major craniofacial resection, the option of intraarterial chemotherapy as induction therapy to preserve the eye should be considered as an alternative treatment.

## NASOPHARYNX

### EPIDEMIOLOGY

The epidemiology of nasopharyngeal carcinoma suggests multiple determinants including diet, viral agents, and genetic susceptibility.<sup>402,403</sup> Endemic areas include Southern China, North Africa, and regions within the far northern hemisphere. The population diets of these regions are what contributes a link to disease development.<sup>404</sup> Populations in endemic areas are characterized by intake of salt-cured fish and meat. The cooking of such food releases volatile nitrosamines that are distributed over nasopharyngeal mucosa when carried by steam.

In addition to diet, considerable epidemiologic evidence incriminates Epstein-Barr virus (EBV) in nasopharyngeal carcinoma development. Old and colleagues first demonstrated the presence of anti-EBV antibodies within the sera of nasopharyngeal carcinoma patients.<sup>405</sup> Knowledge about EBV serology has rapidly progressed, reinforcing the potential causal relationship. More recent advances in molecular biology have provided more direct evidence of the carcinogenic properties of this herpesvirus, including the identification of EBV-related peptides capable of inducing malignant transformation of lymphoblastoid cell lines *in vitro*.<sup>406,407</sup>

Potential genetic determinants of nasopharyngeal carcinoma have been suggested by the increased incidence of disease in individuals with specific major histocompatibility complex profiles.<sup>408</sup> Loci associated with increased relative risk include the H2 locus antigen. Likewise, Simons et al. noted the so-called Singapore antigen, BW46, was associated with a high risk of nasopharyngeal carcinoma.<sup>409</sup> The risk of disease increases significantly in individuals with both the H2 and BW46 antigen. An increased odds ratio of disease was also demonstrated in individuals who carry the B17 antigen.<sup>408</sup> In the latter instance, the disease is associated with an earlier age of onset. The peak incidence of disease occurs in the fourth and fifth decades. The male to female ratio is 2.2:1.

### ANATOMY

The nasopharynx is a cuboidal structure covered by stratified mucociliary columnar epithelium. Anteriorly it is in continuity to the nasal cavity by way of the posterior choanae. The roof is formed by the basisphenoid, the basiocciput, and the anterior arch of the atlas. The roof gradually slopes inferiorly to become the posterior wall. The latter is formed by the first two cervical vertebrae. The lateral walls of the nasopharynx contain the eustachian tube openings, which lie within the elevations of the torus tubarii (i.e., the cartilaginous portions of the internal auditory canal). Behind the torus is the lateral pharyngeal recess or fossa of Rosenmüller, which is the most common site of nasopharyngeal carcinoma development. The floor of the nasopharynx is the upper surface of the soft palate.

Lymphatic drainage from the nasopharynx encompasses all levels within the neck as it proceeds along the jugular vein and spinal accessory nerve. Extensive lymphatics within the nasopharynx also drain into the retropharyngeal nodes medial to the carotid artery. It is of note that involvement of these nodes rarely can be detected clinically. Radiologic assessment, either CT or MRI, is the most sensitive diagnostic technique for detecting retropharyngeal node enlargement.

### PATHOLOGY

The World Health Organization (WHO) has divided nasopharyngeal carcinoma into three types: type 1, keratinizing squamous cell carcinoma; type 2, nonkeratinizing carcinoma; and type 3, the undifferentiated carcinoma.<sup>410</sup> The latter is the most frequently identified neoplasm. It characteristically is associated with a lymphoid infiltrate that accounts for its more familiar description, lymphoepithelioma. The proportion of type 1 nasopharyngeal carcinoma among the North American population is higher than found in other localities.

Additional cancer types noted include lymphoma, juvenile angiofibroma, plasmacytoma, and adenocarcinomas. The latter is of minor salivary gland origin.

### NATURAL HISTORY

Nasopharyngeal cancer grows either by infiltration or by expansion with the former growth pattern predominating. Frequently, mucosal abnormalities may reflect only a small portion of tumor extent. On occasion, no abnormalities of the mucosa are identifiable. In such instances, tumors may exist submucosally and extend into sites outside the confines of the nasopharynx proper.

The most common presenting complaint of nasopharyngeal carcinoma is a mass in the neck occurring in nearly 90% of patients. Additional frequently encountered symptoms include alterations in hearing associated with serous otitis media, tinnitus, nasal obstruction, and pain. Patients may present with symptoms that reflect growth of the disease into the many significant surrounding anatomic structures. Tumors can access the parapharyngeal space through the sinus of Morgagni, an opening in the lateral nasopharyngeal wall through which the eustachian tube courses. Infiltration laterally into paranasopharyngeal space may lead to pterygoid muscle involvement and trismus. Frequently, cranial nerve involvement is manifested with more extensive growth into the skull base. Growth into the cavernous sinus under such circumstances can lead to impairment of cranial nerves II to VI. Additionally, cancer may break through the pharyngobasilar fascia and spread along vascular sheaths (i.e., fascial planes surrounding the jugular vein and carotid artery). Disease extending along these planes may also extend within skull base and lead to cranial nerve involvement.

Any description of the natural history of nasopharyngeal carcinoma must take into account its metastatic potential. Furthermore, the metastatic potential of these tumors is governed by the WHO histopathologic classification. WHO type 1 has a greater propensity for uncontrolled local tumor growth and a lower potential for metastatic spread than the WHO type 2 or 3 cancers. Clinically advanced nodal metastases from WHO type 1 approximates 60%.<sup>411,412</sup> For WHO type 2 and 3 disease, clinical evidence of metastatic disease ranges from 80% to 90%. Distinct from cancers of the oral cavity and oropharynx, metastatic disease frequently presents itself in the posterior triangle. Bilateral neck nodes are present in 53% of patients.<sup>413</sup> Another common location for metastatic disease is in the lymph nodes in the retropharyngeal space, the so-called nodes of Rouviere. Thus, multiple nodal chains can be involved with disease including chains along the special accessory nerve, jugular vein, and the retropharyngeal pathway.

Prognosis for the various WHO classifications of nasopharyngeal carcinoma vary from approximately 15% 5-year survival for type 1 lesions to 60% for type 3 lesions dependent on disease stage.<sup>414,415</sup> The 5-year survival for stage I approximates 67% and decreases to 15% for stage IV.

### STAGING AND SCREENING

The regional lymph node (N) and distant metastases (M) staging are identical to other sites within the upper aerodigestive tract (see [Staging and Screening](#), earlier in this chapter; [Table 30.2-17](#)).

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor limited to one subsite of nasopharynx
T2	Tumor invades more than one subsite of the nasopharynx
T3	Tumor invades nasal cavity, oropharynx, or both
T4	Tumor invades skull, cranial nerves, or both

**TABLE 30.2-17.** Staging for Nasopharyngeal Cancer

## TREATMENT

RT is the standard treatment of almost all nasopharyngeal carcinomas. Surgery is usually not feasible and cannot provide adequate margins of resection. There is also considerable morbidity to nasopharyngeal surgery, even in the most selected patients.

Modern imaging techniques, including CT and MRI, have dramatically changed RT for this disease. Yu et al. and others have shown that CT scans up-stage more than 50% of T2 and T3 patients.<sup>416,417</sup> In addition, these investigators found that CT identified parapharyngeal extension in more than 60% to 80% of cases. Cellai et al. attempted to study the effect that CT staging and treatment planning had on therapeutic results.<sup>420</sup> They found that patients who were treated with CT treatment plans had improved local control and 5-year survival. This result will not come as a surprise to most radiation oncologists. Because CT and MRI scanning have identified disease extensions that were not previously known, the RT plans can now be modified accordingly. An example is shown in [Figure 30.2-7](#). The patient in the figure has parapharyngeal extension. A standard, bilateral opposed field arrangement for the nasopharynx and upper neck would significantly compromise the treatment to the parapharyngeal space. In particular, when the spinal cord block was added, the parapharyngeal extension would be under the block and thereby underdosed. It is not surprising that this would lead to treatment failure. Indeed, Sham and Choy have studied the importance of parapharyngeal extension in the management of nasopharyngeal cancer.<sup>417</sup> This group demonstrated that the degree of parapharyngeal space extension was an important prognostic factor that influenced local tumor control. Using CT scans, they identified four categories of parapharyngeal extension. Type 1 extension involves disease extending up to a line that extends from the medial pterygoid plate to the lateral carotid artery. Type 2 extension goes beyond type 1, up to a line from the medial pterygoid to the styloid process. Type 3 extension goes beyond type 2, up to a line from the lateral pterygoid to the posterior aspect of the ascending ramus of the mandible. Sham and Choy reported that the degree of extension was important, but also that the degree of extension within the T4 group was statistically significant (type 0 and 1 vs. 2 and 3) and approached statistical significance for the T3 group.<sup>417</sup>

**FIGURE 30.2-7.** A patient with squamous cell carcinoma of the nasopharynx that was staged as T2N0. **A:** A computed tomographic (CT) scan shows disease extension posteriorly in the parapharyngeal space. If bilateral opposed portals were used for the nasopharynx, the posterior extent of the disease would be undertreated when the spinal cord block is placed. This demonstrates the need for CT scan in all nasopharynx patients. **B:** Another CT scan shows retropharyngeal adenopathy (arrow). Again, this disease would be undertreated significantly by conventional, opposed lateral portals with a spinal cord block. **C:** This patient was treated before there was three-dimensional treatment planning. A three-field arrangement was used, which included two posterior oblique portals that protected the spinal cord but treated the posterior extent of disease. A small portion of the posterior aspect of the disease is underdosed by 20%, even with this plan. This area was boosted with an <sup>125</sup>I implant. The patient had no evidence of disease at 5 years.

In addition to the benefits of target-volume delineation that these new imaging techniques have provided, the advent of three-dimensional RT treatment planning has been vital. Kutcher et al., as well as the experience at Memorial Sloan-Kettering Cancer Center, revealed that multifield conformal plans were able to achieve excellent coverage of tumor, while reducing the normal tissue doses compared with standard treatment techniques.<sup>421</sup> An example of a treatment plan is shown in [Figure 30.2-8](#). It should be pointed out that this is complicated RT. Anywhere from seven to ten fields might be necessary to provide the best dose distribution to the primary site. This needs to be matched to upper neck fields, which then needs to be matched to lower neck fields. The spinal cord must be protected at each junction. Electron beams are required for the posterior neck and these are matched to the photon fields. The result is that up to 15 fields might be required in a single patient. There is some suggestion that RT in a concomitant boost during the last 2 to 2.5 weeks of radiation may provide better local control.<sup>422,430</sup> This allows for the total dose to be increased with a shortened overall treatment time, yielding an enhanced biologic effect. Total doses in the 70-Gy range are usually given to the primary site. The addition of chemotherapy for selected patients with advanced primary and neck disease is discussed later in this section.

**FIGURE 30.2-8.** A patient with a T4N0 squamous cell carcinoma of the nasopharynx. The patient has a bulky disease, extending into both retropharyngeal areas. **A:** Computed tomographic scan shows target volume outlines. If bilateral opposed lateral portals were used to treat the nasopharynx, and a spinal cord block was placed at 4500 cGy, the posterior aspect of the target volume is underdosed. The retropharyngeal disease cannot be treated with this technique. **B:** Using a three-dimensional treatment plan, it is possible to encompass the entire retropharyngeal area adequately and still protect the brainstem and the spinal cord. This patient has a complete response to radiation therapy and is doing well 10 months after completion of treatment.

All patients with cancer of the nasopharynx require treatment to both sides of the neck. The overwhelming majority present with either unilateral or bilateral

metastases. Those with clinically negative necks still require elective neck irradiation.<sup>418</sup> The pattern of nodal spread is quite orderly with the upper jugulodigastric nodes being involved in the great majority, and the low neck involved far less frequently.<sup>419</sup> It is interesting to note the ability of RT to control neck disease without the need for neck dissection. Neck control is high, even in patients with bulky cervical lymphadenopathy. All patients with nasopharyngeal disease require radiation treatment to regional cervical lymph nodes. Patients with N0 necks are usually treated to 5000 cGy to the entire neck in 180- to 200-cGy daily fractions. Patients with involved necks receive at least 6000 cGy to the region of the involved neck, with boost to higher doses to the gross disease itself. For N1 disease, an additional 500 to 1000 cGy is given. For bulkier necks, doses in the 1000 to 1500 cGy range are added. These additional boost dosages are usually done with electron beams. There has been increasing interest and development of more sophisticated treatment techniques. The role of multileaf and micromultileaf collimators in conformal therapy has allowed for increasing customization and automation of treatment. In particular, micromultileaf systems (leaves less than 5 mm) may be particularly valuable.<sup>423</sup> Three-dimensional intensity-modulated radiotherapy may also be helpful in attempts to maximize tumor dose while decreasing normal tissue dose.<sup>424</sup>

### **Treatment of Recurrent Disease**

For patients with local recurrence, a second course of RT can usually be delivered to the nasopharynx. This can be quite rewarding in selected patients. Wang has shown the importance of high-dose reirradiation in obtaining good results.<sup>425</sup> Five-year survival was 45% in patients who received greater than or equal to 6000 cGy, as compared with zero 5-year survivors in those who receive less than 5000 cGy. Also, the interval of time between the original treatment and the recurrence was of prognostic significance. For patients who had recurrences more than 2 years after their original treatment, 5-year survival could be obtained in 66%. However, only 13% of patients who failed within 2 years of the original treatment were 5-year survivors. Wang emphasizes the importance of combining external beam and brachytherapy in the management of recurrent disease.<sup>425</sup>

Brachytherapy alone has been used for selected patients with local recurrence. Harrison et al. have reported the use of permanent <sup>125</sup>I implants for discreet local recurrences in the nasopharynx.<sup>426,427</sup> Either the transoral or the transpalatal approaches can be used. [Figure 30.2-9](#) shows a transpalatal approach. The transnasal approach can also be used.<sup>428</sup> If patients are selected with localized, discreet lesions that are limited to the mucosa, permanent implants can be quite successful. It also has the advantage of limiting the normal tissue that is reirradiated.

**FIGURE 30.2-9.** A patient with a discrete mucosal recurrence of a nasopharyngeal cancer. The recurrence was superficial and at the roof of the nasopharynx. It was not accessible through the opened mouth or through the nose. He was treated with an <sup>125</sup>I implant via the transpalatal approach. **A:** This view looks into the mouth from above the patient's head, under general endotracheal anesthesia. A mouth retractor holds the mouth open. The tongue is at the top of the figure retracted by the tongue blade. The soft palate is exposed for the incision. **B:** The soft palate has been incised and reflected to expose the interior of the nasopharynx. The torus tubarius is seen, and the glistening mucosa of the nasopharynx is directly visualized. Using this access, <sup>125</sup>I seeds are directly implanted into the roof of the nasopharynx. **C:** Localization films of the implant show the position of the seeds in the roof of the nasopharynx.

In most situations, because the recurrent lesion is not discreet and localized, a combination of external-beam and intracavitary irradiation is important. The field size should be kept as small as possible, preferably smaller than 8 cm in maximum diameter.<sup>429</sup> It would be typical to deliver 4500 to 5000 cGy with external-beam RT, and then boost the nasopharynx with an intracavitary implant with an additional 1000 to 1500 cGy. The techniques for these different brachytherapy approaches have been reviewed by Harrison et al.<sup>430</sup> and Erickson and Wilson.<sup>431</sup> It is important to tailor the implant to the specific location within the nasopharynx that one wants to irradiate. This can help maximize the dose to the target area and minimize the dose to the surrounding normal tissue. The use of charged particle irradiation as well as stereotactic radiosurgery<sup>432</sup> and combining chemotherapy with radiotherapy has been reported. The relative roles of these techniques for patients with recurrent nasopharyngeal carcinoma remain to be determined. The chemotherapy approaches are discussed later in this section.

The role for surgery in nasopharyngeal carcinoma is limited principally to treatment of residual or recurrent disease. Small locally recurrent disease within the nasopharynx has been shown to be amenable to surgical resection with 5-year survival rates of 50% in small patient series.<sup>433,434,435</sup> and <sup>436</sup> Morton et al. have reviewed the various techniques involved in the surgical management of recurrent disease. Various approaches include transpalatal, palatectomy, maxillary swing, infratemporal, and the transcervicomandibulopalatal approach.<sup>435</sup> Complications of such surgery include injury to cranial nerves, cerebral spinal fluid leaks, and hemorrhage secondary to vessel injury.

Management of regional recurrence entails the same considerations as regional recurrence from squamous cell carcinomas elsewhere within the upper aerodigestive tract. If the disease is resectable, an attempt at surgical ablation is indicated. In most instances this requires a radical neck dissection. Brachytherapy can supplement the neck surgery if there is concern about residual disease.

### **Chemotherapy for Nasopharyngeal Cancer: Metastatic or Recurrent Disease**

The natural history of nasopharyngeal carcinoma, WHO types 2 and 3, differs from that of other sites in the head and neck. Local control rates are high, while distant failure is more common and is often the cause of death. The distant metastatic rate at presentation is reported to be 5% to 11%. However, a thorough extent of disease evaluation that includes CT scans of chest and abdomen, a bone scan and bone marrow aspiration, and biopsy reveal distant metastases in up to 40% of patients.<sup>437</sup> Those presenting with bulky or fixed nodes, disease low in the neck, or bilateral involvement are at the greatest risk.<sup>438,439,440</sup> and <sup>441</sup> Bone is the most common site of metastases followed by lung, liver, and extraregional nodes. Autopsy series report distant metastases in up to 87% of patients with nasopharyngeal carcinoma, which is substantially more than found for any other primary site in the head and neck.<sup>442</sup>

Reports of chemotherapy for treating recurrent and metastatic disease have usually been included with outcome data for other sites. The single agents, cisplatin, doxorubicin, epirubicin, bleomycin, and methotrexate have been shown to be active for this disease, whereas the evidence for the activity of 5-FU, cyclophosphamide, and the vinca alkaloids is less certain.<sup>443</sup>

The most effective combinations are cisplatin based. Using these regimens to treat patients with metastatic disease consistently results in a small proportion of long-term disease-free survivors.<sup>444,445,446</sup> and <sup>447</sup> The results of phase II trials generally show higher complete and partial response rates than are attainable for squamous cell carcinoma from other sites. Selected trials are shown in [Table 30.2-18](#),<sup>444,445,446,447,448,449,450,451,452</sup> and <sup>453</sup>

Author (Reference)	No. of Patients	Chemotherapy	% Complete Response + Partial Response (Complete Response)
Choo (448)	70	30 Fluorid 40 Single agents	70 (22)
Marchini (449)	26	PF	75 (23)
Celikovic (447)	46	PF/5-FU	46 (9)
Beaman (444)	49	PF/5-FU	79 (28)
Adl (446)	44	5-FU	45 (20)
Gebbia (450)	40	Fluorid	64 (21)
Fandi (445)	26	PF/5-FU	69 (26)

Fountzilias (452)	14	Fluorid/Carbo	57 (14)
Yeo (453)	42	Carbo F	38 (17)

**TABLE 30.2-18.** Combination Chemotherapy in Recurrent and Metastatic Nasopharyngeal Cancer Patients

Choo and Tannock treated 40 patients with single agents or non-cisplatin-containing combinations and reported response in 25%, three complete and seven partial responses.<sup>448</sup> In contrast, the response to cisplatin-based combination chemotherapy in 30 patients was 70%, 7 complete and 14 partial responses.

A multicenter collaborative group led by investigators from the Institut Gustave Roussy-La Grange, France, has performed a sequence of studies evaluating cisplatin-based combination chemotherapy.<sup>444,445,446</sup> and <sup>447</sup> The best results were achieved with a regimen of cisplatin, bleomycin, and 5-FU that resulted in a 20% complete response rate and 79% overall response rate in 49 patients with metastatic or recurrent undifferentiated nasopharyngeal carcinoma.<sup>444</sup> A total of 165 patients with metastatic undifferentiated nasopharyngeal carcinoma were treated on four consecutive protocols between 1985 and 1996. Twenty patients (12%) were long-term disease-free survivors (42+ to 208+ months), demonstrating the chemosensitivity of this disease in patients with visceral or bone metastases.<sup>445</sup>

Investigators from the Prince of Wales Hospital, Hong Kong, evaluated carboplatin, 300 mg/m<sup>2</sup> day 1, and 5-FU, 1000 mg/m<sup>2</sup>/d, days 1 to 3 every 3 weeks, in 42 patients with metastatic disease.<sup>453</sup> Complete responses were observed in lung, liver, and distant nodal sites of metastases. The overall response rate of 38% was lower than reported for cisplatin-based combinations; however, both agents were administered in lower total doses than customarily used in the United States. This same group subsequently evaluated paclitaxel, 135 mg/m<sup>2</sup> (3-hour infusion), and carboplatin, AUC 6 dosing every 3 weeks.<sup>451</sup> One-third of the 27 patients enrolled had received prior chemotherapy and yet a 59% response rate was observed with acceptable toxicity. Similar results were reported by Fountzilias and associates using a more intensive regimen of paclitaxel, 200 mg/m<sup>2</sup> (3-hour infusion), carboplatin, AUC 7 dosing, and G-CSF support repeated every 4 weeks.<sup>452</sup>

### Combined Modality Therapy for Locally Advanced Disease

Although local control and survival rates are excellent for T1 to T2, N0 to N1 undifferentiated nasopharyngeal carcinoma treated with RT alone, the 5-year survival rate of patients with more advanced disease is unsatisfactory, ranging from 10% to 40%. Because of the high rate of distant metastases, integrating chemotherapy into the primary management is logical. A number of nonrandomized trials evaluating induction, adjuvant, or concomitant chemotherapy and radiotherapy have been performed. Selected trials are shown in [Table 30.2-19](#). These studies and others from older literature may be found in several excellent reviews.<sup>465,466</sup>

Author (Reference)	Treatment Strategy	No. of Patients	Response (% CR)	Survival
<b>Induction chemotherapy</b>				
Beaman (444)	Induction PF/5-FU	49	79% (28)	78% (31)
Fandi (445)	Induction PF/5-FU	26	69% (26)	62% (24)
Adl (446)	Induction 5-FU	44	45% (20)	39% (16)
Choo (448)	Induction PF	30	70% (22)	70% (22)
Gebbia (450)	Induction Fluorid	40	64% (21)	64% (21)
<b>Response after concurrent therapy</b>				
Yeo (451)	Concurrent PF + RT	27	59% (11)	59% (11)
Yeo (453)	Concurrent PF + RT	42	38% (17)	38% (17)
<b>Adjuvant chemotherapy</b>

Yeo (453)	Adjuvant PF/5-FU	42	38% (17)	38% (17)

**TABLE 30.2-19.** Selected Nonrandomized Trials of Combined Modality Approaches for Advanced Nasopharyngeal Carcinoma

### Induction Chemotherapy

Reports of two to three cycles of cisplatin-based induction chemotherapy followed by radiotherapy in patients with locally advanced nasopharyngeal carcinoma suggested survival improvement compared with historic controls.<sup>454,455,456,457,458</sup> and <sup>459</sup> Overall response rates of 82% to 98% and complete responses in up to 66% of patients were observed. Geara et al. reported the results of a single institution study of 61 patients treated with the standard cisplatin and 120-hour infusion of 5-FU for three courses followed by definitive radiotherapy.<sup>459</sup> The 5-year cumulative incidence of distant metastases was 19% for the chemotherapy patients compared with 34% for the matched historic controls receiving radiotherapy alone. This effect on distant metastases was most notable for patients with N2 to N3 disease. Five-year disease-free and overall survival were also improved (64% vs. 42% and 69% vs. 48%, respectively). However, locoregional control rates were not different.

A retrospective comparison was reported by Teo and associates from Hong Kong that also suggested that benefit from chemotherapy was limited to those with advanced disease.<sup>458</sup> Between 1984 and 1989, 209 patients with bulky or low cervical or supraclavicular nodes (less than or equal to 4 cm) were treated with two courses of cisplatin, 100 mg/m<sup>2</sup>, and 3 days of infusional 5-FU followed by radiotherapy. In contrast to the findings of Geara et al., a multivariate analysis, after 5.5 years of follow-up, showed significantly fewer local failures in the chemotherapy group for node-positive T3 and stage IV patients when compared with historic controls, but no difference in survival, relapse-free survival, or distant metastases. There was no apparent benefit for stage II or T1 and T2 disease. These divergent results with induction cisplatin and 5-FU may be due to the difference in the number of treatment courses and intensity of the regimens or simply the nature of retrospective comparisons. These findings emphasized the need for randomized trials.

Three prospective randomized trials of induction chemotherapy have been reported and the results are shown in [Table 30.2-20](#).<sup>467,468,469</sup> and <sup>470</sup> The International Nasopharyngeal Cancer Study Group compared three cycles of bleomycin, epirubicin, and cisplatin (BEC) chemotherapy followed by radiotherapy with radiotherapy alone in 339 patients with N2 and N3 staged nasopharyngeal carcinoma (WHO types 2 and 3). This BEC regimen consisted of bleomycin, 15 mg/m<sup>2</sup> intravenous bolus day 1 followed by a 4-day continuous infusion of 12 mg/m<sup>2</sup>/d; epirubicin, 70 mg/m<sup>2</sup> day 1; and cisplatin, 100 mg/m<sup>2</sup> day 1 repeated every 3 weeks for three courses. Conventional fractionation radiotherapy was used to a total dose of 65 to 70 Gy to the primary. The overall response rate to chemotherapy was 91%, with 47% complete response. The updated 6-year results showed significant improvement in disease-free survival for chemotherapy patients (41% vs. 30%, *P* < .02) for the control group.<sup>468</sup> BEC induction chemotherapy was associated with substantial toxicity including 8% treatment-related deaths. Fewer distant and local recurrences occurred in the chemotherapy arm, but the magnitude of the effect coupled with severe toxicity was insufficient to produce a statistically significant improvement in overall survival.

Trial/Author	No. of Patients	Strongly Favor	Percentage Favor	Percentage Disfavor	Percentage No Opinion	Survival
International Nasopharyngeal Cancer Study Group (INSCG) (1987)	333	107	32%	57%	11%	100% vs 95%
Prince of Wales Hospital (1991)	82	66	80%	19%	1%	100% vs 95%
Asia-Oceania Clinical Oncology Association (1995)	334	110	33%	67%	0%	59% vs 47%
Head and Neck Intergroup (1995)	138	107	77%	23%	0%	80% vs 55%
Italian National Research Council (1995)	229	0	0%	100%	0%	76% vs 76%

**TABLE 30.2-20.** Randomized Trials of Chemotherapy and Radiotherapy for Locally Advanced Nasopharyngeal Carcinoma

The second completed trial was reported by Chan and associates from the Prince of Wales Hospital. From 1988 to 1991, 82 patients with WHO type 3 carcinoma, Ho's N3, or any nodal disease greater than or equal to 4 cm were randomized to receive RT alone or two cycles of cisplatin, 100 mg/m<sup>2</sup> day 1, and 3 days of infusional 5-FU, 1000 mg/m<sup>2</sup>/d, followed by RT.<sup>469</sup> Conventional fractionation radiotherapy was given, 66 Gy to the primary with or without brachytherapy. The response rate to chemotherapy was 81% (19% complete response) and 100% after radiation compared with 95% after radiotherapy alone. An updated analysis after a median follow-up of 60 months showed no difference in survival, disease-free survival, or pattern of failure.<sup>466</sup> Only 55% of patients completed the adjuvant chemotherapy phase of treatment. The less intensive nature of this regimen may account for the lower complete response rate and the absence of any difference in survival outcomes.

The third randomized comparison of induction chemotherapy was reported by the Asia-Oceania Clinical Oncology Association, which included centers from Hong Kong, Thailand, Malaysia, and Indonesia.<sup>470</sup> This study enrolled 334 patients (286 evaluable) with stage III and IV disease or any nodal involvement greater than or equal to 3 cm. All patients had WHO types 2 or 3 histology. The investigational treatment consisted of cisplatin, 60 mg/m<sup>2</sup>, and epirubicin, 110 mg/m<sup>2</sup> day 1, repeated every 3 weeks. Response was assessed after two courses with patients demonstrating at least a partial response proceeding to a third cycle before radiotherapy. The total dose of radiotherapy was 70 Gy to the primary tumor; however, the treatment technique was not standardized but left to each participating center. The response rate to chemotherapy was 84%, with 18% complete. There was a trend for improved relapse-free survival for the chemotherapy-treated patients (59% vs. 47%, *P* = .06) at 3 years, but no difference in overall survival, and local or distant failure rates. In a subset analysis of patients with nodal disease greater than or equal to 6 cm, significantly improved survival and relapse-free survival was apparent for the chemotherapy group. This trial has been criticized for the lack of standardized radiotherapy technique, nonuniform use of CT for staging and response assessment, and the high number of inevaluable patients.

In summary, the only induction chemotherapy trial with a positive result was the International Nasopharyngeal Cancer Study Group (INSCG) trial of three cycles of BEC followed by radiotherapy in which disease-free survival but not overall survival was improved. Although a high response rate was achieved with BEC, it cannot be recommended because of the associated toxicity and failure to sufficiently improve overall survival. Induction chemotherapy, therefore, remains investigational.

### Concurrent Chemotherapy and Radiotherapy

The RTOG conducted a phase II trial of concurrent radiotherapy and cisplatin, 100 mg/m<sup>2</sup> days 1, 22, and 43, in patients with unresectable squamous cell carcinoma from multiple sites. A subset of 27 patients with nasopharyngeal carcinoma had an 89% complete response rate after completing concurrent treatment and a 5-year survival rate of 55%, which was superior to historic controls.<sup>460</sup>

This concept was then tested by the Head and Neck Intergroup. Concomitant chemoradiotherapy and adjuvant chemotherapy (cisplatin, 100 mg/m<sup>2</sup> every 3 weeks for three doses during radiotherapy followed by three cycles of adjuvant cisplatin, 80 mg/m<sup>2</sup>, and 5-FU, 1000 mg/m<sup>2</sup>/d x 4) were compared with radiotherapy alone.<sup>280</sup> Conventional radiotherapy, total dose 70 Gy, was administered in both arms. This trial was closed in November 1995 when an interim analysis of 138 randomized patients showed a highly significant difference in progression-free survival (52 vs. 13 months) and 2-year survival (80% vs. 55%) favoring the chemotherapy-treated patients. Sixty-three percent of patients received all three doses of cisplatin during radiotherapy and 55% completed adjuvant chemotherapy. When all 185 patients enrolled were included in the analysis, the survival results remained significant: 3-year overall survival was 76% versus 46% (*P* < .001), and progression-free survival was 66% versus 26% (*P* < .001). The population of patients in this study differed from other trials in that approximately one-half had WHO type 1 squamous cell carcinoma, a reflection of the U.S. population. WHO type 1 nasopharyngeal carcinoma is associated with lower sensitivity to chemotherapy and radiotherapy as compared with types 2 and 3 found in endemic areas. Because of the small sample size, a subgroup analysis of these two populations was not feasible. For similar reasons, it is impossible to dissect the contribution of adjuvant chemotherapy to these positive results.

A second randomized trial of concurrent cisplatin and radiotherapy was completed by Chan and colleagues at the Prince of Wales Hospital in Hong Kong.<sup>471</sup> A total of 321 patients with advanced nodal disease were enrolled between 1994 and 1999 and randomized to receive conventional fractionation radiotherapy, 62.5 Gy, plus parapharyngeal boost when indicated, or the same radiotherapy plus concurrent cisplatin, 40 mg/m<sup>2</sup>/week for up to eight doses. The preliminary results indicate a significant difference in 2-year disease-free survival (62% vs. 78%, *P* = .01). Further follow-up will be needed to ascertain the effect on overall survival.

### Adjuvant Chemotherapy

Adjuvant chemotherapy after radiotherapy is another strategy that is logical to pursue to improve survival given the propensity of this disease for distant spread. Several small institutional phase II adjuvant chemotherapy trials from the 1980s are listed in Table 30.2-19.<sup>462,463</sup> and <sup>464</sup> Survival comparisons with historic controls indicated significant improvement in disease-free survival, supporting the need for a prospective randomized trial.

One multicenter randomized trial was reported by Rossi et al. for the Italian National Research Council.<sup>472</sup> A total of 229 patients were treated with radiotherapy or radiotherapy and six cycles of adjuvant vincristine, doxorubicin (Adriamycin), and cyclophosphamide. Seventy-four percent completed the adjuvant chemotherapy. No differences in relapse-free survival, overall survival, or pattern of failure were observed. The results of this single trial of adjuvant chemotherapy are inconclusive regarding the potential benefit of this strategy to reduce the incidence of distant metastases. The vincristine, Adriamycin, and cyclophosphamide regimen would be considered ineffective for this disease. Adjuvant chemotherapy for nasopharyngeal carcinoma requires further formal study using more efficacious regimens.

In summary, three randomized trials evaluating cisplatin-based induction chemotherapy have been performed. Only the INSCG trial used an active regimen optimally (three cycles of BEC)<sup>467,468</sup> and observed significant improvement in disease-free survival. None of the induction trials, however, could demonstrate a survival advantage. The role of adjuvant chemotherapy is unclear as only one randomized trial was designed to specifically address this question, but an ineffective chemotherapy regimen was tested.<sup>472</sup> In contrast, the U.S. Head and Neck Intergroup trial of concurrent cisplatin and radiotherapy was highly positive,<sup>280</sup> and the early, preliminary results of the Prince of Wales Hospital, Hong Kong, trial using concurrent cisplatin on a weekly schedule are supportive. These results now suggest that radiotherapy alone is insufficient treatment for patients with T3 to T4 or node-positive nasopharyngeal cancer. Chemoradiotherapy followed by adjuvant chemotherapy as used in this intergroup trial should be considered the standard of care for this disease.

### Results of Treatment

External-beam RT alone has shown to provide excellent local control for T1 and T2 lesions of the nasopharynx.<sup>473,474,475,476</sup> and <sup>477</sup> Wang reported better results when intracavitary RT is added to external-beam treatment alone.<sup>473</sup> However, results with external-beam plus intracavitary RT are equivalent to the results of external-beam RT alone in other large centers. Well-delivered external-beam RT should provide local control in at least 90% of patients with T1 lesions, and between 85% and 90% of patients with T2 lesions. Doses in the 6500 and 7000 cGy range are used.

For T3 and T4 disease, local control rates have been significantly lower than the earlier stages, ranging from 62% to 73% for T3 lesions and 44% to 71% for T4 lesions.<sup>474,475</sup> and <sup>476</sup> There is a suggestion of a dose response curve for RT. Vikram et al.<sup>478</sup> reported a 90% local control rate for T4 patients receiving more than 6700 cGy, although few patients have been followed beyond 4 years. With the use of three-dimensional treatment planning and delivery, dose escalation to 7500 cGy and

beyond may be feasible. Investigators at Memorial Sloan-Kettering Cancer Center have had ongoing experience with both three-dimensional conformal radiation alone and in conjunction with concomitant chemotherapy and concomitant boost radiotherapy.<sup>479</sup> Comparison of the outcomes for patients treated with once-daily RT versus concomitant boost RT, both with concurrent chemotherapy, showed a significant advantage to the concomitant boost technique. The implication of these data is that dose escalation alone is not adequate. However, the combination of three-dimensional treatment planning, concomitant boost fractionation, and concurrent chemotherapy are important in improving the outcome.

Results from M. D. Anderson Cancer Center show control of neck disease in all 35 N0 patients, 27 of 30 (90%) for N1, 24 of 26 (92%) for N2a, and 28 of 33 (85%) for N2b. However, patients with N3a metastases in the neck did worse, with only 10 of 16 (63%) being controlled. Today, most patients with N3 neck disease receive chemotherapy along with irradiation. Neck dissection is reserved for salvage for residual disease that persists after radiation or chemoradiation.

## ORAL CAVITY

### EPIDEMIOLOGY

Oral cavity cancer represents a multiplicity of diseases. Epidemiology as it relates to each of these disease processes likewise differs. However, given that squamous cell carcinoma represents the preponderance of cancers that occur in this region, greater attention is focused on its etiologic determinants.

It is estimated that 30,000 new cases of oral cavity cancer occur annually.<sup>480,481</sup> The relationship between tobacco exposure and disease development has been clearly demonstrated.<sup>482,483</sup> A clear dose-response relationship has been identified with a greater risk being directly proportional to intensity and duration of exposure. Alcohol has been identified as a coagent, most probably through a topical effect.<sup>484</sup> The mucosal areas that are exposed to prolonged contact with alcohol are at greatest risk of cancer development. Readers are referred to reviews on mechanisms of tobacco-induced carcinogenesis for in-depth understanding.<sup>485</sup> Likewise, reviews regarding the role of alcohol in cancer development are available.<sup>482,486</sup>

Cigarette smoking cannot be considered the sole etiologic agent for oral cavity cancer. This fact is made evident by the observation that over 50 million individuals in the United States consume cigarettes. The percentage of the total population that uses tobacco in its various forms is even greater. As mentioned, however, only 30,000 individuals develop oral cavity cancer annually. Other factors must therefore be considered. Arguably it is genetic susceptibility that may be the most significant. Genetic factors associated with increased risk include mutagen sensitivity, which is potentially reflective of an underlying DNA repair deficiency.<sup>487</sup> Syndromes that are characterized by mutagen sensitivity including xeroderma pigmentosum, Fanconi's anemia, and ataxia-telangiectasia have all been associated with oral cavity cancers.<sup>488</sup> Other relevant genetic markers may include inducibility of the cytochrome P-450 enzyme system.<sup>489</sup>

Additional risk factors for oral cavity cancer include diet.<sup>490,491</sup> Patients with vitamin A deficiency have been considered at high risk of malignant transformation of oral mucosa. High dietary consumption of fruits and vegetables have been found to provide a protective effect. Chronic irritants have been considered an etiologic factor, including mouthwash, poor dental hygiene, and syphilis.<sup>492,493</sup> Reports have incriminated marijuana smoking as a contributing factor to oral cavity cancer.<sup>494</sup>

Studies have focused on the viral etiology of cancers within the upper aerodigestive tract. Herpes simplex virus type 1 has long been considered an etiologic agent. The inability to identify herpes simplex virus type 1–related proteins within oral cavity cancers has, however, raised questions as to the significance of this virus.<sup>495</sup> Investigations have identified human papilloma virus within head and neck cancers, specifically types 2, 11, and 16.<sup>496,497,498</sup> and <sup>499</sup> Papilloma transcriptional factors, when inserted within human DNA, can alter normal gene replicative control mechanisms.

### ANATOMY

The anatomy of the oral cavity is covered for each specific site.

### STAGING

T staging for oral cavity cancer applies to all subsites within the oral cavity unless otherwise stated. For the oral cavity the definition of T staging is presented in [Table 30.2-21](#). The regional lymph node (N) and distant metastases (M) staging are identical to other sites within the upper aerodigestive tract (see [Staging and Screening](#), earlier in this chapter).

TX	Primary tumor cannot be assessed
T0	No existence of primary tumor
Tis	Carcinoma in situ
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension
T4(lip)	Tumor invades adjacent structures (e.g., through cortical bone, tongue, skin of neck)
T4(oral cavity)	Tumor invades adjacent structures (e.g., through cortical bone, into deep, extrinsic, muscle of tongue, maxillary sinus, skin)

**TABLE 30.2-21.** Staging for Oral Cavity Cancer

### PATHOLOGY

The most common cancer within the oral cavity is squamous cell carcinoma. Additionally, cancers can arise from minor salivary glands; these latter cancers include adenoid cystic carcinoma, mucoepidermoid carcinoma, and adenocarcinoma. Rare soft tissue neoplasms include mucosal melanoma, plasmacytoma, and soft tissue sarcomas. Also found within the oral cavity are cancers arising from bone including osteosarcomas.

There also exist neoplastic lesions that are not truly malignant disorders of bone growth such as ameloblastoma. These lesions, however, have a propensity for local expansion and destruction. The principles of sound oncologic surgery and radiation thus apply to these processes.

### NATURAL HISTORY

Earliest changes associated with squamous cell carcinoma are associated with erythema and slight mucosal surface irregularities. Many times a punctate lesion also is identified. As disease progresses, several growth patterns emerge that can be typically characterized as exophytic or infiltrative. The latter is more characteristically associated with destruction of surrounding anatomic structures. The exophytic lesions have a less aggressive growth pattern. It should be realized that both patterns are capable of producing metastasis and disease progression. Therapy should be planned accordingly.

Characteristics of the disease are reflected in certain histopathologic criteria. When considering tumor differentiation it has been reported that poorly differentiated disease has a greater propensity for metastasis than well-differentiated disease. This has, however, not been universally accepted. Jacobsson's criteria, as outlined in [Table 30.2-1](#), likewise reflects the natural history of the disease. More specific information regarding natural history is covered in each anatomic subsite.

### LIP

## EPIDEMIOLOGY

Carcinoma of the lip is second only to skin cancer as a site of neoplasia within the head and neck region. It is noted to occur in approximately 3600 cases per year (i.e., 1.8 persons per 100,000 population annually).<sup>480</sup> The majority of these lesions occur on the lower lip and 95% occur in male subjects. A principal etiologic factor, similar to other upper aerodigestive cancer, has been the use of tobacco, including both pipes and cigars.<sup>500</sup> Sun exposure has also been incriminated and may represent the most significant factor. The latter fact is of potential relevance given the increased incidence of other skin cancers as well as lip cancer. Patients genetically susceptible to skin cancers following sun exposure (i.e., patients with xeroderma pigmentosum) are likewise susceptible to lip cancer.<sup>488</sup> Such an observation emphasizes ultraviolet radiation as an etiologic agent. Disease has likewise been noted in renal and homograft recipients, implicating immune suppression as a determinant.<sup>501</sup>

## ANATOMY

The lip is composed of the orbicularis oris muscle and is delineated by the junction of the vermilion border with the skin. Blood supply and sensory nerve supply are by means of the labial artery (a branch of the facial artery) and by cranial nerve V, respectively. The primary lymph node drainage is to levels I and II.

## PATHOLOGY

The principal cancer involving the lip is squamous cell carcinoma. Another common lesion is basal cell carcinoma. Rarely, minor salivary gland cancers can occur.

## NATURAL HISTORY

Patients most frequently present with either an exophytic or ulcerative lesion of the lower lip. Occasionally, these lesions are associated with bleeding and pain. The latter symptom, however, is a late feature of the disease. These lesions are typically slow-growing lesions. With progression there may be associated numbness of the skin of the chin secondary to involvement of the mental nerve, a branch of the third division of cranial nerve V. Furthermore, progression of disease along the mental nerve may extend into the mental foramen of the mandible. Such involvement leads to enlargement of the foramen with bone destruction and widening of the inferior alveolar canal. A Panorex examination of the mandible is recommended as part of each diagnostic evaluation.

Lymphatic spread occurs relatively infrequently in lip cancer; approximately 5% to 10% of patients develop evidence of nodal involvement.<sup>502,503 and 504</sup> Lymph node spread is typically to submandibular nodes or submental nodes. Lesions in the midline may spread bilaterally. The incidence of metastases has been related to histologic grading, with high-grade lesions being at greatest risk. The upper lip tends to metastasize earlier than the lower lip. Upper lesions metastasize to parotid nodes (i.e., preauricular nodes, in addition to submandibular nodes).

The prognosis from lip cancer is principally dependent on the size of the primary tumor.<sup>505,506 and 507</sup> T1 lip cancers have a 5-year survival of 90%. T2 survival is 84%. With evidence of lymph node metastases, survival decreases to 50%. Perineural invasion represents a bad prognostic sign.<sup>508</sup> Likewise, prognosis appears worse in younger adults.<sup>509</sup> Tumors have a greater tendency to metastatic spread in these latter patients.

## TREATMENT

### Early Disease

Surgery or radiotherapy are the mainstays of therapy. Dysplasias and carcinoma *in situ* can be handled by lip shave (i.e., vermilionectomy with advancement of a mucosal flap). Those lesions that involve less than 30% of the lip can be resected with a V excision and primary closure of resulting defects. For larger lesions transposition flaps are required for reconstruction.

Undoubtedly the challenge in the surgical management of lip cancer resides in the best means of reconstruction. Oral competence remains the primary goal. Those lesions that require resection of 30% to 50% of the lip, can be best handled with a transposition flap drawn from the uninvolved opposing lip. This reconstruction technique is termed Abbe-Estlander.<sup>510,511 and 512</sup> When the near total lip is involved (i.e., 50% to 75%), the Karapandzic advancement flap can be used.<sup>513</sup> This has the benefit of providing a competent oral sphincter with an associated neurovascular integrity.

The problem with the Karapandzic reconstruction is the reconstructed lip is tight and significantly foreshortened. Other methods have been devised.<sup>514,515 and 516</sup> These vary from simple nasolabial flaps based inferiorly or superiorly to more formal fan-type flaps such as the Gillies flap and Webster cheek advancement flap.<sup>516</sup>

Most T1 to T3 squamous cell carcinomas of the lip can be managed by either RT or surgery. The choice of radiation or surgery may depend on the size and location of disease. If the lesion is quite small and can be easily excised without functional sequelae, surgery would be the chosen treatment. Lesions involving commissures can be irradiated, without the functional sequelae of surgery. However, involvement of the commissure under such circumstances is rare. Brachytherapy alone can be used for early T1 and small T2 lesions. Temporary implantation with <sup>192</sup>Ir or localized electron-beam irradiation can be used. Implant doses of 60 Gy over 6 days, or external-beam doses of 50 Gy in seven fractions to 60 Gy can be used. [Figure 30.2-10](#) shows a clinical example of the brachytherapy procedure.

**FIGURE 30.2-10.** **A:** A patient with a T1N0 squamous cancer of the lower lip. The lesion measured 2 cm in greatest diameter and involved the commissure. **B:** An implant was used as treatment. Under local anesthesia with 2% lidocaine, 14-gauge angiocatheters were placed through the lesion. After localization and planning films were done, <sup>192</sup>Ir was loaded into these catheters. A total of 6000 cGy in 67 days was delivered. **C:** The patient had no evidence of disease at 3 years. (From ref. 517, with permission.)

Given the infrequency in which early cancers spread to regional lymph nodes, elective treatment of the neck is not necessarily required.

### Advanced Disease

Stage III and IV lip disease are optimally managed with combined surgery and postoperative RT. Selected T3 lesions can be managed with either radiotherapy alone or surgery alone. Reconstructive options are as described in the previous section. Doses in the 6000- to 6300-cGy range, delivered at 180 to 200 cGy per fraction over 6 to 7 weeks, is preferred. If the patient has lymph node metastases in the neck, a neck dissection would be done along with the resection of the primary site. The postoperative RT would then be delivered to both the neck and the primary site. Even if the patient were N0, one should still use elective RT or elective node dissection as part of the management, given the increased risk of microscopic lymph node metastases in these patients.

For patients with T1 to T3 disease who have had an operation, sometimes the radiation oncologist is faced with a positive margin of resection. This can either be managed with brachytherapy alone, or localized superficial external-beam irradiation, with similar doses and techniques as when RT alone is used.

### **Results of Treatment**

The RT results are similar to the reported results of surgical management.<sup>517</sup> Heller and Shah reported approximately 90% local control for T1, T2, and T3 lesions treated with surgery alone.<sup>505</sup> A significant problem in surgical management is local recurrence, which may approach 40% for T3 and T4 lesions.<sup>503</sup> Fitzpatrick has reported the Princess Margaret Hospital experience, which also documents that the results of RT and surgery are basically equivalent.<sup>518</sup>

Jorgensen et al. have reported a series of 869 lip cancers.<sup>519</sup> In 766 patients, treatment was performed entirely with brachytherapy. The remaining cases had external-beam radiation, mainly with orthovoltage beams. The majority of patients had either T1 or T2 lesions, with only 75 having T3 lesions. Local control was in the 90% range. External-beam radiation can also be used. Petrovich et al. reported on 250 patients, most receiving 5100 cGy in 3 weeks with daily fractions of 300 cGy.<sup>520</sup> There were a total of 896 patients in the study, most of whom were treated with orthovoltage beams. Local control was obtained in 94% of T1 and T2 lesions and in 90% of T3 lesions. For T4 disease, 47% of the patients obtained local control with radiation alone, pointing to the need for combined modality treatment for this subset. Sykes et al. reported 26 patients with T1 to T2 squamous cell cancers of the lip treated with electron-beam radiation.<sup>521</sup> With median follow-up of 31 months (range, 1.5 to 60.0 months), there was 100% local control.

## **ALVEOLAR RIDGE AND RETROMOLAR TRIGONE**

### **EPIDEMIOLOGY**

Cancers of the alveolar ridge and retromolar trigone account for approximately 10% of all oral cancers.<sup>522</sup> Male subjects are more frequently affected at a ratio of 4:1. An increased frequency in rural women in the southeastern United States has been stated to occur.

### **ANATOMY**

The alveolar ridge consists of an upper and lower portion. The lower alveolar ridge has as its structural basis the alveolar process of the mandible, extending from the ascending ramus to ascending ramus not inclusive of the retromolar trigone. Its borders extend from the gingival-labial sulcus to the free mucosa of the floor of the mouth. The alveolar process of the maxillary bone constitutes the upper alveolar ridge. The retromolar trigone is a triangular area that is composed principally of mucosa overlying the ascending ramus of the mandible. It is bounded superiorly by the hard palate, inferiorly by the alveolar ridge, medially by the anterior tonsillar pillar, and laterally by the gingival buccal sulcus.

Lymphatic drainage of the alveolar ridge and retromolar trigone is principally to levels I and II.

### **PATHOLOGY**

Squamous cell carcinoma represents the near total majority of lesions in this area. Minor salivary gland lesions (i.e., mucoepidermoid carcinomas and adenoid cystic carcinomas) can occur.

### **NATURAL HISTORY**

Squamous cell carcinoma of the alveolar ridge grows in patterns similar to other squamous cell carcinomas of the oral cavity (i.e., either as exophytic lesions or as infiltrative disease). The latter is commonly associated with bony destruction, which occurs in up to 58% of cases. The presenting symptom is primarily pain, which is exacerbated by chewing. Other symptoms include intermittent bleeding as well as loose teeth. In those patients who are edentulous, the principal complaint relates to ill-fitting dentures. The lower alveolus is affected most often in the molar and premolar region. Delay in diagnosis is characteristic because of confusion with inflammatory conditions such as gingivitis or periodontitis.

These lesions have a higher probability of regional lymph node metastases than other cancers within the oral cavity, with the exception of tongue cancer. Overall, the probability of lymph node metastases increases directly with the size of the primary and averages 30%.<sup>523,524,525,526 and 527</sup> It may increase up to 70% for T4 cancers. It is of note, however, that lymph node metastases tend to occur more frequently from mandibular alveolar ridge cancers than maxillary alveolar ridge disease. Metastatic disease is primarily to lymph nodes in levels I and II. Byers et al. noted that less than 5% of patients develop disease in the posterior cervical triangle.<sup>527</sup>

The prognosis from alveolar ridge carcinoma is reflected by the extent of primary and regional lymph node metastatic disease.<sup>524,525,526 and 527</sup> T1 cancer of the alveolar ridge can be expected to have an 85% survival. T2 lesions and T3 lesions are associated with 80% and 60% survival, respectively. Prognosis with T4 lesions is poor, approximating 20%.

### **TREATMENT**

#### **Early Disease**

Surgical management of carcinomas of the alveolar ridge reflects the management principles of cancers of other sites within the oral cavity. The fundamental feature remains the achievement of tumor-free surgical margins with the preservation of critical anatomic structures.

Early T1 or T2 lesions of the alveolar ridge can be managed successfully by surgery alone. With minimal cortical involvement or with involvement by cancer confined to the mucoperiosteum, resection may include a marginal (coronal) mandibulectomy that preserves structural integrity of the mandible. The ability to preserve segments of the mandible is in part dependent on dental status. Not infrequently, edentulous patients present with thin *pipestem* mandibles that preclude all but a segmental resection.

The tendency for bone invasion by alveolar ridge carcinomas through thin mucoperiosteum or through tooth sockets makes primary radiation less feasible. In general, lesions of the gingiva are best managed by surgery. Studies by McGregor and MacDonald have reinforced the notion that a conservative approach to the management of the mandible can only be justified by a thorough understanding of patterns of spread of squamous cell carcinoma into bone.<sup>528</sup>

The need for neck dissection for alveolar ridge carcinomas is enhanced secondary to its tendency to regional nodal spread. The considerations for elective neck dissection as well as the type of neck dissection have been discussed previously in this chapter (see [Surgical Management of the Cervical Lymph Nodes](#), earlier in this chapter). The infrequency of tumor spread to levels IV and V has led to acceptance of selective neck dissection of levels I through III in instances of a clinically N0 neck.

#### **Advanced Disease**

Advanced staged tumors generally require multimodality therapy including surgery and radiation. Segmental mandibulectomy is required. Advances in the management of such disease has related to improved reconstructive techniques, principally the use of osteomyocutaneous free-tissue transfer.<sup>529</sup>

#### **Treatment Results**

In those studies that report primary surgery results, the actuarial survival for stage I and II was 77% at 5 years, compared with approximately 60% for stage III, and 24% for stage IV.<sup>527,530</sup>

There are relatively few patients reported in the literature with gingival carcinoma who have been managed with primary RT. <sup>530,531</sup> Fuchihata et al. reported a group of patients treated with external-beam irradiation and chemotherapy (bleomycin or peplomycin). <sup>532</sup> Major responders were treated definitively using this approach, whereas others underwent surgery. Responders with T1 and T2 lesions who were not operated on had local control at 3 years of 95%, while those who had surgery had local control of 86%. For T3 and T4 lesions, the nonsurgical group had local control of 45%, while the surgery group had local control of 75%. Thus, there may be a role for nonsurgical management in selected early lesions, but more advanced lesions definitely benefit from surgery followed by postoperative radiation. Early retromolar trigone tumors can be treated successfully by primary radiation, especially when they are superficial. [Figure 30.2-11](#) shows a clinical example.

**FIGURE 30.2-11.** **A:** A patient with a T2N0 squamous cancer of the right retromolar trigone. The patient was treated with definitive external-beam radiation therapy to the primary and ipsilateral neck. **B:** The treatment plan involved a wedged photon pair. The boost field is shown. The contralateral parotid area received less than 10% of the dose, thereby avoiding xerostomia. The primary site received 7020 cGy, at 180 cGy per fraction. The right low neck received 5000 cGy over 5 weeks with an ipsilateral low neck field (not shown). **C:** The patient had no evidence of disease at 6.5 years.

## FLOOR OF MOUTH

### EPIDEMIOLOGY

The annual incidence of cancers of the floor of mouth is 0.6 cases per 100,000 in the United States. <sup>480</sup> It occurs in male subjects approximately three times as frequently as female subjects. Reports, however, have demonstrated an increasing incidence of the disease among women. <sup>533</sup> The median age of individuals developing squamous cell carcinoma is approximately 60 years.

### ANATOMY

The floor of mouth is delineated by the free margin of the mucosa as it extends from the junction of the mobile tongue to the alveolar process. This margin extends from one anterior tonsillar pillar to the other. Within the floor of mouth anteriorly are the openings of bilaterally located submandibular salivary glands, Wharton's ducts. These ductal openings are significant because anterior lesions of the floor of mouth can frequently obstruct associated salivary flow, leading to tenderness and enlargement of the respective submandibular gland. Also within the floor of mouth are minor salivary glands and the sublingual glands. Distinct from mucosa of the tongue, mucosa of the floor of the mouth is nonkeratinizing stratified squamous epithelium under nonpathologic situations. Musculature making up the floor of mouth include the genioglossus, geniohyoid, and mylohyoid muscles. Blood supply and nerve supply are principally from the paired lingual arteries and lingual nerves, respectively.

### PATHOLOGY

Cancers of the floor of mouth account for approximately 10% to 15% of all oral cavity cancers. Squamous cell carcinoma constitutes the majority of lesions within the floor of mouth, with the majority of these lesions being moderate to well differentiated. There are several variants of squamous cell carcinoma of the floor of mouth. This includes verrucous and sarcomatoid squamous cell carcinoma. Cancers derived from salivary gland tissue also are encountered including mucoepidermoid carcinomas, adenocarcinomas, and adenoid cystic carcinomas.

### NATURAL HISTORY

Squamous cell carcinomas of the floor of mouth typically present as infiltrative lesions that are characteristically painful. These lesions may extend anteriorly to invade bone, deeply to infiltrate muscles of the floor of mouth, or posteriorly to invade tongue. On occasion, an enlarged lymph node in the neck is the presenting symptom.

Floor of the mouth cancers can grow to massive size without metastasizing to cervical lymph nodes. However, approximately 12% of T1 lesions are associated with occult metastatic disease, depending on the thickness of lesion. <sup>74</sup> Metastatic rates to cervical lymph nodes occur in 30%, 47%, and 53% of T2, T3, and T4 cancer, respectively. <sup>74</sup> Lymph nodes in the submandibular and submental triangles represent the first echelon of metastatic sites. Distant metastases is infrequently observed in patients who present with previously untreated disease.

Prognosis is influenced principally by disease stage and presence or absence of histopathologically confirmed regional lymph node metastases. The overall 5-year survival for stage I disease approximates 85% to 90%. <sup>534,535</sup> For stage II, III, and IV disease, 80%, 66%, and 32% of patients are alive at 5 years, respectively. Other factors considered to reflect a worse prognosis include evidence of perineural invasion, depth of primary tumor invasion, and poor tumor differentiation. <sup>536,537,538</sup> and <sup>539</sup> Poor tumor differentiation, however, has not been universally accepted as having prognostic significance.

### TREATMENT

#### Early Disease

Treatment of floor of the mouth cancers has been principally surgical resection, but may either be surgery or radiation alone. As is true for cancers of the alveolar ridge, superficial involvement of the mandible can be handled by marginal mandibulectomy ( [Fig. 30.2-12](#) ).

**FIGURE 30.2-12.** Types of mandibular resection for squamous cell carcinomas of the floor of mouth. **A:** Marginal resection that preserves mandibular continuity. **B:** Segmental mandibulectomy in which the entire segment of mandible is removed and mandibular continuity is lost. (From Shah JP, Shemen LJ, Strong EW. Surgical therapy of oral cavity tumors. In: Thawley SE, Panje WR, eds. *Comprehensive management of head and neck tumors*. Philadelphia: WB Saunders, 1987:558, with

permission.)

When radiation is used for early disease, it has been shown that results are improved when at least a portion of the treatment is delivered by an interstitial implant.<sup>539,540</sup> Interstitial implant alone can also be used.<sup>541</sup> Prostheses can be designed to protect the mandible for brachytherapy (Fig. 30.2-13). Lesions that abut or are tethered to the periosteum of the mandible or lesions that extend onto the gingiva are not good candidates for primary radiotherapy. Implants against the mandible can lead to osteonecrosis.

**FIGURE 30.2-13.** Prosthesis with lead lining that fits onto the lower teeth and serves as mandibular protection for brachytherapy. (Compliments of Dr. Joshua Verona, Dental Service, Beth Israel Medical Center.)

The treatment of the neck for early cancer of the floor of mouth is controversial. Most advocate elective neck treatment for clinically N0 disease. The value of this approach as compared with observation with neck dissection and RT being performed for clinically developing disease remains unproven. Some have advocated performing neck dissection depending on the thickness of the primary lesion (i.e., greater than 4-mm thickness).

### **Advanced Disease**

For advanced lesions, combined therapy of surgery and radiation is the treatment of choice. Surgical resection generally entails partial glossectomy and segmental mandibulectomy. Identification of the inferior alveolar nerve and frozen section histopathologic assessment should be performed during the operation. This is to ensure that disease has not extended beyond surgical margins by perineural spread. Resection for most advanced lesions requires removal of the entire thickness of the floor of mouth.

New reconstructive techniques have greatly facilitated rehabilitation following surgical excision of advanced tumors. Techniques include myocutaneous flaps as well as osteomyocutaneous free flaps with microvessel anastomoses.<sup>542</sup>

Elective, therapeutic, or both kinds of neck dissections are considered necessary in each case. Bilateral neck dissections are indicated for those lesions that approach or cross the midline.

Postoperative radiation entails doses in the range of 6000 to 6300 cGy at the primary site. In instances of positive surgical margins, our policy is to treat the area of positive margins to 6300 cGy. Certain patients with positive margins may be treated with adjuvant brachytherapy instead of external-beam RT.<sup>543</sup>

### **Results of Treatment**

Local recurrences after surgical resection of T1 and T2 floor of the mouth cancers are noted in no less than 10% of the patient population.<sup>534,535</sup> As tumors increase in size, the pattern for failure becomes predominately a regional problem. Nearly 40% of failures are solely within regional cervical lymph nodes.<sup>535</sup>

Mazon et al. have reported a large radiotherapy series.<sup>541</sup> The majority of patients were treated to 65 Gy with <sup>192</sup>Ir brachytherapy alone. Local control was 94% for T1 N0, and 74% for T2 N0 lesions and was dependent on size of the lesion as well as the presence or absence of gingival extension. For T2 lesions between 2 and 3 cm, local control was 58%. For lesions with gingival extension, local control was 50%. There is an interest in using high dose-rate brachytherapy for floor of the mouth lesions.<sup>544,545</sup> Inoue et al. reported 2- and 5-year local control of 94% and 94% for a cohort of mainly T1 to T2 lesions treated with high dose-rate brachytherapy alone or combined with 30- to 40-Gy external-beam RT.<sup>545</sup>

Wang et al. have reported excellent results with the use of intraoral cone electron boost and no brachytherapy.<sup>547</sup> The daily dose of radiation via the cone is frequently greater than the conventional 180- to 200-cGy range. Local control was obtained in all 13 patients with T1 lesions, and in 19 of 20 (95%) with T2 lesions.

Fu et al. have published an extensive RT experience with floor of the mouth cancer.<sup>548</sup> When implant was either the only treatment or a part of the treatment, local failure occurred in only 2% (1 of 39 patients) with T1 lesions, 7% (4 of 54 patients) with T2 lesions, and 14% (5 of 35 patients) with T3 lesions. The use of primary radiation may be associated with improved functional outcome as compared with surgery, but this requires more investigation.<sup>546,549,550</sup>

There is a cohort of patients who undergo surgery and are referred for postoperative radiotherapy because the pathology reveals positive or close margins. In this setting, certain patients may be treated with brachytherapy alone, thereby limiting the high-dose region to the area at risk. This is not always technically or oncologically feasible. When it is, it can provide the patient with local control in excess of 80%<sup>543</sup> and can avoid the sequelae of wide-field external-beam irradiation to the oral cavity.

## **TONGUE**

### **EPIDEMIOLOGY**

Tongue cancer is estimated to occur in 6200 individuals per year in the United States.<sup>480</sup> Excluding lip, it exceeds all other sites in the oral cavity. The median age for individuals with tongue cancer is approximately 60 years. The male to female ratio is similar to other disease sites, approximately 3:1. It is of interest that an increase in tongue cancer has been reported among young adult men.<sup>551,552</sup> Some have suggested marijuana use as a contributing factor in this latter population.<sup>494</sup>

### **ANATOMY**

The oral tongue represents the mobile portion of the tongue musculature that extends from the line demarcated by the circumvallate papilla posteriorly to the junction of the floor of mouth anteriorly. It is made up of the genioglossus, hyoglossus, styloglossus, and palatoglossus muscles. All of these muscles are innervated by the hypoglossal nerves. Taste and sensation within the tongue are provided by the lingual nerve, a branch of the third division of the cranial nerve V. Blood is supplied principally from the external carotid artery through the paired lingual arteries. Lymphatic drainage is principally to level II, III, and I in decreasing order.

### **PATHOLOGY**

The primary cancer of the tongue is squamous cell carcinoma. Other cancers are frequent and include minor salivary gland cancers such as adenoid cystic carcinoma and adenocarcinoma. Myeloblastoma represents a rare tumor of the tongue.

## NATURAL HISTORY

These cancers can grow in both an exophytic and an infiltrative fashion. The primary presenting symptom is pain, although many of these lesions can be painless. Difficulty in speech and deglutition is occasionally elicited. It tends to be more rapid in its onset than other cancers within the oral cavity. There may be a history of long-standing leukoplakia before the development of symptoms, especially in younger female subjects.

As compared with other cancers within the oral cavity, tongue cancers have a greater propensity for lymph node metastases. This occurs in ranges from 15% to 75% depending on the extent of primary disease.<sup>553,554</sup> Lymph nodes most frequently involved lie within level II (i.e., jugulodigastric nodes). Nodes within level I, III, and IV are involved in decreasing order. It is of note, however, that all nodes can be involved. The incidence of bilateral nodal metastases occurs in up to 25% of cases. Contralateral nodal metastases are present in 3% of cancers.

Prognosis is principally reflected in extent of nodal metastases, ranging from 75% in early-stage node-negative disease to 30% in those with advanced lesions. Other factors portending more aggressive disease include perineural and vascular invasion and infiltrative versus pushing borders.<sup>555,556</sup> Depth of invasion has likewise been considered significant. Whether or not tongue cancer in young adults represents a worse disease has not been demonstrated.<sup>557</sup>

## TREATMENT

### Early Disease

It is generally considered that disease-control rates for early disease when using either surgery or RT are equivalent depending on treatment bias. Early stage I and II lesions can usually be removed intraorally. Excision usually entails a hemiglossectomy. Special attention to surgical margins should be exercised as disease may spread along muscle bundles beyond that expected by clinical assessment.

Most T1 lesions can be managed with brachytherapy alone. This generally consists of an <sup>192</sup>Ir implant, although high dose-rate implants are also being used.<sup>558,559</sup> and <sup>560</sup>

Whether low dose-rate or high dose-rate is used, the catheters themselves are placed in the operating room under general anesthesia. The <sup>192</sup>Ir is loaded 1 to 2 days postoperatively. Localization films are taken, and computerized dosimetry is performed. The usual dose rate is in the 40 to 60 cGy/h range, and the usual total dose is 6000 to 7000 cGy. The patient wears a tongue prosthesis during the dwell time of the implant to protect the hard and soft palate as much as possible. For high dose rate, 60 Gy fractions given twice a day over 6 days has yielded good results.<sup>558,559</sup>

As the lesion increases in size when using radiation as primary therapy, it is preferred to combine external-beam irradiation with implant. First, the external beam can be used as elective neck irradiation simultaneous with irradiation to the tongue. The implant then serves as the boost to the tongue. Second, the external beam allows a wider margin of tongue to be treated than does the implant. In these situations, it is typical to treat the primary site and the neck to doses in the 5000-cGy range, followed by a 2000- to 3000-cGy implant boost to the tongue.

For N0 patient, this treatment program manages both the primary site and the neck. For those patients with palpable neck nodes, a neck dissection can be performed at the same as anesthesia for the implant, thereby completing the treatment to the primary site and the neck. This can usually be done approximately 3 weeks after the completion of the external-beam irradiation.

RT is certainly suitable for most T1 lesions. For T2 and T3 lesions, it is most suitable for those tumors that are exophytic or have minimal infiltration. Tumors that are deeply infiltrative are preferably managed with a primary surgical approach, usually with postoperative RT.

### Advanced Disease

The surgical management of more extensive lesions requires either a mandibulotomy or a lingual-releasing procedure to gain access to disease. The latter procedure entails removal of neck contents before primary cancer resection. The tongue is delivered into the neck by releasing musculature attachments posteriorly and mucosal attachments within the oral cavity. Large lesions with mandibular involvement require composite resection. The term *composite resection* refers to the removal of tissue involving multiple anatomically defined structures, one of which includes the mandible ( Fig. 30.2-14). Typically, it refers to resection of a portion of tongue, floor of the mouth, and segment of mandible.

**FIGURE 30.2-14.** Composite resection of tongue, floor of mouth, and margin of mandible. (From Shah JP, Shemen LJ, Strong EW. Surgical therapy of oral cavity tumors. In: Thawley SE, Panje WR, eds. *Comprehensive management of head and neck tumors*. Philadelphia: WB Saunders, 1987:558, with permission.)

For patients who require postoperative RT to the primary site alone, this can frequently be done with brachytherapy. This is especially true for the smaller lesions. The decision of how to deliver this irradiation is integrated with the management of the neck. We prefer to use neck dissection as part of the management of all deeply infiltrative or advanced tongue lesions. For the N0 patients, this generally means a staging procedure or a functional neck dissection. For patients who have involved lymph nodes, this means either a radical neck dissection or one of its modifications. Yamazaki et al. have shown a clear relationship between tumor thickness and neck failure in a cohort of patients treated with brachytherapy alone: The incidence of neck metastases was 50%, 40%, and 30% for tumors greater than 11 mm, 6 to 10 mm, and less than or equal to 5 mm, respectively. T stage also correlated with tumor thickness.<sup>560</sup>

### Results of Therapy

Decroix and Ghossein from the Curie Institute in Paris have reported on over 600 patients treated with primary RT for T1, T2, or T3 squamous cell carcinoma of the oral tongue.<sup>562</sup> Although the majority of patients had implants alone, a large cohort had combined external-beam irradiation plus implant. Almost all patients at this center received RT as their primary treatment. Primary control was obtained at 86% for T1, 80% for T2, and 68% for T3. These data compare quite favorably with the results obtained with partial glossectomy.

Pernot et al. have reported a series of 448 patients with brachytherapy alone with or without neck dissection (181 patients) or combined external beam plus brachytherapy (267 patients) for oral tongue cancer.<sup>563</sup> The 5-year local control was 93% for T1, 65% for T2, and 49% for T3 lesions. For T2 lesions managed by

brachytherapy alone, local control was 90% versus 50% for those managed by external beam plus implant. These data emphasize the importance of using brachytherapy as a major part of the radiation program, but patient selection factors clearly play a role as well. The 5-year overall survival for T1, T2, and T3 lesions (all N stages) was 69%, 41%, and 25%, respectively. Severe complications were uncommon. While 15% experienced grade 1 soft tissue injury, and 3% had grade 1 bone necrosis, only 1% and 2% had grade 3 soft tissue and bone complications, respectively. Spiro et al. have reviewed the Memorial Sloan-Kettering Cancer Center experience using partial glossectomy as primary management.<sup>564,565 and 566</sup> As was true for the Curie Institute series, the Memorial Hospital series is also relatively unselected, with primary surgery being offered to the great majority of patients at that institution. Local control was obtained in 85% for T1, 77% for T2, and 50% for T3. These data serve to highlight the similarity in local control rates for surgery or irradiation for most early tongue lesions.

Although the traditional brachytherapy approach has involved low dose-rate implants,<sup>562</sup> there has been an emergence of interest in high dose-rate brachytherapy for oral tongue.<sup>558,559</sup> Either high dose-rate alone or in combination with moderate doses of external-beam irradiation have been used. Inoue et al. compared low dose-rate versus high dose-rate implants in a small randomized trial of T1 to T2 oral tongue lesions, finding no major differences.<sup>558</sup> A program of 60 Gy in 10 fractions given twice a day over 6 days with high dose-rate yielded 100% local control at 2 years. All tumors had a thickness of 1 mm or less. Leung et al. reported similar local control using the same fractionation program.<sup>559</sup> Mucositis related to these implants can last up to 20 weeks.

There are relatively few recent studies that report the results of therapy for surgery alone for advanced disease.<sup>564,566,567</sup> RT is generally used in the postoperative setting.<sup>570,571</sup> Failure is most often within regional lymph nodes and leads to a 5-year determinate survival of 35% for stage III and IV disease.<sup>565,568</sup>

Ange et al. have reviewed their experience using implants after excisional biopsy for patients with positive or close margins.<sup>569</sup> Local control was obtained in nearly 100% of the cases. When the primary site and the neck require postoperative RT, external-beam techniques must be used. Doses in the 60- to 63-Gy range over 6 to 7 weeks are typically used.

Surgical salvage of radiation failures in the oral tongue can be difficult. Yuen et al. reported 47 patients who underwent attempted salvage for either local recurrence, locoregional recurrence, or regional recurrence.<sup>561</sup> Overall, 62% failed their salvage procedure. The 5-year actuarial survival was 39% for local recurrence alone, 27% for locoregional recurrence, and 68% for regional recurrence alone.

## **HARD PALATE**

### **EPIDEMIOLOGY**

Hard palate cancers account for approximately 5% of all oral cavity cancers.<sup>572</sup> The incidence of the disease in the United States approximates 0.4 per 100,000 population. The male to female ratio is 8:1.

### **PATHOLOGY**

Squamous cell carcinoma accounts for approximately 50% of hard palate tumors. The majority of these lesions are well differentiated. Other cancers occurring in this area include the minor salivary gland lesions such as adenoid cystic and adenocarcinomas, which may be as frequent as squamous cell carcinoma.

### **NATURAL HISTORY**

Cancers of the hard palate grow in a multiplicity of patterns including deeply infiltrating, destructive lesions versus diffuse superficial lesions associated with microscopic invasion.

When considering metastatic squamous cell carcinoma of the hard palate, lymph node metastases is less frequently encountered than cancers of other sites within the oral cavity, ranging clinically from 6% to 29%.<sup>553</sup> Likewise, distant metastasis is infrequent. Prognosis in patients with squamous cell carcinoma is 75%, 46%, 36%, and 11% for stage I through stage IV disease, respectively.<sup>573</sup>

### **TREATMENT**

#### **Early Disease**

Surgical management of early disease involves infrastructure maxillectomy (i.e., resection of the palatine process of the maxillary bone). Exposure for such resections is generally obtained through a Weber-Fergusson-type incision.

As stated earlier, carcinoma *in situ* and microinvasive disease can involve a significant portion of the hard palate with extension of disease onto the soft palate and retromolar trigone. Under such circumstances, primary radiation may be used.

Elective treatment of the neck is not generally required unless disease extends beyond the anatomic confines of the hard palate. Selective neck dissection under such circumstances is adequate. Such dissection includes removal of lymph nodes in levels I, II, and III.

#### **Advanced Disease**

Surgical resection of advanced disease may involve a near total palatotomy. Generally, however, lesser operations are required. Advances in the surgical therapy of hard palate cancers involve the immediate use of prosthetic obturators that allow for early restoration of adequate speech and swallowing. The need for postoperative radiation is based on the closeness or involvement of tumor margins by tumor, perineural involvement, the presence of regional lymph node metastases, or all three conditions.

#### **Results of Treatment**

Generally, incorporating the treatment philosophy described previously, Evans and Shah report an overall survival of 75% for stage I, 46% for stage II, and 36% and 11% for stage III and IV, respectively. The majority of patients who die of disease do so in the face of advanced local recurrence.<sup>573,574 and 575</sup>

## **BUCCAL MUCOSA**

### **EPIDEMIOLOGY**

Cancer of the buccal mucosa accounts for approximately 8% of oral cavity cancers in the United States.<sup>572</sup> The disease may be seen much more frequently in other parts of the world such as India depending on tobacco consumption patterns. Indeed, in the southeastern United States, the incidence of buccal mucosal cancer is much higher in women; an observation attributed to the common use of snuff. The median age of individuals with buccal mucosal cancer may be slightly higher than noted in patients with cancers of other sites within the oral cavity.

### **ANATOMY**

The buccal mucosa is composed of a mucous membrane that extends from the lips anteriorly to the retromolar trigone posteriorly. Inferiorly it extends from the lateral alveolar sulcus of the mandible to the lateral sulcus of the maxillary alveolar ridge. Its blood supply and nerve supply are from the facial artery and the third division of cranial nerve V. Lymphatics from the buccal mucosa drain primarily into level II and level I in decreasing order.

### **PATHOLOGY**

As in other sites within the oral cavity, squamous cell carcinoma is the predominant neoplasm. The verrucous variant of squamous cell carcinoma is frequently observed. Only rarely are other cancers, such as minor salivary gland tumors, observed.

## NATURAL HISTORY

Cancers of the buccal mucosa are more frequently exophytic than other cancers within the oral cavity. They are also relatively silent in their presentation and thus present rarely as T1 lesions. Pain is the initial presenting complaint and is subsequently followed by bleeding and difficulty chewing. With extension of the disease outside the confines of the buccal mucosa into the pterygoid musculature, patients may present with trismus. Disease not infrequently invades the mandible, maxillary alveolar ridge, or both.

Lymph node metastases are most frequently observed within levels I and II and are observed clinically in 10% of presenting patients. <sup>575</sup>

Five-year survival ranges from 77% to 18% depending on the stage of disease. <sup>577</sup> Urist et al. have shown that tumor thickness is a significant prognostic factor. <sup>576</sup> Patients with tumors less than 6 mm in thickness have significantly better survival rates than those with tumors greater than 6 mm in thickness, regardless of tumor stage.

## TREATMENT

### Early Disease

Small lesions (T1 and early T2) can be managed with equal effectiveness by either surgery or RT. If the tumor can be excised easily through the open mouth, with minimal functional sequelae, then small lesions are probably best managed in that fashion. Larger T1 lesions and lesions that approach the commissure are best managed with RT. T2 lesions can be managed with RT if they are exophytic or relatively superficial. Deeper lesions are probably best managed by surgery.

In patients with small lesions and a clinically negative neck, the neck can be observed. Neck failure occurs in less than 10% of patients. However, for more advanced lesions, the neck is treated electively with the same therapeutic modality that is used for the primary lesion.

RT can be used with a variety of different techniques. Interstitial brachytherapy, ipsilateral electrons, intraoral cone, or external-beam photon irradiation can all be employed. The exact technique depends on the clinical situation and the expertise of the radiation oncologist.

### Advanced Disease

More advanced disease requires surgery as the principal therapeutic modality, usually with postoperative radiation. The initial factor in such treatment relates to adequate operative exposure. This is generally facilitated by dividing the lip in the midline and resecting the cheek posterolaterally in order to gain optimal exposure.

Postoperative radiotherapy is used for patients with close or positive margins, high-grade lesions, positive nodes, bone invasion, and thick (greater than 10 mm) lesions. <sup>577</sup> Adequate locoregional treatment at initial diagnosis is essential, as locoregional failure is a major cause of death for patients with buccal mucosa cancer and few patients can be salvaged.

Care must be taken in assessing the need for resection of surrounding anatomic structures such as skin of face, upper alveolar ridge, and mandible. Invasion of tumor into buccal fat pad and into dermis of cheek skin occurs not infrequently. Such invasion generally requires full-thickness resections including oral mucosa and cheek skin. Such defects can be repaired with myocutaneous flaps. Free-tissue transfer is a relatively recent option for reconstruction.

Ipsilateral neck dissection is advocated in all instances of T3 or T4 primary disease, regardless of the nodal status.

### Results of Treatment

Nair et al. have reported on 234 patients with buccal mucosa cancer treated with RT. <sup>578</sup> Disease-free survival at 3 years was 85% for stage I, 63% for stage II, 41% for stage III, and 15% for stage IV disease. All 13 patients with T1 N0 disease were controlled with radiotherapy. Fifty percent of patients with T4 disease failed locally. The presence of nodal metastases clearly affected the local regional failure rate.

Lapeyre et al. reported an experience using definitive brachytherapy for epidermoid cancer of the buccal mucosa. <sup>579</sup> A variety of techniques were employed from 1973 to 1991. The loop technique provided the best results, with only 1 of 22 patients with T1 to T3 lesions having local recurrence. Bloom and Spiro reported the results for 90 patients with buccal mucosa cancer treated by surgery. <sup>580</sup> The 5-year survival rate by stage was 77%, 65%, 27%, and 18% for stages I, II, III, and IV, respectively. Local failure was noted in 47% of patients. Regional failure was observed in 37%.

Dixit et al. performed a comparative study on 176 patients with buccal mucosa cancer, comparing surgery alone with surgery plus postoperative radiation. <sup>577</sup> Postoperative radiation was found to improve local control for patients with positive nodes, close or positive margins, high-grade lesions, bone invasion, and thick tumors greater than 10 mm. Mishra et al. reported a randomized trial comparing surgery alone versus surgery plus postoperative radiotherapy. <sup>581</sup> There was improved disease-free survival (68% vs. 38%,  $P < .005$ ) in those who received radiation. This trial only included patients with stage III and IV disease.

## REHABILITATION OF THE ORAL CANCER PATIENT

Over the last decade there has developed an increased effort to address the rehabilitation of the oral cancer patient, the major considerations reflected in speech and swallowing disorders. <sup>582,583,584,585</sup> and <sup>586</sup> There is no question as to the effect of surgical resection of anatomic components of the oral cavity including the mandible, tongue, and other soft tissue components. The need to preserve function through appropriate reconstructive measures is becoming increasingly apparent. Likewise, rehabilitation efforts have been enhanced by improved quantitative assessments of functional outcomes, as well as through improving rehabilitation techniques. No medical center or treating physicians can truly be considered as providing state-of-the-art therapy unless they are prepared to systematically address these issues.

## OROPHARYNX

### EPIDEMIOLOGY

The pharynx is divided into three regions: the nasopharynx, oropharynx, and hypopharynx. Our discussion is limited to the oropharynx and its encompassing sites (i.e., the base of tongue, tonsil and tonsillar fossa, soft palate, and posterior pharyngeal wall). Cancer of the oropharynx is expected to occur in approximately 4000 patients annually in the United States. <sup>481</sup> Most commonly, the disease involves patients in the fifth through seventh decades of life. Men are afflicted three to five times as frequently as women. The etiology of the disease, to the greatest extent, cannot be distinguished from cancers of the oral cavity. Tobacco and alcohol abuse constitute the most significant risk factors.

### STAGING

As was true for staging of oral cavity cancers, staging of tumors of the oropharynx relies on both physical examination as well as a variety of imaging procedures, including CT scan. Staging of the primary tumor is presented in [Table 30.2-22](#). The regional lymph nodes (N) and distant metastases (M) staging are identical to other sites within the upper aerodigestive tract and are as stated in the beginning of this chapter (see [Staging and Screening](#), earlier in this chapter).

T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension
T4	Tumor invades adjacent structures (e.g., through cortical bone, soft tissues of neck, deep, extrinsic, muscle of tongue)

**TABLE 30.2-22.** Staging of Tumors of the Oropharynx

## BASE OF TONGUE

### ANATOMY

The base of tongue is bounded anteriorly by a line demarcated by the circumvallate papillae. Posteriorly, it ends with the epiglottis. Laterally, it extends to the glossopalatine sulcus and includes the pharyngoepiglottic and glossoepiglottic folds. Tongue musculature is composed of the genioglossus, styloglossus, palatoglossus, and hyoglossus muscles. The blood supply and nerve supply are identical to that of the oral tongue and consist of the lingual artery and the hypoglossal nerve, respectively.

Lymphatics are extensive within the base of tongue. Drainage is into numerous node levels including levels II, III, IV, and V in decreasing order. Indeed, disease may involve retropharyngeal lymph nodes in certain instances such as with progression to lateral pharyngeal wall.

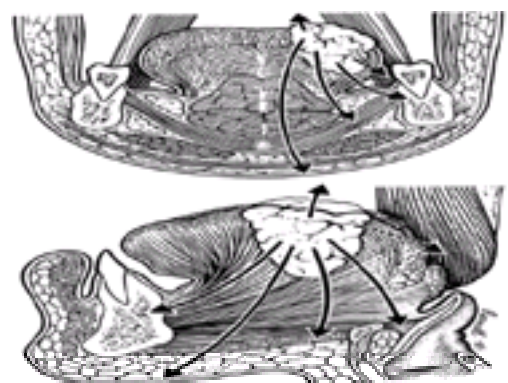

### PATHOLOGY

Base of tongue cancers are less frequent than cancers of other anatomically defined areas of the tongue. Squamous cell carcinoma represents nearly 95% of those cancers that occur in this subsite. Other cancers in this area include those of minor salivary glands origin (i.e., adenoid cystic and mucoepidermoid carcinoma) and lymphomas.

### NATURAL HISTORY

Cancers of the base of tongue are frequently advanced at the time of presentation. This is partly a reflection of the relatively silent location of such disease as well as its aggressive tendencies. Patients usually present with symptoms of pain and dysphagia. Not infrequently, as is true for nasopharyngeal carcinomas, individuals present with a mass in the neck. A history of weight loss is common. Likewise, referred otalgia secondary to cranial nerve involvement is common. With progressive laryngeal involvement, a muffled quality of the voice may become apparent.

As is true for other squamous cell carcinomas of the head and neck, cancers of the base of tongue can grow either in an infiltrative or exophytic pattern. Careful physical examination delineates such growth. An important component of that evaluation should include digital and bimanual palpation. This delineates the extent of base of tongue involvement as well as determines whether or not disease has infiltrated into the preepiglottic space. [Figure 30.2-15](#) shows routes of spread for squamous cell cancers for the base of tongue.

**FIGURE 30.2-15.** Routes of spread of squamous cell carcinoma of the base of tongue. **A:** Coronal view. **B:** Lateral view. (From Shah JP, Shemen LJ, Strong EW. Surgical therapy of oral cavity tumors. In: Thawley SE, Panje WR, eds. *Comprehensive management of head and neck tumors*. Philadelphia: WB Saunders, 1987:553, with permission.)

Base of tongue tumors have a high propensity for metastatic spread to lymph nodes. Nearly 70% of patients with T1 lesions have clinically palpable disease in the neck. The risk of nodal metastases increases with T stage, approaching 85% for T4 cancers.<sup>553</sup> Likewise, tumors of the base of tongue have a high propensity for bilateral cervical lymph node spread, occurring in approximately 30% of patients.<sup>553</sup> Therapy should account for this propensity even in circumstances of early primary disease. Lymph nodes commonly involved include levels II and III. Levels IV, V, and VI, however, are more frequently involved than many other cancers of the head and neck such as oral cavity lesions.

Prognosis for tongue base tumors is generally poor secondary to their advanced stage at presentation.<sup>587,588</sup> and <sup>589</sup> Stage I and II 5-year survival approximates 60% and 40%, respectively. Five-year survival for patients with stage III disease approximates 30%. For stage IV disease, survival diminished to 15% at 5 years.

### TREATMENT

#### Early Disease

Early-stage cancer of the base of the tongue is readily treated by surgery or RT. Results are equivalent. Surgery for early unilateral lesions entails a hemiglossectomy. Surgical approaches can be transoral or by lateral pharyngotomy. The former approach entails a midline labiolingual split.

RT has a high prospect of cure without the functional deficit that occurs with operation. In general, treatment consists of 5000 to 5400 cGy with external-beam radiation and 2000 to 3000 cGy boost to the base of the tongue via an <sup>192</sup>Ir implant. There is debate in the radiation oncology literature as to whether or not to use an interstitial implant as the boost treatment. Altered fractionation programs can also be used, with either twice a day treatment or concomitant boost having its advocates.

Regional lymphadenectomy is recommended regardless of the primary size because of the high propensity for metastatic spread. Bilateral neck dissection is recommended for those lesions approaching midline structures.

## Advanced Disease

For larger lesions involving the tongue base, primarily T4 lesions, total resection of tongue base, and total laryngectomy may be required. The addition of total laryngectomy may be dictated for several reasons. Tumor may infiltrate through the relatively thin hyoepiglottic ligament and extend well into the preepiglottic space. Laryngectomy is required as part of an *en bloc* procedure necessary to ensure complete extirpation of disease. Additionally, the removal of tongue and soft tissues of the neck (i.e., the preepiglottic space) impairs normal deglutition. With such surgery, chronic aspiration represents a major long-term complication. Total laryngectomy may represent the only means to isolate critical air exchange passages from oral secretions. The need for laryngectomy is increased in patients with diminished cardiopulmonary reserve. Restoring bulk of the base of tongue with myocutaneous flaps or free tissue transfer may minimize aspiration problems.<sup>590</sup> Nowadays, patients who would require a total laryngectomy can be managed with an organ-sparing program of chemotherapy and RT, reserving surgery for salvage.<sup>591</sup>

Extended supraglottic laryngectomy may be performed for smaller lesions involving the vallecula. Disease in such circumstances should not extend along the pharyngoepiglottic fold to involve lateral pharyngeal wall. In the circumstances in which such a procedure is performed, pretreatment assessment must in all circumstances confirm adequate cardiopulmonary reserve.

The need for mandibulectomy as part of the surgical procedure for tongue base tumors is controversial. The traditional surgical management involves the composite (jaw, tongue, neck) resection. Such an *en bloc* procedure ensures more adequate tumor removal, including tumor within surrounding lymphatics. Furthermore, closure of surgical defect is facilitated by such resection (i.e., soft tissues are able to collapse with removal of mandible).

Advances, both surgical and in our understanding of patterns of tumor spread, militate against the need for mandibulectomy. Soft tissue defects can be repaired with free-tissue transfer, thus facilitating wound closure. Studies of lymphatic spread of oropharyngeal tumors have shown that cancer not approximating periosteum rarely infiltrates mandible.<sup>592</sup> Resection of bone is thus not required for oncologic reasons.

## Results of Treatment

Surgical results of early base of tongue cancers have been encouraging, with local control rates approximating 85%.<sup>587,592,594</sup> The major determinate of control rate is reflective in tumor growth patterns. Exophytic tumors are controlled in 84% of instances as opposed to 58% with ulcerative-infiltrative disease.<sup>593</sup> With advanced disease, initial surgery is associated with a high probability of positive margins (25%), thus emphasizing the need for combined modality therapy.<sup>615</sup>

Data from Harrison et al.,<sup>595,596,597</sup> and Goffinet et al.,<sup>599</sup> and Puthawala et al.<sup>600</sup> show that the local control rate for T1 to T2 base of tongue tumors is in the 90% range when treated with external-beam RT plus implant. Harrison et al.<sup>595,596</sup> have reported long-term results on 68 patients treated between 1981 and 1995 with combined external-beam RT (54 Gy) plus <sup>192</sup>Ir implant (20 to 30 Gy), combined with neck dissection for patients presenting with positive nodes ( Fig. 30.2-16 shows a clinical example; Table 30.2-23). Actuarial 5- and 10-year local control is 89% and 89%, distant metastasis-free survival is 91% and 76%, disease-free survival is 80% and 67%, and overall survival is 86% and 52%. All T stages (T1, 17 patients; T2, 32 patients; T3, 17 patients; T4, 2 patients) were combined together, as there were no differences when analyzed by T stage. When survival salvage is included, local control rises to 92%. Lee has reported that all 58 patients who underwent external-beam RT plus neck dissection (all of whom presented with palpable nodes) were regionally controlled at 10 years, and the majority had negative surgical experiences.<sup>610</sup> Harrison et al. reported detailed quality-of-life assessment on these patients, reporting that the majority of patients could maintain their incomes, employment status, and socioeconomic quality of life despite having advanced tongue cancer.<sup>598</sup> Understandability of speech and eating in public were excellent, but xerostomia was a major problem. Horowitz et al. also reported excellent performance status scores for eating in public, understandability of speech, and normalcy of diet for their patients treated with external-beam RT plus brachytherapy.<sup>611</sup> Finally, a comparison of the performance status outcomes of eating in public, understandability of speech, and normalcy of diet showed significant advantages in each category to primary radiotherapy over primary surgery.<sup>598</sup>

**FIGURE 30.2-16.** A patient with a T2N2 squamous cancer of the left side of the base of the tongue. The treatment plan consisted of initial external-beam radiation therapy to the primary site and the entire neck bilaterally. This was followed by a left radical neck dissection and an implant, both done with the same anesthesia. **A:** The simulation film shows the primary site outlined and the neck node with wire around it. A bite block is in place. A total of 4500 cGy was given to the primary site and both upper necks, after which a spinal cord block was placed. The primary and upper neck were then treated with 5400 cGy. Fraction size was 180 cGy/d. After that, the bed of the lymph node in the left neck was boosted on the right and to 5940 on the left. **B:** The low neck was treated with a single anterior field to 5000 cGy/5 weeks. A midline block protects the spinal cord at the field junction. **C:** Approximately 3 weeks after the external radiation was completed, the patient was taken to the operating room and a left radical neck dissection and an <sup>192</sup>Ir implant were done. The figure shows the catheters looped through the base of tongue by the submental approach. Also visible are the skin staples from the neck surgery. The implant delivered an additional 2800 cGy. The neck specimen was histologically negative. The patient had no evidence of disease at 6 years. He had a soft tissue ulcer in the tongue that healed with conservative management.

T Stage	Crude Local <sup>a</sup>	Surgical	Overall Crude
	Control	Salvage	Control
T1	10/11	1/1	11/11
T2	13/14	1/1	14/14
T3	8/10	—	8/10
T4	1/1	—	1/1

<sup>a</sup>Crude local control, including salvage by T stage.

<sup>b</sup>Number of patients controlled/total number of patients.

**TABLE 30.2-23.** Treatment of Carcinoma of the Base of Tongue with External-Beam Irradiation Plus Brachytherapy<sup>a</sup>

External-beam RT alone has its advocates.<sup>607,608</sup> However, the only study that sought to compare external-beam RT alone, external-beam RT plus implant, versus surgery plus postoperative radiation was done by Housset et al.<sup>602</sup> They found that the local control rate for both external-beam RT plus implant or surgery plus postoperative radiation was in the 80% range for T1 and T2 lesions, as opposed to 50% for external-beam RT alone. Survival for external-beam RT alone was 17%, as opposed to more than 50% for the other two approaches.

Various hyperfractionated and accelerated fractionated regimens have been updated.<sup>607 and 608</sup> Mendenhall reported 5-year local control of 98% for T1, 91% for T2,

81% for T3, and 38% for T4, and advocated that radiotherapy was a better alternative than primary surgery.<sup>607</sup> Moore et al. reported quality-of-life data on the same group of patients, suggesting excellent outcomes with respect to eating in public, understandability of speech, and good outcomes for normalcy of diet.<sup>609</sup> Neck dissection did not have a major effect on the performance status measurements. Morrison has also reported good outcomes using an accelerated fractionation, concomitant boost technique for oropharynx carcinomas of all subsites.<sup>608</sup> However, all patients developed severe mucositis, and there was a growing risk of bone complications and swallowing problems and gastrostomy tube dependence with longer follow-up. Mak et al. reported that this concomitant boost program of 72 Gy in 6 weeks produced local control at 5 years of 76% (T1 = 100%, T2 = 96%, T3 = 67%), with disease-specific survival of 65% and overall survival of 59%.<sup>605</sup>

Implants have also been used for patients who have received prior RT to the oropharynx, who developed either recurrent base of tongue cancers or a second primary cancer in the base of tongue.<sup>601</sup> Housset et al. reported on 55 patients who had received prior irradiation and in whom they performed <sup>192</sup>Ir implants.<sup>606</sup> The local control rate was in the 50% to 60% range. Vikram et al. reported on ten patients who had previously treated base of tongue lesions.<sup>603</sup> All ten received implants in an attempted salvage maneuver. Local control was obtained in 60% of the patients, with size being the most important prognostic feature. No local failures occurred in patients who had lesions less than or equal to 4 cm, whereas most of the patients with lesions larger than 4 cm were not salvaged. Overall survival in the entire group was poor, mainly due to uncontrolled recurrent neck disease.

## TONSIL, TONSILLAR PILLAR, AND SOFT PALATE

### ANATOMY

The tonsillar pillars anteriorly (the palatoglossal muscle) and posteriorly (the palatopharyngeal muscle) and the glossopalatini sulcus inferiorly constitute a triangular region that houses the lymphoid tonsillar tissue. Extending from the tonsillar pillars is the soft palate. The latter demarcates the oral cavity from the oropharynx as well as the oropharynx from the nasopharynx. It is composed of the following muscles: palatoglossus, palatopharyngeus, levator veli palatine, tensor veli palatine, and the musculus uvulae.

Nerve supply to this region is via the trigeminal nerve. Lymphatics from the tonsillar region drain into the jugulodigastric basin as well as the submandibular triangle. Lymphatics from the soft palate drain into the upper jugulodigastric lymph nodes as well as the retropharyngeal lymph nodes.

### PATHOLOGY

As in other sites within the upper aerodigestive tract, the near total lesions involving this region are squamous cell carcinoma. Occasionally, lymphoepitheliomas have been identified within the tonsillar fossa. Other cancers include lymphomas and those derived from minor salivary glands.

### NATURAL HISTORY

Cancers of these three sites may present and spread in a variety of means. Cancers of the tonsillar pillar tend to be more superficial than those of the tonsillar fossa. Tonsillar pillar cancers progress over a broad region including lateral soft palate, retromolar trigone and buccal mucosa, tonsillar fossa, as well as the glossopalatini sulcus.

Tonsillar fossa cancers more often present in advanced-stage disease than either cancers of the tonsillar pillar or soft palate. Approximately 75% of patients present as stage III or stage IV disease. Disease in this area tends to be bulky and can progress to involve the base of tongue as well as lateral pharyngeal wall. Symptoms include pain, dysphagia, weight loss, and a mass in the neck. Should disease extend posteriorly and involve pterygoid muscles, trismus may be a presenting sign.

Primary disease of the soft palate, however, may behave in a more indolent manner. Tumors in this region may remain in the early stages. Likewise, disease in this area may remain superficial, presenting as diffuse erythroplakia extending into the hard palate or inferiorly along the tonsillar pillar.

Tonsillar pillar cancers metastasize less frequently to regional lymph nodes than cancers of the tonsillar fossa. Patients present with clinical evidence of nodal metastases in 38% of T2 tonsillar pillar cancers, while 68% of T2 tonsillar fossa lesions are associated with clinically evident lymph node disease at presentation. Contralateral metastases are common for tonsillar fossa cancers. Nodal disease in tonsillar fossa cancer, likewise, most often presents in an advanced stage with nearly 55% of patients presenting with N2 or N3 disease.<sup>553</sup> Soft palate tumors are more commonly associated with bilateral lymph node metastases. Approximately 20% of patients present with bilateral disease.<sup>553</sup>

Prognosis for tonsillar fossa cancers ranges from 93% for stage I disease to 17% for stage IV disease.<sup>612,613,614</sup> and <sup>615</sup> For soft palate lesions, 5-year survival ranges from 21% to 85% depending on disease stage.<sup>616,617</sup> and <sup>618</sup>

### TREATMENT

#### *Early Disease*

Except in circumstances of early disease, the distinction between cancers arising in the tonsillar fossa versus tonsillar pillar cannot be made. Early cancers of this region can be treated by single modality therapy, either surgery or RT.

Surgical resection of early disease can occasionally be done transorally. Such an approach, however, should be performed only in circumstances in which free surgical margins can be ensured. Better exposure to early cancers of this region may also be obtained through a combined lip-splitting incision coupled with an anterior midline or lateral mandibulotomy. Careful dissection thus proceeds by first identifying anterior lateral margins. If tumors extend to the periosteum of the mandible but remain superficial, partial mandibulectomy may be performed. Partial mandibulectomy includes a coronal resection, which leaves the body and the ascending ramus of the mandible in continuity.

Early squamous cell carcinomas of the tonsillar region can, likewise, be treated with RT. Radiation can be delivered with either external beam, interstitial implant, or a combination of both. In general, radiation is preferred because it offers excellent cure rates and more comprehensive treatment of primary site, retropharyngeal nodes, and neck, all with a potentially better functional outcome.

Given the high propensity for even early cancers of this region to metastasize to cervical lymph nodes, cervical lymphadenectomy should be included as part of the surgical resection. The various types of neck dissections that could be used have been discussed (see [Surgical Management of the Cervical Lymph Nodes](#), earlier in this chapter). Our choice for early lesions in which cervical lymph nodes are not clinically involved with disease would include a modified supraomohyoid neck dissection. Debate exists as to whether or not such dissection should be performed in continuity with extirpation of the primary disease. Where possible, in continuity dissection should be advocated.

When applying RT as the primary treatment modality, it is usually possible to treat the ipsilateral neck alone and avoid contralateral neck irradiation. With such treatment, radiation dosage to the contralateral salivary gland is minimized, thereby reducing the incidence of xerostomia. Due to the rich lymphatic network in the oropharyngeal region, it is standard practice to radiate the neck in all patients. This includes the retropharyngeal nodes. In fact, one advantage of using radiation is the inclusion of these nodes in the treatment, which is not included in primary surgical management.

Early-stage soft palate tumors are readily treated with RT. Treatment can be delivered with external beam, brachytherapy, or a combination of both. [Figure 30.2-17](#) shows the external-beam technique in a typical patient. Most patients do not have palpable cervical lymph node metastases on presentation. It is unclear whether or not all patients require prophylactic neck treatment. Both prophylactic neck irradiation and observation alone have been used by various authors <sup>619,620</sup> with a successful outcome. Of course, this is retrospective and subject to the selection factors inherent in retrospective reviews. Small superficial lesions can probably be treated locally, with observation of the neck. Larger T1 and all T2 lesions should receive elective neck treatment.

**FIGURE 30.2-17. A:** A patient with a T2N0 squamous cancer of the soft palate. He was treated with external-beam radiation therapy to the primary site and to both necks. Opposed lateral portals were used with a low anterior neck field. **B and C:** The simulated fields are shown. The primary site and both upper necks were then treated with 5400 cGy, including the retropharyngeal nodes. The primary site was treated to a total of 6840 cGy. The patient is asked not to swallow during treatment, so the palate remains in position. Adequate margin is placed around the palate in its plane of motion to avoid geographic miss. Fraction size is 180 cGy/d. The lower neck is treated with an anterior portal to 5000 cGy/5 weeks, thereby delivering elective nodal irradiation to that site. The posterior necks are boosted with electrons to 5400 cGy to protect the spinal cord. The spinal cord is protected at the junction of the lateral fields with the low anterior neck field by a midline block in the low neck field. This block also protects the larynx. For this purpose, the field is purposely junctioned above the thyroid notch but below the hyoid bone. **D:** The patient had no evidence of disease at 2.5 years.

### Advanced Disease

Advanced cancers (i.e., stage III and stage IV disease) generally require combined modality therapy (i.e., surgery and postoperative RT). However, there has been increasing interest in radiation alone for the primary site, combined with neck dissection.<sup>621,622 and 623</sup> Clearly, the choice of treatment relates to the exact T and N stage. For early (T1 to T2) primary lesions with neck metastases, definitive radiation to the primary neck, followed by a neck dissection, is commonly used. For T3 lesions, external-beam radiation alone or combined with an implant can be used for the primary site, with a neck dissection added for those with involved nodes. This approach for T3 lesions is reserved for the exophytic lesions, or those that do not demonstrate highly infiltrative characteristics. The endophytic T3 and T4 lesions are best managed by surgery followed by postoperative RT. Clearly, optimal management requires individual assessment of each patient and close collaboration between the surgeon, radiation oncologist, and patient. If the primary lesion can be managed by radiation, however, the functional outcome with regard to speech and swallowing is usually better than surgically managed patients. The extent of surgical resection should be governed by the size of the primary disease and its pattern of spread. Tumor-free surgical margins generally entail a segmental mandibulectomy in most circumstances of advanced disease in the tonsillar region.

### Results of Treatment

**TONSILLAR PILLARS AND FOSSA.** Surgical resection as the sole modality of therapy for early disease is not frequently used in most series. However, studies have demonstrated that when used, local control rates are excellent.<sup>624</sup> Indeed, even for advanced tumors in highly selected instances, effective local control can approach 80%.<sup>624</sup> The degree to which local control can be obtained depends on disease extension outside the tonsillar fossa. When disease extends to lateral pharyngeal wall or base of tongue, local recurrence approaches 33% and 47%, respectively.<sup>624,625 and 626</sup>

Wong et al. have reported the results of definitive external-beam irradiation for 150 patients with previously untreated squamous cell carcinoma of the tonsillar fossa.<sup>627</sup> Most patients were treated with conventional fractionation with total doses in the 6400 to 7200 cGy range. Local control was obtained in 15 of 16 (94%) patients with T1 lesions, and 51 of 52 (79%) patients with T2 lesions. Other series have reported local control rates for T2 lesions approximating 60%.<sup>625,628,629,630,631 and 632</sup> When surgical salvage is added, local control was 100% for T1 and 85% for T2. Wang has used an accelerated hyperfractionation program for oropharyngeal tumors.<sup>628</sup> During an earlier time period, patients received 1.6 cGy per fraction, two fractions per day, to a total of 38.4 cGy. Due to acute toxicity, a 2-week break was then given. Treatment was then resumed at 1.8 cGy per fraction, one fraction per day, to a total of 65 cGy. This was called the BID-QD program. More recently, the treatment regimen was changed. The initial treatment remained the same, as did the 2-week break. However, when the patient returned for the second part of the treatment, they were resumed at 1.6 cGy per fraction, two fractions per day, to a total of 64 cGy. This was called the BID-BID program. For tonsil lesions (T1 to T4), the 36-month actuarial local control after irradiation therapy was 93% versus 64% for the BID-QD program.

There has been increasing interest in brachytherapy for selected tonsillar lesions.<sup>632,633 and 634</sup> Levendag et al. used fractionated high dose-rate or pulsed dose-rate brachytherapy as a boost, combined with external-beam irradiation for a cohort of tonsillar and soft palate lesions.<sup>634</sup> There were 5 T1, 22 T2, 10 T3, and 1 T4 lesions. Local failure occurred in 13% of cases. These authors believed that this approach was superior to external-beam alone when compared with their data for external beam RT alone. Puthawala et al. reported the results of 80 patients with previously untreated squamous cell carcinoma of the tonsillar region who received 4500 to 5000 cGy with external-beam irradiation, followed by an interstitial <sup>192</sup>Ir implant.<sup>632</sup> Patients with T1 or T2 disease received an implant boost to 2000 to 2500 cGy, and those with T3 to T4 lesions received a boost of 3000 to 4000 cGy. Overall local control was 84%, and absolute 3-year disease-free survival was 72%. When looked at by stage, all three T1 patients obtained local control. For T2, T3, and T4 patients, local control was obtained in 14 of 15 (93%), 32 of 43 (74%), and 11 of 19 (58%), respectively.

Mazon et al. reported the results of external beam, implant, or a combination of the two, for lesions of the tonsil and soft palate.<sup>623</sup> For tonsil lesions, most patients were treated with 45-Gy external beam plus 31-Gy interstitial brachytherapy. A comparison was made for each of the radiotherapeutic techniques for T1 and T2 lesions. Almost all T1 lesions were controlled regardless of technique. However, for T2 disease, 7 of 26 patients failed locally after external-beam RT alone, compared with only 1 of 43 patients managed by external-beam RT plus implant. Behar et al. evaluated combined external-beam RT, brachytherapy, and adjuvant neck dissection (neck surgery mainly for N2 and N3 disease) for a group of 37 patients with cancers of the tonsil and palate.<sup>622</sup> Thirty-two percent had T3 or T4 disease, and 49% had N2 or N3 neck metastases. Local control was obtained in 95% of cases, and neck control was achieved in 87%. Actuarial 5-year survival was 64%, and approximately 25% of the patients developed a second primary cancer.

Pernot et al. accumulated a large series of 361 patients with cancers of the tonsil and soft palate who were managed either by brachytherapy alone or a combination of external-beam irradiation (50 Gy) plus a brachytherapy boost (20 to 30 Gy).<sup>621</sup> In total, 64% of patients had T1 to T2 lesions, and 64% were N0. Only two patients had T4 disease. A select group of 18 patients with small T1 lesions were managed by brachytherapy alone, and all were locally controlled. All others received combined external-beam RT plus implant. Local control was 89% for T1, 85% for T2, and 67% for T3 lesions. The group with lesions on the soft palate, tonsillar fossa, and posterior pillar had a better outcome than those with lesions on the anterior pillar and glossotonsillar sulcus. For T3 lesions, the local control with external-beam irradiation falls considerably. However, it would appear that the subset of T3 tumors with tongue involvement have the highest local failure rate. Tong et al. reported that 18 of 39 (46%) T3 patients ultimately had failures in the primary site after external-beam irradiation.<sup>625</sup> Interestingly, all 18 patients who failed had lesions that extended into the base of tongue. Mendenhall has reported that the addition of interstitial implant to the base of tongue, after external-beam irradiation, can improve the local control.<sup>635</sup> In their T3 patients with base of tongue extension, only five of nine patients were controlled with external-beam RT alone, as compared with 13 of 17 who had full-dose external-beam RT plus a localized base of tongue implant. Puthawala et al. reported local control in 16 of 19 patients with T3 N0 lesions, and 5 of 6 patients with T3 N1 lesions, all treated with external-beam RT and implant.<sup>632</sup> Wong et al. reported local control in only 58% of patients with T3 treated with external-beam RT alone.<sup>627</sup> Leborgne analyzed 140 patients with tonsil cancer who received definitive radiation.<sup>654</sup> The subgroup of patients with lingual extension who had an implant as part of their treatment had better local control than those who received external-beam RT alone. Thus, it appears that many T3 lesions and those with lingual extension may be best served with the addition of an implant, if radiation is used as the primary modality. It would therefore appear that the results of external-beam radiation alone for T3 tonsillar cancer are suboptimal. The addition of an interstitial implant may improve the results in selected patients. There may also be a role for a combination of surgery and radiation.

For T1 to T2, N0 to N1 patients, it is usually possible to treat the ipsilateral neck alone and avoid contralateral neck irradiation. By doing this, the radiation dosage to the contralateral salivary gland tissue is minimized, and the incidence of xerostomia is significantly reduced. Murthy and Hendrickson reported that none of their 20 patients with N0 or N1 disease failed in the untreated contralateral neck when the primary and ipsilateral neck were controlled.<sup>636</sup> Tong et al. reported that none of their patients with either T1 N0 or T2 N0 lesions failed in either neck despite the fact that approximately 40% of the cases had ipsilateral treatment only.<sup>625</sup> It is

considered safe to omit contralateral neck treatment in most of these early lesions, as long as there is no extension into the base of tongue or significant extension onto the soft palate.

The management of patients with more advanced lesions is somewhat controversial.<sup>635,636,637,638,639</sup> and <sup>640</sup> There are advocates of RT alone,<sup>635</sup> reserving surgery for salvage only. Others advocate a approach involving surgery and postoperative radiation.<sup>637,638</sup> Perez et al. analyzed 296 patients with epidermoid carcinoma of the tonsillar fossa.<sup>629</sup> In this group, 127 received radiation alone, 133 were planned to have preoperative RT, and 36 received surgery plus postoperative radiation. There was no statistically significant difference in 3-year disease-free survival for T1 to T2, N0 to N2 patients with radiation alone versus radiation combined with surgery. In patients with T4 or N3 disease, there was an advantage to combined treatment over radiation alone, suggesting a benefit for those who had surgery. The authors concluded that radiation alone was the treatment of choice for early-stage lesions, but there might be an advantage in selected advanced stage patients for a combination of surgery and postoperative irradiation. Dasmahapatra et al., likewise, report that the 5-year survival for patients who had combined radiation and surgery was better than those who had radiation alone in the stage III and IV categories.<sup>637</sup> Spiro and Spiro could not demonstrate a benefit in survival when patients with stage III and IV disease were treated with either radiotherapy alone, surgery alone, or combined surgery and irradiation.<sup>639</sup> This may be a reflection of selection bias, with more advanced and less favorable patients being treated with surgery and radiation combined. The RTOG <sup>574</sup> has performed a prospective randomized trial and analyzed various combinations of radiation and surgery for patients with advanced squamous cell cancer of the oropharynx. Patients with oropharynx tumors were randomized to receive preoperative RT (5000 cGy) plus surgery, surgery plus postoperative RT (6000 cGy), or RT alone (6500 to 7000 cGy) with surgery reserved for salvage. This study revealed that the overall survival, as well as the estimated 4-year local regional control rate, was not statistically different in any of the arms. One of the weaknesses of this study is that it did not stratify the results by subsite within the oropharynx. It is therefore impossible to determine what the specific results would be for tonsil patients. Clearly, treatment must be individualized from patient to patient and should attempt to provide the highest rate of cure as well as the best functional and quality-of-life outcome.

**SOFT PALATE.** There have been emerging data over the past few years advocating the use of brachytherapy for small soft palate lesions.<sup>619,634,641,642</sup> Mazon et al. reported on 59 T1 and T2 squamous cancer of the soft palate and uvula treated with definitive irradiation.<sup>633</sup> Sixteen patients had external-beam RT alone, 14 had <sup>192</sup>Ir implantation alone, and 29 had a combination of external-beam RT plus brachytherapy. Local failure occurred in 25% (4 of 16) after external irradiation alone, 18% (5 of 19) after combined external-beam RT and implant, but in 0% (0 of 14) in the group selected for <sup>192</sup>Ir implant alone. This group preferred the plastic tube technique over the guide gutter technique for implantation. It is unclear exactly how the patients were selected for each of the treatment strategies. The authors believed that severe dry mouth was less frequent in those patients who received all or part of the treatment by implantation compared with those who had external-beam irradiation alone. Similarly, Sealy et al. reported excellent control rates in patients with early squamous cell cancer of the soft palate and uvula treated with <sup>192</sup>Ir implants.<sup>641</sup>

Pernot et al. have reported on 277 patients treated for carcinoma of the oropharynx by exclusive RT.<sup>620</sup> The group (212 patients) lumped soft palate and tonsil and posterior pillar lesions together in the reporting of results. Nine percent of these patients had soft palate lesions. In this group, 7% (8 of 121) of the T1 and T2 lesions exhibited recurrence; 27% (23 of 85) recurred in the T3 category. The overall local control at 5 years was 83%. This series has been updated (361 patients) and already quoted in the section on [tonsil cancer](#). Local control was 89% for T1, 85% for T2, and 67% for T3 lesions. All 18 patients managed by brachytherapy alone for small T1 lesions had local control.

The results of the study by Levendag et al.<sup>634</sup> have already been described in the [Tonsillar Pillars and Fossa](#) section, but included patients with lesions of either the tonsil or the soft palate. Amdur et al. reported an analysis of 75 patients with squamous cell carcinoma of the soft palate, uvula, or both treated with RT alone or in combination with neck dissection.<sup>643</sup> Most patients received 6000 to 7500 cGy. Local control was obtained in all 8 patients with T1 disease, and 14 of 19 patients with T2 disease. Including surgical salvage, 16 of 19 T2 patients obtained ultimate local control (84%). The results were far worse for T3 and T4 disease, with local control being 45% and 25%, respectively, for continuous course external-beam irradiation. This series highlights the poor results achieved with RT for advanced disease, with quite good results for early-stage disease with external-beam RT alone. Clearly, from an oncologic point of view, there is no definitive proof that brachytherapy is required for early-stage soft palate tumors. However, there may be a rationale for using implant as all or part of the treatment in an effort to improve the functional outcome with regard to salivary gland function. Obviously, brachytherapy spares the major salivary glands from receiving significant doses of radiation and decreases the risk of xerostomia. Proper patient selection is required, and the radiation oncologist must have expertise in performing a palatal implant.

Although the local control is excellent for early-stage disease, the overall survival may not necessarily reflect the high local control rate. Intercurrent illness as well as the problem of second primary malignancies represent a significant cause of mortality in this population.<sup>619,643</sup>

Complications from RT are in the 10% range, with severe complications, principally osteonecrosis of the mandible requiring surgical resection, occurring in 5% or less.<sup>619,641,642</sup>

Whether elective neck treatment is required remains an open question. The probability of neck recurrence in patients with early disease is low, regardless of whether or not the neck is treated prophylactically.<sup>619</sup>

Most advanced soft palate tumors should be treated with combined surgery and postoperative radiation. Amdur et al. reported that the results of external-beam RT alone for T3 and T4 disease were suboptimal.<sup>643</sup>

## PHARYNGEAL WALL

### EPIDEMIOLOGY

Epidemiologic considerations are as discussed for oropharyngeal cancers.

### ANATOMY

The pharyngeal wall within the oropharynx extends from the nasopharynx at a line demarcated by the soft palate to the level of the vallecular. It comprises the posterolateral surfaces of the oropharynx. The pharyngeal constrictor muscles constitute the structural framework of the pharyngeal wall. Nerve supply is from the pharyngeal branches of the ninth and tenth cranial nerves. Blood supply is largely from the ascending pharyngeal and superior thyroid arteries, both emanating from the external carotid artery.

The pharyngeal wall is rich in lymphatics. Primary drainage is to retropharyngeal lymph nodes as well as nodes in levels II and III.

### PATHOLOGY

The near total majority of lesions on the pharyngeal wall are squamous cell carcinomas. Occasional minor salivary gland lesions have been identified.

### NATURAL HISTORY

Tumors of the posterior pharyngeal wall are generally identified in the late stages. This is due to the silent location in which they develop. Symptoms at presentation include pain and bleeding. Weight loss is common. Likewise, patients may present with a mass in the neck as their initial symptom. Disease spread can be superiorly to involve the nasopharynx. Posteriorly, disease may infiltrate the prevertebral fascia. Inferiorly, disease spreads to involve the pyriform sinuses and hypopharyngeal walls.

Pharyngeal wall tumors have a propensity for cervical lymph node metastases. Clinically palpable disease is identified in 25% of patients with T1 lesions, 30% of T2 lesions, 66% of T3 lesions, and over 75% of patients with T4 disease. Given that most pharyngeal wall tumors extend past the midline, bilateral cervical metastases are common.

Prognosis for pharyngeal wall cancers ranges from 75% for stage I disease, 70% for stage II, 42% for stage III, to 27% for stage IV disease.<sup>644,645,646,647,648,649,650,651,652</sup> and <sup>653</sup>

## TREATMENT

### Early Disease

Early-stage disease of the pharyngeal wall can be treated by either surgery or radiation. Given the functional impairment that may result from surgical reaction, RT is generally preferred. Surgical resection generally entails a (transhyoid) approach to gain access to the lesion.<sup>645</sup> Wide excision of such lesions includes underlying prevertebral fascia. Split-thickness skin graft coverage is required. A significant morbidity following surgical resection is impaired swallowing secondary to resection of pharyngeal wall musculature.

Bilateral modified neck dissections are indicated in patients with early pharyngeal wall cancers.

An important issue in planning the RT for posterior pharyngeal wall tumors is the proximity of the spinal cord to the primary tumor volume. When opposed lateral fields are used, and the spinal cord block is placed, the posterior edge of the field is dangerously close to the posterior aspect of the tumor. It is important to use a sharp beam edge, so as to avoid underdosing the posterior aspect of the tumor, which can fall in the penumbra of the beam. This is best accomplished by avoiding cobalt 60 and using a 4- or 6-MeV photon beam. Cerrobend blocks are used to define the posterior border. It is also important to make this border as posterior as possible. It has been our practice to place this border at the anterior-most aspect of the spinal cord. This is much closer to the spinal cord than in most other head and neck situations. Frequent portal films must be taken to ensure the accuracy of this field, and for maximal spinal cord protection. This situation represents a difficult challenge to the radiation oncologist. One of the potential advantages to brachytherapy is the delivery of high doses to the tumor with relative sparing of the spinal cord. However, in order for this technique to be useful, tumors have to be relatively small and discrete. Often, this is not the situation.

### Advanced Disease

Advanced disease of the posterior pharyngeal wall is best handled by multimodality therapy. Surgery generally involves a total laryngopharyngectomy. Reconstruction under such circumstances includes either a pectoralis major myocutaneous flap, gastric pull-up, or free-flap transposition with microvascular anastomoses. Free-flap transposition entails a jejunal interposition and is becoming the procedure of choice. Rehabilitation and swallowing with the latter procedure is hastened. This allows for more expeditious use of postoperative radiotherapy.

The use of radiotherapy postoperatively is generally recommended. The high incidence of retropharyngeal lymph node metastases and the associated increased local regional failure rate mandates aggressive multimodality treatment.<sup>647</sup>

### Results of Treatment

Guillamondegui et al. have reported on the surgical management of pharyngeal wall carcinomas.<sup>644</sup> Twenty-eight percent of the entire patient population developed local regional recurrence. Local recurrence predominated. It was of note in that series that salvage therapy consisting of either surgery or radiation was successful in 9 of 22 patients. The success of therapy was governed by the presence of retropharyngeal nodes, with only 25% of such patients disease free at 2 years.

Meoz-Mendes et al. have reported on 164 patients with squamous cell carcinoma of the pharyngeal walls who were treated with definitive RT at the M. D. Anderson Hospital.<sup>648</sup> Their report included patients with both oropharynx and hypopharynx lesions. The primary sites were generally irradiated to a dose of 7000 to 7500 cGy in 7 to 7.5 weeks. Local control was 71% for T1, 73% for T2, 61% for T3, and 37% for T4. The authors recommended RT alone for T1 and T2 lesions. They concluded that resectable T3 and T4 lesions should be treated with combined surgery and radiation.

Marks et al. reported the experience from Washington University on 51 patients with pharyngeal wall cancer treated between 1964 and 1974.<sup>649</sup> Survival was no different for patients treated with low-dose preoperative radiation plus surgery versus those treated with high-dose radiation alone. However, this was not randomized, and the surgical techniques were not standardized. Survival was also poor, with actuarial 3-year survival of 17%. There was a greater complication rate in the patients receiving surgery, with 31% having pharyngocutaneous fistula, 14% having carotid rupture, and an operative mortality of 14%. Marks et al. updated this series with a total of 89 patients treated between 1964 and 1981.<sup>650</sup> Their update led to the suggestion that combined surgery and radiation might yield better results than high-dose radiation alone. Again, definitive conclusions are difficult to make.

Fein et al. analyzed the treatment factors for 99 patients with pharyngeal wall cancer treated with definitive external-beam irradiation at the University of Florida between 1964 and 1990.<sup>651</sup> The main issues relate to the fractionation schedule (once daily vs. twice daily) and the location of the posterior border of the irradiation field (midvertebral body vs. posterior edge of the vertebral body). Local control is clearly improved when the posterior body of the field is maximally posterior, thus allowing better coverage of the posterior wall. This places significant technical demands on the radiation oncologist, who must verify the safety of this border with respect to the spinal cord on the daily treatment setup. Local control with the border at midvertebral body versus posterior was T1, 100% for both; T2, 57% versus 100%; T3, 46% versus 73%; and T4, 29% versus 75%. Local control for continuous course once daily versus twice daily fractionation was T1, 100% for both; T2, 67% versus 92%; T3, 43% versus 80%; and T4, 17% versus 50%. Clearly, the technical and fractionation parameters were less significant for early lesions, but increasingly important for more advanced lesions.

Spiro et al. reported a 12-year experience from the Memorial Sloan-Kettering Cancer Center.<sup>652</sup> A variety of operations were used over this time. There was no standardized treatment, and at least eight different treatment approaches were used during this time period, representing various combinations of surgery, radiotherapy, and chemotherapy. This heterogeneity of treatment approaches highlights the uncertainty as to the optimal management of this disease and the variety of disease presentations. Five-year survival was 32%, and the overall complication rate was 50%. A small group of patients were treated with <sup>125</sup>I implant to the primary site, followed by external-beam RT. The implants were done using surgery for access. Local control in this small group of patients was excellent. Son and Kacinski reported 14 patients treated with a combination of implant and external-beam radiation.<sup>653</sup> Twelve patients had locoregional control, and 18% developed reversible soft tissue and mucosal injury as a result of the RT. It would appear that this technique deserves further investigation. It represents a mechanism for delivering definitive RT with high doses to the tumor. However, it is certainly clear that optimal therapy for tumors in this site has yet to be defined.

## LARYNX

Cancers of the larynx are considerably less frequent than malignancies of other sites, such as lung, breast, prostate, and colon; despite this fact, however, a substantial amount continues to be written on the subject. This seemingly disproportionate body of writing probably reflects the perceived importance of these neoplasms relative to their potential impact on people's communicative skills. It would seem that the mere threat to a person's vocal organ is associated with profound psychological and socioeconomic overtones, and curing the cancer at any cost no longer is accepted casually. More than ever before, a premium is placed on returning the patient to a productive and useful lifestyle (i.e., quality of life after cancer treatment). This attitude is demonstrated more keenly in the treatment of larynx cancer than with almost any other malignancy. In the past, treatment of laryngeal cancer focused predominantly on cure by relentless surgical aggressiveness. That era was followed by the emergence of conservation through larynx-sparing operations, the development of sophisticated radiation methods, and most recently, organ-sparing strategies in which chemotherapeutic, radiotherapeutic, and surgical methods are used in a variety of combinations and sequences.<sup>1,2 and 3</sup> The overall 5-year cure rate for patients with laryngeal squamous cell carcinoma (SCC) is almost 70%, and although those data have not changed dramatically during the last decade,<sup>4,5 and 6</sup> the treatment options and their sequencing have. As a result, a higher percentage of contemporary patients are retaining their larynx.

### EPIDEMIOLOGY AND ETIOLOGY

Although considerable geographic differences exist in the incidence of larynx cancer, the distribution of the disease is consistent within each country. For example, regardless of the culture, this disease most commonly affects middle-aged or older men who have smoked tobacco<sup>7,8</sup> and have consumed excessive alcohol.<sup>9</sup> Laryngeal cancer rarely occurs in people who have done neither. In the United States during the year 2000, more than 12,000 new larynx cancers will be diagnosed, and approximately 10,000 of those cases will be in men. Although this disease has always been more common in men, the gender ratio is changing; in 1956, the ratio was 15:1, whereas current studies show an approximately 5:1 ratio of men to women. This trend is probably due to the predictable effects of the changing smoking patterns of the sexes.<sup>9</sup> Racial differences also exist. Compared with whites, African Americans in the United States have a significantly higher incidence of larynx cancer.<sup>10</sup> Overall, the peak incidence of larynx cancer is in the sixth decade. The disease occurs in young people only rarely.<sup>11</sup>

The etiologic factors that have been implicated in laryngeal cancer are voice abuse and chronic laryngitis<sup>7,12</sup>; dietary factors<sup>13,14 and 15</sup>; chronic gastric reflux<sup>16</sup>; and exposure to wood dust, nitrogen mustard, asbestos, and ionizing radiation.<sup>17,18,19 and 20</sup> The carcinogenic effect on the larynx that results from smoking tobacco—whether by pipe, cigarette, or cigar—is, however, the factor most widely held responsible for this malignancy.<sup>17</sup> Larynx cancer only occasionally occurs in patients who have never smoked.<sup>20</sup> Possibly, human papillomavirus is an important cofactor in aerodigestive carcinogenesis in general, and it may be especially significant in the larynx.<sup>21,22,23,24,25,26,27 and 28</sup>

Heavy alcohol intake appears to be associated with larynx cancer, and it appears to enhance the already present risk factors associated with smoking.<sup>9</sup> On the other hand, some studies have failed to demonstrate an interdependent causal effect for alcohol intake and larynx cancer.<sup>28</sup> The issue of alcohol, smoke, and carcinogenesis is complicated by the nutritional deficiencies that usually occur in alcoholics.<sup>15</sup> In the larynx, this complex issue is more specifically defined by the fact that whatever the role of alcohol, it is apparently more significant in supraglottic than in glottic cancers.<sup>29,30,31 and 32</sup> With the maturation of the current generation of those youngsters using smokeless tobacco, some alteration of the relative incidence in the United States of supraglottic and glottic cancers may be noted. Those worldwide data that show large variations of laryngeal cancer statistics consistently reflect the smoking and drinking habits of the individual country.<sup>33</sup> Also, the sites within the larynx affected by cancers vary considerably between countries. This distribution is shown in [Table 30.3-1](#),<sup>12,24,26,34</sup> which represents a compendium of worldwide data that addresses the relative distributions of cancer within the larynx.

Country	Patients	Site (%)		
		Supraglottic	Glottic	Subglottic
Japan <sup>19</sup>	6360	49	50	0.9
Finland <sup>27</sup>	638	67	32	1
Yugoslavia <sup>27</sup>	722	62	35	3.5
United States <sup>28</sup>	1645	34	65	1
Sweden <sup>28</sup>	578	11	87	2

<sup>a</sup>Relative incidence of larynx cancer by anatomic site and country. Notice the variation between supraglottic and glottic incidence relative to different countries but the relative consistency of subglottic occurrence.

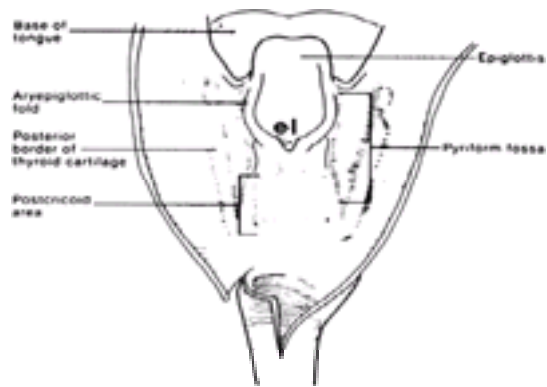

TABLE 30.3-1. Geographic Variations in Larynx Cancer Sites<sup>a</sup>

Koufman and Burke<sup>35</sup> make a strong case for a multifactorial etiology, and they have proposed a model that involves tobacco, environmental factors, alcohol, reflux, viral activation, dietary deficiency, and altered host immunity.

### RELEVANT ANATOMY

The larynx is a uniquely complicated organ that is strategically located so that significant alteration of its anatomy by either surgery or cancer can have a noticeable impact on vocal, respiratory, and swallowing physiology. The organ consists of three subsites: glottis (paired true vocal cords), supraglottis, and subglottis. Thus, clarification of the subsites within the larynx is essential. Because of different embryologic development and different lymphatic patterns that are subsite-specific, to discuss larynx cancers without specific reference to the exact location(s) within that structure invites inaccuracies in staging and miscalculations in treatment planning. Additionally, certain embryologic and anatomic facts are relevant to understanding the natural history of cancers that occur in the larynx. For example, the adjacency of the paraglottic space to the thyroid and cricoid cartilages and to the hypopharynx is critical to the subtle differences between the increasing stages of glottic lesions.

The larynx consists of a complex variety of muscles, an overlying mucous membrane, and a skeletal structure of four cartilages—the cricoid, the epiglottis, the paired arytenoids, and the shield-like thyroid cartilage. Suspended within the endolarynx are the mobile true vocal cords, which are collectively known as the *glottis*. That portion above the glottis, the supraglottis, consists of the false vocal cords, the epiglottis, and the aryepiglottic folds. These folds form the junction (i.e., common partition) between the endolarynx and the hypopharynx. The medial wall of these folds is within the endolarynx, and the lateral wall is actually the medial wall of the adjacent pyriform sinus (Fig. 30.3-1). Those lesions that arise on the rim of the aryepiglottic folds, therefore, have been appropriately referred to as *marginal cancers*, because they bridge the junction between the larynx and the hypopharynx. Those marginal lesions that extend predominantly into the endolarynx behave more like supraglottic cancers, whereas those lesions that spill into the pyriform sinus tend to follow the natural history of the hypopharyngeal malignancies. The subglottis is that portion of the larynx between the underedge of the true vocal cords and the cephalic border of the cricoid cartilage.<sup>36</sup> Although the subglottis is the laryngeal site least likely to harbor a primary cancer, it is critical to the pathogenesis and natural history of glottic (i.e., vocal cord) cancer because it provides an important route of inferior tumor extension.

**FIGURE 30.3-1.** Diagram of internal laryngeal anatomy as viewed posteriorly. Note the endolarynx (el).

The true vocal cords are remarkably engineered, although they are somewhat misnamed; rather than cord-like structures, they really are folds of mucosa that cover vocal muscles. These vocal cords (folds) are attached anteriorly to the inner surface of the thyroid cartilage and posteriorly to the arytenoid cartilages. The vocal muscles are complex in their activity, and their dynamic relationship with overlying mucosa is critical to voice production. Any loss of mucosal mobility relative to the underlying muscle, such as that produced by cancer, surgery or, even to a lesser extent, by radiation therapy, alters the voice. An appreciation of this fundamental fact is an important component in the selection of treatment of vocal cord cancer.

The lining of the endolarynx consists of respiratory epithelium except on the vibratory edges of the true vocal cords, which typically are lined with pseudostratified squamous epithelium.

The paired arytenoid cartilages each sit on the cephalic rim of the cricoid cartilage and rotate in a relatively horizontal axis around a pivot point. Each arytenoid is attached anteriorly to a true vocal cord, and the clockwise and counterclockwise rotation of these cartilages pulls the respective vocal cord attachment with it, causing abduction and adduction of those structures. Invading cancer can damage any or all of the muscles that are responsible for arytenoid rotation and also the recurrent laryngeal nerve fibers that innervate them. The posterolateral aspect of the larynx is particularly vulnerable to the invasion of cancer because of the adjacency of the medial wall of the pyriform sinus. When cancers of this part of the pyriform sinus extend through the mucosa, they gain direct access to the important laryngeal compartment known as the *paraglottic space*, which leads to all parts of the endolarynx, including the vocal muscles and the preepiglottic space ( Fig. 30.3-2). Treatment options for such a tumor are altered significantly because of paraglottic space involvement. Tumors that invade the endolaryngeal muscles or the nerve fibers that innervate them usually create a noticeable effect on vocal cord motion. Of all the findings on laryngeal examination during cancer evaluation, the state of endolaryngeal mobility is one of the most important. This fact has been substantiated by the separate designation that the American Joint Committee on Cancer (AJCC) has assigned to the immobile vocal cord in the staging categorization of this disease.<sup>37</sup>

**FIGURE 30.3-2.** Axial sections of the human laryngopharynx at the level of the glottis. **A:** Notice the relation of the pyriform sinus (PS) to the paraglottic space (PGS) of the endolarynx; the proximity of the lateral wall of the pyriform sinus to the thyroid cartilage (TC); and the relation of the pyriform sinus to the arytenoid (A). Ossification of the area of the thyroid cartilage shown in the axial section renders it vulnerable to skeletal invasion of cancer in this area. The posterior pharyngeal wall (PPW) acts as an extension of the lateral pharyngeal wall and the pyriform sinuses. **B:** Cancer (C) of the pyriform sinus invades the endolarynx (PGS). (Courtesy of Dr. John Kirchner.)

Another more subtle type of motion alteration pertains to the anatomic relation between the vocal cord musculature and the overlying mucosa. An awareness of this relatively recent knowledge has enhanced the understanding of the pathogenesis and treatment of early glottic cancer.<sup>38</sup> The vibratory mechanism that produces the voice is due to the mobility of the mucous membrane overlying the musculature of the vocal cords. The free edge of the true vocal cord consists of a pseudostratified squamous epithelium, under which is a lamina propria of fibroelastic and gelatinous consistency. This arrangement allows a sliding motion of the mucous membrane, which creates a mucosal wave, the fluidity of which is a direct reflection of the freedom of that layer from the underlying muscle. Any surface cancer that invades through the basement membrane, such as any cancer deeper than carcinoma *in situ* (CIS), affects the mucosal wave by creating a tethering effect. These subtle differences are usually not appreciated by routine laryngeal examination but are obvious with stroboscopic evaluation.<sup>39</sup> An appreciation of these subtleties can translate into the practical matter of determining whether to radiate or microscopically excise certain minimal vocal cord cancers.

Because of the different embryologic origins of the supraglottic from the glottic and subglottic larynx, and also because of the independent lymphatic drainage patterns from each of these subsites, the larynx can be thought of as a compartmentalized structure. These features are important influences in determining the spread of various cancers within that organ.<sup>40</sup>

The lymphatics of the supraglottic larynx are profuse, and the frequency of metastasis associated with cancers of this subsite reflects that fact.<sup>41</sup> Lymphatic spread

from the epiglottis is to the false cords, and these channels are directed bilaterally. The drainage from the false cords and the remainder of the supraglottic larynx is lateral and superior, and these channels exit the larynx bilaterally through the thyrohyoid membrane. They then proceed to the adjacent deep cervical nodes. The lymphatics of the infraglottic larynx drain laterally and inferiorly, out of the cricothyroid membrane into the lower deep cervical lymph nodes. The true vocal cords, on the other hand, are unique because they possess little or no lymphatic drainage.<sup>40</sup> From a lymphatic drainage standpoint, the left half of the larynx is essentially independent from the right half, and the supraglottic larynx is independent from the structures below it. These facts are clinically demonstrated: Early-stage supraglottic cancers have little affinity for extension into the lower structures, and those beginning on the true vocal cord do not tend to extend cephalad into the supraglottis.<sup>40,42</sup> Knowledge of this unique pathogenesis has substantial impact on the ability to predict metastasis into various parts of the neck as well as on the planning of the various partial laryngectomies known as *conservation operations*. These techniques combine the removal of laryngeal parts with the preservation of vocal and swallowing functions. Additionally, radiation therapy planning, especially for occult cervical metastasis, is predicated on a thorough knowledge of these and other drainage tendencies of laryngeal cancers.

## PATHOLOGY, PATHOGENESIS, AND NATURAL HISTORY

A variety of laryngeal malignancies, most of which are primary to the larynx and others that are metastatic from other sites, have been reported. A comprehensive classification is shown in [Table 30.3-2](#).

**TABLE 30.3-2.** Classification of Laryngeal Malignancies by Histologic Type

More than 95% of all primary laryngeal malignancies are SCCs, with the remainder being sarcomas, adenocarcinomas, neuroendocrine tumors, and other types.<sup>43</sup> Both spindle cell and verrucous carcinomas probably are variants of SCC.

It should be noted that knowledge and recognition of the neuroendocrine family of malignancies has changed considerably over time, and the exact percentage of these within the overall population of larynx cancers is unknown. In the past, certain tumors were vaguely classified as poorly differentiated malignancies when, in fact, they were neuroendocrine in origin. Modern techniques of immunohistochemical and morphologic analysis will almost certainly lead to the recognition and accrual of more of these tumors in the future, and as a result, they will make up a higher relative percentage of laryngeal malignancies.<sup>44,45</sup>

Laryngeal SCC accounts for approximately one-fourth of all head and neck SCCs.<sup>46</sup> Some variability is seen between series from different institutions and different patient populations; however, more than one-half of laryngeal SCCs present as localized disease without metastasis, one-fourth present as local disease with regional metastasis, and approximately 15% are first seen at an advanced stage with or without distant metastasis. As with other aerodigestive carcinomas, metachronous and synchronous cancers are ongoing considerations in developing appropriate diagnostic and therapeutic strategies. The incidence of metachronous (i.e., second primary aerodigestive SCC) is reported to be between 5% and 35% of all aerodigestive cases,<sup>47,48,49</sup> and<sup>50</sup> with the esophagus being the most common second site overall.<sup>48,50</sup> The larynx, however, seems to demonstrate a more frequent association with lung rather than esophagus carcinoma. This is a logical sequel to the carcinogenic impact of inhaling rather than ingesting offensive chemicals.

Separate consideration must be given to the spectrum of cellular disarray that includes premalignant squamous lesions, CIS, and superficially invasive carcinomas. To discuss the epithelial changes that precede and probably lead to carcinoma of the larynx is of considerable importance because it is with this group of lesions that cancer prevention and conservative management methods are most effective. As our knowledge of this subject has increased, so too has our sophistication in applying the minimal techniques necessary to achieve excellent cure rates in these disorders. The obvious value of a philosophy of preemptive strategies and treatment minimalism is the achievement of an outcome with the least physiologic change. Important also is that, by applying the appropriate minimal treatment, one is able to save radiation in reserve for potential future cancers of the adjacent aerodigestive tissues.<sup>51</sup>

Because the appropriate management strategy for early laryngeal neoplasia depends greatly on a dialogue that is understood by both oncologist and pathologist, the description of the various alterations of the surface epithelium, although not exclusively applicable to the larynx, is important to this discussion. The term *leukoplakia* describes any white lesion on a mucous membrane and does not automatically refer to an associated or underlying malignancy. *Erythroplakia*, on the other hand, is a clinical term that describes any red lesion on a mucous membrane and, in contrast to the white lesions, is often indicative of an underlying malignant tumor. The term *hyperkeratosis* represents an increase in the amount of surface keratin. In the case of the larynx, which normally is lined with a nonkeratinizing epithelium, the use of the term *hyperkeratosis* is redundant; instead, the preferable term is *keratosis*.

Investigators have studied the occurrence of aberrant squamous epithelium in various areas of the larynx, and a predilection seems to exist for carcinogenesis in those respective sites.<sup>52</sup> However, because only those lesions that begin on the true vocal cords are likely to produce early symptoms and signs, the opportunity to treat small cancers on other aerodigestive sites is infrequent. With true vocal cord lesions, however, the early warning symptoms frequently lead to early diagnosis and extraordinary cure rates for glottic malignancies.

The mucosal changes that lead to cancer take years to develop, and that evolution probably follows a consistent pattern. Most laryngeal SCCs result from prolonged exposure to recognized carcinogens that stimulate mucosal hyperplasia and metaplasia. Some of these changes are associated with keratosis, and others are not. In some situations, epithelial atypia or dysplasia may exist, the degree of which probably determines whether a lesion is destined to become malignant.<sup>53,54</sup> and<sup>55</sup> In one large study by Silamniku and colleagues,<sup>56</sup> 3% of patients with vocal cord keratosis unassociated with atypia and 7% with mild atypia developed invasive carcinoma. In those patients with moderate and severe atypia, however, 18% and 24%, respectively, developed carcinoma. Another study by Hjslet and colleagues<sup>57</sup> showed a similar probability of cancer evolution in the group with less atypia and a strikingly higher probability in those patients with severe atypia.

In addition to the morphologic appearance of mucosal alteration, DNA changes seem to show a correlation between cancer potential and cellular aneuploidy. In a study by Munck-Wirland and coworkers,<sup>58</sup> for instance, all of those patients with dysplastic laryngeal lesions that later went on to become carcinoma demonstrated an aneuploid DNA pattern.

Mucosal lesions, whether premalignant or not, have an inconsistent gross appearance; some are white and others are hyperemic. Many investigators believe the risk for cancer development is substantially higher in lesions that are soft and red in appearance.<sup>55</sup> Without histologic study, however, even the most experienced diagnostician cannot consistently predict the presence of cancer or the likelihood of its evolution in any of these lesions. Furthermore, any given point within a lesion does not necessarily represent the balance of that lesion. The facts that CIS is often surrounded by dysplastic epithelium and that many areas of invasive carcinoma are surrounded by zones of both CIS and dysplastic epithelium<sup>59</sup> lend credence to the concept that these morphologic categories of epithelial disturbance are each part of a dynamic spectrum of disorders, each probably related to and possibly representing different stages of the same process. This rationale suggests that dysplasia leads to CIS, which in turn leads to invasive carcinoma.

On the other hand, this concept is challenged vigorously, and contrary thought suggests that the spectrum of abnormal epithelial maturation and individual cellular aberrations can occur in circumstances that may or may not precede invasive carcinoma. *Dysplasia* is a term that is synonymous with atypia, and the degree of dysplasia is graded as mild, moderate, or severe, depending on the extent of involvement of the surface epithelium. In general, the less the degree of dysplasia, the

less likely is the transformation to invasive carcinoma. Conversely, the higher the degree of dysplasia, the more likely is such a progression. In the opinion of some investigators, however, severe dysplasia, especially in the larynx, is not a prerequisite for the development of an invasive SCC. In fact, invasive carcinoma can develop in an epithelium with only mild dysplastic changes.

As classically defined, CIS represents full-thickness, mucosal, epithelial, dysplastic change without violation of the basement membrane. For all intents and purposes, severe dysplasia can be synonymous with CIS. Also, CIS is known to arise from the basal epithelial layer in the absence of overlying dysplastic changes. In this setting, therefore, the definition of CIS can be expanded to include those lesions in which the mucosal alterations are so severe as to signal a high probability for the progression to an invasive carcinoma if left untreated. Extension of the dysplastic process to involve the mucoserous glands should still be considered CIS and not invasive carcinoma. Such is not the case with transgression across the basement membrane, which is the point at which CIS becomes invasive carcinoma.

It is unknown whether those lesions that have achieved the status of carcinoma continue to grow at the same rate as they did during their premalignant state or whether their growth is accelerated. The growth of a cancer through the basement membrane into the lamina propria constitutes the transition from CIS to microinvasive carcinoma, and accompanying this development is a tethering of vocal cord mucosal motion. The degree of this membrane motion restriction is in direct proportion to the extent of invasion into the underlying lamina propria of the vocal cord.<sup>9</sup> Failure to appreciate these subtle changes can result in the administration of suboptimal treatment. For example, high failure rates that have been reported with mucosal stripping in CIS patients almost certainly represent underestimation of these lesions.<sup>60</sup> Some of those lesions that had been classified in the prestroboscopic era as CIS probably contained areas of invasive carcinoma, and the stripping left behind foci of cancer that resulted in recurrence.

The gross appearance of a given laryngeal lesion is suggestive of its general type. SCCs originate within the mucous membrane and are exophytic or ulcerative, are of surface origin (Fig. 30.3-3), and are frequently adjacent to or surrounded by keratoses. Neuroendocrine cancers and tumors metastatic to the larynx are usually submucosal and, as such, do not resemble lesions of surface origin. Metastatic lesions of various types and neuroendocrine tumors are seen throughout the various subsites within the larynx, although the latter group shows a predilection for the supraglottic area. The distribution of SCC within the various laryngeal subsites varies between different countries, a fact that reflects the different social habits within those cultures. In the United States, for example, the ratio of supraglottic to glottic SCCs is 1:2, whereas the reverse is true in certain European countries (see Table 30.3-1).

**FIGURE 30.3-3.** Squamous cell carcinoma (C) of the true vocal cord (TVC). Notice the “surface” appearance of the lesion.

The major differences in the natural histories of the various SCCs of the larynx are related largely to the area anatomy and to the lymphatic drainage patterns of the respective subsite(s).

Cellular characteristics vary by site. In the supraglottis, lesions are more likely to be nonkeratinizing and poorly differentiated, and they have more aggressive local behavior in general.<sup>61</sup> Those lesions of the true vocal cords, on the other hand, are more often well differentiated and tend to be less aggressive locally. Although the degree of cellular differentiation is not thought to be the most significant fact in tumor grading, it does seem to correlate with the probability of cervical metastasis,<sup>32,42,62,63</sup> which in turn strongly impacts on survival.<sup>64</sup> Other local characteristics, such as tumor-host interface,<sup>42,61</sup> peritumor inflammatory response,<sup>65</sup> and vascular and perineural invasion,<sup>66</sup> also seem important in determining performance. Finally, the actual tumor thickness and depth of invasion almost certainly have an influence on metastasis and, ultimately, on survival.

A variety of studies have attempted to standardize the predictive value of thickness in SCCs of the upper aerodigestive tract with the probability of cervical metastasis and, therefore, the prognosis.<sup>65,67,68,69</sup> and <sup>70</sup> Although head and neck oncologists have for some time intuitively favored a direct correlation between the two, a number of studies have failed to demonstrate a statistically significant association between tumor thickness and nodal metastasis.<sup>66,71,72</sup> Also, it should be noted that those studies demonstrating a correlation between thickness and metastasis generally focused on sites other than the larynx, and because of the anatomic complexity and embryologic uniqueness of the larynx, one cannot necessarily transpose such data from other head and neck organs.

## SPECIFIC SITES

### Supraglottis

Lesions of the supraglottic larynx tend to spread locally. If they begin on the epiglottis, they can extend onto the false vocal cords and into the ventricles. Inferior extension beyond the ventricle is initially thwarted, but as growth continues, these cancers can penetrate into the paraglottic space. From there they gain full access to the length of the endolarynx. These cancers often exit the paraglottic space at the top and bottom of the larynx to enter directly into the neck.

Most supraglottic lesions arise on the epiglottis, with fewer being seen on the false vocal cords and aryepiglottic folds. Those lesions that occur on the suprahoid or upper part of the epiglottis are more often exophytic, whereas those that occur on the lower portion of that structure are likely to be endophytic or ulcerative.<sup>61,73</sup> An endophytic growth pattern is especially significant in this particular area of the epiglottis because of the presence of foramina that lead directly through the cartilage into the preepiglottic space. This space is a compartment continuous with the tongue base. What would appear to be a localized tumor in the endolarynx, therefore, can actually involve considerable unrecognized extralaryngeal extension. Tumors are confined initially to the preepiglottic space by the ligamentous boundaries of that compartment, but once those barriers are overcome, the loosely arranged skeletal muscle fibers of the tongue provide no restriction to further tumor extension.<sup>74</sup> Modern imaging, especially magnetic resonance imaging (MRI), has greatly improved the ability to recognize tumor extension into the preepiglottic space and base of the tongue.

Those lesions that occur on the laryngeal surface of the epiglottis are capable of invading and destroying the cartilage of that structure. Supraglottic cancers, on the other hand, almost never destroy the thyroid cartilage.<sup>75</sup> This feature has an influence on the design of treatment plans. For example, an ossified and invaded thyroid cartilage poses a substantial problem for surgeons attempting to perform partial laryngectomy and also for radiation oncologists attempting to deliver curative therapy.

Aryepiglottic fold cancers are somewhat different in their behavior, more commonly following the tendencies of pyriform sinus lesions by spreading in a more diffuse fashion and metastasizing more frequently than their endolaryngeal counterparts. The particularly ominous natural history of these lesions probably relates as much to the abundant and multidirectional lymphatic drainage of the area as it does to individual cellular peculiarities.<sup>76</sup>

Because of the profuse lymphatic network of the supraglottic larynx, carcinomas of this area metastasize frequently to the cervical lymph nodes, and failure of treatment is usually a result of metastasis rather than local disease.<sup>41,54,77</sup> The incidence of patients with clinically positive lymph nodes at the time of diagnosis is 23% to 50% for all supraglottic sites and stages combined.<sup>76,78,79</sup> and <sup>80</sup> A substantial number of those patients with clinically negative necks turn out to have histologic disease as demonstrated when a neck dissection is done, or, if left untreated, they convert to clinically positive necks.<sup>81,82</sup> In supraglottic cancers, the probability of cervical metastasis and the probability of delayed contralateral metastasis increase in direct proportion to the size of the primary (i.e., the T stage).<sup>61,83,84</sup> Lindberg<sup>41</sup> reported impressive overall metastatic rates with various supraglottic carcinomas: Sixty-three percent of T1, 70% of T2, 79% of T3, and 73% of T4 cases

metastasized.

In that group of patients with supraglottic lesions that present with a clinically positive cervical node 2 cm in diameter or more, the possibility for contralateral neck metastasis is 40% or higher.<sup>85</sup> The epiglottis is particularly prone to bilateral metastasis, and even in smaller lesions of that site, the incidence of contralateral metastasis is more than 20%.<sup>72</sup> Much of the data on clinically positive necks and on occult metastasis were compiled before the routine use of computed tomography (CT) and MRI of the neck. With the use of these more sophisticated staging methods added to the already 75% to 85% accuracy of physical examination,<sup>86</sup> the overall incidence of metastasis noted at the time of diagnosis will probably become higher than that reported previously.

### Glottis

Glottic, or true vocal cord (fold), carcinoma is the most common of all laryngeal cancers encountered in the United States. Although these lesions are usually well differentiated, they can demonstrate an infiltrative growth pattern, even when they appear exophytic and well organized. Most true vocal cord cancers occur on the anterior two-thirds of that structure; a small percentage of them develop on the anterior commissure; and they rarely occur on the posterior commissure.<sup>87</sup>

To a large extent, growth characteristics and the natural history of glottic carcinomas are determined by the unique anatomy of the true vocal cords. First, the sparsity of the lymphatic drainage of the true vocal cords in all areas other than the posterior commissure makes metastasis of early lesions extremely unlikely. Second, the elastic layers (conus elasticus) within the larynx often divert cancers that begin on the free edge of the vocal cord and continue into the underlying vocalis muscle and paraglottic space, which is an inferolateral pathway that leads out of the larynx through the cricothyroid space. With penetration into the underlying tissues, all degrees of motion impairment, from subtle mucous membrane stiffness to frank fixation of the vocal cord, can follow. That increasing impairment of motion has a telling effect on local control and survival data, a fact that is reflected in AJCC staging designations. Much discussion continues about mobility change and its therapeutic implications, and it is in the group of glottic cancers that demonstrate this change that the clinical judgment of the physician is most tested. The final anatomic factor unique to the glottis that influences the growth pattern of certain cancers is the anterior commissure ligament, which forms the bridge between the anterior ends of the true vocal cords. This structure lies immediately against the inner lamina of the thyroid cartilage, and its presence initially retards penetration of cancers into that area, often causing their diversion upward onto the epiglottis or downward onto the cricothyroid membrane. From there, these lesions can escape the larynx into the anterior neck. If the cancer overcomes the ligamentous barrier at the anterior commissure, the cartilage is penetrated.<sup>88</sup> This event is particularly likely in thyroid cartilages that are ossified, and when this does occur, substantial therapeutic implications compromise the effectiveness of radiation therapy and dictate specific surgical approaches.<sup>89,90</sup>

### Subglottis

Carcinomas of the subglottic larynx are unusual, making up only approximately 1% to 8% of all laryngeal cancers.<sup>91</sup> These lesions tend to be poorly differentiated and often demonstrate an infiltrative growth pattern unrestricted by tissue barriers. These tumors are, therefore, frequently circumferential and can extend down the trachea. The incidence of cervical metastasis in this group of cancers is reported to be 20% to 30%, but that figure is somewhat obscured by the fact that the primary drainage pattern of these lesions is to the less detectable pretracheal and paratracheal nodes. The actual incidence of metastasis may, therefore, be significantly higher.<sup>85,92,93</sup>

## UNUSUAL AND RARE NEOPLASMS

The pathology and pathogenesis of verrucous carcinoma are unique and deserve special consideration. This unusual tumor is poorly understood, and its origin, classification, and response to treatment are controversial.<sup>94,95</sup> Verrucous carcinoma is described as a distinct neoplastic entity of squamous origin that occurs in the oral cavity, larynx, esophagus, and nose and on the genitalia.<sup>47,96,97,98</sup> and <sup>99</sup> Some authorities have suggested the human papillomavirus as its cause.<sup>100</sup> Although there are views to the contrary, most investigators consider verrucous carcinoma to be an entity unto itself.<sup>101</sup> Just because some tumors originally thought to be verrucous carcinoma are discovered to have features of SCC and can metastasize does not, in their opinion, justify combining the two diagnoses (actually, they think that such tumors were always low-grade SCCs rather than verrucous carcinoma).<sup>98</sup> Other investigators, although conceding verrucous carcinoma to be unique, believe it to be only a variant of well-differentiated SCC. Different authors believe that because verrucous carcinomas neither fulfill the histologic and cytologic criteria of malignancy nor possess the capability to metastasize, they should be renamed *verrucous acanthoma*.<sup>102</sup> When this lesion does occur in the larynx, it usually is on the true vocal cord, where it grows slowly and can cause significant local destruction by expanding gradually. Although these lesions often destroy cartilage, they do not tend to metastasize; instead, aggressiveness is directed locally.

Verrucous carcinoma is consistently difficult to diagnose, even when the clinical index of suspicion is high. This observation relates to the fact that these tumors microscopically demonstrate an exuberant and keratinizing hyperplasia that is benign by pure histologic and cytologic criteria.<sup>103</sup> The diagnosis is largely a clinical one and is most effectively achieved by concert between pathologist and surgeon, but usually only after multiple biopsies have been taken.

Verrucous carcinoma is typically a slow-growing but relentless mass, exophytic and warty in appearance, and broad based at its interface with the mucosa ( [Fig. 30.3-4](#)). Its surface is often necrotic and infected, and the associated inflammation of adjacent tissues can be remarkable. This tendency to cause inflammation can erroneously influence treatment planning. For example, the patient with verrucous carcinoma can demonstrate enlarged adjacent cervical lymph nodes that are worrisome when in fact the adenopathy is only secondary to the inflammatory process. Although this finding has been described in other aerodigestive tumors,<sup>104</sup> the mere presence of lymphadenopathy in the primary drainage area of an impressive primary tumor is worrisome, no matter how benign its histology looks. In such a circumstance, clinical judgment is enhanced greatly by modern imaging and cytopathologic techniques.

**FIGURE 30.3-4.** Verrucous carcinoma of the true vocal cord.

This discussion of the nature of verrucous carcinoma has substantial therapeutic implications, especially when the lesion occurs in the larynx. Essentially, SCC is a radiosensitive cancer, a fact that provides treatment options to the oncologist. On the other hand, verrucous carcinoma seems to be somewhat radioresistant, whether found in the mouth or the larynx.<sup>94</sup> Additionally, anecdotal information suggests radiation-induced dedifferentiation into anaplastic cancer in these lesions. This transformation seems to occur in fewer than 10% of verrucous carcinomas<sup>78,96,105,106</sup> and <sup>107</sup> and may involve alteration of the DNA that facilitates the integration of the human papillomavirus into host cells.<sup>100</sup> Both the concept of radiation resistance and the transformation into anaplastic cancers are vigorously disputed.<sup>98,108,109</sup> and <sup>110</sup>

The neuroendocrine family of tumors represents an evolving database. This is true largely because newer diagnostic techniques have allowed pathologists specifically to label as neuroendocrine a variety of previously undefined cancers. Almost certainly, an immunohistochemical reexamination of laryngeal cancers previously diagnosed as atypical or undifferentiated malignancies would result in the reclassification of many of them as neuroendocrine tumors. The small cell tumors look and act much like their counterpart oat cell lung lesions and, as such, generally are managed by chemotherapy and radiation therapy.<sup>44,111</sup> Surgical procedures do not seem to enhance the likelihood of survival in patients with these tumors.<sup>112,113,114,115</sup> and <sup>116</sup> The other neuroendocrine tumors that occur in the larynx—carcinoids

and paragangliomas—are rare and are best managed surgically.<sup>116,117 and 118</sup>

Cartilaginous malignancies,<sup>119</sup> adenocarcinomas,<sup>120</sup> sarcomas,<sup>121</sup> malignant fibrous histiocytomas,<sup>122</sup> plasmacytomas,<sup>123</sup> granular cell tumors,<sup>124</sup> and primary lymphomas<sup>125</sup> have all been reported but are rare. Primary melanomas of the larynx are equally rare. Of all of the laryngeal cancers reported from Memorial Sloan-Kettering Cancer Center between 1949 and 1983, only three were melanomas.<sup>126</sup>

## DIAGNOSIS AND EVALUATION

Cancers of the supraglottic larynx usually do not produce early symptoms or signs, and it is common for the first hint of such a cancer to be cervical adenopathy. When symptoms do occur, they are often subtle; pain perceived in the primary site or in the ear (otalgia), a scratchy sensation when swallowing, or merely an alteration of one's tolerance for hot or cold foods may be all that is noticeable. Airway alteration, hoarseness, or a tendency to aspirate liquids are all produced by more advanced lesions.

Cancers of the glottis, on the other hand, are often detected early in the course of the disease because even a slight alteration of the vibratory surface of the true vocal cords produces voice change. Smokers are often hoarse, however, and such alteration of the voice may not alarm them. Anyone with a voice change that persists longer than 2 weeks should have a laryngeal examination. Different than in supraglottic lesions, it is unusual for glottic cancer patients to seek medical attention because of cervical adenopathy. In the latter group, metastasis generally occurs late in the course of the disease, long after the early warning signals.

Subglottic cancers are uncommon, but when they do occur, they do not produce early symptoms; therefore, the disease is often advanced by the time of diagnosis.

Almost all laryngeal cancers are squamous carcinomas and, as such, are surface lesions. Most are obvious with routine laryngeal inspection, but a small percentage are located in obscure areas and, therefore, not readily visible. The modern generation of flexible endoscopes ( Fig. 30.3-5) has provided the capability of examining the larynx to a broad range of physicians; thus, the overall process of screening and follow-up after treatment has been enhanced. Importantly, these methods allow the occasional laryngeal examiner to see areas that previously have been visually inaccessible.

FIGURE 30.3-5. Flexible laryngeal endoscope in use.

It is essential that the larynx be examined in the awake patient who is sitting upright. Direct laryngoscopy under anesthesia should be reserved for biopsy and a more detailed tumor mapping (Fig. 30.3-6). Even when done under local anesthesia, the introduction of a direct laryngoscope distorts the natural position and the relaxed motion of the larynx and, by doing so, tends to disguise subtle motion changes that are important in staging of these tumors. Certain subtleties of contour, such as bulging and tethering, are visually not appreciable during direct laryngoscopy.

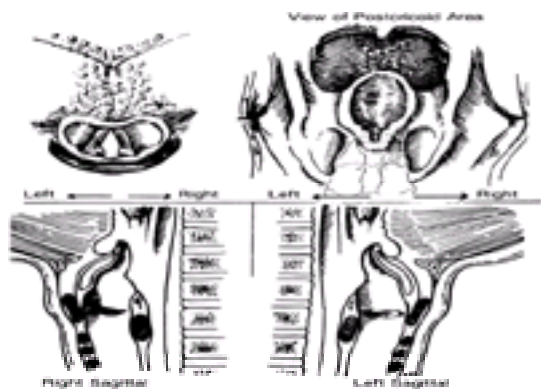

FIGURE 30.3-6. Diagrams of laryngopharynx used for mapping and recording tumors.

The earliest stage of invasive glottic carcinoma through mucosa into the underlying lamina propria is visible as a tethering of the mucous membrane that normally slides over the underlying structures, and the mucosal wave<sup>38</sup> is lost. Although the gross abductive capabilities of the vocal cord may be intact, the early invasive character of a lesion can be appreciated when a stroboscopic examination is used to demonstrate this restrictive feature. As the process of invasion continues into the underlying vocalis muscle, the actual lateral excursion of the vocal cord is limited and eventually lost. The ability of the clinician to view and interpret this scenario is critical to the sophisticated management of vocal cord cancer. Essentially, lesions of the true vocal cord that do not transgress the basement membrane do not cause tethering of the mucosa, and those that enter the underlying lamina propria do cause tethering.<sup>39</sup> Benign lesions and even CIS, therefore, may look extensive topographically, but their lack of depth is revealed by appropriate diagnostic technology. Although contemporary methods of staging tend to emphasize the bulk and topographic size of tumors rather than depth, investigators have begun to focus more on this third dimension. As data are accumulated, more emphasis will be placed on this important matter.

Imaging should not be relied on to detect early larynx cancer, because the routine methods of physical examination are far more suitable. The primary care physician should not, therefore, initially resort to CT or MRI when a laryngeal cancer symptom persists. Instead, someone skilled in the appropriate techniques should examine that patient. Once a lesion is discovered, however, the evaluation of its depth, bulk, and possible cartilage invasion and the status of the regional lymph nodes are often enhanced by CT or MRI. It is not clear which of the two imaging methods is better for larynx cancer evaluation. Both have certain advantages over the other, and both are of limited usefulness in evaluating the radiated larynx. CT of the larynx is most effectively achieved in the axial plane, and because of this, the images are especially efficient in showing lateral tumor extension and the relation of that extension to cervical nodal disease. The axial projection is, therefore, effective in demonstrating the important paraglottic space. CT also effectively demonstrates the vertical extension of tumor, especially in the subglottic and anterior commissure areas. MRI offers the advantages of multiplanar visualization of the larynx and, therefore, is especially valuable in evaluating the preepiglottic space and the adjacent base of the tongue.

Invasion of laryngeal cartilage is important in treatment planning. Determining whether this feature exists has always been difficult because of the inconsistency of the ossification that occurs in the laryngeal framework. Generally, cartilage is vulnerable to tumor invasion in those areas where it is ossified, and it is somewhat resistant where it is not ossified. In fact, healthy, nonossified cartilage provides a considerable natural barrier to cancer invasion. Writings by Castelijns et al.<sup>127</sup> and Towler and Young<sup>125</sup> have suggested that MRI is the method of choice for delineating the important finding of cartilage invasion. Other investigators would dispute this claim. One study correlated MRI findings of cartilage invasion with the effectiveness of radiation treatment, and in so doing, the authors found a surprising number of small glottic

lesions with foci of cartilage invasion.<sup>126</sup> Significantly, it was from this group that most of the radiation failures of the series occurred.

Other imaging methods, such as tomography and laryngography, have been surpassed by more elaborate technology and are only of historic interest.

## STAGING

The AJCC last updated larynx staging in 1997, and that version is presented in [Table 30.3-3](#). Staging provides a commonality of language that is essential for effective outcomes analysis. The larynx is a complex structure because it involves many anatomic and physiologic factors that impact on performance and, therefore, on staging. Although it is essential that pathologic findings always be compared with preoperative analysis, it should be remembered that the staging referred to and that reported by the AJCC is a clinical one, which is based on performance. The accuracy of clinical staging is periodically updated on the basis of better recognition of performance. For example, Pillsbury and Kirchner<sup>130</sup> studied this question by comparing whole-organ sections of nonradiated larynges and compared the actual pathologic findings with the preoperative staging. They found that 40% of cases had been categorized incorrectly, and most of these inaccuracies reflected understaging. Most commonly, the depth of invasion had been underestimated, and the frequency of cartilage invasion was much higher than previously had been realized. Certainly, as imaging technology improves, so will the ability to stage more accurately.<sup>128,129</sup> As clinicians make use of adjuvant chemotherapy treatment protocols for which the assessment of complete versus partial response is required, modern imaging hopefully will enhance the accuracy of that assessment.

**TABLE 30.3-3.** Tumor (T), Node (N), Metastasis (M) Staging System for Larynx

Survival in larynx cancer decreases in a linear fashion with increasing stage. The most remarkable change is between stages II and III, the zone that generally represents the occurrence of cervical metastasis.

## TREATMENT AND SURVIVAL

### Supraglottis

Because the supraglottic larynx is composed of multiple sites, referring to it as one unit is not always accurate when discussing treatment results. Because all of the subsites are intimately related and because the supraglottis is continuous with its neighboring glottic larynx, the hypopharynx, and the oropharynx, it can be difficult to determine the exact site of origin for many larger cancers. For example, when one encounters a lesion that involves the pharyngoepiglottic fold, the aryepiglottic fold(s), and the pyriform sinus(es), it can be difficult to know whether this is a primary hypopharynx cancer extending superiorly or a supraglottic cancer extending inferiorly.

Unlike glottic cancer, in which cervical metastasis is relatively uncommon in early-stage disease, the probability of nodal spread in all supraglottic lesions is substantial.<sup>41,61</sup> A contralateral metastasis is significantly probable in these lesions, and this probability increases in direct proportion to primary tumor size.<sup>83</sup> This finding is especially true for epiglottic lesions, which make up most of the supraglottic carcinomas. It is essential to recognize that the site of treatment failure in supraglottic cancer is usually the neck; therefore, treatment strategies require neck management for virtually all lesions. For the N0 neck, this implies selective neck dissection and/or postoperative radiation, or elective radiation only. For patients with a clinically positive neck(s), this implies neck dissection, therapeutic radiation, or both.

Early-stage supraglottic cancers have equivalent cure rates with either conservative (partial laryngectomy) surgery or primary radiation therapy.<sup>131</sup> This is especially true for those lesions on the most cephalic part of the epiglottis (i.e., the suprahyoid epiglottis), but not for those lesions on the lower part of that structure where there are foramina that lead through the cartilage into the preepiglottic space and, ultimately, into the tongue base. For more advanced lesions, a variety of treatment options are available, including radiation therapy alone,<sup>132,133</sup> and <sup>134</sup> supraglottic laryngectomy with or without postoperative radiation therapy,<sup>135,136</sup> and chemoradiation therapy programs for patients who would otherwise require a total laryngectomy.<sup>137,138,139</sup> and <sup>140</sup>

The results of primary radiation for supraglottic cancer are well established. Mendenhall and colleagues<sup>133,134</sup> Mendenhall and colleagues<sup>134</sup> reported 5-year local control of 100% for T1, 83% for T2, 68% for T3, and 56% for T4 lesions. Wang and associates<sup>133</sup> reported 5-year local control of 96% for T1, 86% for T2, 76% for T3, and 43% for T4 lesions. In this particular study, when laryngectomy was added for salvage, local control was 96% for T1, 93% for T2, 88% for T3, and 51% for T4 lesions.

Different criteria create T3 designation of supraglottic laryngeal cancer, and in selected circumstances of this stage in which there is no vocal cord fixation, supraglottic laryngectomy can be applied efficiently; thus, voice sparing is achieved. Three different studies have applied strict standards to the patient selection for supraglottic laryngectomy in T3 lesions, and disease-free survival of approximately 75% at 3 years can be expected.<sup>141,142</sup> and <sup>143</sup>

Parsons and coworkers<sup>144</sup> reported on 26 T4 invasive SCCs of the larynx treated with radiation therapy. Only 38% achieved local control at 5 years in this report. Other series also demonstrate the similarity of outcomes of primary radiation therapy and surgery, even for moderately advanced disease.<sup>145,146</sup> Supraglottic lesions that cause vocal cord fixation (T3), those that involve the postcricoid region (T3), those that invade the laryngeal cartilage (T4), or those that extend into extralaryngeal sites (T4) can often be effectively managed with total laryngectomy and postoperative radiation therapy. Today, however, it is the exception rather than the norm to offer a patient a total laryngectomy as an initial treatment option in these advanced-stage cancers. Instead, the organ-sparing strategy of chemoradiation, with laryngectomy reserved for unsuccessful cases, is generally the standard of care. It should be emphasized, however, that each case must be individualized, and certain lesions in certain patients warrant the traditional approach whereby laryngectomy is performed first.

For patients who undergo supraglottic laryngectomy, postoperative radiation therapy is occasionally considered. Excellent local control has been reported with this sequencing in selected T3/T4 lesions<sup>136</sup>; however, the combination of these two treatments is morbid, with increased gastrostomy or tracheostomy dependence, airway problems, and delayed independent swallowing.<sup>135</sup> In general, it is best to choose one or the other (i.e., radiation or surgery) as the definitive local therapy. However, because of the extremely low rate of local recurrence after supraglottic laryngectomy, postoperative radiation to the laryngeal segment is not often used after this operation.

An advantage to radiation as the initial treatment of early-stage supraglottic disease is that bilateral elective neck treatment can be included in the plan with minimal morbidity. If an adequate dose of elective neck radiation is given, neck relapse should be less than 5% in the absence of clinically obvious disease. If surgery is chosen as the treatment for a T1 or T2 supraglottic lesion, the supraglottic laryngectomy should be combined with bilateral selective neck dissections, even when the neck is N0. Postoperative radiation therapy is added to the necks of those patients in whom these staging procedures show metastatic disease. The obvious disadvantage to this approach is that it becomes necessary to use two different treatment modalities compared with the strategy in which radiation therapy is used initially to the primary tumor and necks. The disadvantage to the plan that uses radiation therapy initially is that, when it is unsuccessful, total laryngectomy is needed. Such is the case because supraglottic laryngectomy is contraindicated after full-course radiation therapy to the larynx (complications such as persistent swelling,

failure of wound healing, radiation chondritis, and swallowing difficulties are strikingly frequent in this setting).

Pretreatment CT scans can be helpful in predicting outcomes for supraglottic lesions treated with primary radiation therapy. Hermans and colleagues<sup>147</sup> reported that tumor volume derived from CT analysis was the strongest predictor of locoregional failure and that the degree of paraglottic space involvement, subglottic extension, and preepiglottic space involvement all were important prognostic factors demonstrated by this imaging method. Mancuso et al.<sup>148</sup> was able to quantify the correlation between CT findings and local control. For patients with a tumor volume of less than 6 cm<sup>3</sup> who were treated by radiation therapy alone, local control was achieved in 89%. When the tumor volume was 6 cm<sup>3</sup> or greater, the local control was only 52%. A decreased rate of local control and voice preservation was also noted if 25% or more of the preepiglottic space was involved with tumor. A study conducted by Lo and associates<sup>149</sup> also correlated CT tumor volume with radiation failure, but this analysis was unable to demonstrate such a correlation with surgery.

When comparing one type of operation (supraglottic laryngectomy) to the other (total laryngectomy), it is important to note that the former of the two is physiologic and allows retention of vocal and swallowing functions. Furthermore, because of the unique lymphatic drainage patterns of the organ and the presence of certain natural anatomic barriers to tumor spread, this operation is oncologically sound, yielding the same local control rates as achieved by total laryngectomy in comparable lesions.<sup>150,151</sup> Ogura and Biller<sup>151</sup> reported an 85% 3-year control for epiglottis cancers treated with supraglottic laryngectomy, but this result decreased to 71% with extension onto the false cord(s). These figures are comparable to those produced by total laryngectomy for similar lesions.

It is not the mission of this text to provide an elaborate description of the various partial laryngeal surgical techniques used to manage supraglottic cancer; however, the student of this disease should have at least a summary knowledge of the methods known collectively as *conservation laryngeal surgery*. The compartmentalization of the larynx and the directional drainage patterns of the lymph channels within it provide surgeons with the unique opportunity for removing that portion of the larynx above the true vocal cords, and with proper reconstruction, swallowing and vocal functions are retained in the process. Essentially, this procedure is a horizontally directed hemilaryngectomy in which the surgeon removes the upper half of the thyroid cartilage and the contents within it (the false vocal cords, the epiglottis, and the aryepiglottic folds). The edge of the thyroid cartilage is brought up to and attached to the transected base of the tongue. Because the motor nerve supply of the vocal cords comes from below (recurrent laryngeal nerves) and is not in the surgical field, the important vocal cord functions of abduction and adduction are retained, and because of this, voice and the important airway protective functions of glottic closure are preserved.

The supraglottic laryngectomy is, however, physiologically challenging, and patients with chronic pulmonary disease often have difficulty tolerating the aspiration that can follow. Essentially, this elegant technique is oncologically sound in appropriate tumors, but certain patients are not good candidates for its implementation. The correct use of the supraglottic laryngectomy is accomplished only by surgeons properly trained in this methodology and who have the experience to apply the right methods in the right situations. A succinct discussion of the method of selection for all conservation procedures and which patients are suitable for them was developed by Sessions and Parish.<sup>152</sup> Although certain chemoradiotherapy options have been popularized since that discussion was published, the fundamental principles are the same and can be applied to the current philosophy. As those alternative chemoradiation schema are used more frequently, the number of surgeons accomplished in the techniques of conservation laryngeal surgery will diminish. Although the idea of saving more larynges without compromising cure is meritorious, it is worrisome that those subtle skills necessary for achieving excellent functional results with the partial laryngectomies is to some extent being lost by the current generation of head and neck surgeons. A variety of conservation surgery procedures are applied to variations of laryngeal cancer, and although a description of each is beyond the scope of this text, the following classification of these operations should be helpful in placing this important surgical methodology into the proper perspective:

1. Hemilaryngectomy
  - a. Horizontal hemilaryngectomy (supraglottic)
  - b. Vertical hemilaryngectomy
    - i. Lateral hemilaryngectomy
    - ii. Frontal hemilaryngectomy
2. Cordectomy
3. Supracricoid laryngectomy<sup>153</sup>
4. Partial laryngopharyngectomy

Just as with the description of specific surgical methods, elaborate details of radiation therapy technique are not appropriate here. In general, patients with early-stage laryngeal disease are treated with once daily continuous course radiation therapy. Opposed lateral fields are used for the primary site and upper neck(s), and a separate anterior field is used for the lower neck(s). In selected total laryngectomies, the stoma is included in this neck treatment plan. The total dose to the primary site is in the 65 to 70 Gy range.<sup>133,134</sup> For more advanced disease, a variety of fractionation schemes have been used, including once daily, twice daily, and concomitant boost techniques.<sup>133,134,154</sup> A Radiation Therapy Oncology Group randomized trial compared four different fractionation schedules for advanced head and neck cancers treated with primary radiotherapy: once daily radiation to a total of 70 Gy in 7 weeks; twice daily radiation using 1.2 Gy per fraction to a total dose of 81.6 Gy; accelerated hyperfractionation technique with a planned break using 1.6 Gy per fraction twice daily up to approximately 38.4 Gy, followed by a 2-week break, and continuing with 1.6 Gy twice daily to 67.2 Gy; and a concomitant boost technique using once daily fractionation in the beginning of the program, followed by twice daily fractionation for the concomitant boost during the final 12 treatment days, up to a total of 72 Gy. The results show better 2-year locoregional control and disease-free survival using the concomitant boost approach. Acute and late toxicity was acceptable, although increased, over standard fractionation.

### **Glottis**

CIS of the true vocal cord is highly curable with equal efficiency by microexcision, laser vaporization,<sup>155</sup> or radiation therapy.<sup>156,157 and 158</sup> Pure CIS lesions are unusual, and a frequent association exists, more often than not, between such lesions and invasive carcinoma. Those series that have been reported in which numerous recurrences developed after stripping of vocal cord CIS almost certainly consisted of a heterogeneous group that included lesions containing areas of unrecognized invasive cancer. For this reason, we favor microexcision of the involved membrane over laser vaporization, which destroys the specimen and does not allow for the pathologic analysis needed to identify areas of microinvasion.

True CIS, by definition, remains superficial to the basement membrane, and if mucosal excision techniques are confined to that group of patients, the cure rate should be the same as the best that can be achieved by radiation therapy. The advantages of microexcision over radiation is that it is simpler and that radiation therapy is held in reserve for future use. Considering the incidence of metachronous and synchronous second primary, cancers that occur in the aerodigestive tract, the policy of holding radiation in reserve whenever possible is prudent. The advantages of radiation therapy are that the voice is at least as good and often better than with surgery, and it is a more definitive treatment for invasive cancer that may exist within the lesion. In both microexcision and radiation, when treatment fails, a surgical procedure can still salvage most patients and, in the majority of cases, with a voice-sparing operation.

All things considered, if the diagnosis of pure CIS of the vocal cord(s) is fairly certain, microexcision is probably the treatment of choice. So-called vocal cord stripping often has a crippling effect on the voice and is in violation of the contemporary standard of care. Such is not the case with microexcision, which has minimal impact on vocal quality.

The value of a properly excised piece of tissue to a complete histopathologic analysis cannot be overrated. Importantly, microexcision should include a wide zone around the obvious trouble, followed by a thorough pathologic evaluation of the specimen to look for microinvasive areas. Procedures that excise the underlying vocal cord muscle (i.e., cordectomy) produce a crippling vocal effect and do not offer any oncologic improvement over microexcision or radiation; thus, such a procedure should not be considered as one of the treatment options for vocal cord CIS.

Radiation therapy is used either as the definitive treatment of CIS when microexcision is not possible or is refused, or as a salvage treatment for patients with recurrent CIS following prior surgical procedures.<sup>159,160</sup> Series of CIS patients show that, when radiation therapy is used, it is very effective. Medini and coworkers<sup>158</sup> reported 20 patients with CIS treated with radiotherapy, using a dose of 1.75 Gy per fraction to a median total dose of 68.4 Gy. The 4-year disease-free survival rate was 95%. Improved voice was reported in 16 of 20 patients, with no change noted in the other four. In summary, the standard of care for CIS of the vocal cord consists of a strategy that uses primary surgery for most patients and selective radiation therapy in others.

These authors rely heavily on the preoperative evaluation by videostroboscopy<sup>39</sup> to estimate the depth of the surface cancer. Normal membrane motion (i.e., a normal mucosal wave)<sup>38</sup> suggests confinement of the lesion to that area superficial to the basement membrane (i.e., CIS). On the other hand, if stroboscopy demonstrates tethering of the membrane to the underlying tissue, we consider that a sign of microinvasion (more advanced than CIS). Such a patient receives radiation therapy. If

we believe the lesion is entirely superficial to the basement membrane, we do microexcision and examine the specimen carefully for microinvasion. The understaging of CIS in past studies could probably have been avoided by the appropriate use of stroboscopic analysis.

Finally, certain CIS lesions, such as those on the anterior commissure, in the subglottis, or some that extend into the laryngeal ventricle, do not lend themselves to these surgical methods; in these cases, radiation is a better means of initial treatment.

For T1 or T2 invasive glottic cancer, excellent local control is achieved by either radiation therapy or conservation surgery procedures.<sup>156,161,162 and 163</sup> It is generally agreed, however, that vocal quality is better after radiation therapy.<sup>164,165 and 166</sup> Harrison and colleagues<sup>167</sup> reported an ultimate return to normal voice in nearly all radiated T1 and T2 glottic cancer patients. Even though several patterns of vocal dysfunction existed before, during, and immediately after radiation therapy, normalization of these alterations occurred within 3 months after completion of radiotherapy. Daggi,<sup>164</sup> however, showed that the postradiation voice, although better than the surgically treated counterpart, remains abnormal with respect to various subtle parameters, such as maximum vocal intensity, dynamic vocal intensity range, jitter, and mean fundamental frequency. De Graeff and associates<sup>168</sup> also reported objective improvement of speech after radiotherapy but pointed out that there was short-term, temporary deterioration of physical functioning and fatigue. Tsunoda and coworkers<sup>169</sup> stroboscopically studied the changes of the mucous membrane motion after radiation of early glottic cancers. They demonstrated ultimate return to normal motion in all patients studied. Furthermore, these authors suggested the potential value of stroboscopy for detecting early cancer recurrence, thus corroborating the findings of Sessions et al.<sup>38</sup> in a previously reported study.

Finally, there seem to be predictors of poor vocal quality: Vocal cord stripping (instead of biopsy only) before radiotherapy and continued smoking after radiation therapy predicted worse voice quality as well as substandard stroboscopic performance.<sup>170</sup>

It is important to note that, in those lower-staged (i.e., T1 and T2) glottic lesions that are unsuccessfully treated with radiation, salvage partial laryngectomy (hemilaryngectomy) can be performed successfully in a significant number of patients, thus achieving excellent overall cure rates while retaining voice.<sup>171,172</sup>

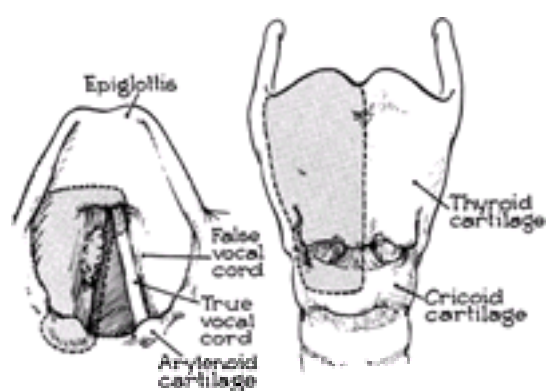

Whether achieved by radiation therapy or by surgery, local control rate decreases with increasing tumor bulk. Dickens and coworkers<sup>173</sup> reported the results for early glottic tumors of various sizes and extent. The lesions were categorized by the type of surgical procedure that would have been necessary had surgery been used. This type of analysis provides an excellent basis for comparing the results of surgery and radiation. In patients suitable for hemilaryngectomy, the local control with radiation alone was 94%. This figure increased to 100% when surgical salvage was added. On the contrary, for patients managed by radiation therapy who would have required total laryngectomy, local control rate was only 65%, but it increased to 91% when surgical salvage was added. Extension of these glottic carcinomas onto the anterior and posterior aspects of the larynx lessens the local control rates achieved with radiation therapy.<sup>174</sup> In this study, the surgical procedure required for salvage usually was a total laryngectomy rather than a hemilaryngectomy.

Essentially, the 5-year survival rates for primary surgery (cordectomy or hemilaryngectomy) and primary radiation for T1 lesions are comparable.<sup>161,162 and 163,175,176,177 and 178</sup> Local control obtained in this same-stage glottic group using conservation surgical procedures is reported to be 78% by Kirchner and Owen<sup>78</sup> and 87% by Ogura et al.<sup>179</sup> Results obtained for comparable T1 lesions treated by radiation therapy show local control of 91% by Harwood<sup>156</sup> and 93% by Pellitteri.<sup>163</sup>

Sessions and colleagues<sup>180</sup> reported a 5-year survival rate of 74% for T1 and T2 lesions that originated in the anterior commissure of the glottic larynx. This study demonstrated that survival and recurrence rates of anterior commissure lesions correlated with the size and stage of the tumor.<sup>181</sup> Olofsson and associates<sup>182</sup> reported an 80% survival rate at 5 years for early-stage anterior commissure lesions, but this study included those recurrences that had been salvaged by surgery. Those anterior commissure lesions that are thin and of low volume and that do not have substantial subglottic extension probably are treated with equal efficiency by partial laryngectomy or radiation therapy. As lesions become more advanced, the natural barrier of the anterior commissure ligament is overcome and the thyroid cartilage is frequently invaded<sup>183</sup>; therefore, radiation therapy becomes less appealing than surgery as the front-line treatment. Most tumors involving the anterior commissure occur as a result of spread from the true vocal cord. Lesions actually arising in the anterior commissure are unusual, making up 1% to 2% of glottic cancers.<sup>181,183</sup> In summary, the standard for treating T1 glottic cancers is radiation therapy, and partial or total laryngectomy is used as a salvage operation in those patients for whom this first line of treatment is unsuccessful.

The management of T2 lesions, on the other hand, is somewhat more complicated because this group is more heterogeneous. Surgical management usually consists of vertical hemilaryngectomy and is associated with 3-year survival rates of 83%<sup>180</sup> and 82%<sup>179</sup> in two major series. Primary radiation therapy with surgical salvage yields a net 5-year survival rate of 92% in Pellitteri et al.'s series,<sup>163</sup> 72% in Wang's series,<sup>161</sup> and 90% in Fletcher et al.'s series.<sup>162</sup> Because of the heterogeneity of the T2 group, Wang<sup>161</sup> has suggested subdividing these lesions into those with normal mobility (T2A) and those with impaired mobility (T2B). He showed that local control was obtained in 86% of the former and 63% of the latter when primary radiation was used. Similar observations were made by Harwood,<sup>156</sup> whose series yielded 77% and 51% local control rates for T2A and T2B lesions, respectively. Medini and colleagues<sup>158</sup> reported a 5-year disease-free survival rate of 80% for T2A and 64% for T2B lesions. Klintenberg and associates<sup>184</sup> reported local control of 73% for T2 lesions, with subglottic extension being the most important factor. In summary, radiation therapy is usually recommended as the primary treatment modality for T2 lesions with no vocal cord mobility impairment (T2A); however, in those lesions that demonstrate impairment of motion (T2B), hemilaryngectomy is preferred. These criteria are variable, however, depending on tumor bulk, and in those less bulky T2B lesions, radiation can be used. It should be noted also that, when vocal cord motion is restricted by actual surface tumor bulk rather than by invasion of the underlying muscle, radiation is often effective.

Those conservation surgical procedures that can be applied to the management of glottic cancer are time honored and tested, and when used in the properly selected case of laryngeal cancer, they consistently yield excellent results functionally and oncologically. The most commonly used of these procedures is the vertical hemilaryngectomy, in which the surgeon bisects the larynx and, to a varying degree, removes a portion or all of the true and false vocal cord along with the respective half of the thyroid cartilage. Because most of the lesions for which this operation is performed are located on the anterior two-thirds of the vocal cord, the most posterior resection line usually is in front of the arytenoid cartilage. In those circumstances in which the cancer extends onto the posterior larynx, this cartilage can be resected (Fig. 30.3-7). By using the perichondrium from the external surface of the half of the thyroid cartilage that has been removed, the operated side of the larynx heals in the midline, forming a firm buttress (pseudocord) against which the opposite and normal true vocal cord vibrates.

**FIGURE 30.3-7.** Axial and frontal views of larynx show that portion of the organ removed by a horizontal hemilaryngectomy (shaded).

Just as with surgery, radiation therapy of T2 glottic cancer need not include elective neck treatment. Fein and coworkers<sup>185</sup> reported that, in this group, the incidence of neck failure was 3.7% with elective neck radiation, and 2.6% when no elective treatment was given. The radiation field arrangement is similar to the technique used for T1 disease. The field size must be large enough to encompass the entire extent of disease, and the total dose is usually approximately 70 Gy range.

Various factors seem to be important prognostically for all glottic cancer treated with radiation. Several series<sup>186,187 and 188</sup> strongly correlate anemia with poorer outcomes for T1 and T2 glottic cancer treated with radiation, with one series<sup>186</sup> revealing a 6% drop in local control for every 1 g drop in hemoglobin. Similar studies have not been accomplished with surgically treated patients.

Data on other potential prognostic markers include contradictions on whether p53 correlates with radiation failure; some suggest such an ability, <sup>189</sup> whereas others fail to demonstrate a significant relationship. <sup>190,191</sup> Growth factor markers such as Ki-67, an indicator of the proliferation index, may be important and may also be prognostic for surgically treated cases. <sup>192,193</sup>

Radiologic imaging is playing an increasingly important role. CT derived tumor volume correlates with outcome for radiation patients <sup>149,194</sup> and may become increasingly important. Emerging data also suggest that positron emission tomographic scanning may be very useful in assessing patients after radiation therapy and in differentiating radiation-related changes from recurrent tumor. <sup>195,196</sup> and <sup>197</sup>

A continued evolution of radiation techniques is largely responsible for the excellent control of early glottic disease in many reported series. <sup>161,163,184,198, 199, 200</sup> and <sup>201</sup> Individualized treatment planning, isodose contours, and beam compensation are mandatory to optimize local control. <sup>201</sup> Lower-energy photon beams (cobalt 60, £4-MV linear accelerators) may have an advantage over higher-energy beams, <sup>202</sup> although proper treatment planning may make 6-MV beams acceptable. <sup>185</sup>

Much has been written about the time-dose relationships and the variety of fractionation schemes used. <sup>186,199, 200</sup> and <sup>201,203, 204, 205</sup> and <sup>206</sup> The optimal fractionation schedule is not known, although many different programs have been successfully conducted. Most authors agree that dose per fraction of 2 Gy or more is preferable to lower dose per fraction. <sup>201,202</sup> and <sup>203</sup> Most institutions use a dose per fraction of 2 Gy or more and a total dose in the 60 to 66 Gy range, with lower total doses in those with higher doses per fraction. <sup>201,202</sup> and <sup>203</sup> It seems clear that longer overall treatment times are associated with worse outcomes. <sup>186,200,204, 205</sup> and <sup>206</sup> Skladowski and colleagues <sup>186</sup> reported that a prolongation of the treatment time from 45 days to 55 days decreased the tumor control probability by 13%. Hayakawa and colleagues <sup>200</sup> reported 5-year local control rates of 95% for those completing treatment in 45 days or less, 81% in 46 to 49 days, and 73% in more than 50 days.

The most commonly used field arrangement is opposed lateral portals measuring between 5.5 × 5.5 cm and 6.0 × 6.0 cm that cover the larynx alone. Patients must be properly immobilized. A larynx contour is taken during simulation, and an appropriate larynx wedge is usually added to keep the dose inhomogeneity to within 5% to 10%.

Involvement of the anterior commissure continues to be a perplexing issue. Certain authors report poorer outcomes, <sup>207,208</sup> whereas others <sup>209</sup> report that proper technique yields satisfactory outcomes not dissimilar to other T1 lesions.

Glottic cancers that cause vocal cord or hemilaryngeal immobilization or fixation (i.e., T3) are substantially more ominous than lesions that do not. At a minimum, such motion impairment reflects vocalis muscle invasion. However, further tumor extension into the paraglottic space is often present, opening the entire larynx and adjacent exit areas to cancer spread. Many of these lesions are associated with thyroid or cricoid cartilage destruction, and the tendency is to underestimate glottic lesions with vocal cord fixation. In Olofsson et al.'s <sup>210</sup> study, a significant number of tumors originally had been understaged as T3 cancers but were actually T4 lesions with extralaryngeal extension. With the unpredictable extent of the disease and the overall high probability of cartilage destruction in mind, surgery, which usually consists of a total laryngectomy, traditionally has been favored over radiation therapy for the primary management of T3 lesions. The overall 5-year survival rate for T3 glottic cancers treated with total laryngectomy is reported to be 55% to 72% in four major series. <sup>78,211</sup> However, it has been shown by Kirchner and Owen <sup>78</sup> that, in carefully selected T3 vocal cord lesions clearly limited to the vocalis muscle and in which no associated cartilage destruction is found, hemilaryngectomy can be performed with oncologic safety. In this series of 22 patients, a 60% cure rate was reported. In another similar study, Som <sup>212</sup> reported a 58% cure rate in 26 patients with selected T3 glottic tumors treated by partial laryngectomy. It should be noted that both of these significant studies were done before the use of CT or MRI. Such technology would almost certainly have made the evaluation of these lesions and the delineation of their dimensions easier and more accurate. Even with this limitation lessened by contemporary technology, the reader should not be led to underestimate the difficulty of correctly selecting the small subset of T3 lesions suitable for hemilaryngectomy. This judgment is appropriately left only to those surgeons with considerable experience in partial laryngeal surgery.

Overall, managing T3 glottic cancer can be challenging. A small number of these lesions can be effectively removed by partial laryngectomy, but because this selection is fraught with hazards, past surgical literature has been slanted toward recommending total laryngectomy. Such is not the case today, however, and those patients with T3 glottic cancer who would require a total laryngectomy are almost always treated with an organ-preservation chemoradiation approach, with laryngectomy being used only for those who are unsuccessful with the former. The survival rate is the same between those that require the three modalities (chemotherapy, radiotherapy, laryngectomy) and those to whom only chemotherapy and radiation are given; however, a substantial percentage of patients retain their larynges in the process. <sup>139,140,213</sup>

A subset of T3 glottic patients can be cured without operation. Van den Bogert et al. <sup>213</sup> reported a local control rate of 53% in a group of patients with operable T3 lesions who had refused surgery. Harwood and colleagues <sup>214</sup> reported a 45% 5-year local control rate for T3 glottic patients, and Wang <sup>215</sup> reported a 36% 5-year actuarial local control rate, which increased to 57% when surgical salvage was added. Mendenhall and associates <sup>216</sup> have reported that T3 glottic cancer treated with radiotherapy alone has a 5-year local control rate of 63%, increasing to 86% with surgical salvage. Pretreatment CT scans helped predict outcome. For tumors whose volume was 3.5 cm<sup>3</sup> or less, local control was 87% compared with 29% for larger-volume lesions. A trend has been noted toward better outcomes with twice daily treatment versus once daily fractionation. <sup>217,218</sup> Finally, no correlation seems to exist between the return of vocal cord mobility and outcome, <sup>217</sup> and it is not uncommon for the vocal cord to remain fixed, even after successful radiation.

T4 tumor designation denotes cartilage destruction or extension of the tumor outside of the confines of the larynx. Grouping together all T4 lesions is misleading, however, because it fails to account for the more favorable tumor of lesser thickness and volume that may have achieved a T4 status only because it originated in a marginal zone and extended to an adjacent area, such as the pyriform sinus or base of the tongue. Just as with T3 supraglottic lesions, there are favorable and unfavorable T4 lesions, and that determination is made appropriately on the basis of tumor volume, depth, and thickness. With this exception in mind, the performance of the group of T4 glottic lesions is expectedly poorer than that of lesser stages. Traditionally, most of the unfavorable lesions are treated with total laryngectomy and some sort of a neck dissection; generally, these patients receive postoperative radiation. This unfavorable subgroup, which has destroyed cartilage, has been analyzed by Jesse, <sup>219</sup> who demonstrated an ominous pattern: Of the 48 patients, 6% had distant metastasis at presentation, 39% had cervical metastasis, and 30% required an urgent tracheostomy at the time of diagnosis. In this series of patients, the 4-year cure rate using laryngectomy and radiation was 54%. In the subset of patients in this study who required tracheostomy, the survival rate decreased to 38%. Other studies have demonstrated 5-year survival rates of 25% to 30% in this subset of larynx cancer patients. <sup>220,221</sup>

It is unusual for the more favorable lesions to be treated with a laryngectomy initially, because we now recognize the effectiveness of the organ-preservation (i.e., chemoradiation) strategies. The concept of organ preservation by using induction chemotherapy to help identify those lesions likely to respond to radiation therapy is a new addition to the treatment armamentarium. Those favorable results of nonrandomized trials <sup>1,2</sup> and <sup>3</sup> and the results of the Veterans Administration Cooperative Study Group <sup>222,223</sup> include a number of patients with T4 lesions. Although we must exercise caution in replacing standard and time-honored therapy with new strategies, the concept of organ preservation is today widely accepted as standard therapy in selected advanced larynx and hypopharynx cancers.

Harwood and associates <sup>214</sup> reported local control in 56% of T4, N0 glottic lesions treated with radical radiation therapy. The 5-year survival rate for radiation with surgical salvage was 49%. Within this group, the local control rate for patients classified as T4 from cartilage invasion was 67% at 5 years. This result was significantly better than for those T4 patients who had pyriform sinus involvement. In this latter group, the actuarial local control rate was only 19%. The T4 patients with hypopharyngeal involvement do not seem to be good candidates for radical radiation therapy. This circumstance parallels the dismal performance of the similar group treated surgically and reported by Jesse. <sup>219</sup> It also is similar to a comparably poor performance for those larynx cancer patients with hypopharyngeal extension noted by Pfister et al. <sup>1</sup> in their larynx-preservation study with induction chemotherapy. The same trend of poor chemoradiation performance for those larynx cancer patients with hypopharyngeal extension was noted by Karp and coworkers. <sup>2</sup> Whatever the treatment variation, these patients consistently seem to do poorly.

### **Subglottis**

Although the preponderance of subglottic tumors are SCCs, adenocarcinomas and adenoid cystic carcinomas are seen occasionally. <sup>92</sup> The cure rate for these tumors is poor, despite combination therapy. Total laryngectomy and appropriate neck surgery, including thyroidectomy, are probably the surgical treatment most recommended, and postoperative radiation therapy should probably be administered. <sup>79,93</sup> Mediastinal dissection of the paratracheal nodal groups does not seem to add substantially to survival rates. <sup>92</sup>

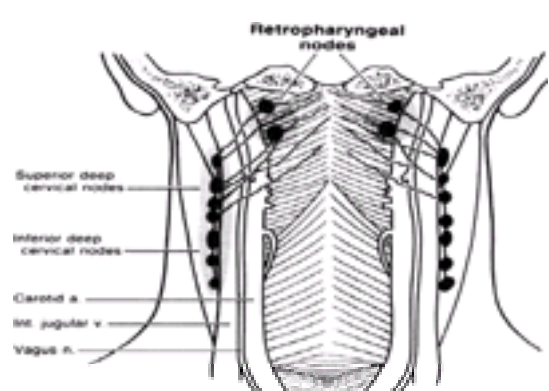

### Chemotherapy for Preservation of Laryngeal Function—Organ Preservation

Surgical management of locally advanced SCCs of the larynx and hypopharynx has often required total laryngectomy. Organ-preservation trials in the form of uncontrolled feasibility series and prospective randomized controlled trials are now available to guide appropriate use of chemotherapy. In general, two nonsurgical strategies—induction chemotherapy followed by definitive radiation therapy in responding patients, and concurrent radiation therapy and chemotherapy—are the alternatives to laryngectomy.

Concurrent chemoradiation has been used for the treatment of unresectable head and neck cancer for decades. Trials of multiagent cisplatin-based chemoradiation strategies have demonstrated improved locoregional control and survival compared with radiation therapy alone in cancers of the nasopharynx, oropharynx, and in unresectable cancers of all aerodigestive sites.<sup>224,225,226 and 227</sup> For resectable stage III and IV cancers of the larynx and stage II, III, and IV cancers of the hypopharynx, mature data is available on the induction chemotherapy strategies as a means of preserving the larynx. Randomized trials evaluating concurrent chemoradiation are nearing completion in the United States and are in progress in Europe.<sup>228</sup>

The concept of induction chemotherapy as a primary strategy evolved for two main reasons. First, high response rates could be achieved with the standard cisplatin (100 mg/m<sup>2</sup> day 1) and infusional 5-fluorouracil (5-FU) (1000 mg/m<sup>2</sup>/d, days 1 to 5) regimen: an 85% overall response rate (complete and partial) and a clinical complete response rate ranging from 30% to 50%.<sup>229,230 and 231</sup> A pathologic complete response was confirmed by biopsy or by resection in two-thirds of clinical complete responders. Second, the response to chemotherapy was generally predictive of radiosensitivity.<sup>3,232</sup> These observations led to a number of uncontrolled trials, mostly in patients with advanced laryngeal and hypopharyngeal cancers that were destined for total laryngectomy.<sup>1,2,233,234,235 and 236</sup> These small published series confirmed the feasibility of the concept of induction chemotherapy followed by definitive radiotherapy to preserve speech and swallowing function, and importantly, they suggested that survival was not compromised in the process. Three randomized controlled trials and a metaanalysis provide data from which to draw conclusions and recommend guidelines for patient management.<sup>138,237,238</sup> The general scheme for organ preservation protocols that was conceptualized by Hong and colleagues<sup>3</sup> is outlined in [Figure 30.3-8](#).

**FIGURE 30.3-8.** Posterior view of pharynx and great vessels shows retropharyngeal lymph nodes commonly involved in hypopharyngeal cancer. a, artery; Int., internal; n, nerve; v, vein.

### Randomized Trials

The first randomized trial<sup>237</sup> using induction chemotherapy for organ preservation was started in 1985 by the Department of Veterans Affairs Laryngeal Study Group in which 332 patients with stage III or IV (M0) cancer of the glottis or supraglottis were analyzed ([Table 30.3-4](#)). These were randomly assigned treatments with either surgery (total laryngectomy) and radiation therapy, or induction chemotherapy and radiation therapy. In the experimental arm, partial or complete responders after two cycles of cisplatin and 5-FU received a third cycle of chemotherapy followed by definitive radiation therapy. Laryngectomy was reserved for salvage of persistent or recurrent disease. Patients demonstrating less than a partial response at the primary site after two cycles of chemotherapy underwent immediate laryngectomy.

Study	Number of Patients	Site of Stage	Treatment	Number of Patients	Survival (%)	Laryngeal Preservation (%)
1985 <sup>237</sup>	332	Supraglottis (50%) Glottis (50%) T1-3 (50%) T4 (50%)	RT vs RT + 5-FU + Cis n = 167	166	55%	48% at 3y
1985 <sup>237</sup>	332	Supraglottis (50%) Glottis (50%) T1-3 (50%) T4 (50%)	RT vs RT + 5-FU + Cis n = 167	166	55%	48% at 3y
1978 <sup>238</sup>	194	Supraglottis (50%) Glottis (50%) T1-3 (50%) T4 (50%)	RT vs RT + 5-FU + Cis n = 97	97	55%	48% at 3y
1985 <sup>237</sup>	332	Supraglottis (50%) Glottis (50%) T1-3 (50%) T4 (50%)	RT vs RT + 5-FU + Cis n = 167	166	55%	48% at 3y

**TABLE 30.3-4.** Randomized Trials of Laryngeal Preservation

Various prognostic factors were analyzed for response to chemotherapy, organ preservation, and survival.<sup>239</sup> For surgically treated patients, the one factor in multivariate analysis that was significant for decreased survival was extracapsular extension of nodal disease, whereas no independent predictive factor of survival emerged for chemotherapy-treated patients. Low T class (T1–T3 vs. T4) was the best predictor of response to chemotherapy (relative risk ratio, 5.6; *P* = .01). T class, p53 overexpression, and elevated proliferating cell nuclear antigen index were independent predictors of successful organ preservation with induction chemotherapy and radiotherapy.

The second randomized induction chemotherapy trial of larynx preservation was conducted by the European Organization for Research and Treatment of Cancer (EORTC) in patients with resectable cancers of the pyriform sinus or the aryepiglottic fold (lateral epiglottis)<sup>238</sup> (see [Table 30.3-4](#)). A total of 194 patients with stage T2–T4, N0–N2b were randomized to surgery (total laryngectomy plus partial pharyngectomy) and radiation therapy in one study arm or induction chemotherapy (cisplatin + 5-FU) and radiation therapy in responders. A clinical complete response at the primary site after two or three cycles of chemotherapy was required to proceed to radiation, and this was achieved in 54% of patients. Survival equivalence was demonstrated at 3 and 5 years, and a functioning larynx was preserved in 48% at 3 years. A delay in development of distant metastases was noted for the chemotherapy-treated patients, whereas no differences were observed in the rates of local or regional failure between treatment groups.

A third randomized trial of patients with locally advanced larynx cancer was conducted by the Groupe d'Etude des Tumeurs de la Tête et du Cou in France<sup>240</sup> (see [Table 30.3-4](#)). This study was limited to patients with T3 tumors and consisted predominately of patients with glottic primaries. This was in contrast to the Veterans Affairs trial in which a majority of the lesions were supraglottic lesions. Laryngectomy was avoided in 41% (15 of 36 patients); however, the trial has been criticized for the small number of patients enrolled, the lack of imaging studies to assess tumor extent before treatment, and the lack of proper response evaluation after chemotherapy and after radiotherapy.

A metaanalysis by Lefebvre of chemotherapy in head and neck cancer limited to the 602 patients enrolled in these three trials shows a statistically nonsignificant difference in survival after a median follow-up of 5.8 years (45% for surgery patients vs. 39% for the induction chemotherapy group).<sup>241</sup> The larynx was preserved in

58% of surviving patients at 5 years.

From these three randomized studies, one can conclude the following for induction chemotherapy as a strategy to preserve the larynx: Survival is not jeopardized; laryngeal function can be preserved in approximately one-half of surviving patients; and the risk of requiring salvage surgery increases with bulky primary and nodal disease. In effect, these trial results confirm a role for induction chemotherapy using the cisplatin plus 5-FU regimen followed by radiation therapy as an alternative nonsurgical treatment for patients with locally advanced cancers of the larynx (stage III and IV) and hypopharynx (stage II, III, and IV) who would otherwise undergo total laryngectomy. A team approach that includes the surgical, radiation, and medical oncologists; nutritionist; and experts in lifestyle behavior modification is critical to the success of combined modality treatment. So that surgery can be performed promptly in nonresponders and for salvage of recurrent disease, it is essential that the surgeon be involved throughout and after the induction chemotherapy and radiation phases of treatment.

Left unanswered by these trials are the following important questions: (1) What is the precise role of induction chemotherapy?, (2) What is the comparative efficacy of radiation therapy as a single modality for preservation of the larynx?, and (3) What is the potential of concurrent chemotherapy and radiation therapy to improve locoregional control and survival? These questions are being addressed for cancers of the larynx and hypopharynx in randomized trials in the United States and Europe in which cisplatin plus 5-FU induction chemotherapy followed by radiation therapy in responding patients (partial response of the primary tumor) serves as the control arm.<sup>228</sup> The U.S. intergroup trial (R91-11) will complete accrual of 546 patients in the year 2000. This trial will provide data on two treatment alternatives: concurrent radiation therapy plus cisplatin compared to the control group, and radiation therapy alone compared to the control group. Until those trial results mature for larynx cancer specifically, induction chemotherapy sequenced with radiation therapy remains the standard of care. The consistent survival benefit observed in recent multisite and oropharynx randomized trials comparing concurrent chemotherapy and radiotherapy to radiotherapy alone is impressive. This suggests that the concurrent rather than the sequential strategy may emerge as the preferred treatment strategy for larynx and hypopharynx primaries as well.

### **Chemotherapy in the Treatment of Far Advanced (Unresectable) Locoregional Disease**

There is no role for induction chemotherapy in the management of patients with advanced locoregional disease in which clear margins cannot be achieved by resection. Many randomized trials of patients with unresectable disease were carried out in the 1980s, which directly compared induction chemotherapy followed by radiation to radiation therapy alone.<sup>242</sup> Survival benefit was reported in a subset analysis of patients with unresectable disease in only a single randomized trial.<sup>243</sup> In contrast, prospective randomized trials of patients with unresectable disease clearly demonstrate a substantial increase in locoregional control and significantly improved survival with the use of concurrent chemotherapy and radiation therapy regimens when compared to either standard or altered fractionation schedules of radiation therapy alone.<sup>224,225,226 and 227</sup> Thus, concurrent chemotherapy and radiation therapy can be recommended as the standard of care in this disease setting, provided the patient has sufficient performance status and psychosocial resources to undergo the generally more toxic treatment. At present, the most widely used regimen with proven survival benefit in a multicenter comparative trial is cisplatin 100 mg/m<sup>2</sup> on days 1, 22, and 43, during which radiation is taken to 70 Gy at a rate of 2 Gy/d.<sup>3</sup> Taxane-based regimens are under investigation in phase I and II trials evaluating a variety of doses and infusion schedules combined with varying radiation therapy fractionation schedules.<sup>244,245,246 and 247</sup> However, insufficient data is available on efficacy and toxicity at this time to recommend any taxane-based chemoradiation regimen as a standard of care. For patients with poor performance status, radiation therapy alone or, in some situations, supportive care alone may constitute appropriate management.

In summary, the selection of a treatment strategy for T4 supraglottic and glottic larynx cancers is dependent on a variety of factors, including the following:

1. If there is bulky neck disease and if the primary tumor does not have extensive hypopharyngeal extension, induction chemotherapy followed by radiation therapy to the primary tumor and neck can be used in chemosensitive tumors. This should be followed by a neck dissection(s). In such lesions that are not chemoresponsive, laryngectomy and neck dissection(s) plus postoperative radiation therapy should be used.
2. If substantial hypopharyngeal extension is present, laryngectomy or laryngopharyngectomy plus neck dissection and postoperative radiation therapy is recommended.
3. If no clinical neck disease is present (i.e., T4, N0), induction chemotherapy followed by radiation therapy to the primary tumor and necks in chemoresponsive tumors should be considered. If such a lesion does not respond adequately to induction chemotherapy, then the logical course should be a laryngectomy. The laryngectomy should probably be accompanied by appropriate selective neck dissection for staging<sup>248</sup> and, depending on the result of the histologic analysis of the neck nodes harvested, postoperative radiation therapy.
4. In these large lesions, especially lesions that demonstrate subglottic extension, radiation must be directed to the tracheal stoma, because recurrence here can be seen in a substantial percentage of these patients. Other indications for postoperative radiation are cartilage and extensive soft tissue invasion.

Most of these strategies for treating patients with advanced larynx or hypopharynx cancer and clinically positive necks must be analyzed in light of the dynamic state of the knowledge and experience with the organ-preservation concepts. Hitherto, we have been comfortable with the notion that substantial neck disease usually required surgery of some sort at some stage in the treatment plan. Armstrong and colleagues,<sup>249</sup> however, have published data that parallel the concept of larynx preservation and that suggest that patients with clinically palpable cervical nodal metastases who have a complete response to chemotherapy and who receive high-dose radiation therapy have excellent neck control and may not need neck dissection. To address this issue, they reviewed the neck management of the first 80 patients treated in the larynx preservation trials at Memorial Sloan-Kettering Cancer Center. Of these, 54 patients presented with clinically positive nodes. Of these, 44% had a complete response and 20% had a partial response in the neck to induction chemotherapy. In 63% of the major responders, surgery to the neck was omitted, and radiation alone was used. Neck control was obtained in 91%, with only 1 in 17 complete responders and 1 of 5 partial responders exhibiting neck failure. These data suggest that major responders to induction chemotherapy may possibly avoid neck dissection. These data require supplementation, and data for concomitant chemotherapy and radiotherapy must also be generated before it can be decided if this observation is sustained. Even if these preliminary suggestions are substantiated, however, the definitive question to be asked is whether the morbidity endured with high-dose radiation is justified when moderate-dose neck radiation plus a tailored neck operation is so well tolerated.

### **Considerations for Neck Surgery**

Management of the neck is critical to successful therapy of supraglottic cancer. Levendag and associates<sup>77</sup> studied elective surgical management of the neck in a group of patients with stage I and II supraglottic carcinoma treated with surgery alone at the Memorial Sloan-Kettering Cancer Center. In those patients who underwent elective neck dissection (i.e., the group with clinically negative necks), 32% were found to have histologically positive cervical lymph nodes. One-half of the patients with involved nodes eventually had cancer recurrence in the dissected neck. Additionally, 19% of patients with negative elective neck dissections had cancer recurrence in the contralateral neck. Finally, in a group of 48 patients who did not have elective neck dissection, 29% had cancer recurrence in the neck. Therefore, a total of 35% of the T1, N0 and T2, N0 patients ultimately developed cervical lymph node metastases. Importantly, nearly two-thirds of those who relapsed in the neck eventually died from their cancer. On the other hand, none of the patients without neck relapse died from supraglottic cancer. These investigators compared their experience with a similar patient group from the other studies that showed similar neck failure rates with surgery alone and when radiation therapy was administered to the necks. Less than 5% failure follows electively radiated necks. These reports indicate that even the smallest supraglottic tumors require elective neck management.

A variety of neck operations are currently used in the various treatment plans for laryngeal cancer: the classic radical neck dissection, the modified radical neck dissection, and a group of regional dissections collectively known as *selective neck dissections*. This group of operations has been standardized and endorsed by the American Academy of Otolaryngology–Head and Neck Surgery and the American Head and Neck Society. The monograph outlining the recommended terminology should be studied, and oncologists are strongly urged to incorporate this classification into their lexicon to facilitate interinstitutional data recording and appropriate comparisons.<sup>248</sup>

Considerable diversity of opinion exists in the surgical community as to which of these operations should be applied to which situation. Exact guidelines are not consistently substantiated by the data available. Generalizations are possible, however. The radical neck dissection is almost never used in the clinically negative neck, even in those lesions in which the probability for metastasis is extraordinary. This procedure is usually reserved for necks in which there is gross metastasis, and even then the selective procedures are often used. Most of the time, however, these selective neck dissections are used as staging procedures in which the goal is to harvest and sample the nodal groups at highest risk for metastasis. This philosophy has evolved as a result of our increasing reliance on radiation therapy as the second half of neck treatment whenever disease is discovered in the neck. Only in very limited circumstances is the selective neck dissection thought to be therapeutic; that is to say, in most necks in which any neck disease is present, postoperative radiation is recommended.

The choice of the appropriate selective neck dissection in larynx cancer is based on a knowledge of the consistent patterns of metastasis that are exhibited by the various subsites within the larynx; for example, lesions of the supraglottis are prone to metastasis bilaterally and to levels II and III. Rarely, however, do they spread to

level I.<sup>41</sup> Based on this knowledge, the logical staging operation for a supraglottic laryngeal cancer with a clinically negative neck would be designed specifically to clean out those various compartments at highest risk. This is but one example of a tailored approach, and the reader is referred to the classic work by Lindberg,<sup>41</sup> in which he mapped the patterns of metastases of the various aerodigestive SCCs. More recently, Shah and Andersen<sup>250</sup> applied the modern classification to this process of selectivity and have established recommendations for the use of these neck operations.

## HYPOPHARYNX

### GENERAL

The hypopharynx is the area of the pharynx that lies behind and below the oropharynx, just outside the view provided by tongue blade and flashlight; as such, it is visually inaccessible by routine office examination. Hypopharyngeal cancers are usually aggressive in their behavior, grow in an area of abundant lymphatic drainage, do not produce early symptoms or signs, and usually occur in people who are nutritionally depleted and immunologically compromised. It is not surprising, then, that the survival rates for these cancers are poor and that their treatment is difficult at best.

The hypopharynx is the area of the pharynx that lies behind and below the oropharynx, just outside the view provided by tongue blade and flashlight; as such, it is visually inaccessible by routine office examination. Hypopharyngeal cancers are usually aggressive in their behavior, grow in an area of abundant lymphatic drainage, do not produce early symptoms or signs, and usually occur in people who are nutritionally depleted and immunologically compromised. It is not surprising, then, that the survival rates for these cancers are poor and that their treatment is difficult at best.

The hypopharynx extends from the oropharynx above to the esophageal inlet below, is cone shaped, and consists of three regions or subsites: the paired pyriform sinuses, the posterior pharyngeal wall, and the postcricoid area. The larynx is located at the anterior aspect of the hypopharynx, indenting it to create the two lateral sulci that are the pyriform sinuses. Although these sulci lie partially within the framework of the thyroid cartilage, they are actually part of the hypopharynx, and cancers that develop within them behave differently than do those of the larynx. The lateral wall of each pyriform sinus continues around to blend with and become the posterior pharyngeal wall. The apex of the pyriform sinuses extends down to a level just inferior to those endolaryngeal muscles of the adjacent true vocal cord. Above, the medial walls of the pyriform sinuses each form the pharyngeal side of the corresponding aryepiglottic fold, which is the partition between the hypopharynx and endolarynx. Laterally, the pyriform sinuses extend superiorly to the glossoepiglottic fold. The posterior aspect of each pyriform sinus is open and connects with the hypopharyngeal cavity. In effect, each pyriform sinus is a three-walled space that opens into the general hypopharyngeal cavity (see [Figs. 30.3-1](#) and [30.3-2](#)).

The funnel-shaped postcricoid area begins just below the arytenoids and extends to the level of the cricopharyngeus muscle below. It is lined with the mucosa that overlies the posterior lamina of the cricoid cartilage and that continues into the cervical esophagus. Laterally, the postcricoid mucosa blends with that of the pyriform sinuses, and because of this, the same cancer often affects these two areas.

Approximately 70% of hypopharyngeal lesions occur in the pyriform sinuses, and the remaining 20% to 30% occur on the posterior pharyngeal wall and in the postcricoid area.<sup>251</sup> Postcricoid cancers make up a small percentage of the latter group. Cancer of the hypopharynx is uncommon; approximately 2500 new cases are diagnosed in the United States each year. Overall, these lesions occur more often in men by a significant ratio, but there does seem to be a higher incidence of lower hypopharyngeal, or postcricoid, cancers in women. The upper hypopharyngeal lesions are more common in men. Those lower lesions are more often associated with nutritional abnormalities, whereas the lesions in the remainder of the hypopharynx seem to be associated more with heavy smoking and drinking.<sup>252</sup> Those ratios vary somewhat in different countries and change in accordance with the incidence of vitamin deficiencies.<sup>253</sup> For example, a higher incidence of carcinoma of the postcricoid area is seen in patients with Plummer-Vinson syndrome, a condition that includes an iron deficiency anemia. This condition is especially prevalent in northern Europe and is seen in nonsmoking women. Also, other metabolic deficiencies, such as vitamin B<sub>12</sub> malabsorption, may play a role in the development of these lesions.<sup>254</sup>

### PATHOLOGY, PATHOGENESIS, AND NATURAL HISTORY

Almost all hypopharynx malignancies are SCCs that have developed in an environment of deranged mucosa. The generalized effects of the carcinogens encountered over a lifetime can lead to the occurrence of multiple mucosal sites of epithelial disturbances that range from dyskeratosis to frank cancer. The concept of field cancerization is in part responsible for the multiple, synchronous primary malignant lesions that occur in approximately 12% to 20% of hypopharyngeal cancers.<sup>255,256</sup>

Cancers of the hypopharynx are generally aggressive in their behavior and demonstrate a natural history that is characterized by diffuse local spread, early metastasis, and a relatively high rate of distant spread. The anatomy of the area is such that, once a cancer has penetrated the mucosa, little restriction is placed on diffuse tumor extension in the submucosal plane. Because of this fact and also because of the abundant lymphatic network of the region, a localized hypopharyngeal tumor is exceptional rather than expected. An important study by Harrison<sup>256</sup> demonstrated pathologically that, in 40% of hypopharynx lesions, the true extent of the cancer had been underestimated initially. Tumors of the pharyngeal walls are more often ulcerative than exophytic and are particularly prone to an insidious and deceptive growth pattern characterized by skip metastasis and ill-defined margins; once submucosal, these lesions can resurface at various locations remote from the primary site. They can extend upward in this fashion and can travel all the way to the base of the skull. Cancers of the postcricoid area also tend to spread laterally and can cause vocal cord paralysis by invading the recurrent laryngeal nerve just as it enters the larynx. Postcricoid lesions can extend inferiorly and can develop skip metastases in the cervical esophagus. Gross involvement of the esophagus with postcricoid cancer is uncommon. These lesions usually do not produce early symptoms, and when discovered, they often have caused cricoid cartilage destruction.

It is significant that the lateral walls of the pyriform sinuses lie against that area of the thyroid cartilage that is often ossified, a state that renders the cartilage vulnerable to tumor invasion<sup>257</sup> (see [Fig. 30.3-2](#)). In Kirchner and Owen's series<sup>78</sup> of 500 whole-organ larynx sections, more than 50% of the pyriform sinus cancers demonstrated cartilage invasion. This fact is relevant to the strategies of radiation oncologists and surgeons, because cancer involvement in the cartilage probably lessens radiocurability and substantially compromises the potential for conservation laryngeal surgery. Depending on the degree of ossification present, tumor that has invaded the thyroid or cricoid cartilage in one area can permeate the entire framework by extending within the cartilage and can even travel all the way to the opposite lamina of the structure.

Overall, the distribution of metastatic hypopharynx cancer is to all levels of the neck, with the level II (jugulodigastric) nodes being most common; level III the next most common site; and level I, IV, and V the least likely sites of metastasis.<sup>41</sup> Overall, the risk for cervical metastasis from pyriform sinus cancer is 75%; from posterior pharyngeal wall, 60%; and from the postcricoid area, 40%. Because the pyriform sinuses are located laterally, only 10% of these lesions present with bilateral metastasis. Such a pattern of spread occurs more commonly in postcricoid cancers, and it is the norm in posterior pharyngeal lesions.<sup>258</sup> Approximately 60% of posterior pharyngeal wall lesions demonstrate bilateral cervical nodes at the initial examination.<sup>259</sup> Metastasis occurs early in the course of hypopharynx cancers. Approximately 60% of pyriform sinus lesions are associated with clinically positive necks at the time of diagnosis, and many of those that have clinically negative necks turn out to have occult metastasis in the thyroid gland or in the paratracheal node chain.<sup>81,83</sup>

Because a significant number of postcricoid and pyriform sinus apex lesions metastasize to the less obvious paratracheal and thyroid gland lymphatics, the incidence of occult metastasis from those sites is somewhat greater than in the higher pyriform sinus and posterior pharyngeal wall lesions that typically metastasize to the deep jugular nodes.<sup>260,261</sup> Because of this fact, calculating occult metastatic rate is a problem in hypopharyngeal cancers.

The retropharyngeal lymph nodes that are located high in the neck are primary drainage sites for hypopharyngeal cancers and are involved in more than 40% of patients with posterior pharyngeal wall and pyriform sinus lesions.<sup>262</sup> It is, therefore, especially important in the staging and treatment of this particular group of tumors to include these nodes in the field of dissection, radiation, or both. These lymphatics are part of the deep jugular chain, are outside of the constrictor muscles, and are readily visible by imaging (see [Fig. 30.3-8](#)). Involvement of the retropharyngeal nodes may produce a symptom complex characterized by pain and stiffness in the neck, with pain radiating to the ipsilateral eye and forehead.

The incidence of distant metastasis from hypopharyngeal cancer is substantial, occurring in 24% of all sites and in all stages. This incidence is initially lower, rising in those subpopulations that live longest.<sup>263,264</sup>

### DIAGNOSIS, EVALUATION, AND STAGING

Hypopharyngeal cancer is usually not diagnosed in its early stages. In fact, most series reported include few T1 lesions. This finding is due, in part, to the fact that many patients with these cancers have abused their health by smoking and drinking heavily and therefore they have a high tolerance for throat symptoms; however, it is also true that these lesions are often indolent and produce few symptoms until they are substantial in size. This is especially so for posterior pharyngeal wall cancers. More than 50% of patients with hypopharyngeal cancer have clinically obvious cervical metastasis at the time they are first encountered, and in one-half of these individuals, the neck mass is actually the presenting symptom.<sup>265,266</sup> Pyriform sinus and posterior pharyngeal wall lesions can cause a sensation of irritation and mucus retention that is felt only with swallowing. Otalgia is characteristic of pyriform sinus lesions and is a manifestation of cancer compromising the sensory fibers of the superior laryngeal nerve, the axons of which synapse with sensory nerves of the external auditory canal. The pain generated is typically dull and is perceived by the patient in the posterior and inferior aspects of the canal and on the posterior aspect of the auricle. In the absence of ear findings, persistent pain in these areas must be viewed with suspicion, and a careful examination of the upper aerodigestive tract must be done by someone skilled in the appropriate methods. Voice change associated with pyriform sinus or postcricoid lesions is a late symptom and usually represents impairment of vocal cord function by invasion into the endolarynx or of a recurrent laryngeal nerve. Patients often have lost their ability to swallow comfortably or have a lack of willingness to swallow because of fear of aspiration. Therefore, they often become debilitated during the course of this disease.

Many patients with hypopharyngeal cancer are chronically ill before the development of their lesion, having the pulmonary and hepatic diseases that accompany a lifetime of tobacco and alcohol excesses. Recognition of the compounding nature of these associations with hypopharyngeal cancer is essential in the formulation of an appropriate treatment plan.

Physical examination of the hypopharynx has become much less problematic since the development of the flexible, fiberoptically lighted endoscopes that are easily included in basic outpatient facilities (see [Fig. 30.3-5](#)). The crevices and partially hidden areas of the laryngopharynx are effectively visualized using these instruments; however, the conventional hand-held mirror examination is still the state of the art when used by the experienced head and neck diagnostician. For the occasional examiner, however, the benefits of the flexible endoscopes are significant. What is most essential is that the primary care physician not be reassured falsely by a normal tongue blade and light examination. In those patients with persistent symptoms of swallowing alteration or discomfort, otalgia, or voice change, such an examination is inadequate, because only a small part of the hypopharynx and none of the larynx is visualized in such an examination.

Examination of the hypopharynx can reveal pooling of secretions in all lesions of the area, but this finding is especially impressive in postcricoid and pyriform sinus cancers because of impairment of the passage of food and secretions into the esophagus. Often, such pooling is the only sign of a small lesion. In larger tumors, the abundance of secretions sometimes obscures the actual lesion. Occasionally, small and less obvious lesions of the medial wall and apex of the pyriform sinuses cause subglottic edema in the adjacent larynx. Postcricoid carcinomas generally produce esophageal obstructive symptoms sooner than tumors in other areas of the hypopharynx.

In deeply invasive postcricoid or posterior pharyngeal wall cancers, fixation of the larynx and the pharyngeal wall to the prevertebral fascia often is associated with a loss of normal laryngeal crepitation when the examining physician attempts to move the thyroid cartilage from side to side. As with other sites in the head and neck, the importance of lesion thickness and depth is becoming more obvious, especially as the search continues for nonsurgical means of treating these cancers. The thickness, or third dimension, of hypopharyngeal tumors; their lateral extension into the neck; and finally, the status of the adjacent lateral cervical and retropharyngeal nodes are visualized well by CT or MRI.<sup>267</sup>

Barium esophagogram is a relatively effective tool for detecting second primary cancers in the esophagus and also for evaluating postcricoid lesions<sup>268</sup>; however, this study is of limited value because it visualizes only the surface of the area and does not accurately demonstrate the total tumor volume. Because of tissue edema and the resulting image distortion that can be caused by instrumentation, these studies should be obtained before endoscopy and biopsy whenever possible.

Each hypopharyngeal cancer should be examined, staged, and carefully mapped on a permanent record (see [Fig. 30.3-6](#)); importantly, this should be accomplished on the awake and upright patient. Direct endoscopy and biopsy should then be done on all patients under general anesthesia, so that adequate tissue can be sampled and the third-dimensional appreciation for the tumor better achieved. Finally, considering the significant incidence of multiple synchronous primary tumors that occur with hypopharyngeal cancer, esophagoscopy and bronchoscopy should be done at this time.

## STAGING SYSTEM

As with most cancers, a workable staging system is critical to the evaluation of treatment methods and for the comparison of data between institutions ([Table 30.3-5](#)). This is especially true now that the use of sophisticated imaging allows for a relative quantification of tumor volume and extension. Although staging based on physical examination alone is fairly accurate, imaging is especially important in those lesions treated by nonsurgical means, because pathologic positivity or negativity of the neck is never proved unless a recurrence develops. Although considerable effort has been expended to develop workable and descriptive terminology, there continue to be limitations to current staging for hypopharyngeal cancers. For example, the system is satisfactory for disease of the pyriform sinuses, but it cannot be applied completely to lesions of the posterior pharyngeal wall, because they usually do not invade the larynx, and fixation is not part of the natural history. Rather, posterior pharyngeal wall tumors would be more appropriately staged by tumor diameter, as is the case with oropharyngeal lesions. According to the current system, a 5 × 4–cm posterior pharyngeal lesion without laryngeal fixation would still be classified as a T1 lesion, but in fact, it would have a prognosis similar to that for a T3 lesion.<sup>37,269</sup> The nodal staging and the stage grouping for the hypopharynx are the same as with other head and neck sites.

T1	Tumor limited to one subsite of hypopharynx and is 2 cm or less in greatest dimension.
T2	Tumor invades more than one subsite of hypopharynx or an adjacent site, or measures more than 2 cm but not more than 4 cm in greatest diameter without fixation of hemilarynx.
T3	Tumor measures more than 4 cm in greatest dimension or with fixation of hemilarynx.
T4	Tumor invades adjacent structures (e.g., thyroid/cricoid cartilage, carotid artery, soft tissues of neck, prevertebral fascia/muscles, thyroid, and/or esophagus).

## TREATMENT AND SURVIVAL

A variety of prognostic factors have been identified for squamous carcinomas of the hypopharynx. Women and patients younger than 50 years of age seem to have a more favorable outcome. Because these tumors can affect swallowing, significant weight loss can occur, and extreme nutritional deficiency and debilitation may even prevent the delivery of curative therapy. Because many of the symptoms of this disease result from an advanced state, most patients are stage III or IV when diagnosed, and therefore, most are candidates for combined-modality treatment. This treatment involves surgery, radiation therapy and, more recently, chemotherapy programs. Surgeon, radiation oncologist, and medical oncologist must collaborate closely in the multidisciplinary evaluation and treatment of patients with hypopharyngeal cancer.

The fact that most patients with hypopharyngeal cancers currently are managed with combined-treatment modalities probably is not entirely explained by an inherent biologic difference between these tumors and other SCCs in the upper aerodigestive tract; rather, it may also reflect the fact that only a small number of these patients present with T1 or T2 disease. Higher percentages of poorly differentiated carcinomas are seen in the hypopharynx, but cell for cell, it is not entirely clear that these cancers are different from other poorly differentiated SCCs found in other sites. What makes hypopharyngeal cancers particularly ominous is probably related in large part to the anatomy of the area that allows extensive spreading of these tumors. On the other hand, even early-stage lesions do not do as well as other aerodigestive SCCs, and furthermore, in all larynx preservation protocols, the hypopharyngeal lesions fare worse than the larynx lesions. Finally, poor performance relates to debilitation, chronic anemia, to the extensive lymphatic drainage of the area, and to the fact that the diffuse carcinogenic effects that led to the initial problem also

create an environment of condemned mucosal multifocality and *de novo* carcinoma formation.

The appropriate therapy for tumors of the hypopharynx is predicated on several factors, such as the patient's performance status, extent of disease, laryngeal involvement, and the presence and extent of metastasis. If, for example, the only surgical option available for removal of a given lesion of the hypopharynx involves a total laryngectomy, then organ preservation strategies using chemotherapy and radiation therapy become more appealing. However, total laryngectomy is not always necessary with resection of hypopharyngeal cancers, and a few selected patients who have tumors of the pharyngeal wall and pyriform sinuses are candidates for partial laryngopharyngectomies. The physiologic stress imposed on older and debilitated patients by these partial operations, however, can be unacceptable. Thin, early-stage cancers of the hypopharynx are probably as curable with radiation therapy as with surgery.

Excision of postcricoid cancers always involves a total laryngectomy. In a select subset of patients, lesions of the posterior pharyngeal wall can be resected even while retaining laryngeal integrity. Even in the smaller of these lesions, however, the larynx can be preserved in only a few cases.<sup>258</sup> Because of the tendency of pharyngeal wall lesions to have ill-defined margins, generous resections are necessary; with such liberal tissue removal, much of the sensory innervation normally used in the act of swallowing is violated. With large T3 and T4 tumors, laryngectomy is mandatory to achieve adequate surgical margins and to avoid the significant chronic aspiration that usually follows pharyngectomy in these cases. With the contemporary techniques of reconstruction in head and neck surgery being as sophisticated as they are, the limitations to this form of surgery do not relate to anatomic realignment; rather, they are physiologic, and an ill-conceived larynx preservation procedure may cure the cancer but condemn the patient to an unacceptable lifestyle. Newer techniques of hypopharyngeal reconstruction are being developed that use reinnervated free flaps. This reconstitution of the sensory apparatus so important to deglutition may to some extent solve the problems currently limiting the ability to resect this area radically.<sup>270</sup>

Limited T1 and T2 lesions on the medial wall of the pyriform sinus may be removed by partial laryngectomy, but either extension to the apex of the sinus or involvement of the adjacent postcricoid area mandates total laryngectomy. These medial wall lesions are particularly prone to penetrate the paraglottic space of the larynx (see Fig. 30.3-2), and when this does occur, partial laryngectomy becomes oncologically unsafe. In a pyriform sinus lesion, any motion change noticed in the vocal cord suggests invasion into the larynx. Some notable surgeons are skeptical of any indication for the use of partial laryngectomy for cancers of the pyriform sinuses. However, whatever the indications, it is fundamental that any attempt to remove a pyriform sinus cancer with less than a total laryngectomy should be done only by those surgeons with considerable experience in making the subtle judgments so often involved in this type of surgery. With the alternatives to surgery that are now available to treat these tumors, and considering our consistent ability to restore voice function after laryngectomy, any oncologic gamble associated with inadvisably trying to save the larynx is unacceptable. Overall, partial laryngopharyngectomy with preservation of voice and swallowing can be justifiably performed in fewer than 5% of all hypopharyngeal cancers.<sup>271</sup>

Radiation therapy is effective for early lesions of the hypopharynx, especially when they are exophytic. Mendenhall and associates<sup>272</sup> report local control in 79% of T1 and 71% of T2 lesions treated with radiation; however, the 5-year survival rate in this group was only 60%. Vandenbrouck and coworkers<sup>273</sup> reported a 5-year survival rate of only 40% in an extensive series of smaller lesions treated with radiation therapy. Itami et al.<sup>274</sup> reported local control of 49% for T1/T2 lesions of the pyriform sinus, which fell to 25% for T3/T4 disease. Doses of 70 Gy or higher are generally used, depending on the fractionation program. Pameijer and colleagues<sup>275</sup> evaluated the role of CT scans in predicting the outcome for patients treated with definitive radiation for T1/T2 disease. Tumor volume was found to be prognostic. For tumors larger than 6.5 mL, local control was 25% compared with 89% for tumors of less than 6.5 mL. These data are similar to those achieved surgically for early disease. For instance, Shah et al.<sup>276</sup> reported 5-year survival rates of 43% and 38%, respectively, for surgically managed T1 and T2/T3 (N0) hypopharyngeal disease.

Disease control drops significantly for more advanced lesions. In the series by Mendenhall et al.<sup>272</sup> and Bataini and colleagues,<sup>277</sup> T3 lesions treated with primary radiation therapy had approximately a 40% local control rate but a dismal 5-year survival rate of less than 20%. Results of surgery for advanced disease are not any better. Shah and coworkers<sup>276</sup> reported a 16% 5-year survival rate for patients with T3 disease. When comparing single-modality therapy of hypopharyngeal cancers, results of surgery and radiation therapy are roughly equivalent, with both yielding suboptimal outcomes.

Because of the consistently poor survival data associated with the single-modality methods of treating more advanced hypopharyngeal cancer, combined therapy consisting of radiation administered after pharyngectomy or laryngopharyngectomy is the method currently being practiced in most centers.<sup>272,278,279</sup> The sequencing of the modalities is fairly standard, with the radiation generally administered postoperatively in all but selected circumstances. Essentially, this sequence allows the safe delivery of radiation doses in the 6000- to 7000-cGy range. Various trials from the Radiation Therapy Oncology Group and others have compared preoperative with postoperative therapy, and those data suggest better locoregional control and a trend toward better survival in the group treated with postoperative therapy.<sup>280,281</sup> Select circumstances exist, however, in which radiation therapy is recommended before surgery. For example, in those circumstances in which the primary tumor is small and exophytic and is therefore suitable for definitive radiation therapy, but in which the degree of neck disease precludes management with radiation alone, curative therapy to both the primary tumor and neck followed by neck dissection is an acceptable treatment plan. Mendenhall and associates<sup>272</sup> have reported an 80% 2-year control rate for disease above the clavicle in patients with advanced neck disease and early primary tumors that have been treated in this fashion. Just as with other head and neck sites, the clonal progeny in cervical metastasis is often more prominent than in the primary tumor.

Several groups have reported results of a treatment strategy that consists of primary radiation with surgery being used only for salvage. Keane and colleagues<sup>282</sup> reported 41% disease control using this approach. Most patients (75%) in this series had been staged as T3 or T4. Approximately two-thirds had palpable nodal metastases, and the 5-year survival rate was only 15%.

Traditional treatment programs of surgery and radiation therapy for hypopharyngeal carcinomas have been augmented by organ-preservation induction-chemotherapy strategies. Organ preservation for hypopharyngeal cancer may be feasible, but the percentage of patients who preserve their larynx long term is unsatisfactory. Future trials exploring concomitant chemotherapy and radiotherapy are more likely to yield better locoregional control and to affect survival.

Two randomized trials of organ preservation for patients with cancer of the hypopharynx have been published. The EORTC randomized 202 patients with operable squamous cancers of the pyriform sinus or the aryepiglottic fold (stage T2, T3, or T4 and N0, N1, N2a, or N2b) to receive either induction chemotherapy and radiation or standard treatment with total laryngectomy, partial pharyngectomy, and radiation.<sup>238</sup> In the experimental treatment group, only patients achieving a clinical complete response of the primary tumor proceeded to radiotherapy; all others underwent resection. The preliminary results after a median follow-up of 51 months show no difference in survival for the two treatment groups; 3- and 5-year survival estimates are 57% and 30% for patients randomized to chemotherapy and 43% and 35% for those randomized to surgery. Fifty-four percent of patients had a clinical complete response at the primary site and 52% in the neck after chemotherapy. Three- and 5-year estimates of survival with a functional larynx were 28% and 17%, respectively. If only the deaths from local progression are considered, to account for patients who died with a functional larynx, then these survival estimates with a preserved larynx are 42% and 35%, respectively. The EORTC is now embarking on a trial that will compare sequential to simultaneous chemotherapy and radiotherapy for organ preservation of patients with cancer of the hypopharynx.

Mahe and colleagues<sup>283</sup> evaluated the role of surgery for patients with T3/T4 or N2/N3 cancer of the hypopharynx. Ninety-one patients were randomly assigned treatment with induction chemotherapy followed by surgery and radiation or induction chemotherapy followed by radiation. Median and 5-year survival rates were significantly better with resection: 40 versus 20 months, and 37% versus 19%, respectively. This difference was explained by a significantly higher local failure rate in the nonsurgical group of 61%, compared with 37% in the surgical group. Because of the nature of the study design, no conclusions regarding the impact of induction chemotherapy can be made.

Survival data vary considerably between sites within the hypopharynx. Few postcricoid cancers are treated by radiation, but anecdotal experience suggests that a small subset of patients with smaller thin lesions are treatable with curative therapy. In almost all postcricoid lesions, extensive surgery consisting of laryngopharyngectomy or laryngopharyngoesophagectomy with reconstruction is followed by postoperative radiation and yields a 20% to 25% 5-year survival rate.<sup>284</sup> Posterior pharyngeal wall lesions of earlier stages can be treated with equal effectiveness by radiation or surgery. More advanced lesions are best treated by combined surgery followed by postoperative radiation. Meoz-Mendez and colleagues<sup>285</sup> reported that 91% of T1 and 73% of T2 lesions of the pharyngeal wall can be controlled with primary radiation, requiring a dosage greater than 6500 cGy. For T3 and T4 disease, similar doses controlled 61% and 37%, respectively. Pyriform sinus lesions of early stage are curable by radiation, whereas the much more common advanced lesions are best treated by combined therapy. Data accumulated by Vandenbrouck and coworkers<sup>280</sup> showed a 3-year survival rate of 48%, which dropped to 33% at 5 years for lesions treated with total and partial laryngectomy plus postoperative radiation therapy. In that same series, the 3-year survival rate was 67% in the group treated by partial laryngectomy plus postoperative radiation therapy. This latter statistic probably reflects the increased survival expected in lesser-stage disease.

All treatment plans for hypopharyngeal cancer must consider certain facts: The overwhelming majority of these lesions metastasize to cervical lymph nodes, and in the case of the posterior pharyngeal wall, bilateral metastasis is the rule rather than the exception; 40% of posterior pharyngeal wall lesions and probably an equal

number of upper pyriform sinus lesions metastasize to the retropharyngeal nodes; in those patients with clinically negative necks, the incidence of occult metastasis is substantial; and between 20% and 30% of pyriform sinus lesions, and probably an equal number of posterior pharyngeal wall lesions, are associated with distant metastasis. Even in the lesser-stage hypopharyngeal lesions, the high rate of regional metastases requires inclusion of the neck(s) in all management plans.

## SPECIFIC TREATMENT METHODS

Patients treated with primary radiation therapy require treatment to the primary site and both necks. The primary site and upper neck fields are treated with bilateral opposed portals, and the low-neck fields are treated with anterior portals. If lymph nodes are involved, a neck dissection usually is added. If no neck dissection is planned, the node-bearing regions must be treated with higher doses.

When patients who have had a total laryngectomy are receiving postoperative radiation, it is important to radiate the tracheal stoma. For postoperative radiation, the total doses recommended to the primary site and involved areas of the neck are between 6000 and 6500 cGy in 6.5 to 7.5 weeks. The tracheal stoma is treated with a total dose of 5000 to 5500 cGy.

Lesions of the hypopharynx often require laryngopharyngectomy or laryngopharyngoesophagectomy, after which the means of reconstruction consist of free jejunal graft with microvascular anastomosis,<sup>286</sup> various myocutaneous flaps or, in the cases that include esophagectomy, gastric transposition.<sup>287</sup> Reconstruction of the hypopharynx has been enhanced greatly by the interposition free jejunal graft, which is less morbid than gastric transposition and is associated with a high rate of success.

Surgical management of the neck is similar to that of other sites in the upper aerodigestive tract. In those patients with substantial and multilevel disease, at least a modified radical neck dissection usually is performed in continuity with the primary resection, unless the primary tumor has been treated with curative radiation. In those patients with minimal neck disease or with clinically negative necks, radiation alone can suffice, or any of a variety of selected neck dissections can be used as a means of removing gross disease from the neck in preparation for radiation.<sup>248</sup>

## MAJOR SALIVARY GLAND TUMORS

The same neoplasms affect all salivary gland tissue, but with predictable variations for the different anatomic sites. The major salivary glands consist of paired parotids in the preauricular area, paired submandibulars deep and inferior to the mandible, and paired sublinguals in the floor of the mouth. The minor salivary glands, on the other hand, are ubiquitous in the upper aerodigestive tract, occurring throughout the oral and nasal cavities and the paranasal sinuses. The probability of any given salivary neoplasm being malignant is highest in the sublingual glands, next highest in the minor salivary glands, third highest in the submandibular glands, and least in the parotid glands. Overall, salivary cancers make up approximately 3% of all head and neck malignancies that are diagnosed in North America each year; most of these are in the parotid glands. Sublingual and minor salivary gland cancers are unusual.<sup>1</sup>

## ANATOMY

The parotid gland is tightly compacted in the area immediately anterior and inferior to the external ear. It is best thought of in three dimensions, with the deep portion extending medially behind the posterior rim of the ascending ramus of the mandible into the parapharyngeal space. The superficial part of the gland lies on the masseter muscle and extends inferiorly to overlie the sternocleidomastoid and digastric muscles (Fig. 30.4-1). The same fascia that engulfs both of these muscles also forms a substantial capsule around both the parotid and submandibular glands, thus forming a barrier that confines tumors to their site of origin. The most inferior extent of the parotid gland extends a variable distance, and in those necks in which this extension is exaggerated, the glandular tail overlies the transverse process of the second cervical vertebrae as well as the deep jugular lymph nodes adjacent to this level. Not infrequently, a prominent transverse process or an enlarged lymph node in this area is misinterpreted as a parotid tail mass. This circumstance is encountered less frequently today, however, because contemporary imaging has helped to define that which is abnormal.

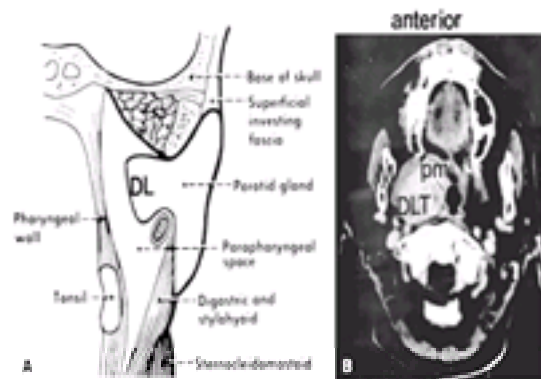

**FIGURE 30.4-1.** Representation of parotid gland and facial nerve anatomy. Lower part of diagram shows details of the relation of the nerve to the surrounding gland. Various branches of the nerve are directed to various parts of the facial musculature. (CIBA Collection, Frank Netter.)

The facial nerve leaves the stylomastoid foramen at the base of the skull and almost immediately penetrates the posterior capsule of the parotid gland. Once within that structure, the nerve divides into five main branches—temporal, zygomatic, buccal, mandibular, and cervical—all of which extend in a consistent direction and depth, and all of which gradually become more superficial as they extend anteriorly. In addition to being more superficial, the more anterior branches of the nerve are more delicate; thus, increased risks are associated with dissection of tumors located more anterior in the gland.

Although no actual lobes are defined by fascial planes, that part of the parotid gland superficial to the facial nerve is arbitrarily referred to as the *superficial lobe*. That portion deep to the nerve is called the *deep lobe*. These facts have considerable bearing on dissections done within the parotid gland (see Fig. 30.4-1). The deep lobe of the parotid gland extends into the parapharyngeal space; thus, tumors of that portion of the gland can come into contact with the carotid sheath and its contents, which form the posterior boundary of that space. These deep lobe tumors can press against the constrictor muscles of the pharynx that normally form the medial wall of the parapharyngeal space (Fig. 30.4-2). A large deep lobe parotid tumor can, therefore, present as a submucosal bulge of the tonsil pillar, a finding that is easily misinterpreted by the inexperienced diagnostician as an oropharyngeal neoplasm (Fig. 30.4-3). The distinction between a deep lobe parotid tumor and an oral lesion becomes clear on either magnetic resonance imaging (MRI) or computed tomography (CT). There is some difficulty, however, in distinguishing these deep lobe neoplasms from tumors that have their origin in the parapharyngeal space. Correct diagnosis depends on the presence or absence of a fat plane between the deep lobe and the tumor. The distinction between the two is important, because the differential diagnosis of tumors that originate in the parapharyngeal space must include lymphomas, neurogenic tumors, and paragangliomas,<sup>2,3</sup> none of which is likely to occur primarily in the parotid gland. Most parotid tumors originate in the superficial lobe, probably because that portion of the gland is considerably larger than the deep lobe. Because no identifiable histologic differences exist between deep and superficial lobes, no reasonable explanation can be provided for this distribution of tumors other than the amount of salivary gland tissue available for tumor development. The distribution of different types of tumors is probably the same in the various parts of the gland.

**FIGURE 30.4-2.** Presentation of deep lobe parotid gland tumors. **A:** Schematic diagram shows frontal view just posterior to mandible where the deep lobe (DL) enters parapharyngeal space. Notice the proximity of the deep lobe to the pharyngeal muscles and the palate. **B:** An axial computed tomographic scan of the skull shows the deep lobe tumor (DLT) occupying parapharyngeal space and pressing against the pharyngeal constrictor muscles (pm). The retromandibular tunnel extends the deep lobe behind the mandible (M).

**FIGURE 30.4-3.** Intraoral photograph of soft palate mucosal bulge caused by parotid gland deep lobe tumor (DLT). (Courtesy of Dr. Ronald Spiro.)

The lymphatics in and around the parotid gland consist of two groups, and a knowledge of that distribution is essential to the understanding of the natural history of these tumors. The preauricular (periparotid) nodes lie superficially to the gland capsule and drain the external auditory canal, the facial and auricular skin, and the temple scalp. They are especially important drainage sites for squamous carcinomas and melanomas of adjacent skin. Parotid gland cancers usually do not drain into these nodes. The second nodal group consists of five to seven intraparotid lymph nodes that do play a role in the pathogenesis of parotid cancer. The efferent channels of the superficial nodes drain into the superficial jugular chain, whereas the intraglandular nodes drain into the upper and middle deep jugular lymph nodes.<sup>1,4</sup> The extraparotid (periparotid) nodes are readily palpable and are distinguished easily from primary parotid tumors; however, nodes within the substance of the gland are not easily palpated and become noticeable only when they are enlarged. Distinguishing them from primary parotid gland tumors by palpation or by imaging can be difficult.

The submandibular gland lies in the submandibular triangle of the neck with its posterior extent adjacent to, but not contiguous with, the tail of the parotid gland. The deep surface of the submandibular gland lies against the muscular diaphragm of the floor of the mouth and is best examined bimanually, with one finger in the mouth and the external hand on the surface of the gland. Lymph nodes do not exist within the submandibular gland, but instead they lie around its surface. A mass outside the submandibular gland may represent a metastatic node from some other site, such as the lateral tongue or the floor of the mouth. Drainage from the submandibular gland goes into the adjacent nodes and upper deep jugular chain. Three important nerves, the marginal mandibular branch of the facial nerve (motor) and the lingual (sensory) and hypoglossal (motor) nerves to the tongue all lie in close proximity to the submandibular gland.

The sublingual glands are located submucosally in the floor of the mouth, just superficially to the muscular diaphragm. They are oval and lie along the inner table of the mandible. The sublingual glands drain into submandibular lymphatics and then into the deep jugular nodes.

### ETIOLOGY, PATHOLOGY, AND CLASSIFICATION

The causes of salivary gland cancer have not been determined. Certain factors have been etiologically suggested, including ionizing radiation with all salivary cancers,<sup>5</sup> a familial predisposition in parotid cancer,<sup>6</sup> and chronic wood dust inhalation in certain individuals who develop minor salivary gland adenocarcinomas of the nasal and paranasal sinuses.<sup>7</sup> Proof of cause and effect does not exist, however, in any of these postulated associations, and the etiology of most salivary gland cancers cannot be determined.

Overall, the majority of salivary gland neoplasms are benign, a fact that reflects an overwhelming predominance of parotid tumors, three-fourths of which are nonmalignant. Different classifications of salivary gland neoplasms have been established, but the one that seems to be the most consistently workable is shown in [Table 30.4-1](#).

<b>BENIGN</b>
Benign mixed tumor (pleomorphic adenoma)
Warthin's tumor (papillary cystadenoma lymphomatousum)
Benign lymphoepithelial lesion
Oncocytoma
Monomorphic adenoma
<b>MALIGNANT</b>
Mucoepidermoid carcinoma
Adenoid cystic carcinoma
Adenocarcinoma
Malignant mixed tumor (or carcinoma expleomorphic adenoma)
Acinic cell carcinoma
Epidermoid carcinoma

**TABLE 30.4-1.** Classification of Salivary Gland Neoplasms

### Benign Tumors

**PLEOMORPHIC ADENOMA.** Also known as the *benign mixed tumor*, the pleomorphic adenoma is the most common of the neoplasms that originate in the major salivary glands.<sup>8</sup> This tumor is more correctly referred to by its formal name, which describes its multiple histologic components, including myxoid, mucoid, chondroid, and other elements. Although these lesions can occur in all salivary gland tissues, most often they are seen in the parotid gland.

The distinction between this tumor and its malignant counterpart, malignant mixed tumor, is often difficult, but the histologic features that most reliably separate the two include a tendency in the malignant version for perivascular and perineural invasion and significant cellular atypia and mitosis. Malignant lesions can be

underinterpreted and their true nature not appreciated until metastasis occurs; even then, the metastases can appear histologically benign. <sup>9,10 and 11</sup> At the opposite extreme, a benign but extremely cellular pleomorphic adenoma can be overinterpreted as a malignant mixed tumor. These factors must be critically considered when doing retrospective interinstitutional outcomes research.

The natural history of these tumors is characterized by slow growth and few symptoms. Even when growing to large size, those lesions that remain benign rarely affect clinical facial nerve function. In such tumors, however, the nerve is often stretched around the mass and seems to become more fragile with increasing tumor size. In that circumstance, tumor removal may more likely be associated with postoperative nerve weakness.

There is controversy over the evolution of pleomorphic adenomas into their malignant counterparts. Many authors believe that the latter originates in a preexisting benign setting; hence, the term *carcinoma expleomorphic adenoma*. Other researchers, however, believe that malignant mixed tumor arises *de novo*.<sup>9,10,11 and 12</sup>

**PAPILLARY CYSTADENOMA LYMPHOMATOSUM (WARTHIN'S TUMOR).** Papillary cystadenoma lymphomatousum (Warthin's tumor) is a slow-growing, often cystic, and usually innocuous tumor that almost always occurs in older men, seems to favor the tail of the parotid gland, and occurs bilaterally in 10% of cases. Because of its benign nature and because it can be easily diagnosed cytologically, surgical removal is not always necessary, especially in older or unhealthy patients.

**MONOMORPHIC ADENOMA.** The monomorphic adenomas are a group of benign lesions that can have a variety of growth patterns. The most common monomorphic patterns are the basal cell and the oxyphilic adenomas (oncocytomas). Other monomorphic adenomas are the sebaceous lymphadenomas and sebaceous adenomas. The parotid gland is the most common site of these lesions.

**BENIGN LYMPHOEPITHELIAL LESION.** Benign lymphoepithelial lesion (BLL) was first described in association with systemic conditions such as Sjögren's and Mikulicz's syndromes.<sup>13</sup> An apparent increase in its incidence has been seen in patients with human immunodeficiency virus (HIV). BLL now encompasses a spectrum of cystic changes seen in the parotid glands of HIV-infected persons, the common denominator of which is atypical lymphoid hyperplasia. It is thought that these changes are the direct result of HIV infection of intraparotid lymph nodes.<sup>14</sup>

Several reports of HIV-associated malignancies of the parotid have been published, including non-Hodgkin's lymphoma,<sup>15</sup> Kaposi's sarcoma,<sup>16</sup> and adenoid cystic carcinoma.<sup>17</sup> Some of these have arisen on a background of BLL. Malignancy in association with prior BLL, however, was described before the acquired immunodeficiency syndrome (AIDS) epidemic,<sup>18</sup> and it remains unclear whether HIV infection predisposes this lesion to malignancy.

Treatment of BLL in HIV-infected patients is controversial. Some clinicians cite the association of malignancy as justification for parotidectomy.<sup>19</sup> Others have proposed observation of the lesion with intermittent fine-needle aspirations (FNAs) for decompression of cyst.<sup>20</sup> Still others have recommended low-dose radiation therapy.<sup>21</sup> Optimally, therapy should be individualized, depending on the clinical and diagnostic suspicion of malignancy, the status of the patient's HIV infection (asymptomatic, AIDS-related complex, or AIDS), and risk-benefit analysis for patient and surgeon.

### Malignant Tumors

Spiro and Spiro<sup>1</sup> have developed a compendium of the various series of salivary gland cancers reported and, in their survey, have outlined the relative occurrence rates of the various cancers in both the parotid and submandibular glands. The various reports from nine studies total 1778 parotid gland cancers, the distribution of which is abbreviated and summarized in [Table 30.4-2](#). Summarized in [Table 30.4-3](#) are comparable data for the submandibular gland that are taken from eight studies and that, when combined, reflect the relative distribution by type of 383 submandibular gland cancers.

Histologic Type	Prevalence (%)
Mucoepidermoid	32
Adenocarcinoma	16
Malignant mixed tumor	14
Adenoid carcinoma	11
Acinic carcinoma	11
Undifferentiated + squamous cell	16

\*Total of 1778 cases from Memorial Sloan-Kettering Cancer Center. (Adapted from ref. 1, with permission.)

**TABLE 30.4-2.** Relative Prevalence of Histologic Types of Parotid Gland Cancer <sup>a</sup>

Histologic Type	Prevalence (%)
Adenoid cystic	41
Acinic cell	17
Mucoepidermoid	12
Malignant mixed tumor (carcinoma expleomorphic adenoma)	10
Squamous cell	9
Undifferentiated	9
Adenocarcinoma	2

\*Total of 383 cases from Memorial Sloan-Kettering Cancer Center. (Adapted from ref. 1, with permission.)

**TABLE 30.4-3.** Relative Prevalence of Histologic Types of Submandibular Gland Cancer <sup>a</sup>

**ACINIC CELL CARCINOMA.** Acinic cell carcinoma is an uncommon malignancy that probably accounts for fewer than 10% of all salivary gland cancers.<sup>22</sup> Although acinic cell lesions usually are seen in the parotid gland, they occasionally occur in the submandibular gland.<sup>23</sup> They are low grade, only infrequently invade the facial nerve, and are late to metastasize. When they do metastasize, however, it is usually to the lungs, and under these circumstances, death usually follows. Because of their slow growth, survival data are good when generous surgical excision is performed.<sup>24,25</sup>

**MUCOEPIDERMOID CARCINOMA.** In major salivary glands, mucoepidermoid carcinoma occurs more frequently than any other malignancy. It is relatively more common in the parotid than in the submandibular gland, where it is third in prevalence after adenoid cystic carcinoma and adenocarcinoma (see [Table 30.4-2](#) and [Table 30.4-3](#)). Mucoepidermoid carcinoma is unique in that it demonstrates a broad spectrum of aggressiveness, from the low grade that rarely kills to its high-grade counterpart that frequently does. Low-grade mucoepidermoid carcinomas tend to create mostly local problems and can have a long natural history. A locally aggressive surgical approach is usually associated with cure. Although metastasis can occur from these lesions, it is the exception rather than the rule. In fact, such a striking performance gradient is apparent between low- and high-grade mucoepidermoid carcinomas that some investigators believe that the former should be referred to as *mucoepidermoid tumor* rather than *carcinoma*. When low-grade mucoepidermoid cancer metastasizes, however, it can be lethal,<sup>26,27 and 28</sup> and to diminish the appreciation of its potential seriousness by this name change seems ill advised. The high-grade and, to a great extent, the intermediate-grade mucoepidermoids are often troublesome because they are locally aggressive and are prone to invasion of nerves and vessels as well as to early metastasis. Spiro<sup>26</sup> have reported that 44% of the previously untreated patients with intermediate- or high-grade mucoepidermoid parotid tumors develop nodal involvement at some stage. Analysis of only the high-grade lesions reveals an incidence of nodal metastasis from all salivary gland sites that is probably even higher.<sup>26,29,30</sup> Because of the propensity for regional

nodal metastasis in high-grade mucoepidermoid carcinomas, regional nodal dissection combined with generous local or primary resection plus postoperative radiation therapy is important in the treatment of these lesions.

Grading of mucoepidermoid lesions relates in part to the ratio between epidermoid and glandular elements, the high-grade tumors having a larger proportion of the former.<sup>30</sup> It is common for those higher-grade tumors that demonstrate little glandular component on routine hematoxylin and eosin stains to be misinterpreted as epidermoid or squamous cell carcinomas.

**ADENOCARCINOMA.** Adenocarcinomas make up approximately 16% of parotid gland and 9% of submandibular gland cancers (see [Table 30.4-2](#) and [Table 30.4-3](#)). These lesions are encountered more frequently in the minor salivary glands of the nose and paranasal sinuses. A difference in survival seems to correlate with grade, with the high grade having a poorer prognosis and the low grade a much more favorable one.<sup>9,22,31</sup> In the higher-grade tumors, treatment failures result predominantly from distant metastasis. Along with the overall poor performance, this fact is important in helping to judge the degree of aggressiveness with which locoregional disease should be treated.

**SQUAMOUS CELL CARCINOMA.** Squamous cell carcinomas are uncommon in salivary tissue, making up approximately 7% of parotid gland and 10% of submandibular gland cancers.<sup>22</sup> Individuals with high-grade tumors do poorly and usually present with an advanced stage of cancer.<sup>32,33</sup> Squamous cell carcinomas of the parotid gland frequently are not primary to that gland but instead represent metastasis into parotid nodes from adjacent sites, such as temple, auricular, and facial skin. Skin lesions that come from virtually any site on the face tend to metastasize to the superficial lymph nodes that lie external to the parotid capsule.<sup>34,35</sup>

**MALIGNANT MIXED TUMOR.** Malignant mixed tumors make up approximately 14% of parotid gland and 12% of submandibular gland cancers (see [Table 30.4-2](#) and [Table 30.4-3](#)). The diagnosis is often difficult because of the similarities with the tumor's benign counterpart, the pleomorphic adenoma. Many of the malignant mixed tumors seem to originate in previous pleomorphic adenomas (carcinoma ex-pleomorphic adenoma), but just how often they occur *de novo* is not known. Thus, controversy has continued for some time. Those proponents of the malignant transformation theory believe that the evolution of malignancy within a pleomorphic adenoma is the explanation for the circumstance encountered periodically in which a longstanding and stable tumor begins to grow significantly. When this does occur, they believe the assumption of malignant development should be made and management tailored accordingly. Although growth acceleration of a previously dormant salivary mass is not pathognomonic of malignancy, we agree that this behavior pattern dictates such a treatment strategy. The exact probability of any given benign mixed tumor becoming malignant is unknown but probably occurs in approximately 5% of pleomorphic adenoma cases.<sup>36</sup> Survival from malignant mixed tumor must be measured over a lengthy period, because the natural history of this lesion can be characterized by protracted but inexorable growth. Metastasis to regional lymph nodes occurs in more than one-fourth of cases.<sup>22,31,37</sup>

**ADENOID CYSTIC CARCINOMA.** In most series, adenoid cystic carcinoma accounts for almost one-fourth of the malignant salivary gland tumors treated and constitutes approximately 10% to 15% of all parotid gland malignancies (see [Table 30.4-2](#)). This cancer is relatively more common in minor than in major salivary glands. It is unique because of its protracted natural history, even when local recurrence or distant metastasis has developed. For instance, patients are known to live 10 to 20 years despite pulmonary metastasis, the most frequent manifestation of distant spread. When visceral or bone metastasis occurs, however, death usually follows within a relatively short time.<sup>1</sup> The actual cure rate of adenoid cystic carcinoma is poorly defined, because long-term follow-up often is not included in data analyses. Also clouding the issue of cure is the fact that some 10- to 20-year studies have shown disease-related deaths that continue to occur throughout the follow-up period.<sup>30,38</sup> Some investigators believe that most adenoid cystic carcinomas recur if followed long enough. Overall, the rate of pulmonary metastasis from these cancers is approximately 40%.

Adenoid cystic carcinoma has an exceptional capability to invade nerve tissue, and when this occurs, local control and survival are compromised. Such a morphologic finding is the rule rather than the exception in this cancer, and recognition of the tendency is essential in planning treatment, which usually consists of wide surgical excision and radiation therapy. Treatment failure most often occurs in the primary tumor site. Some authors have drawn a correlation between histologic patterns of adenoid cystic carcinoma and clinical behavior.<sup>39</sup> Others, although conceding certain behavior pattern differences in the different histologic variants of adenoid cystic carcinoma, do not believe a correlation exists between these features and long-term outcome.<sup>38</sup>

## NATURAL HISTORY, BEHAVIOR STAGING, AND TREATMENT PRINCIPLES

Malignant tumors of major salivary gland origin are a heterogeneous group of diseases; three primary sites and at least eight different histologic patterns have been identified for this relatively uncommon group of cancers. Studies reporting treatment results have, therefore, often grouped primary sites and histologic types. This method is flawed, however, and because the problem often has been compounded by analyzing short-term results in diseases that often have a long natural history, many questions remain unanswered.

Most patients with benign tumors, whether in minor or major salivary glands, present with asymptomatic swelling of the lip or the parotid, submandibular, or sublingual glands (floor of the mouth). Neurologic signs, such as mucosal or tongue numbness, associated with a floor of mouth mass usually indicate a malignancy. In the presence of a lip mass, a numb lower lip can result from tumor involvement of the submental nerve. Facial nerve weakness that is associated with a parotid or submandibular tumor is an ominous finding. Even in huge tumors of the parotid gland that are benign, the facial nerve usually is not affected. Essentially, any compromise in nerve function greatly heightens concern for malignancy. Overall, malignant parotid gland tumors are associated with facial nerve paralysis in 10% to 20% of patients.<sup>40</sup> Although benign tumors occasionally cause facial discomfort, persistent facial pain is strongly suggestive of malignancy in a salivary gland tumor; in fact, approximately 10% to 15% of patients with malignant parotid neoplasms present with pain.<sup>29</sup> Furthermore, those malignancies that are characterized by pain seem to have a worse prognosis.

The majority of parotid tumors, whether benign or malignant, present with an asymptomatic mass in the gland; in fact, this is the case even in the majority of malignant tumors.

The most common benign tumor, the pleomorphic adenoma, can be problematic. Usually a pseudocapsule is found around this lesion, and, importantly, finger-like projections of tumor penetrate into the surrounding glandular parenchyma, whether it is parotid or submandibular. Enucleation of these lesions tends to leave behind foci of tumor that result in frequent local recurrence. It should be remembered that benign mixed tumor, although not classified as malignant, can ultimately cause great hardship for a patient. Multiple recurrences, skull base involvement, facial nerve paralysis, malignant transformation and, ultimately, incurable disease can all result from a casual initial approach to this neoplasm. This tumor should be regarded as locally dangerous, and any operation should provide a wide margin of normal tissue.

Special problems exist with tumors of the parotid deep lobe, because they are frequently surrounded by little or no glandular parenchyma; thus, even the best of operations consists largely of tumor enucleation. In this circumstance, the probability is high for leaving behind histologic disease, and postoperative radiation therapy must be considered.

Malignant tumors of the parotid can be locally aggressive, demonstrating invasiveness that leads to involvement of the facial nerve, skin, bone, and surrounding soft tissue. Prognosis is related to tumor size and stage and is affected by histologic grade. Decreasing survival occurs for many years, especially in patients with adenoid cystic carcinoma and malignant mixed tumor, and in those lesions, distant metastasis may not always represent a terminal event. The treatment of primary disease, therefore, is not necessarily precluded by lung metastasis, especially in adenoid cystic carcinoma.

Overall, the prognosis for parotid gland cancer is better than it is for the submandibular gland lesions: 50% to 81% 5-year survival is reported for the former and 30% to 50% for the latter<sup>29,41</sup>; the 10-year survival rate declines in both sites. The lower survival rate for the submandibular gland group probably relates to the larger proportion of adenoid cystic carcinomas in that group. Spiro and colleagues<sup>42</sup> reported survival results in 474 patients with major salivary gland tumors treated at the Memorial Sloan-Kettering Cancer Center from 1944 to 1986. The 5-, 10-, and 15-year survival rates were 54%, 43%, and 34%, respectively, with determinate survivals of 63%, 47%, and 42%, respectively. Multivariate analysis showed that advanced stage, higher histologic grade, and submandibular location were prognostic for a poorer outcome. In addition, treatment after 1966 was found to be an important prognostic factor and was thought to relate to an increased use of postoperative radiation therapy beginning during this latter period.

Differences in histologic features affect natural history. The prognosis for acinic cell carcinoma is the most favorable for the major salivary cancers; more than 75% 5-year and more than 65% 10-year survivals are reported in various series.<sup>26,37</sup> Low-grade mucoepidermoid carcinomas show 76% to 95% 5-year survival rates, whereas only 30% to 50% of those with high-grade tumors are alive at 5 years.<sup>26,32</sup> The survival rates for intermediate-grade mucoepidermoids are between those of

the low and high grades. Adenoid cystic carcinoma, on the other hand, must be analyzed with the realization that 5-year survival rates are always better than 10-year figures, which in turn are better than those at 15 years, and so on. Most series show 50% to 90% 5-year survival rates, 30% to 67% 10-year survival rates, and 25% to 15-year survival rates for treated adenoid cystic carcinoma.<sup>38,39,41,43</sup> Patients with adenocarcinomas of major salivary glands show gradual deterioration of survival statistics with the passage of time; 76% to 85% survival at 5 years and 34% to 71% at 10 years.<sup>31</sup> Patients with malignant mixed tumors do not do well; only 31% to 65% survive 5 years and 23% to 30% survive 10 years.<sup>6,41</sup>

Distant metastasis is predictive of a poor prognosis, and it occurs in approximately 20% of parotid malignancies.<sup>44</sup> Distant metastasis is a significant concern in most higher-grade salivary gland malignancies. At least 40% of patients with adenoid cystic carcinoma and 26% to 32% with malignant mixed tumors demonstrate this feature.<sup>38</sup> Even with lower-grade tumors, such as acinic cell carcinoma, a measurable incidence of distant metastasis is found.<sup>9,26</sup> In all of these lesions, the site of distant metastasis is most often the lung(s). Overall, the likelihood of metastasis from the submandibular gland is almost twice that from the parotid gland.<sup>22</sup>

Regional lymphatic metastasis is a subject of considerable importance in relation to malignant salivary gland tumors. In the extensive series reported from Memorial Sloan-Kettering Cancer Center, 14% of patients presented with palpable nodal metastases. Thirty-four percent of the patients with high-grade tumors demonstrated this finding, compared to only 2% of patients with low-grade lesions. Additionally, in the group of patients who had clinically negative necks but underwent elective neck dissections, 49% of the high-grade and 7% of the low-grade tumors turned out to have histologically positive necks.<sup>45,46</sup> These statistically significant figures suggest that the rates of occult and clinically positive node disease are increased with high-grade malignant salivary gland tumors.

With submandibular gland malignancies, as with parotid tumors, prognosis is dependent on a number of factors, the most significant of which seem to be clinical stage and perineural invasion.<sup>47,48</sup>

Spiro and associates believed that the most important prognosticator for survival is tumor stage. Accordingly, in 1975, they proposed a staging system that was later incorporated into the current American Joint Committee on Cancer staging system.<sup>29,45</sup> This system addresses the size of the primary lesion and the presence or absence of fixation or facial nerve dysfunction. It was first applied only to parotid sites but seems to serve all salivary sites. [Table 30.4-4](#) describes the American Joint Committee on Cancer staging system. According to Spiro,<sup>22</sup> cumulative survival exceeds 90% at 10 years for patients with stage I or II disease, whereas only 22% of stage III or IV patients are alive after 10 years.

**TABLE 30.4-4.** Staging System for Major Salivary Gland Malignancies

## CLINICAL EVALUATION AND WORKUP

Short of surgical exploration, the physical examination remains the most important tool of the experienced diagnostician. A hard mass with fixation or nerve palsy is likely to be malignant; however, any malignancy can masquerade with a more benign appearance and presentation. Cytologic analysis achieved through FNA is helpful in selected circumstances, especially when the index of suspicion for malignancy is high or when the patient is not a good candidate for surgery. In the latter circumstance, the patient is somewhat reassured by benign cytologic findings and is more secure in choosing a nonsurgical approach. In a patient with disseminated metastatic disease in whom a salivary gland mass also is found, making a diagnosis easily with FNA of the parotid lesion can be of considerable value to the patient. For example, if the FNA reveals lymphoma, the appropriate diagnostic cascade is different than in the nonlymphomatous mass. Finally, if an older patient has FNA findings suggestive of Warthin's tumor, surgery can be avoided. Some concern has been expressed that the false-negative rate with cytologic evaluation of salivary gland cancers is somewhat higher than in other tumor families, and because of the heterogeneity of salivary gland tumors, a negative FNA does not substantially alter the treatment plan in most circumstances. False-positive rates for malignancy, on the other hand, are very low. To know in advance of a malignancy is helpful in both treatment strategizing and in patient education. Malata and colleagues<sup>50</sup> reported 88% sensitivity for FNA-cytologic evaluation for the parotid gland. Overall, the accuracy rate of FNA is extraordinary, and we use it in the vast majority of parotid and submandibular masses.

CT and MRI are helpful in analyzing the important third dimension of larger tumors, especially those that involve the deep lobe of the parotid gland. Imaging technologies are especially important in studying malignant tumors; however, these expensive methods are not necessary for the evaluation of all parotid or submandibular gland tumors. As it pertains to tumors, sialography is of historic interest only and is superfluous.

## TREATMENT

The initial treatment for salivary gland neoplasia, whether benign or malignant, whether of minor or major gland origin, is almost always surgical, and whenever possible, removal of parotid, submandibular, and sublingual gland tumors should be excisional rather than incisional. The diagnosis of parotid tumors usually is established by removal of the involved part of the gland, thus avoiding lumpectomy whenever possible. In the case of a lesion of the parotid superficial lobe, for instance, the least extensive or most conservative operation should be superficial parotidectomy. With benign tumors, the diagnostic operation and the definitive operation are, therefore, usually the same. Before surgery, it is helpful for the surgeon to have a sense of whether the tumor is benign or malignant, and this is achieved by physical examination, history, and technological aids such as FNA and imaging.

An important general principle of management that applies particularly to higher-grade adenocarcinomas, malignant mixed tumor, and adenoid cystic carcinoma is that, by combining postoperative radiation therapy with moderate locoregional surgery, mutilation and physiologic compromise are often avoided. The preoccupation with liberal resection of facial nerve, mandible, and other important structures solely because they are in the field no longer dominates surgical philosophy. Instead, the realization that "more" does not necessarily improve survival has spawned a form of surgical minimalism. When failure does occur, it is frequently at a distant site and is probably not influenced by the degree of the local treatment. Important anatomic structures are rarely sacrificed unless obviously invaded by tumor. The surgeon's reliance on postoperative radiation therapy to manage histologic disease has dramatically altered the surgical feats required to deal with many malignant salivary gland tumors. It should be pointed out, however, that although local and regional control of these tumors is enhanced by this combined therapy, its impact on the development of distant metastasis and, therefore, on survival is less clear.

Some investigators have proposed the routine use of postoperative radiation therapy for almost all malignant tumors of the parotid,<sup>51</sup> but the absence of randomized data complicates the issue. Armstrong and associates<sup>52</sup> performed a matched-pair analysis comparing surgery alone versus surgery plus postoperative radiotherapy. Patients with stage III/IV disease and those with positive nodes experienced improved locoregional control and survival with postoperative radiation. A trend also was seen toward improved local control for high-grade lesions treated with postoperative radiation (63% vs. 44%). The 5-year determinant survival rate tended to be better for high-grade lesions treated with adjuvant radiotherapy than with surgery alone (57% vs. 28%). No benefits were achieved for lower-grade or lower-stage tumors. Malata and coworkers<sup>50</sup> reported 51 patients with malignant parotid tumors, most of whom (73%) received postoperative radiation. The crude 5- and 10-year survival rates were 68% and 49%, respectively, and 10-year actuarial local control was 79%.

Surgical resection is the mainstay of the management of benign pleomorphic adenoma. Renehan et al.<sup>53</sup> reported the cumulative experience of more than 1400 salivary gland tumors treated at Christie Hospital between 1947 and 1992. For 551 patients with previously untreated parotid pleomorphic adenoma treated by surgery, the recurrence rate (median follow-up of 12.5 years) was 1.6%. The recurrence rate rises to 15% in patients undergoing surgery for recurrence. Dawson and

Orr<sup>54</sup> reported long-term outcomes for pleomorphic adenomas treated by “lumpectomy” plus radiotherapy. The 10-year local recurrence rate was 1.5%, with cumulative risk rising to 8% at 20 years. Most late recurrences were malignant, with one of four developing malignant recurrence at 15 years, and three at 18 years. The possibility of radiation-induced malignancy, therefore, must be added to the known possibility of malignant transformation when considering treatment options. Given these considerations, surgery alone seems to be the obvious initial treatment of choice.

Management of parotid pleomorphic adenomas that recur despite surgical removal can be particularly challenging. Generally, recurrences develop slowly, and frequently their appearance is not noted for years after surgery. Furthermore, recurrences often present in the form of multifocal nodules, all of which are inevitably engulfed in scar tissue from the previous surgery, and in this setting, the identification and protection of the facial nerve is substantially more difficult than in the nonoperated circumstance. Leverstein and colleagues<sup>55</sup> reported on 40 patients with recurrent pleomorphic adenoma of the parotid. In three patients, no tumor resection was performed. Two received radiotherapy, and both were controlled. In the remaining 37 cases, *en bloc* resection was done. Pathology remained benign in 36 cases, and 16 received postoperative radiotherapy. None of the patients developed local failure with a median follow-up of 106 months. One patient experienced facial nerve paralysis and two developed malignant transformation. It would seem, therefore, that in high-risk circumstances, such as multifocality, positive surgical margins, and certain deep lobe tumors, selective use of radiation therapy after appropriate surgical excision should be the treatment of choice.

Cervical metastasis is an ominous event in salivary gland malignancy, and the standard management approach is to do a modified radical neck dissection followed by postoperative radiation. In malignant parotid and submandibular tumors in which no clinical adenopathy is present, the first echelon lymph nodes should be sampled because of a surprisingly high rate of occult metastasis. In a multivariate analysis, Armstrong et al.<sup>52</sup> reported that the risk of occult metastasis is 20% in primary malignancies larger than 4 cm, with a 49% risk for high-grade tumors. Frankenthaler and colleagues<sup>56</sup> found a 33% risk of occult metastases for parotid malignancies associated with facial nerve paralysis and 18% risk for high-grade tumors in general. At the present time, however, no compelling data support the benefit of elective neck dissection for the clinically negative neck in malignant high-grade tumors.<sup>57</sup>

Other series consistently have shown improvement in locoregional control when patients with major salivary gland cancers received postoperative radiation therapy.<sup>37,43,58,59,60,61 and 62</sup> These consistent data are a marked improvement over the substantial local failure rates (39% for parotid gland and 60% for submandibular gland) reported for patients treated by surgery alone.<sup>22</sup>

Specifically, the indications for adding radiation to surgery for management of malignant tumors are positive surgical margins, advanced primary tumor stage (including facial nerve involvement, positive neck nodes, high-grade histology, and deep lobe involvement), and tumor spillage during the operation.

Other data suggest that, for lesions that are locally advanced at the time of initial treatment and for patients with involved margins, intraoperative brachytherapy plus postoperative external-beam radiation therapy might be useful in improving local control.<sup>59</sup> Fu and associates<sup>63</sup> showed that, with positive resection margins, local control improved with the addition of radiation. Overall, only 14% of those with microscopic disease at or close to the surgical margin experienced local recurrence when postoperative radiation therapy was given, as compared with 54% who recurred locally in the surgery-only group. Most patients in this series received total doses between 5000 and 7500 cGy.

Although a detailed technical description of parotidectomy is inappropriate here, several points should be made about this meticulous but safe surgical technique. Were it not for the presence of the facial nerve within the substance of the parotid gland, the procedure would be far less challenging; however, this important motor nerve, along with all of its branches, weave through the parotid parenchyma in such a way that almost all tumor operations involve nerve identification, isolation, and dissection. The approaches vary somewhat, but consistent with all parotid operations is the fundamental surgical tenet of generous and well-planned incision, skin flap elevation, and wide exposure. When well designed, the parotidectomy incision, even though long, leaves little obvious scarring. The incision usually is begun anterior to the auricle, extends behind the edge of the external ear canal to minimize its exposure, then swings along the lower edge of the ear lobe down to the first horizontal crease of the cervical skin and then anteriorly for some distance ( Fig. 30.4-4). A skin flap is then lifted anteriorly to an extent that exposes the entire external surface of the parotid gland. The gland is separated from the anterior border of the sternocleidomastoid muscle, and the posterior belly of the diaphragm muscle is identified lying deep to the sternocleidomastoid. The diaphragm muscle and the cartilaginous ear canal serve as landmarks for identification of the main trunk of the facial nerve as it exits the stylomastoid foramen and extends anteriorly. The various branches of the nerve are dissected and, in the case of the tumors within the superficial lobe of the parotid gland, that lobe and the tumor within it are removed without violating the capsule of the neoplasm. To remove tumors that lie within the deep lobe (i.e., under the nerve), the superficial lobe of the gland is often removed, and various manipulations of the nerve are necessary to remove the tumor under it. For a large, deep lobe neoplasm, other techniques of deep lobe exposure, such as submandibular gland excision, with or without mandibulotomy, may be necessary to accomplish safely and effectively the important goal of *en bloc* tumor removal.

**FIGURE 30.4-4.** Typical parotidectomy incision. **A:** The drawing of the incision is designed to blend into natural skin folds and minimize visibility. **B:** One-year postoperative result of an actual parotidectomy incision like the one depicted in **A**.

Often, the oncologic principles of wide excision with ample surrounding normal parenchyma are not attainable in deep lobe tumors, and the adequacy of the surgery must be sternly questioned. Generally speaking, one should apply liberal criteria in this circumstance for the use of postoperative radiation therapy. Modern imaging provides the means by which the surgeon can be forewarned about deep lobe involvement, its size, and the probability of needing extended methods, such as mandibulotomy, to extricate the tumor from the parapharyngeal space. Whether partial or total parotidectomy is done, the defect incurred is usually reasonable. With proper attention to detail, dissection of the facial nerve and removal of most tumors can be accomplished with minimal risk of postoperative facial weakness. Closure of the skin incision usually is followed by a pleasing esthetic result.

Radiation therapy techniques vary, depending on the anatomic and pathologic situation. Submandibular lesions are usually treated with parallel opposed portals to cover the entire tumor bed and submandibular/submental area. The cervical lymph nodes are included for node-positive patients, and the occasional, high-risk, node-negative patient. For parotid, treatment-planning CT scans should routinely be done. A variety of techniques have been reported.<sup>59,64</sup> Yaparpalvi and coworkers<sup>65</sup> reported a comparison of nine different techniques using dose-volume histogram analysis of exit dose to contralateral parotid, hot spots in mandible and temporal lobe, and other key parameters. They concluded that an ipsilateral wedged pair; a three-field anteroposterior (wedged), posteroanterior (wedged), and lateral portal using 6-MV photons; and a mixed 6-MV photon beam with a 16-MeV electron beam (1:4 weighting) provided the best target coverage with minimal normal tissue dose. Garden et al.<sup>64</sup> reported a preference for ipsilateral mixed beam over the wedged pair technique with respect to complications. Modern conformal techniques should provide excellent coverage of the target area and minimum dose to surrounding normal tissue using either approach.

The exact dose required for postoperative radiation therapy has not been determined. In a study in which patients who received doses of at least 5750 cGy were compared with patients who received smaller doses, Harrison and colleagues<sup>59</sup> compared dose with outcome. The 10-year local control rate for the higher-dose group was 72%, compared with 53% for those in the lower-dose group. However, despite the suggestion of a trend in favor of high doses, the difference was not statistically significant. In another important study, Garden and associates<sup>64</sup> reported no clear dose-response relationship, except in patients with positive margins or tumor involvement of major named nerves, and in those, he noted better local control with doses of more than 60 Gy. Hosokawa and coworkers<sup>66</sup> reported that patients with mucoepidermoid cancer of salivary gland origin experienced no local recurrences with postoperative doses of more than 55 Gy, whereas 3 of 17 patients recurred locally with doses of less than 55 Gy. The difference was statistically significant. McNaney and coworkers<sup>61</sup> reviewed treatment failure and the total dose for patients

who received at least 6000 cGy or more. The doses that were associated with treatment failure did not lend themselves to a specific dose-response relation. In general, doses in the 6000 to 6500 cGy range given over 6 to 7 weeks are used for postoperative radiation therapy, except in patients with involved margins or T4 disease, who may require even higher doses. In this subset of patients, the expected high local failure rate that has been reported supports the need for dose intensification with either conformed external-beam techniques or intraoperative brachytherapy/radiotherapy approaches.

Because of the unique natural history of adenoid cystic carcinoma and because of its affinity for neural involvement, this tumor deserves special and separate consideration. Data from three different studies consistently show that postoperative radiation therapy should be added for almost all adenoid cystic carcinomas. When regional nodes are involved, the neck should be included in the treatment planning.<sup>56,67,68</sup> When these nodes are uninvolved, elective neck radiation generally is not recommended.

Management of the neck in general includes the consideration of important variables such as T stage and grade. In a study by Armstrong and associates,<sup>52</sup> 474 patients with major salivary gland cancers were reviewed. High-grade tumors had a 49% risk for occult metastases, as compared with only 7% for intermediate- or low-grade tumors. The risk for epidermoid cancers was 41%, but only 10% for all other histologies combined. Submandibular tumors had a higher risk for occult metastases, occurring in 21% as compared with 9% for parotid tumors. Occult disease was found in 7% of T1 and T2 tumors, 16% of T3 tumors, and 24% of T4 tumors. Most agree that, in patients with clinically positive regional nodes, postoperative radiation therapy should be administered. The question of how to manage the clinically negative neck is less clear, but the thinking is aided by Armstrong's data. In patients who would otherwise need postoperative radiation therapy because of concerns about the primary site, elective neck treatment with radiation can be used. It is appropriate to electively harvest the first echelon nodes in high-risk patients as a means of staging the neck. If histologic nodal examination reveals disease, postoperative radiation therapy to the neck should be added. In Armstrong's study, the periparotid nodes were the ones most commonly involved, and in those that were positive, 25% had positive nodes at levels III and IV. This was because of skip metastases to level III and IV without level II metastases. This point emphasizes the need for treatment of the entire neck when involved nodes are found.

For patients with a clinically positive neck, surgery and postoperative radiation therapy are indicated. Although with squamous cell carcinoma of the head and neck, nodal disease in one side of the neck frequently places the contralateral neck at risk, this does not appear to be the case with major salivary gland cancers. King and Fletcher<sup>69</sup> and Harrison et al.<sup>59</sup> showed that elective contralateral neck radiation is not necessary in this circumstance.

The role of chemotherapy in the management of both the major and minor salivary gland malignancies is limited to treating distant metastasis that is progressing and to circumstances of palliation of local/regional disease not amenable to either salvage surgery or radiation therapy. Although a few patients have been reported who have been given combination chemotherapy in the neoadjuvant setting or as adjuvant therapy after surgery, too few patients are available for study.<sup>70,71</sup> Similarly, no data has been published evaluating concurrent chemotherapy and radiotherapy administered in an attempt to improve outcome by increasing radiation cell kill.

The interpretation of response data from phase II trials of single agents and combination chemotherapy regimens is limited by the heterogeneity of histologic types of salivary gland cancer, by the fact that response probably differs by histologic type, and by the small numbers of patients enrolled in any one study. Mucoepidermoid, adenoid cystic, and adenocarcinoma histologies constitute the bulk of patients referred to medical oncologists and therefore those that are included in clinical trials. Patients with other salivary gland malignancies, such as malignant mixed tumors, epithelial-myoepithelial carcinomas, salivary duct carcinomas, acinic cell carcinomas, and squamous cell carcinomas, are rare and therefore not separated out in the chemotherapy literature.

Mucoepidermoid and squamous cell carcinomas are thought to arise from the salivary excretory duct and generally respond to cisplatin-based chemotherapy regimens used for other sites in the head and neck. Adenoid cystic carcinomas and adenocarcinomas arise from the intercalated ducts of the salivary glands and tend to be lumped together in study reports but often have a different clinical course; adenoid cystic carcinoma may be surprisingly indolent and only manifested by the chronic pain of perineural tumor infiltration. Metastatic adenocarcinoma, on the other hand, generally has a more aggressive course that is reflected in proportionately more obvious responses to chemotherapy.

Table 30.4-5 lists single-agent and combination regimens reported to have activity in salivary gland cancers. Cumulative response rates to single agents range from 10% to 40%, with the higher rates reported from older literature.<sup>72,73,74,75,76,77,78</sup> and <sup>79</sup> Retrospective reviews of patients treated for adenoid cystic carcinoma before 1980 at both the M. D. Anderson and Princess Margaret hospitals indicated that Adriamycin and 5-fluorouracil were the most effective single agents,<sup>80,81</sup> whereas methotrexate, vincristine, and cyclophosphamide showed little activity. A review published by Suen and Johns<sup>82</sup> in 1982 noted clinical efficacy for cisplatin as well.

Single agents	
Cisplatin	80-100 mg/m <sup>2</sup> , or 100 mg/m <sup>2</sup> q 4wk
5-FU	500 mg/m <sup>2</sup> q wk, or 320-360 mg/m <sup>2</sup> q 2wk
Adriamycin	60 mg/m <sup>2</sup> q 2wk
Epirubicin	50 mg/m <sup>2</sup> q wk, or 60 mg/m <sup>2</sup> q 2wk
Mitomycin	1.4 mg/m <sup>2</sup> q 2wk
Vincristine	300 mg/m <sup>2</sup> q wk
Combination regimens	
CAP (q 2wk): Cyclophosphamide + Adriamycin + Cisplatin	400 mg/m <sup>2</sup> day 1 60 mg/m <sup>2</sup> day 1 80 mg/m <sup>2</sup> day 1
PAF (q 2wk): Paclitaxel + Adriamycin + 5-FU	100-160 mg/m <sup>2</sup> day 1 60 mg/m <sup>2</sup> day 1 500 mg/m <sup>2</sup> day 1
PF (q 2-3wk): Cisplatin + 5-FU	100 mg/m <sup>2</sup> day 1 500 mg/m <sup>2</sup> day 1
PEP (q 2wk): Epirubicin + Paclitaxel + 5-FU	60 mg/m <sup>2</sup> day 1 100 mg/m <sup>2</sup> day 1 500 mg/m <sup>2</sup> day 1
PAB (q 2wk): Paclitaxel + Adriamycin + Bleomycin	100 mg/m <sup>2</sup> day 1 60 mg/m <sup>2</sup> day 1 60 mg/m <sup>2</sup> day 1

TABLE 30.4-5. Single Agents and Combination Regimens with Activity in Salivary Gland Malignancies

In the 1990s, three new agents were tested in multicenter trials with adequate numbers of patients with adenoid cystic carcinoma. The European Organization for Research and Treatment of Cancer (EORTC) conducted a phase II evaluation of epirubicin in 20 patients and reported two responses that lasted 7.5 and 20 months, respectively, and ten patients with disease stabilization.<sup>76</sup> Symptomatic improvement was documented in 29% in this particular study. Phase II trials of mitoxantrone in adenoid cystic carcinoma patients were carried out by the EORTC<sup>77</sup> and the Southwest Oncology Group.<sup>78</sup> EORTC investigators observed four partial responses and 22 with stable disease in a total of 32 patients; the Southwest Oncology Group investigators reported one complete response and 12 patients with stable disease out of the 18 treated.

Paclitaxel at a dose of 200 mg/m<sup>2</sup> over 3 hours every 3 weeks was tested in the Eastern Cooperative Oncology Group, using a standard two-stage statistical design, in three patient cohorts: individuals with adenoid cystic carcinoma, adenocarcinoma, or mucoepidermoid carcinoma. The trial was closed for the adenoid cystic carcinoma cohort after no responses were observed in 15 patients, but patients with adenocarcinoma and mucoepidermoid carcinoma continue to be enrolled, with both arms demonstrating responses.<sup>83</sup>

A fourth new drug studied is vinorelbine. Airoidi et al.<sup>79</sup> conducted a phase II trial in 20 patients with salivary gland malignancies (13 adenoid cystic carcinomas, five adenocarcinomas, one malignant mixed tumor, and one undifferentiated carcinoma). Four patients achieved a partial response and nine demonstrate stable disease. In summary, modest activity has been shown for epirubicin, mitoxantrone, and vinorelbine in patients with adenoid cystic carcinoma. Paclitaxel does not appear to be active for adenoid cystic carcinoma, but preliminary findings from the Eastern Cooperative Oncology Group suggest activity for adenocarcinoma and mucoepidermoid carcinoma.

Combinations that include cisplatin, Adriamycin, or 5-fluorouracil (5-FU) have been the cornerstone of palliative treatment for salivary gland malignancies, a fact particularly true in adenoid cystic and adenocarcinomas. Complete and partial response rates in the 30% to 60% range have been reported. In addition, some trials note prolonged disease stabilization and relief of pain among patients with adenoid cystic carcinoma.<sup>76,84,85</sup> Median response duration is in the range of 6 to 9 months, with some responses lasting more than 1 year. It is unknown whether survival is improved with chemotherapy.<sup>86</sup> Two- and three-drug regimens combining cyclophosphamide with Adriamycin and cisplatin (CAP)<sup>17,18,19,20</sup> and <sup>21</sup>; cisplatin with Adriamycin or epirubicin plus 5-FU (OAF or OEF)<sup>70,87,88,91</sup>; cisplatin plus 5-FU (PF)<sup>3,16,19,21</sup>; or cisplatin, Adriamycin, and bleomycin (PAB)<sup>84</sup> all appear equally effective. Combinations that incorporate mitomycin C or vincristine<sup>71,88,90</sup> or use more than three drugs<sup>92</sup> do not seem to offer any advantage.

In summary, no standard drug therapy has been established for treatment of salivary gland cancer because of the lack of formal trials with adequate numbers of patients. For the treatment of adenoid cystic carcinoma, the information at hand would suggest that combination chemotherapy is superior to single-agent strategies and that two- or three-drug combinations of cisplatin, doxorubicin, and 5-FU would be reasonable initial treatment. The slow growth rate of adenoid cystic carcinoma may be one of the factors that account for the lack of response observed in some studies. Relief of symptoms and stabilization of disease may be more achievable palliative end points for evaluating drug efficacy. Adenocarcinomas of salivary gland origin may be treated with the same regimens. High-grade mucoepidermoid carcinoma appears to be sensitive to the same spectrum of drugs that are commonly used to treat squamous malignancies (cisplatin, bleomycin, methotrexate, and 5-FU).<sup>72,93</sup> Thus, the combination of cisplatin and 5-FU or taxane-based combinations are reasonable regimens to use. No data are available about treatment of the less common malignancies, such as acinic cell carcinoma and malignant mixed tumors. All patients should be considered candidates for trials of investigational new drugs. Studies of adjuvant chemotherapy, particularly for high-grade mucoepidermoid carcinoma, have not been undertaken because of the small number of patients available for study. The optimal way to assess new therapies for salivary gland carcinoma is in a multiinstitutional setting in which patient resources can be pooled and treatments made uniform.

## MINOR SALIVARY GLAND TUMORS

Minor salivary gland tumors can occur in any age group, and they have no particular gender predilection. The glands are ubiquitous in the upper aerodigestive tract, so tumors originating in minor salivary glands can occur anywhere in the head and neck; however, the palate is the most common site for both benign and malignant lesions. Rarely, ectopic salivary gland tissue can lead to tumors in such diverse locations as the middle ear or the thyroid area. [Table 30.4-6](#) shows the distribution by site of origin in the Memorial Sloan-Kettering Cancer Center's experience with these tumors. Minor salivary gland lesions occur in the nasal cavities and paranasal sinuses, nasopharynx, larynx, lip, floor of the mouth, trachea, and other sites in the head and neck, but overall, they are most frequently seen in the oral cavity. It is often impossible to differentiate between a primary sublingual tumor and a minor salivary gland tumor in the anterior floor of the mouth.

Site	Benign	Malignant	Total
Palate	58	114	172
Tongue	9	62	71
Cheek	9	38	47
Maxillary sinus	1	43	44
Nasal cavity	3	20	23
Gingiva	0	22	22
Floor of mouth	0	21	21
Lip	5	11	16
Larynx	0	15	15
Tonsil	1	9	10
Retromolar trigone	0	9	9
Nasopharynx	0	6	6
Ethmoid sinus	0	5	5
Pharynx	2	3	5
Total	81	378	459

\*Total of 459 cases from the Memorial Sloan-Kettering Cancer Center. (Adapted from ref. 1, with permission.)

**TABLE 30.4-6.** Incidence by Site of Origin of Minor Salivary Gland Tumors<sup>a</sup>

Between 65% and 88% of all of minor salivary gland tumors are malignant.<sup>94</sup> Adenoid cystic carcinoma is the most common histologic type, occurring in as many as 55% of patients with minor salivary gland tumors.<sup>95</sup> Otherwise, the presenting types are the same as for major salivary gland tumors, including mucoepidermoid carcinoma, adenocarcinoma, malignant mixed tumor, and anaplastic carcinoma. Small cell (oat cell) carcinoma of minor salivary gland origin also has been reported.<sup>96</sup> Minor salivary gland tumors tend to present as painless submucosal masses and can be present for many years without change. Malignant tumors can persist without change, but more often they increase in size.

Any submucosal mass in the head or neck should be considered a minor salivary gland tumor until proved otherwise. Malignancies can spread to invade local tissue, including bone and nerve. Tumors of the floor of the mouth or the tongue can extend into the neck and into the mandible. Adenoid cystic carcinoma has a particular tendency to grow along the perineural spaces and to extend great distances from the primary tumor along nerve pathways, and it is important for the surgeon to realize that skip areas of tumor involvement can occur along the nerve. For instance, when this lesion occurs in the lateral aspect of the palate, it can infiltrate the branches of the greater palatine nerve, extend centrally, and can ultimately occupy the gasserian ganglion in the middle cranial fossa. This fact should be taken into account, and treatment planning should include the ganglion. The presence of a negative frozen section taken from the nerve trunk proximal to the originally discovered peripheral nerve lesion does not rule out the possibility that the nerve is involved with tumor more centrally. Adenoid cystic carcinomas can also spread along the haversian canals of bone. Therefore, when involvement of the mandible is questionable in floor of mouth lesions, the surgeon must be prepared to deal with further extension than what is obvious.

Fewer than 20% of patients with minor salivary gland malignancies present with lymph node metastases, and approximately 10% who demonstrate a clinically negative neck subsequently develop nodal metastases. As with major salivary gland tumors, the incidence of nodal metastases is related to grade and tumor size (i.e., stage).

No uniform staging system has been developed for minor salivary gland tumors. Survival seems to correlate with clinical stage. Olsen and coworkers<sup>97</sup> showed that tumor size was significant for mucoepidermoid carcinoma of the oral cavity. In their study, patients with lesions larger than 2 cm did much worse than those with lesions smaller than 2 cm. None in the latter group died from mucoepidermoid carcinoma.

## TREATMENT

Surgery is usually the treatment of choice for minor salivary gland tumors, whether benign or malignant. Enucleation is considered inadequate and is associated with a recurrence rate in excess of 93%.<sup>106</sup> therefore, wide excision or regional excision must be performed whenever possible. The surgeon should not hesitate to remove underlying bone, such as palate or sinus wall(s), to achieve such excision. Paranasal sinus malignancies often require partial maxillectomy for complete removal. Speech and swallowing rehabilitation for hard palate defects that have been created by tumor resection is easily accomplished by prosthetic devices. Defects of the soft palate, however, are more problematic.

Limited information exists on the effectiveness of primary radiation treatment. Ellis and colleagues<sup>98</sup> reported their results, in which a total of 20 patients with minor salivary gland malignancies received only radiation therapy for their disease. Seven had early-stage tumors and 13 had advanced tumors. Local control was obtained in six of the seven early-stage lesions (86%), a result that is comparable with those for surgical management. For more advanced lesions, however, radiation alone controlled only 2 of 13 (15%), a result considerably inferior to that following combined therapy. Parsons and associates<sup>99</sup> reported local control in 13 patients treated with radiotherapy alone for adenoid cystic cancer, and five of these patients have follow-up longer than 10 years. A total of 20 of 51 cases treated with radiotherapy alone are locally controlled with follow-up ranging from 2.5 to 21.0 years. Several surgical failures were salvaged with radiotherapy as well. Although this and other limited studies suggest that radiation can be effective for small lesions, surgery usually is considered the treatment of choice whenever possible. Advanced lesions should always be treated initially with surgery, and usually that procedure is followed by postoperative radiation therapy. Exactly which patients should receive postoperative radiation therapy remains unclear. We tend to recommend the guidelines that have been established for major salivary gland tumors: Patients with advanced-stage disease, lymph node metastases, high-grade tumors, or inadequate surgical margins are treated with postoperative radiation. Many patients have a combination of these factors.

Long-term follow-up is now available for patients with minor salivary gland tumors. Parsons and associates<sup>99</sup> reported 20-year local control of 57%. The most important factors affecting local control were tumor stage and combined modality therapy (surgery plus radiotherapy). It is significant that, with longer follow-up, the distant metastasis rate at 12 years was 40%.

Eapen and colleagues<sup>100</sup> reported 70 patients with salivary gland carcinomas. Approximately one-third had minor salivary gland tumors, and the indications cited for postoperative radiation therapy were inconsistent. However, a significant decrease in locoregional recurrence was noted among patients who were given postoperative radiation therapy. The actuarial risk of locoregional recurrence in the nonradiated patients was 62%, as compared with 20% for the radiated group.

Ninety percent of the patients received between 5500 and 6590 cGy over 5.0 to 6.5 weeks. In 95% of radiated patients, the regional lymph nodes were treated along with the primary site.

Tran and coworkers<sup>95</sup> reviewed the University of California, Los Angeles, experience with salivary gland tumors of the oral cavity. A total of 62 patients with previously untreated lesions were analyzed, all of whom were treated with primary surgical resection. Twenty-four patients received postoperative radiation therapy owing to advanced local disease, involved margins of resection, or both. Most of the lesions in this series were adenoid cystic carcinomas, and the palate was the most common primary site. Local tumor control in patients with positive margins was 50% for surgery alone, as compared with 71% with combined surgery and postoperative radiation therapy. A trend toward less successful disease control and poorer survival for patients with adenoid cystic carcinoma was noted as compared with the other malignant tumors.

The experience with minor salivary gland tumors of the nasal cavity and paranasal sinuses was also reported by Tran and coworkers.<sup>95</sup> Thirty-five patients seen and treated between 1962 and 1985 were included, most of whom (68%) had adenoid cystic carcinoma. Adenocarcinoma was seen in approximately one-half the ethmoid and nasal cavity lesions. Local control for the combined surgery and radiation group was 62%; for surgery alone, it was 18%, and for radiation alone, it was 9%. This benefit of radiation was present despite the fact that the radiated group had higher-stage disease and fewer patients had adequate surgical margins. Among those with positive margins, local recurrence was seen in 67% with surgery alone and 30% with postoperative radiation therapy.

Just as with the major salivary glands, data on the treatment of adenoid cystic cancer of minor salivary gland origin clearly demonstrate a local control advantage from combined surgery and postoperative radiation therapy over surgery alone. The authors recommend this combined strategy for almost all adenoid cystic carcinomas of minor salivary gland origin. A young patient with a small lesion that is resected completely may be an exception to this rule. Essentially, all treatment decisions must be individualized.

Koss and associates<sup>96</sup> reported 14 patients with small cell carcinoma of minor salivary gland origin. Although no conclusive data were obtained from this or other series, these lesions may be managed optimally with resection, chemotherapy, and local radiation therapy.

The technique of radiation therapy for minor salivary gland tumors is similar to that for squamous cancer at the corresponding primary site. For postoperative radiation, doses in the 6000- to 6500-cGy range are used over 6 to 7 weeks. Wide portals are required, especially for adenoid cystic cancer. The nerve pathways up to and including the base of the skull should be included in the treated portals. When radiation therapy alone is used for early-stage disease, doses of at least 7000 cGy in 7.0 to 7.5 weeks should be used. Brachytherapy can be used for a portion of the treatment, especially for oral cavity lesions. Elective nodal radiation usually is indicated only in selected circumstances, such as the occasional patient with minor salivary gland tumors of the nasopharynx. Whether elective nodal radiation is required here is unclear, but it can certainly be justified on the basis of the rich lymphatic drainage of the nasopharynx.

### SPECIFIC STRATEGIES FOR SPECIAL SITUATIONS

Deep lobe parotid tumors, whether benign or malignant, are often inaccessible in standard parotidectomy. In such a circumstance, a variety of mandibulotomy techniques are available to surgeons that provide excellent exposure to the area into which these tumors expand (i.e., the parapharyngeal space). Because deep lobe tumors often are not surrounded by parotid gland parenchyma, removing the lesion without fragmentation can be difficult. Additionally, this potential space is at the skull base, and the carotid sheath forms part of its perimeter.<sup>101</sup> Although these mandibulotomy techniques are seldom required, in selected circumstances the efficient and safe removal of deep lobe tumors is greatly enhanced by their use.

Occasionally, the facial nerve or one of its branches is encased within (but not invaded by) a benign tumor; thus, sparing the nerve requires meticulous and painstaking removal of the neoplasm. Radiation therapy is not usually part of the primary management of benign lesions; however, for a lesion that encases the nerve, for recurrent benign lesions, and when complete gross tumor removal is not possible, radiation therapy is often recommended.<sup>54</sup> Postoperative radiation therapy is probably important for recurrent deep lobe parotid tumors, whether benign or malignant, even though all gross tumor has been removed. Even with gross tumor removal, large pleomorphic adenomas of the deep lobe are associated with a high local recurrence rate. To add radiation after routine and uncomplicated removal of a benign tumor of the superficial lobe of the parotid or from the submandibular gland seems unwarranted.

In cancers that involve the facial nerve or its branches, the involved segment is best resected and grafted with an interposition of nerve harvested from another site. In most cases, however, nerve can be dissected off a tumor surface and, with the use of postoperative radiation therapy, control results are achievable that are similar to those from a more radical approach. However, sacrifice of the facial nerve is rarely required; when it is necessary, the consequence of the surgery and the gravity of the prognosis take on added dimensions. The functional and esthetic results of correctly done nerve grafting, although not perfect, are good in a substantial percentage of cases. Essentially, oncologists are working in an era of surgical minimalism when the tendency is to sacrifice the facial nerve only in extraordinary circumstances. The substantial body of knowledge showing the effectiveness of postoperative radiation therapy has in large part been responsible for this more conservative approach to dealing with the facial nerve in parotid gland surgery. No prospective studies have been done that document the effectiveness of this approach, which has evolved from considerable anecdotal information. It is axiomatic that those patients who require nerve resection and grafting have advanced-staged disease and, therefore, require postoperative radiation therapy. Even though no definitive studies have been done to analyze the impact of external-beam radiation on nerve regeneration, it is generally felt that nerve grafts do equally well despite radiation. The important addition of postoperative radiation therapy for these advanced malignancies should not, therefore, be avoided or even delayed because of concern for neural regeneration.

Although most data for major salivary gland cancers involve the parotid gland, selected reports have focused on submandibular tumors. Sykes and colleagues<sup>51</sup> reported 30 cases of carcinoma of the submandibular gland treated with radiation therapy. Most were treated postoperatively, but 12 patients were radiated after grossly incomplete surgery or after biopsy alone. The 5- and 10-year local control rates were 85% and 73%, respectively. Cancer-specific survival was 79% and 57%, respectively. Late recurrences were seen, especially for those with adenoid cystic histology. Interestingly, 9 of 12 patients radiated for gross disease had local control.

Not infrequently, a particular situation arises in which a patient with a submandibular mass is explored, and for various reasons, only gland resection is done at the initial operation (i.e., none of the adjacent tissue is removed), and pathologic examination later reveals the existence of a malignancy. The literature is not clear in its recommendations, but the value of reoperation usually lies in the removal of gross disease such as that left behind at the primary site or metastatic nodes. To reoperate and radically remove regional nerves such as cranial nerve XII or to remove mandible in the absence of such gross disease does not seem warranted. Neck dissection of some sort is often recommended, and postoperative radiation to the primary bed and neck should be conducted. Considering the potential for locoregional control with this plan, and considering that more radical measures at the locoregional site do nothing to prevent distant metastasis, this moderate approach seems appropriate.<sup>102</sup>

A unique accumulation of data has assessed the value of fast-neutron radiotherapy for malignant salivary gland tumors.<sup>103,104,105,106</sup> and <sup>107</sup> Douglas et al.'s report<sup>103</sup> of the results of neutron radiotherapy in 148 patients with major salivary gland malignancies is particularly noteworthy. The 5-year actuarial locoregional control rate for patients treated with curative intent for gross tumor was 59%. Tumor size was an important determinant of outcome. Tumors smaller than 4 cm were controlled in 80%, whereas larger tumors were only controlled in 35%. All patients who had complete resection followed by postoperative neutron therapy had local control. In yet another report,<sup>104</sup> Douglas and colleagues assessed fast-neutron radiotherapy for minor salivary tumors. They reported on 84 patients with adenoid cystic cancers treated between 1985 and 1994. Overall 5-year actuarial locoregional control was 59%. For advanced lesions that involved the skull base, cavernous sinus, or nasopharynx, locoregional control was only 15%, whereas it was 63% when these sites were uninvolved. Recurrence-free survival of 53% at 5 years also has been reported for adenoid cystic carcinoma in a European series.<sup>106</sup>

Buchholz and coworkers<sup>108</sup> also reviewed a limited experience of six patients with large, advanced, or recurrent pleomorphic adenoma who, because surgery was deemed excessively morbid, were treated with neutron beam therapy. With median follow-up of 52 months, all tumors are locally controlled. Although the method is alluring, the unavailability of neutrons precludes most patients from receiving this therapy.

### PARAGANGLIOMAS

Throughout modern medical literature, the paragangliomas have been known by a variety of names, including *glomus tumors*, *chemodectomas*, *nonchromaffin paragangliomas*, *glomercytomas*, *carotid body* and *tympanic body tumors*, and *receptomas*. These names and others make up a heterogeneous and confusing list that addresses certain individual characteristics of various tumors but does not achieve the necessary consistency of classification.<sup>109,110,111,112,113,114,115,116,117,118</sup> and <sup>119</sup>

Essentially, these tumors make up a family of neoplasms that develop from the paraganglia tissues, which are themselves chemoreceptor organs that are distributed throughout the body. These organs are of neural crest origin and have similar functions and histologic appearances.<sup>112</sup> Their cells of origin are part of the *diffuse neuroendocrine system* (DNES), a name that has replaced the previous designation of *amine precursor uptake and decarboxylase system*. The newer terminology acknowledges that the primary products of the paraganglia, neuropeptides, and catecholamines may serve as neurotransmitters, neurohormones, hormones, and parahormones.<sup>113</sup>

Paragangliomas can be broadly categorized as either sympathetic or parasympathetic. The former arise from the adrenal medulla (pheochromocytomas), certain extraadrenal sympathetic paraganglia, and visceral autonomic paraganglia.<sup>120</sup> Parasympathetic paraganglia are found throughout the body, and it is this group that gives rise to almost all the paragangliomas of the head and neck.

The chief cell is probably the principal component of the paraganglia, serving as its chemoreceptor. These cells contain acetylcholine, catecholamines, and serotonin. They are of neural crest origin and, hence, are neuroendocrine in nature. The chief cells render the paraganglia receptive to hypoxia and pH changes, and to fluctuations in the blood carbon dioxide concentration.<sup>114</sup>

As members of the DNES, the chief cells of the paraganglia are functionally and ultrastructurally linked with thyroid C cells, ultimobranchial cells, and adrenaline/noradrenaline-producing cells of the adrenal medulla.<sup>121</sup> These chief cells migrate with autonomic ganglion cells and are, therefore, in close association with sympathetic ganglia around the aorta and its main branches.<sup>115</sup> Many head and neck paraganglia, and their respective neoplasms, are distributed in relation to the vessels and cranial nerves of the primitive branchial arches and are therefore referred to as *branchiomic paraganglia*.<sup>109,116,117</sup> For example, the jugulotympanic paragangliomas are branchiomic by virtue of their relation to the third gill arch. The intravagal paragangliomas, on the other hand, are not associated with either the gill arches or their arterial derivatives.<sup>109</sup>

Although paragangliomas can be seen in a variety of head and neck locations—orbit, maxilla, larynx, trachea—most are found on the carotid body, the vagus nerve, or in the jugulotympanic area. This follows the consistent sites occupied throughout the body by the paraganglia. They can be classified as follows:

- I. Branchiomic paraganglia
  - a. Temporal bone (tympanicum, jugulare)
  - b. Carotid body
  - c. Other head and neck (orbit, laryngeal, nasal)
  - d. Subclavian, aortic, pulmonary
- II. Intravagal (upper mediastinal) paraganglia
- III. Aorticosympathetic (retroperitoneal) paraganglia
- IV. Visceral (pelvic, vagal, mesenteric) paraganglia

The term *glomus* was applied to paragangliomas because it was believed that the chief cells within the paraganglia were derived from specialized pericytes or from blood vessel walls, as is seen in true arteriovenous glomus complexes.<sup>109</sup> Depending on whether they began in the ear or on the jugular bulb, those tumors that develop in the jugulotympanic paraganglia usually are referred to as *glomus tympanicum* or *glomus jugulare tumors*, respectively. The paraganglia from which these neoplasms arise are associated with the tympanic branch of the glossopharyngeal nerve and the auricular branch of the vagus nerve, respectively.<sup>119</sup> The paragangliomas of the intravagal area are often referred to as *glomus intravagal*<sup>122</sup> or *vagal body tumors*.<sup>123</sup> Although the term *glomus* enjoys considerable name recognition, it is deceiving because of the suggestion of pathologic uniqueness. Such is not the case, however, because all the head and neck paragangliomas have similar histologic, ultrastructural, and cytochemical features, irrespective of the site of origin.<sup>109,112,117</sup> In point of fact, location and functional capabilities, rather than appearance, separate them from one another. It is noteworthy that the first description of a temporal bone glomus tumor by Lubbers<sup>124</sup> referred to a carotid body-like tumor that was thought to be metastatic from a contralateral carotid body tumor.

## PATHOGENESIS

The word *functionai* is used to describe paragangliomas that secrete catecholamines (epinephrine and norepinephrine) and serotonin. Even though the capacity for catecholamine synthesis and secretion has been documented for both jugulotympanic and intravagal paragangliomas, these two tumors actually have the lowest catecholamine content of all paragangliomas.<sup>109,122,123,125,126</sup> Other functional capabilities have been documented in paragangliomas, but the significance of any secretory activity should be evaluated by its clinical impact. The incidence of clinically functional paragangliomas is only 1% to 3%<sup>127</sup>; however, because of the potentially serious consequences of a catecholamine crisis during manipulations of a functional tumor, evaluation of patients with paragangliomas should include screening for symptoms and signs of catecholamine secretion and in selected circumstances, even the measurement of the appropriate blood and urine products.<sup>128</sup> Although all paraganglia are chemically capable of secreting these products, no physiologic function of the jugulotympanic or the intravagal paraganglia has been established. For the carotid body paraganglia, however, a physiologic role is clearly defined. The carotid body and carotid sinus function as complementary chemoreceptor and baroreceptor, respectively, to effect homeostatic regulation of both ventilation and perfusion.

Overall, paragangliomas are uncommon neoplasms that occur as nonfamilial and familial tumors; the former develop more frequently in women and the latter in men. The mode of inheritance is thought to be autosomal dominant with incomplete penetration. The affected gene is probably located in the long arm of chromosome 11, but there have also been abnormalities found in chromosomes 5 and 7.<sup>117,129,130,131,132,133, and 134</sup>

Multiple paragangliomas occur synchronously or metachronously, unilaterally or bilaterally, in 25% to 50% of the familial and in approximately 10% of the nonfamilial tumors.<sup>130,132,135,136, and 137</sup> Any combination of two, three, or more sites of origin of synchronous tumors can occur, but the most frequent combination involves concurrent carotid body and jugulotympanic tumors.<sup>131</sup> Synchronous occurrence is seen between paragangliomas and other DNES lesions, such as pheochromocytomas.<sup>130,136</sup> Although this occurrence is unusual, the serious consequences of not being forewarned before surgery mandates screening for this tumor in all paragangliomas. Specifically, in patients with certain catecholamine profiles, the existence of a pheochromocytoma must be ruled out before any surgery is undertaken. Parathyroid adenomas, thyroid carcinomas, and certain other neural crest tumors also can be concurrent with jugulotympanic, intravagal, and carotid body paragangliomas.<sup>117,138,139</sup> Essentially, this group of neoplasms must always be thought of as potentially systemic afflictions, especially in patients with a family history of similar tumors. Carotid body tumors are much more common in people living at high altitudes than in those living at sea level.<sup>140</sup>

## CLINICAL BEHAVIOR AND NATURAL HISTORY

Although the clinical behavior of paragangliomas is determined somewhat by cellular characteristics, tumor location is the more influential factor. Malignancy is rare and typically is defined by the existence of metastasis rather than by cellular characteristics. Metastasis is usually to lungs, lymph nodes, liver, bone, or spleen.<sup>139,141,142</sup> Because paraganglia tissue is not usually found in these structures, its presence in them constitutes metastasis. Metastasis apparently is more frequent in intravagal and jugulotympanic paragangliomas than in carotid body tumors,<sup>143</sup> a fact that is probably related to tumor proximity to the jugular vein.<sup>144,145</sup> DNA ploidy studies do not seem to be predictive of behavior.<sup>146</sup> In the final analysis, no criteria other than metastasis can consistently be used to gauge aggressiveness of a primary paraganglioma.<sup>147</sup> Malignancy also varies by site of origin: Up to 13% of carotid body, 7% to 15% of vagal, and a substantially smaller percentage of jugulotympanic paragangliomas are malignant.<sup>148,149,150,151 and 152</sup> Malignant lesions metastasize to either the regional lymph nodes or to distant sites, the more common of which are lung and bone. Much like the primary paragangliomas, which are late to metastasize, metastatic sites are characterized by a quiescent natural history; some patients with known lung and bone metastases can live as long as 25 years after the lesions are discovered. Spontaneous remission of metastatic paraganglioma has been reported.<sup>153</sup>

The natural history of primary benign paragangliomas usually is characterized by slow and inexorable growth, and the alterations of the structures into or around which they grow determines the clinical symptoms and signs that occur. Furthermore, different lesions have different structure, and this fact probably impacts on the type of expansion that ultimately occurs. For example, carotid body paragangliomas are encapsulated and rubbery, whereas their jugulotympanic counterparts are friable. Regardless of their site of origin, most paragangliomas are extremely vascular and tend to bleed profusely when manipulated. The jugulotympanic tumors extend into the skull, the eustachian tubes, and the normal cracks and furrows of the ear space. If the tumor originates in the hypotympanicum or on the jugular bulb, it often can be seen through the tympanic membrane. A bluish red mass behind the membrane or a polyp in the external ear canal can be but the surface of an extensive paraganglioma, and a casual biopsy or myringotomy can lead to troublesome bleeding. Only by appropriate imaging can the true extent of the tumor be

determined.

The jugulotympanic paragangliomas often initially create a sense of fullness in the ear, followed by a conductive hearing loss and pulsatile tinnitus. Destruction of the temporal bone can lead to facial nerve weakness, vertigo, deafness, and intracranial complications such as cerebrospinal fluid leak and meningitis. When a tumor occurs in the jugular bulb area, its otologic manifestations often precede vagal nerve signs.

Paragangliomas of the vagus nerve, on the other hand, almost always create vocal cord paralysis before otologic symptoms and signs occur.<sup>154</sup> That is not to say, however, that vagal nerve paragangliomas always produce vocal cord paralysis; such is not the case. Overall, only approximately 3% of paragangliomas are vagal in origin.<sup>155</sup> These slow-growing tumors occur most often at the base of the skull and in the parapharyngeal space but may arise anywhere along the course of the nerve or its branches. When the tumors are located high on the nerve, they tend to displace the internal carotid artery anteriorly. Such a vagal paraganglioma is demonstrated by the arteriogram shown in [Figure 30.4-5A](#). The arteriographic appearance is, therefore, different from that of carotid body paragangliomas, which generally cause splaying of the external and internal carotid arteries ([Fig. 30.4-5B](#)). Vagal paragangliomas often present as asymptomatic cervical masses,<sup>156</sup> and in the absence of unusually aggressive local behavior, neurogenic signs such as those caused by involvement of the sympathetic trunk and cranial nerves X, XI, and XII usually occur only after extensive growth.

**FIGURE 30.4-5.** Arteriogram shows vagal paraganglioma and anterior displacement of internal carotid artery (ICA) **(A)** and carotid body paraganglioma **(B)**. Notice the splaying of the ICA and external carotid arteries.

Laryngeal paragangliomas are extremely uncommon.<sup>157</sup> Most originate in the supraglottic portion of that organ and, as such, do not present with early symptoms, such as hoarseness, or with airway compromise. When discovered, they present as a discolored, submucosal mass that is atypical in appearance and is often confused with other tumors, especially neuroendocrine carcinoma. These malignancies have a distinctly different behavioral pattern. Studies have concluded that laryngeal paragangliomas are benign neoplasms.<sup>157</sup> Malignant behavior of these lesions is so unusual as to suggest misdiagnosis. These lesions are effectively managed by surgical excision.

Most commonly, carotid body paragangliomas present as painless masses located deep to the anterior border of the sternocleidomastoid muscle in the upper or midneck. These are generally slow growing and often have been obvious for years before diagnosis. They are usually nonfunctional, but they do have the capability of function.<sup>148</sup> Carotid body paragangliomas actually can grow to impressive dimensions without creating neurologic or vascular findings. Large tumors occasionally produce compressive carotid artery symptoms. These facts are important in determining treatment philosophy, especially in older, asymptomatic patients. They begin in the arterial adventitia, usually at or around the bifurcation of the internal and external carotid arteries. Because these tumors generally develop from the medial aspect of the great vessels, the arteries generally are displaced laterally. This typical appearance of splayed and lateralized vessels distinguishes the carotid body tumors radiographically from vagal nerve paragangliomas (see [Fig. 30.4-5](#)). The radiography is important in diagnosis, because it is unique. As these neoplasms become larger, they can occupy the parapharyngeal space, actually presenting as a bulge in the tonsil area, and encroachment into this area can produce dysphagia.

## EVALUATION

The diagnostic workup of paragangliomas should consist of CT or MRI and, in selected situations, angiography. Imaging should delineate bone destruction and complete tumor, intracranial and extracranial. CT scanning is more effective for imaging bone, but MRI offers a superior capability in accessing intracranial extension, as well as the relation of tumor to bone. With proper enhancement techniques, one or both of these images plus clinical evaluation can provide sufficient information to plan treatment of most paragangliomas. This point is relevant to overall management strategy; if radiation therapy is the planned treatment, the radiation oncologist must be comfortable enough with the diagnosis to proceed without a biopsy. FNA and cytologic analysis can be helpful, but because of the location medial to the carotid artery and because of the dense vascularity of most of these lesions, this study may not always be practical. Open biopsy becomes necessary when the diagnosis is not achieved by these other means.

Invasive arteriography is valuable in preoperative preparation because it provides a picture of contralateral vascular crossover and because it allows tumor embolization to be done before contemplated surgery. Paragangliomas are usually very vascular, and when surgery is planned, intraluminal embolization of the main arterial supply and the tumor bed is helpful for safe and less morbid removal of large tumors. The continued concern for the purity of the commercial blood supply is such that surgeons should avoid transfusion whenever possible, and preoperative embolization can be extremely helpful in pursuing this goal. This technique has its most impressive impact in the removal of larger carotid body and jugular bulb tumors and is probably unnecessary for most small tumors. The techniques of embolization are beyond the scope of this chapter, and the reader is referred to the literature on the subject; it must be emphasized, however, that use of this technology carries significant risks and should be undertaken only by an experienced interventional radiology team. Finally, embolization of paragangliomas is only an adjunct to surgery and should not be considered primary treatment for these highly vascular tumors, no matter how successful the devascularization. If embolization is not followed promptly by tumor removal, undesirable collateral circulation and vascular shunting can develop, ultimately complicating an already challenging surgical process. In fact, the sooner the surgery follows the embolization, the more effective the hemostasis will be during surgery. If surgery is not to be the treatment of choice, then embolization should probably not be done.

## TREATMENT AND RESULTS

Paragangliomas usually are considered benign, and although they can metastasize or be locally aggressive, such is the exception rather than the rule. Traditionally, the mainstay of treatment has been surgical removal,<sup>158,159</sup> but repeated series of cases treated by radiation therapy have demonstrated its effectiveness in achieving local control of these tumors.<sup>160,161,162,163,164</sup> and <sup>165</sup> Investigators have reviewed the literature and have compared surgical with radiation therapy results, which show no difference in local control achieved by either modality. Accordingly, treatment decisions should be based on a formula that considers tumor size, patient age and general health, symptoms and signs present before treatment, treatment-related morbidity, and the expertise of those involved in the planned treatment.

Reluctance to use radiation therapy in paragangliomas probably stems from a historic bias against radiating benign tumors. Furthermore, series that have compared the two treatment methods have been somewhat biased because many tumors radiated in various series were not favorable lesions by virtue of their size and recurrent state. As in any study that compares treatment results, an accurate comparison of radiation and surgery should analyze comparable tumors. An important aspect of radiation therapy of paragangliomas relates to the definition of local control. In traditional cancer thinking, sustained complete response after radiation is the criterion by which local control is usually judged. Such cannot be the case, however, with paragangliomas. Instead, these tumors typically partially regress or remain stable after therapy. Because the tumors are composed predominantly of vascular tissue, the proliferative (i.e., neoplastic) elements make up but a minor portion of the overall tumor volume, and although successful radiotherapy kills the proliferative cellular component, the remaining vascular tissue typically does not change significantly. For purposes of assessing local control, therefore, the absence of disease progression with the resolution or even halting of symptoms after radiation is the ultimate goal. In fact, there may even be some short-term postradiation edema or swelling of the involved area, but this generally resolves within several months. When radiation is used as the treatment modality, therefore, it is important that both the treatment team and the patient understand this important aspect of local control, and all concerned should exercise patience in judging the outcome. Some investigators have been skeptical of the persistence palpable tissue after radiation, expressing concern for its capacity to proliferate after 20 to 30 years' dormancy.<sup>166</sup> However, it has never been demonstrated that this has occurred. In the future,

genetic mutations of p53, p16INK4A, and others may provide markers for local tumor progression and regression. <sup>167</sup>

Cummings and coworkers<sup>160</sup> have reported 45 patients radiated for glomus tumors. Only three patients (6.6%) have had symptomatic recurrences, two of which were believed to be due to a "geographic miss." The radiation therapy was effective in relieving the presenting symptoms of most patients. For example, 27 of 35 patients (77%) who received 3500 cGy in 3 weeks had complete relief of their tinnitus. The remaining 23% had partial relief or stabilization of symptoms. All patients with pain, vertigo, discharge, bleeding, and abnormalities of the fifth cranial nerve had complete relief of their symptoms with radiation therapy. All patients with abnormalities of cranial nerve IX through XII had partial relief or stabilization of their cranial nerve abnormalities. The authors of this study noted that symptomatic improvement often did not occur until many months after radiation therapy, highlighting the need to follow these patients for a lengthy period. As long as no clinical progression was noted, the authors believed there would be no need to intervene in the postradiation setting.

Kim and associates<sup>161</sup> have analyzed the dose-response relation for radiation of paragangliomas. The literature was reviewed, and the rate of failure was correlated with dose. Overall, the recurrence rate was 25% when the radiation dose was less than 4000 cGy. With doses greater than 4000 cGy, local recurrence was rare. Overall, only 2 of 142 patients (1.4%) who received more than 4000 cGy had local recurrence. The authors recommended doses in the 4000- to 4500-cGy range delivered over 4.0 to 4.5 weeks. Cole and Beiler<sup>163</sup> treated 39 glomus jugulare or vagal tumors with radiotherapy. The last 32 of those patients were treated with megavoltage radiotherapy (cobalt 60) or linear accelerator; the first seven patients had been treated with orthovoltage therapy. In the first seven patients, the results were unpredictable; however, 30 of the 32 later patients show no evidence of recurrence.

Evenson et al.<sup>168</sup> have reported the results of 15 patients with 23 paragangliomas treated with radiotherapy. Eighteen of these tumors were previously untreated, whereas five had been unsuccessfully treated with prior therapy (one with radiation therapy, four with surgery). Most patients received doses in the 15-Gy range over 5 weeks. The local control for previously untreated patients was 100% at 10 years. The cause-specific survival rate was 100% for the 14 patients that were previously untreated. No cranial nerve injuries were seen. The patient who was re-radiated developed a transient lethargy syndrome. Mumber and Greven<sup>169</sup> also reported that all 15 patients treated in their series with definitive radiotherapy had long-term local control. Doses of more than 4500 cGy did not improve the outcome.

Complications are associated with both methods of treatment; most series show the rate to be higher in patients managed by surgery. <sup>170</sup> It should be pointed out, however, that most series have studied cases accumulated over many years, and when many of the earlier surgical cases were done, modern temporal bone and carotid artery bypass techniques had not yet been developed. The contemporary methods of reducing intraoperative bleeding by preoperative embolization usually are not included in these series. The intraoperative precision achieved by using contemporary methods surely render previous complication data invalid. The complications associated with radiation therapy are dose related. Bone and brain necrosis and abscess are the most serious of those reported. Each of these has occurred in approximately 1% of treated patients. These complications should not occur as long as doses in the 4000- to 4500-cGy range are used. Fuller and colleagues<sup>171</sup> reported one fibrosarcoma in their series that was considered a radiation-induced malignancy. Malignant transformation of tissue secondary to radiation has been reported in these tumors, and although unusual, this occurrence is a concern.

The decision to operate or radiate should be based on a formula that considers tumor size and location, patient age and health, symptoms or signs present before treatment, potential morbidity, and the expertise and availability of those involved in treatment. The decision should be made in consultation between the head and neck surgeon and the radiation oncologist and with an appreciation for the fact that this group of tumors is one of the most complex and dangerous head and neck tumors to be treated. To do nothing is an acceptable option in some patients, because these lesions are often tolerated well and for a prolonged period. In general, a reasonable plan in patients with head and neck paragangliomas is to operate and remove those lesions (whether jugulotympanic, intravagal, laryngeal, or carotid body in origin) that are smaller and less likely to be associated with significant operative morbidity. For large tumors that demonstrate extensive bone destruction, intracranial involvement, or both, or in which considerable operative morbidity is expected, radiation therapy is probably the method of choice for achieving local control. In young patients, radiation therapy should be avoided if a reasonable surgical option is available. On the other hand, the risk for radiation-induced cancer is small, and these authors do not hesitate to recommend it to young patients if the surgical procedure required is likely to be associated with unreasonable morbidity. Older patients are especially suited for radiation therapy, because local control usually is sustained throughout the balance of their lifetime.

Removal of jugulotympanic lesions should only be attempted by surgeons trained in otologic and skull base techniques. Those intravagal paragangliomas that are located high in the neck are often very challenging surgical endeavors, being too high to approach by conventional cervical exposure and too low to be handled from an intracranial approach. These are true skull base lesions, often having an epicenter within the jugular foramen. This mostly inaccessible location is best approached by complex but precise and well-described skull base techniques. <sup>159,172</sup> Paragangliomas of the temporal bone can be a challenging group of patients. <sup>173</sup> De Jong and colleagues<sup>174</sup> reported on 38 patients radiated for temporal bone paragangliomas between 1956 and 1991. Fourteen patients were treated primarily, 13 in combination with surgery, and 11 as salvage. Local control was achieved in 79% of the primary radiation group, 100% of the combined therapy group, and 91% in the salvage group. Complications were few and minor.

Because resection of vagal paragangliomas is almost always followed by complete vagal paralysis, the choice of a radiation versus a surgical strategy in these lesions should be based on a particularly flexible paradigm. Rehabilitation after resection of midcervical vagal lesions is more easily accomplished than those at the base of the skull. This is partly because of the fact that, in the latter group, multiple cranial nerve injuries are more common. Older individuals have much more physiologic difficulty after vagal nerve resection than do younger patients, regardless of the part of the nerve involved. One must factor into the decision process the fact that a significant percentage of patients with vagal paragangliomas demonstrate a vagal nerve paralysis at the time of diagnosis, and that fact certainly alters the decision process somewhat.

Surgery of carotid body paragangliomas, although safe overall, is fraught with hazards, and only head and neck surgeons competent in vascular techniques should attempt to remove these lesions, especially in recurrent lesions. Carotid artery bypass or shunt, or even artery resection and reconstruction, are sometimes necessary to achieve complete tumor removal. Additionally, and with regard to the surgical removal of carotid body paragangliomas, the input from both chemoreceptor and baroreceptor mechanisms is mediated via a common neural pathway; therefore, function of the entire system is affected by the resection of tumors involving the intercarotid paraganglia. Whereas the resection of unilateral carotid body lesions is generally well accepted, excision of bilateral tumors or of a unilateral carotid tumor with a contralateral vagal paraganglioma is often problematic from two standpoints: the potential of sustaining bilateral vagal nerve injury and the baroreceptor dysfunction that potentially can result from the bilateral denervation of the carotid sinuses. Labile hypertension and hypotension, headaches, diaphoresis, and emotional anxiety occur in a substantial percentage of patients who undergo bilateral excision. <sup>175</sup> Apparently, the loss of the parasympathetic regulatory system and the subsequent unopposed sympathetic system leads to this cardiovascular syndrome. Surprisingly little emphasis has been placed on this finding in the literature. Considering the gravity of the potential morbidity, we do not recommend bilateral carotid body paraganglioma removal, especially simultaneously. If bilateral surgery is contemplated, the procedures should be staged, both to ensure the functionality of the vagus nerve on the first side, and to minimize the risk of baroreceptor dysfunction. Surgery on one side and radiation therapy to the contralateral lesion is an accepted alternative to bilateral surgery. Finally, one can also consider radiation to both lesions.

Overall, the most accepted treatment for paragangliomas is surgical extirpation; however, radiation therapy is an effective alternative to surgery for achieving local control in certain patients. An asymptomatic paraganglioma in an elderly patient or one in ill health is of questionable concern, and therefore, consideration should be given to observation only.

Malignant paragangliomas are managed most effectively with surgery, radiation therapy, or both. Essentially, chemotherapy has no defined role for treatment at any stage. Patients with disease that cannot be approached with surgery or radiation should be treated when symptoms require palliation, but because these are rarely encountered, only a few anecdotal reports of experience with chemotherapy have been published. These patients should be considered for investigational therapies.

#### INTRODUCTION

In the 1980s and 1990s, concern for posttreatment function restoration became a primary part of management of head and neck cancer. Conservation surgery, radiation strategies, reinnervation of free flaps, and larynx-sparing protocols continue to be used under various circumstances in an attempt to maintain or reestablish functional speech, voice, and swallowing in head and neck cancer patients. The ideal multidisciplinary concept requires interactions, therefore, among the surgical, radiation, and medical oncologists, reconstructive surgeons, speech pathologists, maxillofacial prosthodontists, dental oncologists, nutritionists, nurse oncologists, psychologists, audiologists, and social workers during pretreatment assessment and posttreatment intervention. To say the least, the standard for the complete head and neck team is complex.

Pretreatment counseling for persons with oral cavity and pharyngeal cancer is well established; the same should apply to organ preservation patients with laryngeal and hypopharyngeal cancers. Patients benefit from discussions with the speech pathologist regarding swallowing and voice and speech difficulties that can result from radiation therapy and chemotherapy regimens. Regrettably, however, patients entering organ preservation protocols often are inadequately counseled, if at all. Should failure of the treatment protocol occur, surgery is performed immediately, and the patient and family are forced to enter a frightening and stressful period unprepared for either the surgical experience or the rehabilitation that lies ahead. Optimal rehabilitation for all patients requires consideration of future strategies should one particular treatment plan fail.

#### PRETREATMENT ASSESSMENT

Preoperative consultation with the speech pathologist should be scheduled soon after the physician has made the final diagnosis and a treatment plan is formulated. During this consultation, the speech pathologist reviews what the patient already knows and further explains normal anatomy and physiology as well as the anticipated changes resulting from treatment. Patients with glottic carcinoma who are scheduled to be treated with radiation are counseled regarding vocal changes and swallowing difficulties that might occur during or after the treatment. Patients scheduled to undergo oral, pharyngeal cavity, or conservation laryngeal surgical procedures should be counseled in a special way, with an emphasis on their immediate postsurgical needs that relate to nasogastric, gastrostomy, and tracheostomy tubes. Additionally, short- and long-term rehabilitation strategies for speech, voice, and swallowing are summarily discussed in this initial consultation. The speech pathologist must be sensitive to the fine line between appropriate coverage and information overload; patients labor under a heavy emotional burden at this stage of their treatment and can easily be overwhelmed by someone insensitive to this potential. It is important, however, to accomplish as much of this as possible before the treatment. Depending on the specific treatment used, the patient's ability to communicate may be largely or completely impaired afterward. Even though there are substitute means of communicating during this period, none are as effective as an interactive dialogue between patient and speech pathologist. If loss of oral communication is expected after treatment, patients will need information regarding augmentative or alternative communication methods or devices. Patients scheduled for total laryngectomy learn about alternatives to natural voice: the availability of the electrolarynx and the mastery of esophageal or tracheoesophageal puncture speech (or both). Frequently, patients will consent to trial use of an electrolarynx and will order the recommended device before surgery. We have found that patients who are willing preoperatively to experiment with speech replacement devices feel more empowered and are relieved that they will be able to express their needs immediately after surgery. We frequently incorporate patient volunteers to meet patients and their families, thus allowing them to relate to and question a person who has had a similar treatment experience. Even candidates not scheduled for laryngectomy (i.e., laryngeal preservation protocol patients) should meet with the speech pathologist to discuss potential problems with voice and swallowing during or after the treatment.

#### DIAGNOSTIC EVALUATION

The correct rehabilitative effort after treatment is enhanced greatly by the initial evaluation of speech and swallowing. In matters pertaining to potential speech rehabilitation, baseline reading samples of standardized articulation sentences, nonnasal and nasal paragraphs, and conversational speech samples are audio-recorded from patients whose tongue, velum, or jaw will be affected by surgery. These recordings serve to establish baseline speech patterns of articulation, fluency, rate, dialect, intonation, and nasality. A spectrogram that portrays frequency, intensity, and format information descriptive of resonant frequencies of the vocal tract provides additional baseline data regarding tongue placement and resonance. Standardized articulation testing typically is not performed for patients undergoing treatment for early- or later-stage laryngeal carcinoma unless modification of the articulators (lips, tongue, cheek, etc.) is planned. The speech pathologist, however, should document any articulation, fluency, rate, or dialectal patterns observed during this conversation with the patient. Additionally, orofacial structures, sensation, and function should be carefully examined. Plans for pretreatment dental care or postoperative radiation are discussed at this time because they also can have an impact on articulation, voice, and deglutition. Finally, because of the fact that patients with hearing deficiencies often have difficulty in monitoring the intelligibility and precision of their articulation, it is important to evaluate hearing before treatment.

If preexisting swallowing problems are present, a modified barium swallow (MBS),<sup>1</sup> fiberoptic endoscopic evaluation of swallowing (FEES),<sup>2</sup> or FEES with sensory testing (FEESST)<sup>3</sup> should be performed. If dysphagia does exist postoperatively, it is important that these studies be performed at the time to aid in the development of a management strategy. The MBS is a videofluoroscopic study of the motor aspects of the oral, pharyngeal, and esophageal stages of the swallow with varying food consistencies. This procedure permits measured amounts of barium bolus to be followed from the lips to the stomach and incorporates the effects of compensatory strategies, such as head position, chin tuck, and the like.<sup>4</sup> Because of its clear documentation of the oral preparatory and oral stages of the swallow, the MBS is ideal for patients with oral-stage dysphagia; in fact, it is the diagnostic test of choice. If pharyngeal or laryngeal swallowing problems exist, however, the FEES or FEESST should be performed. The FEES uses a fiber-optic nasoendoscope to observe the pharyngeal and laryngeal structures directly during the pharyngeal phase of the swallow. A bolus of contrasting color is used to note premature spillage into the hypopharynx or laryngeal vestibule before swallowing and vocal fold closure and the presence of residuum in the hypopharynx and laryngopharynx after a swallow. Although penetration (i.e., aspiration) may be identified during a FEES or MBS examination,<sup>5</sup> the primary purpose of these procedures is to analyze the motor components of swallowing. The FEESST combines the FEES with a technique that determines laryngopharyngeal sensory discrimination thresholds by endoscopically delivering air pulse stimuli to the mucosa that is innervated by the superior laryngeal nerve.<sup>3</sup>

Because vocal and aerodynamic parameters may be affected by the presence of a lesion or a biopsy (or both), baseline acoustic and aerodynamic analysis should be performed on all early glottic cancer patients, regardless of whether destined for radiation, microsurgery, or laser excision. Vocal measures of fundamental frequency, amplitude, frequency perturbation (jitter), amplitude perturbation (shimmer), and noise-to-harmonic ratio are obtained from a sustained vowel *a*. Sophisticated instruments, such as the Computerized Speech Laboratory (Kay Elemetrics Corp., Lincoln Park, NJ), Speech Viewer III (IBM, Austin, TX), Dr. Speech (Tiger Electronics, Seattle, WA), and Speech Master III (Speech-Master, Vero Beach, FL), all obtain and record these measures quickly. Baseline airflow rates, subglottal

pressure, and laryngeal resistance are calculated using the Aerophone II (Kay Elemetrics), Glottal Enterprise MS-100 (Syracuse, NY), or Nagashima Phonatory Function Analyzer. Documentation of these measures prior to treatment and at specific intervals during and after treatment is important for objective comparison of vocal changes after surgery or radiation therapy (or both) for glottic carcinoma.

## POSTTREATMENT INTERVENTION

### SPEECH AND SWALLOWING AFTER ORAL CAVITY SURGERY

Restoration of speech and swallow function after glossectomy appears to be highly dependent on a number of factors: the quantity and mobility of residual tongue after surgery, the particular reconstructive technique used, the integrity of motor and sensory nerve supply to the tissue, the functional recovery after reconstruction, the degree of scarring and fibrosis to the residual tongue musculature after surgery and radiation, the early intervention of speech therapy, and patient psychosocial factors, such as age, medical condition, motivation, and family support.<sup>6,7 and 8</sup> Even patients undergoing resection of the anterior portion or less than 50% of the mobile tongue can develop a delayed swallowing reflex and reduced ability to manipulate the bolus in the oral cavity.<sup>5</sup> The return of normal speech intelligibility and deglutition for small, anterior tongue lesions of up to 3 cm has been reported.<sup>9,10</sup> Articulation deficits are mild and often characterized by only a lisp. Speech therapy should focus on oral motor exercises to achieve adequate linguoalveolar and linguopalatal contact for accurate phoneme productions.

Owing to decreased tongue bulk and mobility, patients who have been treated for larger tongue lesions present with poor bolus formation, poor bolus manipulation, delayed elicitation of the swallow reflex, and increased oral transit time.<sup>1</sup> Finally, because of the loss of tongue volume, glossopalatal contact and closure are often severely compromised: Vertical capabilities of the tongue are diminished. Compensatory speech patterns, such as contacting the tongue behind the lower teeth, are used to obtain intelligible linguoalveolar ( *t, d, n, l, s, z*) and linguopalatal ( *sh, ch*) sound production if the tongue cannot contact the alveolar ridge or palate. If contact remains difficult, a palatal drop prosthesis is often helpful in lowering the contact point of the palate; thus, the vertical deficiency of the tongue is diminished, and linguopalatal contact is achieved.<sup>5,12</sup>

Speech and swallowing difficulties can be profound when more than 50% of the tongue is sacrificed; when the base of tongue, floor of mouth, or lateral pharyngeal walls are altered<sup>13</sup>; or when an extensive oral lesion requires a composite resection that might include total glossectomy, floor-of-mouth resection, radical neck dissection, and mandibulectomy.<sup>14,15</sup> Reconstructive methods for large tongue or floor-of-mouth tumors (or both) in which split-thickness skin grafts, reinnervated free flaps,<sup>16,17</sup> and pectoralis major<sup>17</sup> myocutaneous flaps are used generally provide a speech and swallowing outcome that is superior to those techniques in which the defect is closed primarily.<sup>18,19</sup> In particular, the bilobed, sensate radial forearm flap allows maximum functional speech and swallowing return after extensive oral cavity surgery.<sup>20,21 and 22</sup> The design allows for one part of the flap to provide bulk for restoring the floor of the mouth, whereas the other lobe provides volume to the mobile tongue.<sup>23</sup> Excellent speech and swallowing have been reported using the infrahyoid muscle flap for medium-sized defects in the floor of the mouth, tongue, buccal mucosa, and lateral pharyngeal wall.<sup>24</sup> Salibian et al.<sup>25</sup> found that the successful outcome of swallowing and speech correlated with the shape and position of the tongue root and the surface area of the floor of the mouth.

In the realm of nonsurgical treatment of tongue cancer, excellent to good functional speech and swallowing outcomes were reported in 18 of 20 patients with tongue base lesions (11 of 12 patients with stage T1 or T2 cancer; 8 of 9 patients with stage T3 or T4 cancer) treated with external-beam radiation followed by an interstitial implant boost with iodine 125 several weeks later.<sup>26</sup>

As reconstructive techniques and organ preservation protocols proliferate, additional diagnostic studies, such as videonography,<sup>27</sup> high-speed cineradiography,<sup>28</sup> and perfusion manometry<sup>29</sup> may be needed to measure and compare functional aspects of swallowing recovery accurately after different radiologic and rehabilitative treatments. The short- and long-term effects of radiation therapy, chemotherapy, or surgery on the sensory aspects of swallowing also will become more apparent as FEESST becomes an integral part of cancer management.

### VOICE AND SWALLOWING CHANGES AFTER TREATMENT OF LARYNGEAL CANCER

There is general agreement that voice quality in early glottic cancers (T1a and T2b) is better after radiation than before radiation<sup>30,31 and 32</sup> and better after radiation than after surgery.<sup>30,31</sup> Studies vary, however, regarding whether the postradiation voice ever becomes normal. Harrison<sup>33</sup> reported an ultimate return to normal voice within 3 months after completion of radiation therapy in nearly all irradiated T1 and T2 glottic cancer patients. Tsunoda<sup>34</sup> found ultimate return of normal mucosal wave motion stroboscopically in his patients with early glottic cancer that had been treated with radiation. Other studies report that voice after radiation therapy cannot be considered normal. Dagli et al.<sup>30</sup> investigated vocal parameters in patients successfully treated with radiation therapy for T1a and T1b glottic carcinoma. They found less than normal values for maximum vocal intensity, dynamic vocal intensity, range, jitter, and mean fundamental frequency. Aref et al.<sup>32</sup> reported abnormal acoustic and aerodynamic measures on T1 glottic cancer patients 3 months to 7 years after completion of radiation therapy. Increased laryngeal resistance that affected communication function was reported in laryngeal cancer patients treated with chemotherapy and radiation.<sup>35</sup> Longitudinal multiinstitutional standardized stroboscopic, acoustic, and aerodynamic investigations of early-stage glottic carcinoma patients are needed to allow more systematic predictions of vocal quality after radiation and surgical treatment. At present, there seem to be several predictors of poor vocal quality: Vocal fold stripping before radiation and continued smoking during and after radiation therapy predicted worse voice quality.<sup>36</sup> Nevertheless, as changes in vocal quality are common among patients after either radiation therapy or laser excision, patients should be seen by the speech pathologist for at least one posttreatment therapy session. Adherence to a vocal hygiene program with certain daily exercises results in a more efficient, resonant voice.

Patients in whom radiation therapy for early glottic carcinoma has failed or selected glottic lesions that are not suitable for radiation are frequently treated with conservation surgery (i.e., hemilaryngectomy). Voice and swallowing problems after hemilaryngectomy vary according to the extent of surgery. For example, if the arytenoid has been resected, the risk for aspiration is greater. If the hemilaryngectomy is isolated to one true vocal fold, one false vocal fold and the ventricle, with preservation of the epiglottis, swallowing may be improved with a chin tuck to assist in airway protection and head turning toward the operated side to direct food from the compromised area.<sup>5</sup> Vocal characteristics of the hemilaryngectomee have been described as rough, low-pitched, and breathy, all of which are probably due to compensatory efforts to achieve adequate glottal adduction.<sup>37</sup> Therapy techniques, such as forced adduction exercises, digital pressure to the side of the thyroid cartilage, decreased speaking rate, and increased phrasing, may decrease vocal strain, improve voice quality, and increase vocal intensity by reducing glottal opening.<sup>5</sup> Surgical augmentation techniques deserve consideration to improve glottal closure.

Those supraglottic cancers that fail radiation are not candidates for supraglottic laryngectomy; however, those nonradiated patients with supraglottic lesions who are able to undergo supraglottic laryngectomy not infrequently experience dysphagia due to the combined effects of supraglottic sensory denervation, incomplete posterior motion of the partially resected tongue base, restricted arytenoid motion, partial closure of the airway, and delays in bolus propulsion from narrowing at the laryngeal entrance.<sup>38</sup> These patients must avoid thin liquids and learn the special techniques and maneuvers of supraglottic<sup>5,39</sup> and supersupraglottic<sup>40,41</sup> swallow to ensure feeding safety. Commercially available thickening agents may be used to thicken the consistency of thin liquids for safer swallowing. Supraglottic laryngectomy patients frequently experience breathiness or hoarseness (or both), which may respond to short-term voice therapy. They may also demonstrate an increase in fundamental frequency, which may result from added tension to the vocal cords, thought to be the result of forced adduction exercises.<sup>5</sup>

It is not widely appreciated that a significant percentage of total laryngectomy patients experience dysphagia. Although they often do not complain of this, various studies have reported that 10% to 58% of laryngectomees have the problem,<sup>42,43 and 44</sup> which appears to center around the pharyngoesophageal (PE) segment.<sup>43</sup> Total laryngectomy may produce increased resistance to bolus transfer from stenosis and decrease of negative pressure in the upper esophageal segment. Resections of the hyoid bone and thyroid cartilage further aggravate this problem by allowing the pharyngeal lumen to collapse.<sup>45</sup>

Dysphagia that is secondary to surgery, chemotherapy, radiation therapy, and concomitant chemoradiation can cause swallowing dysfunction by compromising salivary flow; by causing edema, myositis, and fibrosis; by causing a delayed pharyngeal motor response stimulus; by decreasing laryngopharyngeal sensation; by causing pharyngeal incoordination; and by decreasing laryngeal elevation as a result of scarring and fibrosis.<sup>45,49</sup> Patients in whom dysphagia is suspected should undergo objective assessment with MBS, FEES, or FEESST. The MBS and FEES primarily analyze the motor components of swallowing, whereas the FEESST analyzes the sensory component that is frequently present in patients who have undergone conservation laryngeal operations and also in patients treated on preservation protocols. The short- and long-term effects of radiation therapy, chemotherapy or surgery on the sensory aspects of swallowing will almost certainly become more apparent as we learn and extend the range of FEESST-type testing as a routine part of cancer management.

For some laryngectomy patients, concerns regarding loss of speech are more important than survival itself.<sup>47</sup> Alternative voice sources for the laryngectomee include the use of a pneumatic or an electronic speech aid, esophageal speech, or the gold-standard tracheoesophageal puncture (TEP) speech. Patients who have undergone a partial or total glossectomy are unable to use these alternative voice sources, and they should be introduced to computerized speaking systems or talking keyboards.

### Artificial Larynges

A 1987 study of voice rehabilitation practices revealed that the use of an artificial speaking device was widely recommended by 90% of 400 head and neck surgeons surveyed, in many cases as a temporary means of communication after total laryngectomy.<sup>48</sup> These battery-operated or pneumatic devices simulate vocal sound, are relatively inexpensive, are easy to operate, and can be used by a patient 1 to 2 days after surgery. These devices continue to serve a useful purpose, and surgeons and speech pathologists should encourage all patients to own an artificial device as a primary or auxiliary speech system. Pneumatic devices consist of a piece that fits over the tracheal stoma, a unit containing a reed that produces sound, and a tube that directs sound into the mouth to be articulated. These particular devices are less popular in the United States than they are in Europe.

On the other hand, a variety of battery-operated, hand-held artificial larynges (electrolarynges) are currently available. Examples are illustrated in [Figure 30.5-1](#). The Cooper-Rand Electronic Speech Aid (Luminaud Inc., Mentor, OH) is an electrolarynx that is used exclusively with an intraoral adapter. This adapter directs sound into the oral cavity through a tube placed in the mouth. The NuVois 1 and NuVois 2 (Mountain Precision Manufacturing, Boise, ID), Servox Inton (Siemens Hearing Instruments, Inc., Prospect Heights, IL), Romet (Romet, Inc., Las Vegas, NV), OptiVox (Bivona Medical Technologies, Gary, IN), TruTone and SolaTone (Griffin Laboratories, Temecula, CA), Denrick (Denrick, Inc., Honolulu, HI), SPKR (UNI Mfg. Co., Ontario, OR; not pictured), and Amplicord model 55 (Amplicord, Inc., Rome, Italy) are neck-type devices that transmit sound through the tissues of the neck into the oral cavity for speech production. These devices are activated with an on-off switch and are equipped with an adapter so that they can be used either as intraoral or when pressed against the neck. The availability of both options is important because patients can use the intraoral adapter immediately after surgery when the neck is edematous. The Amplicord model 95 is pressure-activated as it contacts the neck rather than being activated by a switch. The UltraVoice (UltraVoice, Ltd., Berwyn, PA; [Fig. 30.5-2](#)) is an intraoral electrolarynx custom-built into a denture or retainer and activated by a remote control switch.

### Esophageal Speech

Esophageal speech involves learning to inject or inhale air into the esophagus through the reservoir created by surgical closure of the PE segment or gullet after laryngectomy. The trapped air is then released through the upper esophageal segment, which is the vibratory source for sound in the laryngectomee.<sup>49,50,51,52 and 53</sup>

Typically, the speech pathologist encourages the laryngectomee to attempt esophageal sound soon after the patient is able to swallow food comfortably. The details of the techniques taught by speech pathologists are beyond the scope of this text, but certain basic principles should be pointed out. The patient traps air in the mouth and forces it into the esophagus. Some patients learn the inhalation method, in which a lowered pressure in the esophageal segment relative to atmospheric pressure allows air to enter the gullet; thus, the source and the location of vibratory sound are fulfilled.

Even though esophageal speech can be introduced to the patient 1 or 2 weeks after the total laryngectomy, the development of functional capabilities with this method may take from 6 months to 1 year to learn; in fact, some patients never master it. Previous reports regarding the success rate in learning esophageal speech have varied from 26% to 55%<sup>54,55,56 and 57</sup>; however, Fujii<sup>58</sup> found that 74% (51 of 69) of their patients successfully used esophageal speech in daily communication. Age was the most important factor in success and failure. Ninety percent of the patients in this study who were younger than 60 were successful in learning esophageal speech as compared to 10% of those older than 75.<sup>58</sup> Although motivation and age appear to be important to the achievement of esophageal speech,<sup>56,59</sup> abnormalities of the vibrating esophageal segment—tonic and hypertonic spasms—are the most common reasons cited for esophageal speech failure.<sup>60,61</sup> Botulinum toxin type A injections have been used to combat other muscular spasmodic conditions, including the cricopharyngeus muscle spasm sometimes responsible for failure of TEP patients to achieve satisfactory speech.<sup>62,63</sup> Perhaps some of the speakers who cannot master esophageal speech would benefit from this same treatment.

In patients in whom esophageal speaking has failed, the tonicity or relaxation of that esophageal segment that vibrates (the PE segment) can be accurately evaluated by simultaneous use of videofluoroscopy and esophageal insufflation.<sup>64</sup> This is not routinely performed in the postoperative laryngectomee. An easier and reliable way to assess initial opening pressures of the PE segment is a portable manometry system that can be used 4 weeks after laryngectomy.<sup>65</sup> An initial opening pressure of between 15 and 20 mm Hg has been found to correlate with the production of a good esophageal voice.<sup>65,66</sup>

### TRACHEOESOPHAGEAL PUNCTURE

Most head and neck surgeons and most professionals who rehabilitate laryngectomy patients think that in properly selected patients, TEP, introduced by Singer and Blom in 1980,<sup>67</sup> is the standard of care for reconstitution of voice after laryngectomy. Rather than relying on the trapping of air in the esophagus, the creation of a permanent puncture through the tracheoesophageal wall permits the shunting of pulmonary air into and up the esophagus; thus, the basis for noise—vibration of the PE segment walls—is generated. Importantly, unlike esophageal speech, the reservoir of air does not depend on the gulping or trapping of air; instead it is limited only by expiratory capacity and, as such, more closely resembles normal voice. A valved prosthesis is placed into the puncture and, when the tracheal stoma is occluded, directs pulmonary air into the esophagus for speech. The one-way valve design of the prosthesis prevents aspiration from the esophagus into the trachea. An outer housing that contains a soft diaphragm allows normal respiration during silent periods; however, when speech is used, an alteration of the patient's expiratory effort shuts off the diaphragm, thus diverting the air through the tracheoesophageal conduit into the esophagus. This external housing, called a *tracheostoma breathing valve*, was developed in 1982, and is of immeasurable value in rehabilitation of these patients because it eliminates the need for manual occlusion of the stoma during speech.<sup>68</sup> A patient can, therefore, wear normal clothing over the lower neck to cover the apparatus, as there is no need for involvement of the hands. For a historical review of the evolution of voice restoration procedures and prostheses, the reader is referred to Singer<sup>69</sup> and Singer and Blom.<sup>70</sup> Although TEP is the method of choice for voice and speech rehabilitation in the United States, some patients and some cultures are not so enthusiastic about its implementation.

Initially, TEP was performed as a second surgery in patients who had been laryngectomized; however, many surgeons and speech pathologists now prefer that TEP be done at the time of the laryngectomy. The controversy as to the value of the secondary versus primary TEP is ongoing and is unlikely to end. Recently, Chan<sup>71</sup> performed a TEP as an outpatient office procedure using a flexible endoscope with local anesthesia and intravenous sedation. Those surgeons and speech pathologists who advocate secondary or delayed TEP think that waiting for 1 to 3 months after laryngectomy allows better control of factors, such as stoma size, vibration of the PE segment, and migration of the puncture site after radiation. Proponents of the primary puncture argue that patients are psychologically uplifted<sup>72</sup> by the fact that they can speak 3 weeks after surgery. Furthermore, primary TEP proponents cite the value of technical simplicity, effectiveness, low morbidity, and cost-effectiveness of the one-stage procedure. Success rates for both primary and secondary procedures are reported to be between 73% and 95%, respectively.<sup>73-74</sup> and<sup>75</sup> Regardless of time of puncture, an average of 7 hours of speech therapy is needed to learn to manage the prosthesis and to obtain optimal communication using the TEP.<sup>73</sup> Researchers have reported a decrease in TEP speech success rates from an initial 84% to 67% at 9 months<sup>74</sup> and 65% at 10 years<sup>75</sup> due to such "patient factors" as delays in seeking medical attention when the valve becomes dislodged and failure to care for the equipment properly. Although the Blom-Singer technique is popular in the United States, specialists in other parts of the world favor different methods to restore phonation.<sup>76</sup> Most interesting was a study by Quer,<sup>77</sup> who performed TEP at the time of the laryngectomy and also provided intensive esophageal speech instruction to 24 patients. Seventy percent of the patients (16 of 23) later chose to use esophageal speech rather than TEP speech even though they agreed that TEP speech was superior to esophageal speech.

### Candidacy for Tracheoesophageal Puncture

The success of voice restoration depends on a multidisciplinary team committed to thorough patient assessment, consistent management, and flexibility in problem solving. Success with TEP depends on good stoma construction, adequate stomal size, and accurate placement and angle of the TEP.<sup>78</sup> The tracheal stoma should be at least 1.5 cm and not retracted behind the manubrium. If stomal stenosis is a problem, a Bivona-Colorado stent can be used by the surgeon to create the puncture. A Bivona-Colorado prosthesis (Fig. 30.5-3), which is built into the tracheostoma vent, is inserted into the puncture.

**FIGURE 30.5-3.** Bivona and Atos voice restoration products. **A:** Bivona ultra-low-resistance prostheses and inserter. **B:** Bivona-Colorado button, template and sizing devices. Bivona-Colorado products are designed in cooperation with Bruce Jafek, M.D. and Bryan Spofford, M.D. **C:** Atos Medical Provox 2 prostheses. **D:** Bivona Tracheostoma Valve II and housing assembly. (Courtesy of Bivona Medical Technologies, Gary, IN.) (From Miller SD, Levine DK. Rehabilitation of speech, voice and swallowing functions after treatment of head and neck cancer. In: Harrison LB, Sessions RB, Hong WK, eds. *Head and neck cancer*. Philadelphia: Lippincott-Raven Publishers, 1999, with permission.)

Patients with emphysema, severe allergies, or pulmonary complications are generally not good TEP candidates, owing to copious amounts of secretions and reduced air volume associated with these conditions. The patient's cognitive status, physical health, and desire for communication should be considered before TEP. The presence or absence of radiation therapy does not seem to have a significant relationship to the success or failure of TEP.<sup>79</sup>

Because of the development of low-resistance, self-retaining prostheses inserted by the speech pathologist or surgeon (or both) and composed of materials designed to last approximately 3 to 6 months, manual dexterity and visual acuity are no longer essential for the use of this technology. These prostheses include Inhealth Indwelling (Inhealth Technologies, Santa Barbara, CA; Fig. 30.5-4); Provox-2<sup>80</sup> (Atos Medical, Sweden, Milwaukee, WI; see Fig. 30.5-4); Voicemaster<sup>81</sup> (Amsterdam, Netherlands), and Nijdam<sup>82</sup> (Sweden; not pictured). The Provox (Atos Medical), and Groningen prostheses (Groningen, Holland; not pictured) are popular indwelling prostheses in Europe.

**FIGURE 30.5-4.** Inhealth voice restoration products. **A:** Fistula measurement probe, duckbill prostheses, and inserters. **B:** No. 16 and No. 18 Fr. low-pressure prostheses, gel cap, and inserters. **C:** Indwelling voice prosthesis and gel cap. **D:** Tracheostoma breathing valve (without humidifier). In: Harrison LB, Sessions RB, Hong WK, eds. *Head and neck cancer*. Philadelphia: Lippincott-Raven Publishers, 1999, with permission.)

In following up TEP patients over 13 years, Lavertu<sup>83</sup> found that the absence of PE stricture was the only significant predictor of good to excellent speech. Because the tonicity of the PE segment in a primary puncture patient before the laryngectomy cannot be assessed, surgeons often perform a pharyngeal constrictor myotomy, a unilateral pharyngeal plexus neurectomy, or a unilateral pharyngeal plexus neurectomy with a cricopharyngeal myotomy at the time of surgery. Although all three

methods are equally effective in preventing pharyngospasms, Singer et al.<sup>84</sup> advocate use of the pharyngeal plexus neurectomy, as it preserves the vascular supply to the pharyngeal wall and preserves any residual resting tone in the PE segment, resulting in a higher speaking fundamental frequency compared to the other methods.

Many speech pathologists perform air insufflation testing before a secondary puncture, although the value of this has been challenged.<sup>85</sup> Lewin<sup>86</sup> reported greater than 90% success in predicting TEP failures when intraesophageal peak pressure levels are obtained in conjunction with the air insufflation test. The air insufflation test is performed by insertion of a transnasal catheter approximately 25 cm into the upper thoracic esophagus. The catheter is attached to a circular tracheostoma housing, which is secured to the patient's skin by an adhesive. As air is insufflated into the catheter, patients are instructed to inhale, occlude the stomal assembly, and sustain a vowel sound for as long as they can. Success is determined by patients' ability to sustain a vowel for 15 to 20 seconds and count from 1 to 15.<sup>87</sup> To ensure optimal results, it is important for the patient to feel relaxed and comfortable with the examiner. Multiple trials and a repeat visit are often necessary to confirm test results.

If insufflation testing fails but speech is achieved in a patient after a pharyngeal plexus nerve block with lidocaine, PE spasm is suspected. This should be confirmed via a videofluoroscopic MBS performed during rest and swallow and during speech with air insufflation. If the PE segment is confirmed to be highly resistant to airflow, botulinum toxin type A injection should be considered as a first-line treatment<sup>87</sup> before consideration of surgical procedures, such as a pharyngeal constrictor myotomy, a unilateral pharyngeal plexus neurectomy, or a unilateral pharyngeal plexus neurectomy with cricopharyngeal myotomy. If speech during the air insufflation test is faint or whispery, the PE segment may be hypotonic. Digital pressure on the outside of the neck may help to produce a stronger sound. The existence of hypotonicity is not a contraindication for TEP, although it may indicate the need for a neck band or digital pressure postoperatively to enhance contact of intraluminal vibratory surfaces.

### **Post-Tracheoesophageal Puncture Intervention**

With primary TEP, a catheter is placed in the newly created fistula that penetrates the posterior wall of the trachea and enters the esophageal lumen. The catheter provides a stent that keeps the fistula open during the weeks in which the tract is regenerating mucosae. Removal of the catheter and fitting of the voice prosthesis in a primary TEP patient generally takes place from 10 to 21 days after surgery.<sup>88</sup> If radiation therapy is planned, the patient should be advised that speech may diminish during the third to fourth week of radiation, owing to mucositis and radiation-induced edema. In the secondary, or delayed, TEP patient, the device is measured and inserted approximately 1 week. The 14-Fr. catheter placed during surgery is removed, and the patency of the tract is assessed by asking the patient to take a breath and say "Ah" on exhalation while the speech pathologist or patient occludes the stoma. If the tract is patent but sound cannot be attained, the patient can be fitted with a prosthesis but should be counseled that speech may not occur until there is further healing of the tissue tract. To determine the proper prosthesis size, the Inhealth fistula measurement probe (see Fig. 30.5-4) or the Bivona fitting kit (see Fig. 30.5-3) are used to measure the length of the fistula tract. Once appropriate length has been determined, the patient is fitted with a 16-Fr. duckbill or lower-resistance prosthesis (see Figs. 30.5-3 and 30.5-4).

During this initial session, patients are taught to occlude their stoma digitally. They are taught how to phrase their speech and how to apply appropriate abdominal support to initiate sound. Patients are also instructed regarding the possibility of fistula closure and how to manage the problem if the prosthesis becomes dislodged. It is essential that the speech pathologist be available for the first few days after fitting of a patient's prosthesis should problems arise.

### **SWALLOWING AND SPEECH AFTER EXTENSIVE RECONSTRUCTION OF THE PHARYNX OR CERVICAL ESOPHAGUS**

Several researchers think that after extensive pharyngeal resection or cervical esophageal resection (or both), the tubed radial forearm free flap maximizes functional rehabilitation of the patient by providing the best swallowing and speech results.<sup>89,90 and 91</sup> Free jejunal transfer also has gained wide acceptance in PE reconstruction because the jejunum is well vascularized and is associated with a low incidence of fistula formation and stricture. Voice restoration has been successfully achieved in these jejunal interpositions with the creation of either a primary tracheojejunal shunt at the time of the surgery<sup>92,93</sup> or a secondary procedure.<sup>94</sup> Reconstruction with jejunal interposition and gastric pull-up have demonstrated better swallowing results than those with myocutaneous (pectoralis and latissimus dorsi) flaps, and colon interposition.<sup>25,95</sup> Performance of a TEP in gastric pull-up patients has been successful in certain small heterogeneous patient groups,<sup>96,97</sup> but this is unpredictable, and the overall experience is limited.

Dysphasia in jejunal interposition patients may occur from discoordination of jejunal peristalsis with occasional oral and nasal regurgitation. Regurgitation of food is frequently noted in the gastric pull-up patient, owing to an absent esophagogastric sphincter. These patients are encouraged to eat small meals throughout the day. From a functional and from a morbidity standpoint, the jejunal interposition is generally considered to be a superior method of reconstruction compared to the gastric pull-up.

Patients undergoing total laryngopharyngectomy or laryngopharyngoesophagectomy with jejunal graft reconstruction experience a lack of innervation and muscle in the wall of the jejunum that causes hypotonicity. Therefore, sound may be easier to attain than esophageal speech; however, it is often softer in intensity and limited to fewer syllables per air charge.<sup>108</sup> Voice quality is often described as *wet*, owing to mucus in the jejunum; however, the success rates of primary or secondary tracheojejunal puncture are reported to be 72% to 93%.<sup>99,100 and 101</sup>

### **COMPARISON OF ESOPHAGEAL, TRACHEOESOPHAGEAL PUNCTURE, AND NORMAL SPEECH**

Acoustic and temporal studies indicate that TEP speech more closely approximates laryngeal speech in fundamental frequency, intensity, reading rate, percent silent time, and maximum phonation time.<sup>102,103</sup> Significantly higher fundamental frequencies were found during reading in neurectomized primary TEP patients as compared to primary TEP patients receiving myotomy or a neurectomy with myotomy. In addition, TEP speakers using the tracheostoma-breathing valve demonstrated faster speaking rates and fewer pauses. The valve prevents the escape of air sometimes observed with digital occlusion of the tracheostoma.<sup>88</sup> Although TEP speech in general is more intelligible and preferred over esophageal speech, the monotonous tone, voicing errors, and fricative errors are similar in TEP and esophageal speakers.<sup>88</sup> When TEP speech after a total laryngectomy is compared to TEP speech after a laryngopharyngectomy with pectoralis major flap reconstruction, no significant differences were noted for soft and loud intensity levels, fundamental frequency for soft voice, and jitter, although perceptual analysis revealed significant differences.<sup>104</sup> Speech in the tracheojejunal-esophageal puncture patients has even less pitch variation, more noise in the signal, shorter mean phonation time, a wet quality, and a softer intensity voice than TEP speech.<sup>105</sup>

### **VOLUNTEER AND SUPPORT ORGANIZATIONS**

The diagnosis and treatment of head and neck cancer may proceed quickly; however, a patient's adjustment to the diagnosis of a malignancy, its management, and the subsequent disability is not a short-term process.<sup>106,107 and 108</sup> Patients and their families will require different information and support throughout various times of the treatment process. A variety of resources are available to laryngectomees and their families.

### **WRITTEN MATERIALS**

Several good books are available for the laryngectomee that may be provided to the patient preoperatively or postoperatively. These guides provide useful information regarding anatomic changes, stoma care, first aid, alternative communication options, practice exercises, and support groups. They include the following titles:

- *Self-Help for the Laryngectomee*, by Edmund Lauder  
Lauder Enterprises, Inc., 11115 Whisper Hollow, San Antonio, TX 78230-3609  
800-388-8642  
E-mail: [lauder@voicestore.com](mailto:lauder@voicestore.com)  
<http://www.voicestore.com>
- *A Handbook for the Laryngectomee*, by Robert L. Keith  
PRO-ED, 8700 Shoal Creek Boulevard, Austin, TX 76001  
512-451-8542
- *Looking Forward* by R. Keith, H. Shane, H. Coates, K. Devine.  
Thieme Medical Publishers, Suite 1501,

- 381 Park Avenue South, New York, NY 10157-0208
- *Rescue Breathing for Laryngectomees and Check the Neck* (videotape)  
IAL, 7822 Ivymount Terrace, Potomac, MD 20854  
301-983-9323
  - *The Clinician's Guide of Alaryngeal Speech Therapy*, by Minnie S. Graham  
(available from Lauder Enterprises, Inc.; see first item in this list)  
Butterworth-Heinemann, 225 Wildwood Avenue,  
Woburn, MA 01801-2041  
1-800-388-8642

Booklets about cancer treatment and living with cancer can be obtained free of charge by writing the Office of Cancer Communications, National Cancer Institute, Building 31, Room 1024, Bethesda, MD 20892, or calling 1-800-4-CANCER.

## VOLUNTEERS

Patients are encouraged to meet before or after surgery with individuals who have undergone similar procedures. Some otolaryngology or speech pathology departments require that patient volunteers participate in formal volunteer training; other departments choose well-adjusted individuals and attend the patient visit with the volunteer. Many laryngectomee clubs maintain a laryngectomee volunteer-patient visitation program coordinated with medical professionals in local hospitals and clinics.

## SUPPORT GROUPS

Patients and their spouses should be encouraged to join the International Association of Laryngectomies (IAL) and the American Cancer Society (ACS). The IAL is a voluntary, nonprofit, organization dedicated to total rehabilitation of laryngectomees. The purpose of the IAL is to facilitate the formation of new laryngectomee clubs, foster improvement of hospital laryngectomee visitor programs, and upgrade standards for teachers of alaryngeal speech. The IAL provides educational support to more than 200 member clubs located throughout the United States, Canada, Europe, South America, Asia, and Australia. The IAL publishes *IAL News*, conducts an annual meeting, and sponsors an annual Voice Rehabilitation Institute. The Voice Rehabilitation Institute is attended by laryngectomees and speech pathologists for alaryngeal speech instructor training. The IAL publishes a directory of certified alaryngeal speech instructors. It can be contacted at International Association of Laryngectomies, 7822 Ivymount Terrace, Potomac, MD 20854; 301-983-9323; <http://www.larynxlink.com>.

The various geographic, state divisions, and local units of the ACS assist IAL member clubs and sponsor field work of benefit to laryngectomees. Some ACS offices are able to lend equipment and other types of support. The ACS can be contacted at 1599 Clifton Road NE, Atlanta, GA 30329; 404-320-3333.

The American Speech-Language-Hearing Association (ASHA) is a professional organization that oversees certification of speech pathologists and audiologists. ASHA defines position statements and guidelines for practice standards within the profession. Several policy statements are related to the management of head and neck cancer patients and to instrumental diagnostic procedures for swallowing and evaluation and treatment of tracheoesophageal fistulization and puncture. ASHA can provide patients and their families with speech pathology resources in their area. ASHA can be contacted at 10801 Rockville Pike, Rockville, MD 20852; 1-800-638-6868; or <http://www.asha.org>.

## INTRODUCTION

Lung cancer cells have accumulated a number of molecular genetic and epigenetic lesions, which appear necessary to transform normal bronchial epithelium to an overt lung cancer. There is complex interaction between the various molecular changes that ultimately result in the abrogation of key cellular regulatory and growth control pathways. Of the three major classes of human “cancer” genes, the protooncogenes and tumor suppressor genes (TSGs) are involved in lung carcinogenesis, whereas evidence implicating DNA repair genes is not yet conclusive. Many of the protooncogene and TSG changes are present in both major lung cancer subtypes: small cell lung cancer (SCLC) and non-small cell lung cancer (NSCLC), although certain mutations have subtype specificity ( [Table 31.1-1](#)). Protooncogenes generally encode proteins that are positive effectors of the transformed phenotype and can simplistically be considered positive growth regulators. Their “activation” results in their functional deregulation, leading to a gain in function or “dominant” effect. Conversely, TSG products are negative growth regulators and their “inactivation” results in a loss of function that contributes to malignancy. Interacting with yet other biologic changes, these fundamental molecular events appear to underlie the characteristics of dysregulated growth, clonal expansion, and immortality, which are typical of overt lung cancers. In addition, these, and yet other to be discovered molecular changes, may affect the processes of invasion, metastasis, and resistance against cancer therapy. In translating these laboratory discoveries into the clinic, it is important to identify these various changes, determine the frequency of occurrence, and test whether they have clinically important associations (e.g., with histologic type, stage, survival, response to therapy), as well as to determine if they could be used for early diagnosis, to monitor prevention and treatment efforts, and as targets for the development of new treatments. In addition, these abnormalities will probably also give us important understanding about lung development and differentiation.

	Small Cell Lung Cancer	Non-Small Cell Lung Cancer
Microsatellite instabilities	~55%	~22%
Asymmetric loops	GRP/GRP receptor	TGF- $\alpha$ /EGFR; Herceptin/HER2/neu
RAS point mutation	SCF/RET	HGF/MET
MYC family overexpression	<1%	15–20%
p53 inactivation	15–50%	5–10%
RB inactivation	~90%	~50%
p16 <sup>INK4A</sup> inactivation	~90%	15–30%
FHIT inactivation	0–10%	80–90%
Frequent allelic loss	~75%	~50–75%
	3p, 4p, 4q, 5q, 8p, 10q, 13q, 17p, 22q	3p, 4q, 8p, 9p, 13p, 17p, 19q
Telomerase activity	~100%	80–85%
BCL2 expression	75–85%	10–55%

EGFR, epidermal growth factor receptor; FHIT, fragile histidine triad; GRP, gastrin-releasing peptide; HGF, hepatocyte growth factor; RB, retinoblastoma protein; SCF, stem cell factor; TGF- $\alpha$ , transforming growth factor- $\alpha$ .

TABLE 31.1-1. The Most Frequent Acquired Molecular Abnormalities in Lung Cancer

## GENETIC AND EPIGENETIC ALTERATIONS IN LUNG CANCERS

### CHROMOSOMAL ABNORMALITIES

Lung cancer cells display numerical abnormalities (aneuploidy) of chromosomes, which are suggestive of allele loss or gain, as well as structural cytogenetic abnormalities. The latter include nonreciprocal translocations and deletions, whereas the presence of double minutes and homogeneously staining regions indicate gene amplification, such as for the *MYC* gene family.<sup>1</sup> In SCLCs, losses from chromosomes 3p, 5q, 13q, and 17p predominate, but double minutes may be common late in disease. In NSCLCs, deletions of 3p, 9p, and 17p, together with +7, i(5)(p10), and i(8)(q10) are often seen. Molecular cytogenetic analysis with comparative genomic hybridization has identified hitherto unrecognized abnormalities, including deletions at 10q26, 16p11.2, and 22q12.1-13.1 and amplification at 1q24, 3q, 5p, 17q, and Xq26.

It has been proposed that human tumors may be genetically unstable at two levels: at the chromosomal level, including losses and gains (amplification), and at the DNA nucleotide level, including single or several base changes.<sup>2</sup> It will thus be important to determine if aneuploidy and structural cytogenetic abnormalities, apart from targeting key genes, actually represent the phenomenon of chromosomal instability in lung cancers.

### MICROSATELLITE INSTABILITY

A genetic change that manifests itself as a mutator phenotype (often called the *replication error repair phenotype*) in human cancers results in widespread microsatellite instability. The result of microsatellite instability is a “laddering” of short-tandem DNA repeat sequences at multiple loci seen on high-resolution polyacrylamide electrophoretic gels. This phenotype is usually due to mutational inactivation of DNA mismatch repair enzymes, resulting in marked instability of these polymorphic DNA repeat sequences. This phenotype was initially reported in hereditary nonpolyposis colon cancers. Lung cancer frequently exhibits microsatellite instability; however, this occurs at only a few loci and results only in “shifts” of individual allelic bands (“microsatellite alterations”) compared to normal DNA in the same patient. The abnormal mechanism underlying this phenotype is currently unknown, and apparently mutations in DNA mismatch repair enzymes are very uncommon in lung cancer. The human 8-oxoguanine DNA glycosylase (*hOGG1*) gene, involved in the repair of oxidative DNA damage, is another candidate for involvement in generating multiple lung cancer mutations. However, abnormalities in this gene only rarely occur in lung cancer, and mutations in other DNA repair genes have not yet been reported in lung cancer. Overall, approximately 35% (37 of 106) of SCLCs and 22% (160 of 727) of NSCLCs showed some examples of microsatellite alterations at individual loci.<sup>3</sup> Microsatellite alterations in lung cancer have been reported to be associated with younger age, reduced survival, and advanced tumor stage. Regardless of the underlying mechanism, many groups are testing the possibility of using this microsatellite alteration phenotype for the early

diagnosis of lung cancer by detecting these shifted DNA bands in sputum, bronchial washings, or blood.

## ABERRANT DNA METHYLATION

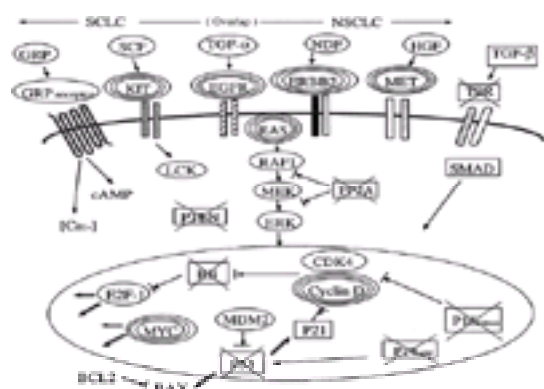

DNA methylation involves covalent modification at the fifth carbon position of cytosine residues within CpG nucleotides of DNA, which tend to be clustered around the 5' ends of many housekeeping genes (CpG islands). Hypermethylation in the 5' promoter region of genes is associated with transcriptional silencing and is an alternative mechanism for down-regulating TSG expression rather than gene deletion or mutation.

Hypermethylation of the promoter region of the *p16<sup>INK4A</sup>* gene in a subset of NSCLCs results in its down-regulation and may be an early event in lung cancer pathogenesis.<sup>4</sup> Other genes also have been found to undergo aberrant promoter methylation in lung cancer but are not found in the normal lung associated with these tumors, including *DAF* (death associated protein) kinase, *GSTP1* (glutathione S-transferase), and *MGMT* (*O*<sup>6</sup>-methylguanine-DNA-methyltransferase).<sup>5</sup> In addition, DNA containing these methylated sequences could be detected in the corresponding blood samples from the same patients, indicating that the tumor cells had shed DNA into the peripheral blood. Thus, aberrantly methylated DNA sequences, which can be sensitively detected among a background of normal DNA, represent an attractive strategy for early molecular detection. Other sites of hypermethylation, including 3p, 4q34, 10q26, and 17p13, have been implicated in lung cancer pathogenesis, although the precise gene targets are uncertain. In addition to use as an early detection target, it may be possible to reverse methylation pharmacologically. In tissue culture systems, this is routinely done with the demethylating agent 5-aza-2'-deoxycytidine. Clinical trials with such agents have been attempted in other diseases, and agents with less toxicity need to be developed and tested in lung cancer.

Another acquired tumor abnormality is loss of imprinting (loss of methylation) to allow the expression of genes in lung cancer. Methylation plays a role in mediating genomic imprinting, which is a gamete-specific modification causing differential expression of the two alleles of a gene in somatic cells. Loss of genomic imprinting of the insulin-like growth factor-2 (*IGF-2*) gene and the *H19* gene (associated with hypomethylation of its promoter region) also occurs in lung cancer.

## PROTOONCOGENES AND GROWTH STIMULATION

The activation of protooncogenes requires mechanisms such as gene amplification or point mutation of a single allele leading to constitutive overexpression. In some cases, however, the mechanisms causing overexpression are still unclear. Protooncogene products include several growth factor receptors, such as epidermal growth factor receptor (EGFR), ERBB2, KIT, and MET. Indeed, many growth factor/receptor systems are expressed by either the lung tumor or adjacent normal cells, thus providing autocrine or paracrine growth stimulatory loops (Fig. 31.1-1). For example, overexpression of the EGFR encoded by the *ERBB1* gene is more common in NSCLC than SCLC and may be related to tumor stage and differentiation. Coexpression of EGFR and their ligands, especially transforming growth factor- $\alpha$  (TGF- $\alpha$ ), by lung cancer cells indicates the presence of an autocrine (self-stimulatory) growth factor loop. Overexpression of EGFR occurred in 70% of NSCLCs, and overexpression of both EGFR and TGF- $\alpha$  occurred in 38%.<sup>6</sup> Clinically, the presence of this loop had no significant impact on overall survival in early-stage NSCLCs and thus seems to play a role in lung tumor formation rather than tumor progression.<sup>6</sup> ERBB2 (HER2/neu) is highly expressed in more than one-third of NSCLCs, especially adenocarcinomas. Its expression correlates with a shorter survival in lung adenocarcinomas and may also be a marker for intrinsic multidrug resistance in NSCLC cell lines.<sup>7</sup> KIT and its ligand, stem cell factor (SCF), are both preferentially expressed in many SCLCs. Activation of this putative autocrine loop may provide a growth advantage, or it may mediate chemoattraction. The SCF/KIT signal transduction pathway has been shown to be associated with Lck, a src-related tyrosine kinase.<sup>8</sup> MET and its ligand, hepatocyte growth factor (HGF), are involved in fetal lung development. Coexpression of this putative loop is observed in most NSCLCs, and high HGF levels were associated with a poor outcome in resectable NSCLC patients.<sup>9</sup> There are several clinical applications of these growth factor receptor abnormalities that have occurred in other cancers, which also need to be explored as new treatments for lung cancer. These include treatment with humanized monoclonal anti-HER-2/neu receptor antibody Herceptin alone or in combination with chemotherapy, treatment with monoclonal anti-EGF receptor antibody combined with radiotherapy, and new drugs that would inhibit the tyrosine kinase activity of these receptors.

**FIGURE 31.1-1.** The common growth stimulatory and inhibitory cascades involved in lung cancer cells. A *single circle* denotes growth stimulatory molecules, and *multiple circles* denote activation caused by some tumor-acquired abnormality. A *box* denotes growth inhibitory molecules, whereas their inactivation is indicated by a cross within the box, again acquired (for example) by mutation in the tumor. *Double arrows* indicate transcriptional activation of target genes that regulate cell growth. cAMP, cyclic adenosine monophosphate; CDK4, cyclin-dependent kinase-4; EGFR, epidermal growth factor receptor; ERK, extracellular regulated kinase; GRP, gastrin-releasing peptide; HGF, hepatocyte growth factor; NSCLC, non-small cell lung carcinoma; RB, retinoblastoma protein; SCF, stem cell factor; SCLC, small cell lung carcinoma; TGF- $\alpha$ , transforming growth factor- $\alpha$ .

Apart from protooncogene products, other growth stimulatory loops are found in lung cancer. The best known is that governed by gastrin-releasing peptide (GRP) and other bombesin-like peptides, together with their receptors, which participates in lung development and repair as well as promoting SCLC growth via an autocrine loop. This loop represents a future therapeutic target because a clinical trial of an anti-GRP monoclonal antibody showed some antitumor activity in patients with previously treated SCLC.<sup>10</sup>

Because downstream effectors are needed to transduce incoming growth factor/receptor signals to the nucleus, it is not surprising that cytoplasmic signal transduction cascades are also implicated in carcinogenesis. For instance, the receptor tyrosine kinases initially signal the guanosine triphosphate-binding RAS protein. The RAS gene family (*KRAS*, *HRAS*, and *NRAS*) can be activated by point mutations at codons 12, 13, or 61, and one member of this family is mutated in approximately 20% to 30% of NSCLC (particularly adenocarcinomas) but probably never in SCLC.<sup>11</sup> *KRAS* accounts for 90% of the RAS mutations in lung adenocarcinomas, with approximately 85% of the *KRAS* mutations affecting codon 12. Characteristically, approximately 70% of *KRAS* mutations are G to T transversions, with the substitution of the normal glycine (GGT) with either cysteine (TGT) or valine (GTT). Similar G to T transversions also affect the *P53* gene in lung cancer and represent the type of DNA damage expected from bulky DNA adducts caused by the polycyclic hydrocarbons and nitrosamines in tobacco smoke. Further evidence for a causative role for tobacco smoke is the correlation of *KRAS* mutations with cigarette consumption. The presence of *KRAS* mutations portends a poor prognosis in both early- and late-stage NSCLCs,<sup>12</sup> although the data conflict.<sup>13</sup> Nonetheless, a metaanalysis of eight studies of 217 (of 881) NSCLC patients positive for *KRAS* mutations suggested a negative prognostic role.<sup>14</sup> A prospective study has shown that neither chemosensitivity or survival correlated with *KRAS* mutation in advanced lung adenocarcinomas.<sup>15</sup> New drugs, farnesyltransferase inhibitors, were developed to specifically kill or inhibit the growth of tumor cells with RAS mutations. However, these drugs appear to be active against tumors with and without RAS mutations and are coming into clinical trials against lung cancer.

A direct downstream effector of RAS is the *RAF1* protooncogene product. Unexpectedly, the experimental growth arrest of SCLC by activated *RAF1* suggests that it has more of a TSG function.<sup>16</sup> Although one copy of *RAF1* is frequently lost; however, mutations in the *RAF1* gene have not been detected in human lung cancers. Molecules downstream of *RAF1* in the signal transduction pathway, such as MEK, MEK, and mitogen-activated protein kinase/extracellular-regulated kinase (MAPK/ERK), may also be involved occasionally in lung carcinogenesis.<sup>3</sup> The *PPP2R1E* gene, encoding the beta isoform of protein phosphatase 2A (PP2A), which regulates the RAS/MAPK cascade, is also infrequently mutated in lung cancers.<sup>17</sup>

Ultimately, signal transduction cascades result in the activation of nuclear protooncogene products such as those encoded by the *myc* family genes (*MYC*, *MYCN*, *MYCL*). *MYC*, when heterodimerized with a protein called MAX, functions as a transcription factor, necessary for normal cell-cycle progression, differentiation, and programmed cell death. *MYC* is most frequently activated via gene amplification or transcriptional dysregulation in both SCLC and NSCLC, whereas abnormalities of

*MYCN* and *MYCL* generally occur in SCLC. Indeed, *MYCL* was originally isolated from a SCLC cell line. The *myc* family gene amplification has been differentially observed in the major lung cancer subtypes. In SCLC, one member of the *MYC* family was amplified in 18% of tumors and 31% of cell lines, compared to 8% of NSCLC tumors and 20% of cell lines, respectively.<sup>11</sup> Amplification appears more frequent in patients previously treated with chemotherapy, the “variant” subtype of SCLC, and its presence correlates with adverse survival. In terms of therapy, all-*trans*-retinoic acid (RA) treatment inhibited the *in vitro* growth of a SCLC cell line overexpressing *MYC*, a process associated with increased neuroendocrine differentiation and increased *MYCL* and decreased *MYC* expression.<sup>18</sup> Lastly, there also have been reports of *MYCL* amplification with rearrangement in which *MYCL* fuses to the *RLF* gene causing a chimeric protein.<sup>19</sup>

Occasional reports have implicated other oncogenes, such as *ERBA*, *MYB*, *JUN*, and *FOS* in lung cancer, but data are relatively few.

## TUMOR SUPPRESSOR GENES AND GROWTH SUPPRESSION

### p53 PATHWAY

p53 (or TP53) maintains genomic integrity in the face of cellular stress from DNA damage (for example caused by  $\gamma$ - and UV irradiation, carcinogens, or chemotherapy). It functions as a transcription factor to activate the expression of genes that control cell-cycle checkpoints (e.g., *p21<sup>WAF1/CIP1</sup>*), apoptosis (*BAX*), DNA repair (*GADD45*), and angiogenesis (thrombospondin). The *p53* gene is the most frequently mutated TSG in human malignancies, and mutations affect approximately 90% of SCLCs and 50% of NSCLCs.<sup>20,21</sup> Most mutations occur in the evolutionarily conserved p53 exons 5 to 8. In NSCLCs, p53 alterations occurred more frequently in squamous cell (51.2%) and large cell (53.7%) carcinomas than adenocarcinomas (38.8%).<sup>21</sup> p53 mutations correlate with cigarette smoking and most are of the type of G to T transversions expected from tobacco smoke carcinogens. More evidence linking smoking damage with p53 mutations is the finding that a major cigarette smoke carcinogen, benzo(a)pyrene, selectively forms adducts at the p53 mutational hot spots.<sup>22</sup> The types of p53 mutations are varied and include missense, nonsense, and splicing abnormalities as well as larger deletions. Missense mutations (the most common type of mutation) often prolong the half-life of the p53 protein to several hours, leading to increased levels detectable by immunohistochemistry and thus the use of immunohistochemistry as a surrogate assay for p53 mutation.<sup>23</sup> Whether the occurrence of p53 mutations (detected by either immunohistochemistry or molecular analysis) in a patient's tumor affect survival is controversial.<sup>24</sup> Approximately 15% of lung cancer patients develop antibodies to the p53 protein, raising the possibility that mutant p53 protein overexpression can lead to a humoral immune response. Although p53 antibodies have been proposed as a marker for early diagnosis<sup>25</sup> and chemoresponsiveness,<sup>26</sup> the development of these antibodies does not appear to improve prognosis in lung cancer.<sup>27</sup> There have been several promising gene therapy clinical trials with objective response rates of approximately 10% to 15% in which lung cancers are treated by intratumoral injection [endobronchially, or by computed tomography (CT)-guided needle injection] with a normal (wild-type) p53 gene using retroviral<sup>28</sup> or adenoviral vectors.<sup>29</sup> These local injections are now being combined with chemo- and radiotherapy to test if gene therapy increases sensitivity to conventional treatments. Also, systemic methods (such as with lipid vesicles) of delivering p53 gene therapy to disseminated tumors are being developed. In another approach, clinical trials are being conducted to immunize patients against either mutant p53 or RAS proteins occurring in patients' tumors in attempts to generate a tumor-specific cytotoxic T-cell response.

p53 functions in a biochemical pathway; thus it is reasonable to consider that other components of this pathway may be mutated in lung tumors that are wild-type for p53. One of the upstream components is the kinase that phosphorylates p53 encoded by the ataxia telangiectasia (*ATM*) gene. However, this gene has not yet been found to be mutated in lung cancer. Other components are the *MDM2* and *p14<sup>ARF</sup>* genes (see *p16<sup>INK4A</sup>*, later in this chapter), which regulate the levels of p53 protein, but so far they have not been implicated in lung cancer. Two proteins homologous to p53—p51 and p73—have been discovered, leading to the hypothesis that they may be mutated in p53 wild-type tumors. However, they are only infrequently, if ever, mutated in lung cancers. Finally, the Li-Fraumeni syndrome of inherited susceptibility to cancer determined by an inherited germline mutation of p53 may also lead to increased susceptibility to lung cancer in adults in these pedigrees.

### THE p16<sup>INK4A</sup>-CYCLIN D1-CYCLIN-DEPENDENT KINASE-4-RETINOBLASTOMA PROTEIN PATHWAY

#### p16<sup>INK4A</sup>

The p16<sup>INK4A</sup>-cyclin D1-cyclin-dependent kinase-4 (CDK4)-retinoblastoma (RB) protein pathway is a key cell-cycle regulator at the G<sub>1</sub>/S phase transition, and one of the components of this pathway is abnormal in the majority of lung cancers. The activation of CDKs by cyclins eventually leads to the phosphorylation (inactivation) of the growth-suppressive RB protein (see [Fig. 31.1-1](#)). As p16<sup>INK4A</sup> is an inhibitor of CDKs, especially CDK4 or CDK6 (which phosphorylate and keep RB in an “inactive” state), its normal role is to positively regulate RB's growth-controlling function by keeping RB unphosphorylated. However, if p16<sup>INK4A</sup> is inactivated by mutation, RB remains chronically phosphorylated and thus cannot function to regulate growth (see [Fig. 31.1-1](#)).

The p16<sup>INK4A</sup> (also called *CDKN2*) gene locus on chromosome 9p21 is frequently abnormal in human malignancies. In lung cancer, p16<sup>INK4A</sup> abnormalities are frequent in NSCLC but rare in SCLC (in which, by contrast, *RE* is mutated in 90% of cases). Thus, these two major histologic lung cancer types have this pathway inactivated by mutation of one or the other gene, and double mutants in the same tumor are very rare. A summary of 20 studies showed that p16<sup>INK4A</sup> point mutations in NSCLCs were observed in only 14% of primary tumors.<sup>3</sup> However, homozygous deletions or aberrant promoter methylation can also down-regulate p16<sup>INK4A</sup>. Indeed, aberrant methylation of p16<sup>INK4A</sup> may be the most frequent as well as an early preneoplastic event in the pathogenesis of squamous cell carcinomas.<sup>4</sup> Taken together, these mechanisms ultimately result in absent p16<sup>INK4A</sup> expression in approximately 40% of primary NSCLCs,<sup>3</sup> indicating that this may be the most common way to inactivate the p16<sup>INK4A</sup>-cyclin D1-CDK4-RB pathway in NSCLC. Because of the frequency of the abnormalities, p16<sup>INK4A</sup> is an attractive clinical trials candidate for replacement gene therapy or induction of re-expression with antimethylation drug therapy.

Complicating matters is the discovery of an alternative reading frame at the p16<sup>INK4A</sup> locus, p14<sup>ARF</sup>, which encodes a protein that binds p53/MDM2 complex, leading to p53 protein stabilization. If p14<sup>ARF</sup> is missing because of mutations in the p16 locus, p53 is less stable and its function diminished. It thus emerges that inactivation of the p53 pathway may also be triggered by abnormalities of the p16<sup>INK4A</sup> gene locus. Another CDK inhibitor gene, p15<sup>INK4B</sup> is situated close to p16<sup>INK4A</sup> and can be co-deleted with p16<sup>INK4A</sup> in NSCLC. However, it appears that the majority of lung cancer abnormalities focus on p16<sup>INK4A</sup> and not on p15<sup>INK4B</sup>.

#### Cyclin D1 and Cyclin-Dependent Kinase-4

Because cyclin D1/CDK4 complex inhibits RB activity by stimulating its phosphorylation, cyclin D1 or CDK4 overexpression is an alternative way to disrupt this pathway. Immunohistochemically, cyclin D1 is overexpressed in 12% to 47% of primary NSCLCs and, in some cases, cyclin D1 overexpression is associated with a poor prognosis.<sup>30</sup> How this overexpression occurs in lung cancer is unknown.

#### Retinoblastoma Protein

The RB gene (*RB*), located at chromosomal region 13q14, encodes a growth-suppressive nuclear phosphoprotein. When active (i.e., hypophosphorylated), RB binds and inactivates proteins such as transcription factor E2F-1, which is essential for G<sub>1</sub>/S transition of the cell cycle (see [Fig. 31.1-1](#)). *RE* mutations (truncation by deletion, nonsense mutation, or splicing abnormalities), together with loss of the wild-type *RE* allele, have been demonstrated in lung cancers, particularly SCLC. The RB protein is absent or structurally abnormal in more than 90% of SCLCs and 15% to 30% of NSCLCs.<sup>31</sup> Absent RB expression may be associated with poor prognosis in NSCLCs, although this is not a consistent finding. The relatively low frequency of *RE* abnormalities in NSCLC is consistent with the frequent disruption of the p16<sup>INK4A</sup>-cyclin D1-CDK4-RB pathway in these histologic types. Essentially, lung cancers can be characterized as having either *RE* mutation (mostly SCLC) or p16<sup>INK4A</sup> inactivation (mostly NSCLC). Gene therapy with replacement of RB function has been considered, but because of the large size of the *RB* coding region and the necessity for systemic delivery in, for example, typical widely metastatic SCLCs, such therapy has not been actively pursued. Mutations of two other *RE* related genes, *p107* and *RB2/p130*, also have been implicated in lung cancer. In the case of RB2, loss of protein expression and restoration of growth control by genetically re-introducing a normal copy of *RB2* have been demonstrated.<sup>32</sup> Finally, retinoblastoma patients or their relatives who carry a mutant *RE* in the germline have an excess risk of developing small cell lung cancer if they survive into adult life.<sup>33</sup>

### PTEN, FHIT, RAR- $\beta$ , PUTATIVE 3P TUMOR SUPPRESSOR GENES, AND OTHER TUMOR AND GROWTH-SUPPRESSIVE GENE SITES IN LUNG CANCER PATHOGENESIS

Besides the p53, p16<sup>INK4A</sup>, *RB*, and loci, cytogenetic and allelotyping studies show nonrandom, hemiallelic loss at many other chromosome regions in lung cancer. Such tumor-specific somatically acquired loss of heterozygosity is a hallmark feature of traditional TSG inactivation. In other words, the consistent identification of

multiple sites of loss of heterozygosity at various chromosomal regions suggests the existence of underlying TSGs in these regions. Usually the remaining allele is silenced by point or small mutations, epigenetic hypermethylation of the promoter region or, less frequently, by a larger deletion. These sites of allele loss have been defined at more than 30 regions dispersed on 21 different chromosomal arms, although the molecular targets of most of these sites is not known.<sup>34</sup> Although several of these chromosomal arms contain known TSGs, including *VHL* (3p25), *APC* (5q21), *WT1* (11p13), *DCC* (18q21), and *NF2* (22q12), these genes are not known to be mutated in lung cancer. The TSG *PTEN*, which encodes a phosphatase, is located at chromosome region 10q23, another common area of allele loss in lung cancer. However, *PTEN* is mutated in only a subset of lung cancers.<sup>35</sup> Frequent loss (60% to 80%) of several 4p and 4q regions were found in thoracic malignancies (particularly SCLC and mesotheliomas); however, the genes involved are not yet known.<sup>36</sup>

Among these chromosomal locations, chromosome 3p allele loss (occurring at more than four different 3p regions) stands out as a very frequent and early event in lung cancer pathogenesis. 3p loss occurs in more than 90% of SCLCs and more than 80% of NSCLCs. In addition, it appears to be the earliest genetic change found in lung cancer development, occurring at great frequency in patches of normal epithelium accompanying lung cancer or in smokers, as well as in sites of hyperplasia, dysplasia, and carcinoma *in situ* of respiratory epithelium (see [Molecular Changes in Preneoplasia](#), later in this chapter). Multiple distinct 3p regions have been identified by allelotyping, including 3p25-26, 3p21.3-22, 3p14, and 3p12. Furthermore, homozygous deletions are found in several lung cancer cell lines (at several 3p21.3 sites, as well as at 3p12 and 3p14.2). Several candidate TSGs have been identified in an approximately 600-kilobase 3p21.3 region homozygously deleted in three SCLCs, and another 800-kilobase deletion region at 3p21 also has been described.<sup>37,38</sup> The *FHIT* (fragile histidine triad) gene is found in the 3p14.2 homozygous deletion region. Forty percent to 80% of lung cancer cells express abnormal *FHIT* messenger RNA transcripts but paradoxically almost always also express wild-type *FHIT* transcripts.<sup>39</sup> Regardless of these molecular complexities, the FHIT protein is absent in many lung cancers, particularly in the squamous cell type (87%) compared to adenocarcinoma (57%) and may also be lost in some preneoplastic lesions. The loss of FHIT protein expression is also strongly associated with smoking.<sup>40,41</sup> Functionally, FHIT may be involved in the regulation of apoptosis and in cell-cycle control.<sup>42</sup> Transfection of wild-type *FHIT* into lung cancers induces apoptosis and blocks tumor formation *in vivo* in mouse models.<sup>43,44</sup> Because of the occurrence of *FHIT* abnormalities early in lung cancer pathogenesis (e.g., in preneoplastic stages), it is possible to consider delivering *FHIT* gene therapy to airways containing multiple preneoplastic lesions by using aerosols.

TGF- $\beta$ 1 is a potent inhibitor of proliferation of most epithelial and hematopoietic cells, and its signal is mediated through TGF- $\beta$  receptors and subsequently SMAD proteins. In SCLC cells, down-regulation of the type II receptor (TGF $\beta$ -RII) located in chromosome region 3p, has been shown to correlate with the resistance to growth inhibition by TGF- $\beta$ 1.<sup>45</sup> However, the TGF $\beta$ -RII or SMAD family genes are rarely mutated in lung cancer.

There is considerable evidence of dysfunction of retinoic acid receptor beta (RAR- $\beta$ ), located in chromosome region 3p24, in lung cancers, leading to resistance of lung cancer cells to retinoids and making it an excellent candidate 3p TSG.<sup>46</sup> Although initial studies did not find RAR- $\beta$  mutations, more recent studies have shown loss of expression of RAR- $\beta$  protein in approximately 50% of clinically overt lung cancers.<sup>47</sup> It is quite likely that this loss of expression without genomic changes occurs because of methylation of the promoter region. Because of the widespread testing of retinoids as chemoprevention agents, it will be important to characterize the timing of loss of RAR- $\beta$  function in lung cancer preneoplasia. It is possible that loss of expression of RAR- $\beta$  may occur at such an early stage that chemoprevention with retinoids cannot succeed.

## OTHER BIOLOGIC ABNORMALITIES FOR LUNG CANCER DEVELOPMENT

### TELOMERASE ACTIVITY

During normal cell division, telomere shortening leads to cell senescence and thus governs normal cell "mortality." Telomeres are maintained in normal stem cells by the enzyme telomerase. However, with abnormal expression of the enzyme in, for example, tumors, telomerase has been implicated in contributing to human cell immortalization and cancer cell pathogenesis. Telomerase is a ribonucleoprotein complex, and ectopic expression in tumors of its catalytic subunit, human telomerase reverse transcriptase, appears critical for the cellular immortalization typical of cancer cells. Using the highly sensitive telomere replication amplification protocol assay, approximately 100% of SCLCs and 80% to 85% of NSCLCs were demonstrated to express high levels of telomerase activity. High telomerase activity was associated with increased cell proliferation rates and advanced stage in NSCLCs.<sup>48</sup> Further tests must be performed to conclusively demonstrate that true telomerase-negative NSCLCs exist. If these telomerase-negative tumors truly exist, debulking therapy with surgery and radiotherapy should be considered, even for metastatic disease. It would be predicted that eventually such tumors would "senesce" and stop growing when their telomeres got too short. Telomerase activity and expression of its RNA component are also dysregulated in carcinoma *in situ* lesions associated with lung cancer, indicating that the timing of telomerase activation for lung cancer development can occur in preneoplasia.<sup>49</sup> Because of the nearly ubiquitous expression of telomerase in human tumors, including lung cancer, there is much interest in developing anti-telomerase drugs as new therapeutics.

### APOPTOSIS

Unlike normal cells, tumors have acquired the ability to escape from programmed cell death (apoptosis), which usually occurs under adverse conditions such as DNA damage. In addition to p53, other molecules of the complex apoptotic signaling pathways are abnormal in lung cancer cells. For example, the anti-apoptotic gene, *BCL2*, can be abnormally overexpressed in SCLCs (75% to 95%) and some NSCLCs (25% to 35% of squamous cell carcinoma and an approximately 10% of adenocarcinoma). Because of the potent role *BCL2* plays in suppressing apoptosis and thus also in inhibiting responses to chemotherapy and radiotherapy, there is considerable ongoing effort to develop antisense *BCL2* therapeutics, which are entering clinical trials. Also, extracellular matrix proteins may protect SCLC against chemotherapy-induced apoptosis via  $\beta_1$  integrin-stimulated tyrosine kinase activation.<sup>50</sup> In addition, Fas (CD95) and its ligand (FasL), which play key roles in the initiation of one apoptotic pathway, also have been implicated in lung cancer.<sup>51</sup> In this case, lung cancers express Fas ligand but not the receptor, whereas T cells express the receptor. In this way, lung cancers could cause the clonal deletion of immune T cells that were directed against lung cancer antigens and thus provide a mechanism for escape from immune surveillance.

### METASTASIS AND ANGIOGENESIS

Many potential factors influencing metastasis from primary lung cancers have been studied, including cell adhesion molecules. For instance, reduced E-cadherin expression, which can occur by promoter hypermethylation, was associated with tumor dedifferentiation, increased lymph node metastasis, and poor survival in NSCLC patients.<sup>52</sup> Reduced  $\alpha_3$  integrin expression correlated with a poor prognosis of patients with lung adenocarcinoma.<sup>53</sup> Specific CD44 isoforms may be associated with lung cancer metastasis. Meanwhile, matrix metalloproteinases inducing stromal degradation may also be involved in lung cancer invasion: Gelatinase A expression was observed in approximately 50% of SCLCs and 65% of NSCLCs, and stromelysin-3 overexpression was detected in stromal elements of primary NSCLCs. Because of this expression, several ongoing clinical trials of matrix metalloproteinase inhibitors in the treatment of lung cancer are ongoing. Finally, multiple other as yet unidentified genes may also be involved in lung tumor progression and metastases, as evidenced by the development of additional allelic losses (at 2q, 9p, 18q, and 22q) in brain metastases compared to the primary NSCLCs in the same patients.<sup>54</sup>

Tumor angiogenesis is necessary for a tumor mass to grow beyond a few millimeters in size. Currently, angiogenesis is thought to be regulated by the balance of inducers and inhibitors that are released by both tumor cells and host cells. Vascular endothelial growth factor (VEGF) and basic fibroblast growth factor are two major angiogenesis inducers produced by human lung cancers.<sup>55</sup> Angiogenic CXC chemokines, such as interleukin-8, also have been implicated in lung cancer. Mutations in p53 lead to decreased expression of thrombospondin, a negative regulator of angiogenesis. Overall it is thought that lung cancers produce factors that stimulate angiogenesis and stop producing others that would inhibit this process. Thus, tumor angiogenesis has become a major new therapeutic target for lung cancer. Clinical trials with humanized recombinant anti-VEGF monoclonal antibody combined with chemotherapy in NSCLC are already ongoing. In addition, several new small molecules that inhibit the tyrosine kinase activity of the VEGF receptor(s) are entering clinical trials as new drugs.

## CARCINOGENS IN TOBACCO SMOKE AND GENETIC SUSCEPTIBILITY TO LUNG CANCER (GENETIC EPIDEMIOLOGY)

The major cause of lung cancer, of course, comes from smoking, and tobacco smoke contains many substances, including carcinogens, co-carcinogens, and tumor promoters. Among them, 20 carcinogens convincingly cause lung tumors in laboratory animals or humans and are likely to be involved in lung cancer induction.<sup>56</sup> The carcinogenic effects of tobacco smoke in the lung involve the induction of carcinogen-activating and inactivating enzymes, as well as covalent DNA adduct formation, which may cause DNA misreplication and mutation. DNA adducts have been identified in the bronchial tissue of lung cancer patients, and adduct levels correlate with the amount of tobacco smoke exposure. Of great importance is preventing children from starting to smoke. In this regard, it was found that, in former smokers, age at smoking initiation was inversely associated with DNA adduct levels.<sup>57</sup> Thus, after controlling for the amount of smoking, the earlier one started smoking, the worse the long-term damage. In addition, for reasons that are not yet clear, it appears that women are more susceptible to developing lung cancer from cigarette smoking than men.<sup>58</sup> Of the three major classes of carcinogens in tobacco smoke (polycyclic aromatic hydrocarbons, such as benzo[a]pyrene; nitrosamines; and aromatic amines),

much interest focuses on the nitrosamines, especially 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), partly because it induces tumors of the lung—primarily adenomas and adenocarcinomas—independent of the route of administration in mice.<sup>56</sup>

The finding that not every heavy smoker develops lung cancer has led to the concept of interindividual variation and the hypothesis that individuals may exhibit genetic polymorphisms in carcinogen-metabolizing pathways that determine individual lung cancer risk. Clearly, such genetic susceptibility operates in close interaction with smoking and other external carcinogenic factors (“gene-environment” interaction, with smoking being the primary environment factor). Among genes for carcinogen-metabolizing enzymes, polymorphisms in the cytochrome P-450 genes *CYP1A1*, *CYP2D6*, *CYP2E1* and in mu-class glutathione S-transferase (*GSTM1*) have received the most attention. Although studies have suggested that there may be a modest association of *GSTM1* null polymorphism with lung cancer,<sup>59</sup> studying single candidate genes may not be adequate to predict lung cancer risk due to complexity of carcinogen metabolism and gene-gene and gene-environment interactions.<sup>56</sup> In addition to carcinogens, it also appears that persons may inherit different susceptibility to become addicted to nicotine, for example, through polymorphisms in one of the dopamine receptors. Overall, molecular epidemiology, aided by DNA microarray technology together with the Human Genome Project, should in the near future help to identify individuals at highest risk of developing lung cancer. Such information will be of great value in new lung cancer screening trials (for example with spiral CT scans) and in chemoprevention trials.

## MOLECULAR CHANGES IN PRENEOPLASIA

Before clinically recognizable lung cancer develops, a series of morphologically distinct changes (hyperplasia, metaplasia, dysplasia, and carcinoma *in situ*) can be observed in the bronchial epithelium of smokers. It is felt that dysplasia and carcinoma *in situ* represent true preneoplastic (precancerous) changes. These sequential changes found with squamous cell cancers arising from central bronchi have long been recognized, whereas other changes in peripheral bronchioles and alveoli (adeno- and large cell cancers), such as adenomatous and alveolar hyperplasia, are more recently described.

It is now clear that preneoplastic cells contain several genetic abnormalities identical to some of the abnormalities found in overt lung cancer cells. Immunohistochemical analysis has confirmed abnormal expression of protooncogenes (cyclin D1) and TSGs (p53) in these lesions.<sup>60</sup> Allelotyping of precisely microdissected, preneoplastic foci of cells shows that 3p allele loss is currently the earliest known change, suggesting that one or more 3p TSGs may act as “gatekeepers” for lung cancer pathogenesis. This loss is followed by 9p allele loss, 8p allele loss, and 17p allele loss (and *p53* mutation) (Fig. 31.1-2).<sup>61</sup> Even the histologically normal bronchial epithelium adjacent to cancers has been shown to have genetic losses. Similarly, atypical alveolar hyperplasia, the potential precursor lesion of adenocarcinomas, also harbors *KRAS* mutations.<sup>62</sup> These observations are also consistent with the multistep model of carcinogenesis and a “field cancerization” process, whereby the whole tissue region is repeatedly exposed to carcinogenic damage (tobacco smoke) and is at risk for developing multiple separate foci of neoplasia. Although all types of lung cancers have associated molecular abnormalities in their normal and preneoplastic lung epithelium, small cell lung cancer patients in particular appear to have multiple genetic alterations occurring in their histologically normal-appearing respiratory epithelium. Molecular changes have been found not only in the lungs of patients with lung cancer but also in the lungs of current and former smokers without lung cancer.<sup>63,64</sup> These molecular alterations are thus important targets for use in the early detection of lung cancer and for use as surrogate biomarkers in following the efficacy of lung cancer chemoprevention. In this regard, it appears that the smoke-damaged lung has thousands of multiple clonal or subclonal patches of approximately 90,000 cells each in the respiratory epithelium containing clones of cells with 3p and other allele loss abnormalities.<sup>65</sup>

**FIGURE 31.1-2.** Timing of genetic changes found in preneoplastic lesions in respiratory epithelium, best studied to date in squamous cell lung carcinoma. Note that not every change is necessary, and the sequence may not always be the same. EGFR, epidermal growth factor receptor; RAR- $\beta$ , retinoic acid receptor beta.

## MOLECULAR TOOLS IN THE LUNG CANCER CLINIC

Our understanding of the molecular genetic changes in lung cancer pathogenesis is advancing rapidly. Some abnormalities also occur in other human cancers, whereas others appear more specific for lung cancer. Where their biochemical function is known, the proteins rendered abnormal appear to fall into several regulatory pathways. Thus, the “wiring” diagram of the lung cancer cell is becoming clear. There is a substantial effort to translate this current scientific knowledge of these abnormalities from the bench to the bedside. These approaches fall into four general categories:

1. Identification of persons at highest risk of developing lung cancer to enable chemoprevention and intensified smoking cessation efforts. In this regard, with improved methods of molecular identification of true precancerous lesions, our paradigm will become “treatment” of precancerous lesions rather than “chemoprevention.” Obviously, because this treatment would occur in individuals without clinically evident cancer, the treatments must have low toxicity and high risk-benefit ratios.
2. Early detection tools to identify primary and recurrent disease (e.g., polymerase chain reaction–based molecular methods for testing body fluids).<sup>5,66</sup> Again, such “early detection” of invasive but clinically occult disease would require careful analysis of risk-benefit ratios. Because only one out of ten cigarette smokers eventually develops lung cancer, the identification of persons with a genetic susceptibility to lung cancer should allow targeting and intensification of smoking cessation, early detection, and chemoprevention efforts. In this regard, the encouraging new information on spiral CT scanning for the early detection of lung cancer<sup>67</sup> should be greatly targeted and enhanced by combining radiologic screening with identification of genetic epidemiology markers and acquired respiratory genetic alterations to identify the individuals at highest risk.
3. Identification of prognostic biomarkers<sup>68</sup> that would also include markers that would predict the response to various therapies such as chemo- and radiotherapy.
4. The designing of new cancer-specific therapies based on knowledge of genetic abnormalities. This includes replacing mutant TSGs; developing drugs targeted against activated protooncogenes; interfering with autocrine or paracrine loops; and inhibiting angiogenesis, metastasis, and apoptotic pathways in cancer cells. Although new therapies may be dramatically effective, it is probably more reasonable to assume that they would complement rather than replace existing therapies.

## EPIDEMIOLOGY

### INCIDENCE

Lung cancer is among the most commonly occurring malignancies in the world and is one of the few that continues to show an increasing incidence. In the United States, lung cancer is the leading cause of cancer death in men, and it surpassed breast cancer as the leading cause of cancer death in women in the latter part of the 1980s.<sup>1</sup> In the year 2000, there will be approximately 164,100 new cases and approximately 156,900 deaths from this disease ( [Fig. 31.2-1](#)).

**FIGURE 31.2-1.** The age-adjusted cancer death rates for selected sites in males (**A**) and females (**B**) in the United States from 1930 to 1996. It appears that lung cancer deaths from smoking are leveling off in males but are continuing to rise in females. Data adjusted to the age distribution of the 1970 U.S. Census Population (U.S. National Center for Health Statistics and U.S. Bureau of the Census).

Excluding this malignancy, most developed countries have shown declines in death rates from cancer in the last 20 years. During the same period in countries such as the United States and Canada, the death rate from lung cancer increased more than threefold but, in the last 5 years, it has finally begun to decline. In developing countries, the death rate from lung cancer continues to accelerate. These changes appear to be affected significantly by the observed difference in smoking habits and cigarette tar levels in developed and developing countries.<sup>2</sup>

The incidence of lung cancer now exceeds 70 per 100,000 men in the United States. As we enter the twenty-first century, it is expected that the altered smoking habits of the nation's population during the last two decades and the decreased tar content of cigarettes consumed in the United States will lead to a further decline in lung cancer incidence.

### MORTALITY

In the United States, only 14% of patients who develop lung cancer survive 5 years. These mortality rates (>150,000/year) far exceed those of the acquired immunodeficiency syndrome epidemic. However, this survival rate has only slightly increased in the last two decades, and it appears unlikely that marked

improvements will occur in the near future. With the anticipated decreased incidence, however, it is hoped that the lung cancer epidemic, at least in developed countries, will abate and that the total number of deaths per year attributed to this cancer will decline even further.

## LUNG CANCER CONTROL

With the solid base of scientific information linking cigarette smoking habits to the development of lung cancer, many countries have launched programs to decrease tobacco use and educate the population. Included in these programs are legislative activity (e.g., increased taxes, smoke-free areas, banning tobacco advertisements), educational activities through mass media and schools, and interventional approaches (e.g., smoking-cessation clinics) targeted to groups at the highest risk for developing tobacco-related cancer. The greatest impact on decreased smoking habits appears to be the societal stigma directed at smokers. These activities have reduced the percentage of the U.S. population who smoke from a high of approximately 40% to approximately 30%. However, this decline has now leveled off. The only cohort that has demonstrated an increasing smoking habit in the United States is younger women. It is hoped, however, that with the societal pressures and the educational programs in developed countries, the incidence of smoking will continue to decrease. It is also hoped that a similar trend will occur in developing countries, where smoking activity continues to increase at present.<sup>3</sup>

## SMOKING

The epidemiologic data on smoking and lung cancer fulfill the following criteria for causal association: the consistency of results across studies, the strength of the relation and its specificity, the correct temporal sequence between exposure and disease, and the coherence of the association as evidenced by a dose-response relation.<sup>4</sup>

It has been estimated that 80% of lung cancer deaths among men (approximately 65,000 deaths per year) and 75% of lung cancer deaths among women (approximately 27,000 deaths per year) are attributable to smoking.<sup>5</sup> Mattson et al.<sup>6</sup> calculated that a 35-year-old man who smokes 25 or more cigarettes per day has a 13% risk of dying of lung cancer before the age of 75 years, a 10% chance of dying of coronary heart disease, and a 28% chance of dying of smoking-related disease.

There is clear evidence for a dose-response relation between smoking and lung cancer. The risk of lung cancer increases with the number of cigarettes smoked, years of smoking duration, earlier age at onset of smoking, degree of inhalation, tar and nicotine content, the use of unfiltered cigarettes, and passive smoking,<sup>4</sup> and it decreases in proportion to the number of years after smoking cessation.<sup>7</sup> These relationships to lung carcinogenesis are discussed in more detail in [Chapter 11](#) and are incontrovertible.<sup>8,9,10,11,12,13,14,15,16,17,18,19,20,21,22 and 23,24,27</sup>

## OCCUPATION

Increases in lung cancer risk accompany exposure to carcinogens, such as asbestos,<sup>28,29,30,31,32,33,34,35,36,37,38 and 39</sup> radon,<sup>40,41,42,43 and 44</sup> bis(chloromethyl)ether, polycyclic aromatic hydrocarbons, chromium, nickel, and inorganic arsenic compounds.<sup>25,26</sup> The association with occupational exposure to these agents appears to be independent of cigarette smoking.

## DIET

The role of dietary antioxidant micronutrients in the prevention of lung cancer is reviewed in [Chapter 23.3](#). The presumed mechanism leading to prevention of carcinogenesis by these nutrients is that antioxidant micronutrients, including carotenoids, vitamins C and E, and selenium, have an important role in scavenging free radicals produced endogenously and exogenously by tobacco smoke, solvents, and pollutants. Carotenoids and vitamins C and E trap free radicals and reactive oxygen molecules, whereas selenium is a component of antioxidant enzymes.<sup>45</sup> Analysis of the role of nutrients in the cause of lung cancer is confounded by methodologic problems and by the conflicting results of studies.<sup>45,46,47,48 and 49</sup> However, to date, chemoprevention studies have failed to have an impact on lung cancer incidence.<sup>50,51,52,53,54,55,56,57,58,59 and 60</sup>

## EVIDENCE FOR A GENETIC PREDISPOSITION

There is limited evidence that genetic factors may contribute to lung cancer risk. Variations in the metabolism of carcinogens have been implicated.<sup>61</sup> The pathways to create these toxic metabolites are genetically determined. The metabolism of the antihypertensive drug debrisoquin is genetically determined by a single gene. The metabolisms of many drugs and chemicals correlate with that of debrisoquin,<sup>61</sup> and this may also apply to carcinogenic components of cigarette smoke ([Table 31.2-1](#)), although this has not been proven for any one substance with respect to lung carcinogenesis.<sup>61,62,63,64 and 65</sup> Several approaches have been adopted to detect a genetic association: studies of familial clustering, studies of naturally occurring antigens, and studies of the metabolism of drugs. Studies of familial clustering have been interpreted as showing no substantial genetic predisposition.<sup>66,67 and 68</sup> Braun et al.<sup>66</sup> conducted a twin cohort study and found no genetic factors to be predictive of lung cancer. Highway et al.<sup>69</sup> observed that the allele K-ras occurred in 29% of non-small cell lung cancer (NSCLC) cases, compared with 15% of controls ( $P = .03$ ). Numerous other chromosomal abnormalities (rearrangements and deletions) are present in lung cancer. These abnormalities are thought to result from the effects of carcinogens or the genetic instability observed in malignant transformation.

Substance	Effect	Mutagen
<b>PARTICULATE PHASE</b>		
Nuclear fraction	C	Radicals
Benzo(a)pyrene	C	
Dibenz(a,h)anthracene	C

C, carcinogenic; M, mutagenic; TP, toxic products.

**TABLE 31.2-1.** Major Mutagens, Carcinogens, and Related Substances in Tobacco Smoke

Although the molecular and genetic events underlying the pathogenesis of lung cancer are an area of active investigation, no genetic abnormality has conclusively defined the risk of lung cancer. In NSCLC, the most frequently identified abnormalities are deregulation of tumor suppressor gene p53, aberrant expression of the epidermal growth factor receptor (EGFR) and one of its ligands, and the presence of K-ras abnormalities in adenocarcinoma (discussed in [New Potential Prognostic Markers](#)).<sup>70,71,72,73 and 74</sup>

## APPLICATIONS OF ADVANCES IN LUNG CANCER BIOLOGY TO CLINICAL PRACTICE

Advances in our understanding of the biology of lung cancer have the potential to affect all areas of lung cancer management. The identification of specific mutations related to tobacco exposure has elucidated the possible molecular foundation for the association of cigarette smoking and lung cancer and may allow us better to identify at-risk people for chemoprevention programs. The presence of autocrine growth factor receptors, specific mutations, or chromosomal deletions may provide additional or more accurate means for diagnosing, staging, choosing therapies, and establishing prognosis for patients with lung cancer. The presence of K-ras point mutations has been shown to be associated with a shortened survival in patients with completely resected NSCLC.<sup>72</sup> Clinical trials targeting adjuvant therapies for patients with resected NSCLC with K-ras point mutations are in progress. Monoclonal antibodies or other drugs blocking the action of epidermal growth factor are in clinical trials.<sup>75,76</sup> The activation of cellular receptors for virtually all autocrine growth factors involves the activation of a protein kinase.<sup>77</sup> This observation has given us a new therapeutic target, and the search for agents specifically inhibiting this enzyme is under way. The mutated sequences of p53 provide a unique,

tumor-specific antigen at which to direct therapeutic strategies.<sup>78</sup> New treatment approaches using viral vectors to reverse discordant p53 mutations are in progress.

## **PATHOLOGY**

The World Health Organization (WHO) classification of lung cancer is accepted worldwide ( [Table 31.2-2](#)). NSCLC includes carcinoma, adenocarcinoma, and large cell (undifferentiated) carcinoma.

Category	Subtype	Frequency (%)
Squamous Cell Carcinoma	Well-differentiated	15-20
	Poorly differentiated	10-15
Adenocarcinoma	Well-differentiated	30-40
	Poorly differentiated	10-15
Large Cell Carcinoma	Well-differentiated	5-10
	Poorly differentiated	5-10
Small Cell Carcinoma	Well-differentiated	1-5
	Poorly differentiated	1-5

**TABLE 31.2-2.** World Health Organization Histologic Classification of Epithelial Tumors of the Lung

## **HISTOGENESIS**

Evidence is increasing that lung cancer is derived from a pluripotent stem cell that is capable of expressing a variety of phenotypes. This epithelial stem cell, in normal histogenesis, differentiates to those cells found in the tracheobronchial tree, including pseudostratified reserved cells, ciliated goblet columnar cells, neuroendocrine cells, and type I and II pneumocytes seen lining the alveoli. Cells that are capable of division can express hyperplastic, metaplastic, or neoplastic change.<sup>79</sup> Frequently, a lung cancer exhibits two or more histologic patterns. The frequency of this occurrence depends on the assiduity of the pathologist and the number of sections examined. In one study, when at least 10 blocks from each tumor were examined, 45 of the 100 cases demonstrated heterogeneity, and 10% of cases showed elements of both squamous cell carcinoma and adenocarcinoma.<sup>80</sup>

It appears that squamous cell carcinoma and small cell carcinoma have a distinct dose-response relation, with increasing tobacco exposure producing increasing numbers of these histologic subtypes. Worldwide, however, adenocarcinoma appears to be increasing, especially in women, despite the fact that it does not have this significant dose-response relation with smoking. This increasing incidence of adenocarcinoma is especially seen in the United States and is less apparent in Europe and Japan.<sup>81</sup>

### ***squamous Cell Carcinoma***

Although at one time the most frequent of all lung cancers, squamous cell carcinoma in North America has not seen the marked increase observed with adenocarcinoma, the latter tumor accounting for most of the recent increased incidence of lung cancer. Some of these differences may be related to the change from nonfiltered to filtered cigarettes and their relation to site of deposition of the carcinogens. Squamous cell carcinoma arises most frequently in proximal segmental bronchi and is associated with squamous metaplasia. In its earliest form, carcinoma *in situ*, stratified squamous epithelium is replaced by malignant squamous cells without invasion through the basement membrane. Because of the ability of these cells to exfoliate, this tumor can be detected by cytologic examination at its earliest stage. With further growth, the tumor invades the basement membrane and extends into the bronchial lumen, producing obstruction with resultant atelectasis or pneumonia.

Histologically, the squamous cell tumor is composed of sheets of epithelial cells, which may be well or poorly differentiated. Most well-differentiated tumors demonstrate keratin pearls. The more poorly differentiated tumors, if determined to be squamous cell carcinoma, have positive keratin staining ( [Fig. 31.2-2](#)).

**FIGURE 31.2-2.** Moderately differentiated squamous cell carcinoma. Sheets of tumor cells with variable amounts of cytoplasm and moderate nuclear atypia are present. Focal keratinization is evident ( *arrow*). **A:** Low-power magnification. **B:** High-power magnification.

These tumors tend to be slow-growing, and it is estimated that up to 3 or 4 years are required from the development of *in situ* carcinoma to a clinically apparent tumor.

### ***Adenocarcinoma***

In North America, adenocarcinoma is the most frequent tumor, accounting for 40% of all cases of lung cancer. Some of this increase is due to the better identification of adenocarcinoma using immunohistochemical staining, with fewer tumors classified as undifferentiated large cell tumors. Most of these tumors are peripheral in origin, arising from alveolar surface epithelium or bronchial mucosal glands; they also can present as peripheral tumors arising in areas of previous infections, so-called scar tumors ( [Fig. 31.2-3](#)).

**FIGURE 31.2-3.** Well-differentiated adenocarcinoma. Well-formed glands with a focal cribriform arrangement ( *arrows*) are surrounded by a cellular stroma. **A:** Low-power magnification. **B:** High-power magnification.

**FIGURE 31.2-4.** Bronchoalveolar carcinoma. Columnar cells with minimal nuclear atypia are arranged along intact alveolar septa. The lepidic growth pattern is associated with no stromal reaction. Mucin vacuoles are present in the apical cytoplasm ( *arrows*). **A:** Low-power magnification. **B:** High-power magnification.

Other than T1N0 tumors, it appears that adenocarcinoma has a somewhat worse prognosis, stage for stage, than does squamous cell carcinoma. Immunohistochemistry and electron microscopy have been used by pathologists with increasing frequency to identify adenocarcinoma.<sup>83</sup> Using these techniques, adenocarcinoma cells stain positive for carcinoembryonic antigen and mucin. Specific monoclonal antibodies recognizing adenocarcinoma have been identified.<sup>84</sup>

### Large Cell Carcinoma

Large cell carcinoma is the least common of all NSCLC tumors, accounting for approximately 15% of all lung cancers. With immunohistochemical staining, electron microscopy, and monoclonal antibodies, many tumors previously diagnosed as undifferentiated large cell carcinoma can now be classified more appropriately as poorly differentiated adenocarcinoma or squamous cell carcinoma. For this reason, the incidence of this type of tumor continues to decrease ( [Fig. 31.2-5](#)).

**FIGURE 31.2-5.** Large cell undifferentiated carcinoma. Sheets of highly atypical cells with focal necrosis ( *arrows*) are present. There is no evidence of keratinization or gland formation. **A:** Low-power magnification. **B:** High-power magnification.

Although the WHO classification subdivides this group into giant cell and clear cell varieties, these subclassifications have little clinical relevance. Few true giant cell tumors have been identified, although they do represent a poorly differentiated subtype with what appears to be a poorer prognosis. The prognosis of large cell undifferentiated carcinoma appears to be similar to that of adenocarcinoma and, in most clinical trials, these two histologic types are grouped together using immunohistochemical staining. Pathologists are increasingly identifying neuroendocrine features in large cell tumors. These tumors appear to have a worse prognosis, and their relation to small cell lung cancer remains to be defined.

### METHODS OF SPREAD

After a variable period as a primary tumor growing within lung parenchyma or within the bronchial wall, the tumor ultimately invades the vascular and lymphatic channels, resulting in spread by these channels to regional draining lymph nodes and distant metastatic sites. Occasionally, airborne or lymphatic metastases (so-called satellite nodules) can be seen in the lung parenchyma near the primary tumor or in ipsilateral lobes other than that containing the primary tumor. These satellite nodules auger a worse prognosis and alter the stage of the disease.

In most instances, it appears that lymphatic spread occurs earlier than spread to metastatic sites elsewhere. The regional lymphatic drainage of the lung is outlined in [Figure 31.2-6](#). In the lung tissue, lymphatic drainage follows the bronchoarterial branching pattern, with lymph nodes situated at the origin of these branchings. These lymphatic channels coalesce, draining into lymph nodes situated around segmental and lobar bronchi. Lower lobe lymphatics then drain to the posterior mediastinum and, ultimately, to the subcarinal lymph nodes. In the right upper lobe, lymphatics drain toward the superior mediastinum; in the left upper lobe, lymphatic channels run anterolateral to the great vessels (aorta and subclavian artery) in the anterior mediastinum as well as along the main bronchus into the superior mediastinum in one-third of cases.

**FIGURE 31.2-6.** The regional lymphatic drainage of the lung as described by Noel. Most of the lymphatic drainage ultimately reaches the right superior mediastinum and right supraclavicular regions. (From ref. 416, with permission.)

Ultimately, all these lymphatic channels drain to the right lymphatic or left thoracic ducts. Metastatic lymphatic spread of lung cancer follows these lymphatic channels with tumor involving bronchopulmonary (N1), mediastinal (N2-3) and, ultimately, supraclavicular (N3) lymph nodes. Retrograde lymphatic spread to the pleural surface can occur, especially in peripheral tumors.

The primary tumor can also spread locally, ultimately invading contiguous structures, including mediastinal pleura or organs and the chest wall or diaphragm. Once vascular or lymphatic invasion occurs, metastatic spread to distant sites is common. The most frequent sites involved include bone, liver, adrenals, and brain. As demonstrated in autopsy studies, however, lung cancer metastases can be found in every organ system.<sup>85</sup> Metastases within the lung are thought to result from a variety of mechanisms, including airborne spread by bronchi, retrograde lymphatic spread, and blood-borne spread.

## CLINICAL FEATURES

The signs and symptoms manifested by patients suffering from lung cancer depend on the location of the tumor, its locoregional spread, or the effects of metastatic spread (Table 31.2-3). Lung cancer is associated with paraneoplastic syndromes more frequently than any other tumor. Many patients present with an asymptomatic lesion discovered incidentally on chest radiography.

Symptoms secondary to central or endobronchial growth of the primary tumor	
Cough	
Hemoptysis	
Wheeze and stridor	
Obstruction of bronchi	
Pneumonia from obstruction (fever, purulent sputum)	
Atelectasis from obstruction of the primary bronchus	
Pain from pleural or chest wall involvement	
Cough	
Obstruction of a bronchus	
Large abscess formation from tumor cavitation	
Symptoms related to regional spread of the tumor to the chest by contiguity or by metastases to regional lymph nodes	
Local obstruction	
Esophageal compression with dysphagia	
Recurrent laryngeal nerve paralysis with hoarseness	
Phrenic nerve paralysis with hiccups and chest pain	
Sympathetic nerve paralysis with Horner's syndrome	
Right or left arm and face edema from venous obstruction	
Superior vena cava syndrome from vascular obstruction	
Pericardial and chest wall metastases with chest pain, tamponade, anasarca, or cachexia	
Metastases to other sites	
Lymphangitic spread through lungs with hypoxemia and dyspnea

**TABLE 31.2-3.** Common Signs and Symptoms of Lung Cancer

### Locoregional Manifestations

Tumors arising in the larger airways produce symptoms related to the growth of the tumor. Frequently, patients present with a persistent cough. In larger airways, with encroachment of the lumen, a wheeze or stridor may develop. As the tumor grows, areas of necrosis may develop, resulting in bleeding. Massive hemoptysis is a rare event, with most patients experiencing blood-streaked sputum.

With continued tumor growth, airways may become obstructed, resulting in atelectasis, pneumonia and, occasionally, abscess formation. These obstructive complications often result in fevers and the signs and symptoms of pulmonary infection. If pleural surfaces are involved in the infection, pleuritic pain may develop with or without a detectable pleural effusion. With endobronchial obstruction and the failure of ventilation of segments or lobes or even an entire lung, increasing shortness of breath can ensue.

Depending on the location of the primary tumor, adjacent structures, such as the chest wall or mediastinum, may ultimately become involved by direct spread. Radicular chest wall pain then develops. With apical tumors, the classic Pancoast's syndrome (lower brachial plexopathy, Horner's syndrome, and shoulder pain) may become manifest, owing to local invasion of the lower brachial plexus (T1 and C8 nerve roots), chest wall, and stellate ganglion.

Similarly, tumors invading or involving lymph nodes in the mediastinum may encase the phrenic nerve, vagus nerve, or recurrent nerve, resulting in malfunction of the specific end organs (e.g., diaphragm, vocal cord). It is not uncommon for patients to present initially with symptoms of a recurrent nerve palsy, including hoarseness and cricopharyngeal dysphagia, especially with left upper lobe tumors.

Superior vena cava syndrome usually results from mediastinal lymphadenopathy encroaching on this structure rather than primary tumor invasion. Direct invasion of the pericardium or metastases to this structure can occur and lead to a malignant pericardial effusion, with signs and symptoms of pericardial tamponade.

Visceral pleural invasion or retrograde lymphatic spread can ultimately result in visceral and parietal pleural seeding. Pleuritic pain or increasing shortness of breath due to a massive pleural effusion can ensue.

Nodal involvement or tumor invasion of the posterior mediastinum, usually from lower lobe tumors, can produce partial or complete obstruction of the esophagus, resulting in dysphagia and, with further invasion, symptoms of a tracheoesophageal fistula. Nodal involvement of the superior mediastinum can cause a nonproductive cough or, when extensive, superior vena cava obstruction.

In addition to these specific symptoms related to the presence of tumor or lymphadenopathy in a locoregional area, nonspecific and vague chest pains, generally referred to as the ipsilateral hemithorax, are frequent occurrences in patients suffering from lung cancer. These pains are of visceral origin and are unrelated to invasion of local structures. Other nonspecific symptoms, including weight loss and a general unwell feeling, are common and usually indicate advanced disease.

### Metastatic Manifestations

Nearly all patients with advanced inoperable NSCLC demonstrate symptoms referable to their disease at the time of initial presentation.<sup>86,87</sup> Most patients, in fact, have more than one symptom at the onset of their illness.<sup>87</sup> Fatigue and decreased activity were reported by more than 80%, and most patients also experienced cough, dyspnea, decreased appetite, and weight loss. The high incidence of lung cancer symptoms, the occurrence of multiple symptoms in most patients, and the severity of these complaints demand both prompt treatment of the lung cancer and careful attention to the management of each symptom while definitive therapy is in progress.

Although lung cancer can metastasize to virtually any organ, the most common sites of spread that are clinically apparent are the pleura, lung, bone, brain, pericardium, and liver.<sup>85</sup> The presenting complaints of a patient with metastatic spread are largely determined by the specific metastatic organ site involved. For example, bone metastases present with pain and limitation of function in the affected area.

We cannot explain the high incidence of adrenal metastases in NSCLC, detected in 41% of patients at autopsy.<sup>85</sup> Most adrenal metastases are asymptomatic and are discovered incidentally during a staging evaluation or at autopsy. The computed tomographic (CT) scan is the most frequent method of diagnosis. Fine-needle aspiration provides a safe method to confirm the presence of metastatic disease in the adrenal gland if pathologic documentation is necessary, although other imaging studies, such as magnetic resonance imaging (MRI) and positron emission tomography (PET) can be confirmatory. Adrenal hormone insufficiency due to bilateral adrenal metastases from lung cancer is rare but can occur.<sup>88</sup>

**FIGURE 31.2-8.** Actuarial survival curves according to different stages (1986 staging). **A:** Survival after clinical staging. **B:** Survival after final pathologic staging. Note that early stages are understaged by clinical staging resulting in a poorer survival than after pathologic staging. However, the higher the stage, the less likely that clinical staging understages the disease. (From ref. 91, with permission.)

The TNM staging includes clinical, surgical, and pathologic collection. Even with the use of pretreatment minimally invasive techniques only, a significant percentage of patients are clinically understaged as compared with the ultimate stage identified by surgical and pathologic staging. Despite these inadequacies, it is clinically relevant to stage all lung cancer patients before treatment (clinical) and after therapy (surgical and pathologic).<sup>93,94</sup>

In patients suspected of harboring lung cancer, accurate diagnosis with confirmatory cytology or histology is of supreme importance, as is an estimation of the clinical stage of the disease, since clinical staging will determine treatment. Since many of the modalities used for diagnosis are also important in clinical staging, these are discussed simultaneously (Fig. 31.2-9).

**FIGURE 31.2-9.** Schema to indicate the diagnostic procedures depending on the presenting lesion. CT, computed tomography. PET, positron emission tomography.

## HISTORY AND PHYSICAL EXAMINATION

A detailed history and accurate physical examination remain the most important steps in assessing a patient with lung cancer. Smoking history, past exposure to environmental carcinogens, and family history may suggest a higher probability of lung cancer. New symptoms, including a change in cough, hemoptysis, or history of recurrent respiratory infection, are of concern. Symptoms suggesting locoregional spread include chest pain, symptoms of recurrent nerve palsy, or superior vena cava obstruction. Symptoms suggestive of metastatic disease frequently include focal neurologic symptoms, bone pain, or weight loss. Occasionally, patients suffering from NSCLC present with symptoms and signs of a paraneoplastic syndrome but not as frequently as with small cell tumors.

Physical examination should look for signs of partial or complete obstruction of airways, atelectasis or pneumonia, and pleural effusions. Examination of the head and neck, including the draining regional lymph node areas in the supraclavicular area, may demonstrate lymphadenopathy, indicating regional lymphatic (N3) spread.

## SPUTUM CYTOLOGY

Once the disease is suspected, a simple and effective method of obtaining a positive diagnosis of lung cancer is sputum cytology. The yield from sputum cytology depends on many factors, including the ability of the patient to produce sufficient sputum, the size of the tumor, the proximity of the tumor to major airways and, to a lesser extent, the histologic type of the tumor.

With sputum samples, up to 80% of central tumors can be diagnosed. The yield is much smaller for peripheral tumors, dropping to less than 20% for peripheral tumors smaller than 3.0 cm in diameter. A 3-day collection of early morning sputa, preserved in Saccamano's solution, appears to be the optimal method of assessment. Squamous cell tumors, being more proximal, are more frequently diagnosed by cytology than adenocarcinoma or large cell tumors. Another factor affecting the ability of sputum cytology to diagnose malignancy is the experience and training of the cytopathologist. Viral infections and other acute inflammations can produce cellular changes that are difficult to distinguish from malignancy, especially adenocarcinoma. Frequently, severe dysplasia is misinterpreted as a malignancy, and vice versa. Tockman et al.<sup>95,96</sup> and<sup>97</sup> have described a monoclonal antibody–staining technique that may more accurately diagnose the presence or absence of malignancy in severely dysplastic cells. This is being tested prospectively in a large North American effort.

## IMAGING STUDIES

### Chest Radiography

Chest radiography is probably the most valuable tool in the diagnosis of lung cancer. A perfectly normal chest radiograph rules out this diagnosis in most instances, except for the rare occult tumor.<sup>98</sup> Plain chest radiography can reveal peripheral nodules and hilar and mediastinal changes suggestive of lymphadenopathy or pleural effusions, all suggestive of possible malignancy. Areas of subsegmental, segmental, lobar, or lung collapse suggest an endobronchial obstruction. Improvements in plain radiography (e.g., digital radiography) may improve the diagnostic yield of this modality.<sup>99,100</sup>

### Computed Tomography

With the introduction of CT scanning in the late 1970s, a giant step was taken in the ability to diagnose and stage lung cancer employing noninvasive imaging techniques. CT imaging can confirm abnormalities seen on plain chest radiographs, can often detect early (<1 cm) lesions that cannot be seen on chest radiographs, and has played an important role in staging of lung cancer, especially spread to areas of the mediastinum undetected on plain films. There is general agreement that to be considered “normal,” mediastinal lymph nodes must be smaller than 1 cm in transverse diameter. Any lymph node larger than this suggests lymphadenopathy and should be investigated further by more invasive techniques.<sup>101,102</sup>

CT scans may also suggest possible areas of local invasion of the primary tumor to chest wall, vertebrae, or mediastinal structures. Small pleural effusions or pleural nodules, often undetected on plain films, may be evident on CT scans.

An added advantage of CT scanning is the ability to detect abnormalities below the diaphragm, especially metastases to liver and adrenal glands. For the

investigation of lung cancer, CT scanning should include upper abdominal scanning to the level of the kidneys to include imaging of the liver and adrenal gland.

Abnormalities seen on CT scan, unless associated with unequivocal signs of malignancy, should be confirmed by more invasive cytologic or histologic investigation.<sup>103</sup>

### **Magnetic Resonance Imaging**

MRI investigation of pulmonary lesions has been disappointing and has offered no improvement over CT scanning. Exceptions to this rule include investigation of paravertebral tumors, because imaging of the spinal canal without contrast media is possible. Changes in bone marrow of the vertebrae suggestive of carcinoma can be detected with greater accuracy with MRI. Also, invasion of tissue planes and vascular structures within the mediastinum and at the thoracic inlet can be assessed with greater accuracy using MRI. Routine MRI of all lung cancer is unnecessary and should be reserved for situations in which local tumor invasion of the mediastinum, thoracic inlet, or paravertebral region is questioned on CT scanning.<sup>104,105 and 106</sup>

### **Radionuclide Scanning**

Until the advent of PET scanning, the ability of radionuclide scanning to diagnose and stage lung cancer was limited by its lack of specificity. Nuclide scanning with gallium citrate or cobalt-bleomycin previously was used mainly for detecting unsuspected mediastinal spread once the diagnosis had been made. The rate of incorporation of the radioisotope by the primary tumor and its metastatic foci was variable, however, and thus has limited its clinical use in both diagnosis and staging.<sup>107,108</sup> Isotope-labeled monoclonal antibodies have also been investigated as a technique for staging and diagnosing lung cancer. Specific monoclonal antibodies directed to lung cancer cells may prove valuable as diagnostic and staging modalities in the future. Routine radionuclide bone scanning to rule out asymptomatic, unsuspected bone metastases in early-stage disease has never been shown to be cost-effective but is still advocated by many practitioners. In clinical stage III disease, before curative therapy is considered, bone scans may be more cost-effective and certainly are of value when bony syndromes are present.<sup>109</sup>

### **Positron Emission Tomography**

During the last decade, an exciting new modality, whole-body PET scanning, came into use. This scanning technique, which has yet to be completely investigated, is based on the uptake of a radioactive glucose, fluorodeoxyglucose, in metabolically active cells. In North America and Europe, PET centers are opening almost on a daily basis. It appears to be exceptionally valuable in diagnosing and staging lung cancer and, in the United States, has now been accepted for reimbursement in investigating this disease. Virtually all reports demonstrate higher accuracies than CT imaging and bone scanning in identifying occult metastatic disease in the mediastinum and distant sites.<sup>110,111 and 112</sup> In addition, it appears useful in differentiating benign from malignant lesions when investigating a solitary pulmonary nodule. However, granulomatous inflammation can be metabolically active, whereas bronchoalveolar carcinomas may be metabolically inactive. This limits PET's usefulness in diagnosing with absolute certainty the etiology of a solitary pulmonary nodule.

The amount of activity seen in the tumor—the standard uptake value (SUV)—has been analyzed with regard to ultimate outcome. It does appear that tumors with high SUV numbers have a poor prognosis, which is independent of other prognostic indices, such as stage of disease. The exact level of SUV activity that is independently prognostic has yet to be defined but appears to be somewhere in excess of 7. In addition, the response to therapy (e.g., induction chemotherapy or radiotherapy) as measured by a declining SUV is being investigated with the use of PET. In the future, chemotherapy response rates may be able to be assessed with repeated PET scans; this is being actively investigated. The response to primary chemoradiotherapy may also be assessed using this technique. The exact place of PET scanning in assessing response to therapy, however, has yet to be defined.<sup>112</sup>

## **PERCUTANEOUS FINE-NEEDLE ASPIRATION**

Fine-needle aspiration biopsy of pulmonary nodules is an excellent method of obtaining cytologic and histologic material for positive identification of malignancy. This is performed using fluoroscopic or CT-guided techniques. The positive yield in experienced hands can be as high as 95%. An indeterminate biopsy, however, cannot be accepted as negative. False-negative examination results are frequent and must be considered indeterminate unless a positive benign diagnosis (e.g., hamartoma, tuberculosis) can be made.<sup>113</sup>

Abnormalities identified by imaging scans in bone, liver, or adrenal gland and suggestive of metastatic disease can be confirmed by fine-needle aspiration biopsy using ultrasonographic or CT-guided techniques, and abnormalities identified on physical examination (e.g., large supraclavicular nodes) are very accessible to fine-needle aspiration. In some centers, confirmation by PET scanning or MRI has been considered accurate enough and has replaced the necessity of biopsy confirmation (e.g., of adrenal tumor).

## **BRONCHOSCOPY**

Although rigid bronchoscopy was used for many years to confirm the diagnosis of lung cancer, the introduction of flexible fiber-optic bronchoscopy more than 20 years ago has revolutionized this approach. The procedure, although invasive, can be performed under local anesthesia with or without sedation and with minimal morbidity and exceptional safety. Using flexible instruments, the proximal tracheobronchial tree can be examined up to the second or third subsegmental division, and cytologic or histologic specimens can be obtained from identified abnormal lesions. The diagnostic yield of fiber-optic bronchoscopy with cytology brushing and biopsy for histology when a visible lesion is identified is higher than 90%. Even with no visible lesion seen, the bronchus draining the area of suspicion can be irrigated and lavaged, yielding cytologic material. With fiber-optic bronchoscopy and image intensification, peripheral lesions can be reached by cytology brushes, needles, or biopsy forceps, and specimens can thus be obtained. This is most effective in lesions larger than 2 cm in diameter.

The increased yield of postbronchoscopy sputum cytology (as compared with routine induction sputum cytology) renders this maneuver valuable as an added diagnostic tool. The bronchoscope is also valuable for staging. The site of the primary tumor in a major airway may affect its stage (T3 vs. T2 vs. T1), and transbronchoscopic needle aspiration through the airway wall, as popularized by Wang, can confirm the presence of malignancy in enlarged mediastinal lymph nodes (N3 vs. N2 vs. N1).<sup>113a,113b</sup> Care must be taken, however, with this latter technique, because false-positive examination results have been reported, and differentiation between resectable N2 and unresectable N2 or N3 disease cannot always be determined by needle aspiration alone; a more invasive approach (e.g., mediastinoscopy, thoracoscopy) may be required.<sup>114</sup>

## **MEDIASTINOSCOPY AND MEDIASTINOTOMY**

Mediastinoscopy was developed by Carlens approximately 45 years ago to facilitate staging of superior mediastinal lymph nodes (N2 or N3) before consideration of therapy in patients with lung cancer. It remains the most accurate lymph node staging technique to assess superior mediastinal lymph nodes, which are frequently involved in this disease. The procedure is simple, safe, and effective in experienced hands. In two large series,<sup>115,116</sup> the mortality rate was 0%, and the major morbidity rate was less than 1%. In patients suspected of having inoperable disease by virtue of mediastinal involvement as detected by CT or PET scanning, confirmation by mediastinoscopy is indicated. Depending on the philosophy of management of patients with minimal mediastinal involvement, mediastinoscopy is used to a greater or lesser extent by individual practitioners. Mediastinoscopy is extremely valuable for accurate staging of the disease before neoadjuvant (induction) chemotherapy.

In the future, PET scanning may replace this invasive procedure as a method of accurately identifying superior mediastinal involvement. However, prospective studies have suggested that in "negative" PET scans related to the superior mediastinum, approximately 10% of individuals will be found to have microscopic mediastinal nodal involvement.<sup>23,117</sup> Whether a negative PET scan result is sufficient to allow primary surgery in patients without the addition of mediastinoscopy is yet to be determined. Granulomatous inflammation within the mediastinal lymph nodes will be identified as increased activity on a PET scan. For this reason, "positive" PET imaging in the superior mediastinum must be confirmed histologically as representing metastatic cancer.

Involvement of anterior mediastinal lymph nodes, which occurs frequently in left upper lobe tumors, can be assessed by the extended mediastinoscopy technique,<sup>118</sup> by an anterior mediastinotomy (as advocated by McNeil and Chamberlain<sup>119</sup>), or by video-assisted thoracoscopy. Because this is the first level of mediastinal lymph nodes involved in disease, many practitioners defer this examination when cervical mediastinoscopy fails to reveal metastatic disease in the superior mediastinum unless these lymph nodes appear involved on imaging studies. Patients without superior mediastinal involvement have a good prognosis after resection, even when

anterior mediastinal (first-level) nodes are microscopically involved. [120](#)

## THORACENTESIS

Thoracentesis of a pleural effusion associated with a presumed lung cancer can identify pleural disease (T4). Classically, a bloody pleural effusion is considered malignant; however, unless malignant cells are identified in the cytologic assessment of these pleural effusions, for the sake of the patient, a bloody pleural effusion should be considered traumatic. In these instances, thoracoscopy may be required to prove, without a doubt, the existence of pleural metastases.

## THORACOSCOPY

Video-assisted thoracoscopy has been used in the diagnosis and staging of lung cancer. Peripheral nodules can be identified and excised using video-assisted minimally invasive techniques, and mediastinal lymph nodes can be sampled for histologic examination. This technique also can identify suspected pleural disease and has the ability to assess accurately the status of pleural effusions when thoracentesis does not. The exact indications and use of this minimally invasive technique await further prospective studies, [121](#), [122](#) and [123](#) but it has been used for assessment of mediastinal nodes and T4 status, especially when pleural effusions with nonmalignant cytology are present.

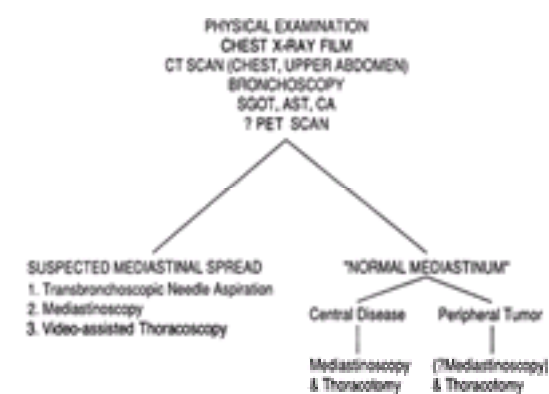

## THORACOTOMY

Thoracotomy continues to be used in the diagnosis and staging of lung cancer. With less invasive procedures, however, more than 95% of tumors can be accurately diagnosed and staged prior to thoracotomy. Despite this, there remains a small minority of patients in whom the diagnosis of lung cancer is made only at thoracotomy. At the time of thoracotomy, the diagnosis can be confirmed by fine-needle aspiration, incisional or (preferably) excisional biopsy, and frozen-section analysis. All these techniques can provide tissue that can be rapidly assessed by pathologists.

At the time of thoracotomy, further staging is mandatory by the surgeon by sampling hilar and mediastinal lymph node or performing a complete ipsilateral lymph node dissection. Not infrequently, unsuspected involvement of adjacent structures is recognized only at the time of surgery, identifying a T3 or T4 tumor invading adjacent structures.

## EVALUATION OF EXTENT OF DISEASE

Once the diagnosis of lung cancer has been made and before consideration of definitive therapy, a clinical evaluation of extent of disease is required ( [Fig. 31.2-10](#)). Frequently, the history and physical examination suggest evidence of lymphatic or distant metastatic spread. These symptoms or signs should be confirmed by appropriate radiologic studies directed at the organs suspected to be involved ( [Fig. 31.2-11](#)).

**FIGURE 31.2-10.** Clinical staging of lung cancer: a schema to indicate extent of disease evaluation. AST, aspartate aminotransferase; CA, serum calcium; CT, computed tomography; PET, positron emission tomography; SGOT, serum glutamic oxaloacetic transaminase.

**FIGURE 31.2-11.** Chest radiographs of patients with different presentations of lung cancer. **A:** A centrally located tumor on cavitation, suggestive of squamous cell carcinoma. **B:** A peripherally located nodule with possible pleural involvement. **C:** A large hilar mass in mediastinal adenopathy, suggesting stage IIIB disease. **D:** Multiple bilateral pulmonary nodules of bronchoalveolar carcinoma. **E:** Small cell lung cancer involving a large, bulky central mass with hilar and mediastinal adenopathy and obstruction of the right upper lobe.

Regarding patients suspected of having disease localized to the hemithorax, there has been significant debate about the minimum required investigations to prove or disprove metastatic spread. After an accurate medical history and physical examination, routine studies should include chest radiographs, hematologic survey, and specific biochemical markers, including serum calcium, alkaline phosphatase, and aspartate aminotransferase. Elevation of these biochemical markers indicates the need for investigation for bony or liver metastases.

In the United States, virtually all patients considered for curative treatment of lung cancer undergo routine CT scanning of the chest and upper abdomen to detect mediastinal lymph node enlargement, unsuspected pulmonary metastases, and unsuspected liver and adrenal metastases. Whether the use of CT scanning is cost-effective in detecting these unsuspected metastases is a moot point. Frequently, abnormalities found with this examination lead to further invasive testing, ultimately revealing a false-positive investigation result. Similarly, the routine use of bone scans despite the absence of clinical or biochemical abnormalities is probably not cost-effective.

PET scanning is being used with increased frequency to assess both regional and metastatic spread of tumor. Because of the inherent high metabolic activity within the brain, this area cannot be accurately assessed by this new imaging technique.

The routine use of mediastinoscopy before surgical intervention for the treatment of lung cancer is also debated. With mediastinoscopy, inoperable superior mediastinal disease can be identified, thereby avoiding some unnecessary thoracotomies. Approximately 10% of patients harbor inoperable unsuspected mediastinal disease if mediastinoscopy is not used as a routine staging operation, despite the use of CT and PET scanning.

In clinical practice, for peripheral nodules smaller than 3 cm in diameter with no other abnormalities detected on chest radiograph, physical examination, or biochemical screening, it is probably not cost-effective to pursue all these investigations. The role of routine PET scanning in this early stage of disease has yet to be

defined.

In patients with more locally advanced disease (clinical stage II or III) and in patients with suggestive adverse prognostic signs (e.g., weight loss), a more complete metastatic survey might be advantageous, although as yet there is no evidence of cost-effectiveness.<sup>124</sup> The routine use of CT scanning or MRI of the brain to detect asymptomatic cerebral metastasis has not been settled but is probably not cost-effective, especially in early-stage (I and II) disease.

## RETREATMENT PROGNOSTIC FACTORS

After establishing the diagnosis and clinical stage of NSCLC, it is desirable to determine the likely clinical course and survival outcome. This is important for both the patient and the treating physician, because this estimate is essential to guide the choice of therapy. Such information is also vital for the design and interpretation of clinical trials when it is necessary to discriminate between the effectiveness of a new therapy and the natural history of disease for a particular group of patients.

Several retrospective analyses have evaluated traditional and newer prognostic factors for patients with operable and patients with inoperable NSCLC ( [Table 31.2-6](#) ).<sup>125,126,127,128,129</sup> and <sup>130</sup>

**TABLE 31.2-6.** Univariable Survival Comparison of Three Large Retrospective Datasets

## EARLY-STAGE (I, II, AND RESECTABLE STAGE III) DISEASE

The major clinical prognostic determinants for patients with early-stage disease are the size of the tumor and the presence or absence of lymph node spread. These features are well captured in the TNM staging classifications.<sup>131</sup> Additional clinical adverse prognostic factors are age older than 60 years and male gender and performance of a wedge resection instead of lobectomy or pneumonectomy.<sup>132</sup> Histologic subtype does not provide consistent additional prognostic information.<sup>133</sup> Expression of mucin has been shown to be a poor prognostic factor.<sup>126,129,134,135</sup> Mucin decreases tumor cell aggregation and may facilitate formation of metastases. Overall, clinical stage remains the most important prognostic tool.<sup>136</sup> However, newer diagnostic techniques are likely to continue to refine our precision in staging patients. For example, the detection of disseminated tumor cells in lymph nodes or the bone marrow using immunohistochemical analysis has been shown to correlate with a poor prognosis,<sup>137,138</sup> as do high SUV numbers in the primary tumors on PET scan.

## ADVANCED-STAGE (UNRESECTABLE STAGE III AND IV) DISEASE

Because advanced-stage lung cancer has few 5-year survivors, TNM staging is not as valuable in assessing prognosis within these groups. Several comprehensive evaluations have searched for pretreatment prognostic factors in patients with advanced-stage NSCLC.<sup>139,140,141,142,143,144</sup> and <sup>145</sup> Pretreatment stage, performance status, and weight loss are the most important factors. The definitions of weight loss have varied among the reviews. Many trials evaluated small numbers of women. Those that included larger numbers of women generally found them to survive longer than men.<sup>141,142,144</sup> Serum lactate dehydrogenase, a predictor of survival in small cell lung cancer and many other malignancies, also appears to be an independent survival variable. The use of chemotherapy has also been shown to be of prognostic importance.<sup>144</sup> Histologic subtype is of no prognostic importance.

Whether any specific metastatic disease site confers a survival advantage or disadvantage remains controversial. Bone and liver metastases have been cited most often as predicting shorter survival. The total number of metastatic sites or total tumor burden has been shown to influence prognosis. In particular, patients with a solitary metastasis have a better prognosis, and an aggressive surgical approach should be considered. As yet, there is no clinically meaningful model combining the various independent factors that can be recommended either to select appropriate therapy or predict outcome for individual patients.

## NEW POTENTIAL PROGNOSTIC MARKERS

With the increasing availability of sophisticated molecular testing, a variety of novel potential prognostic factors has emerged. These factors have largely been studied in earlier-stage disease, owing to the ready availability of surgical specimens. Activation of oncogenes (RAS, MYC C-ERB B-2, and BCL-2) or loss of the tumor suppressor genes (RB, p53, and p16) have frequently been described.<sup>125,126,127,128,129</sup> and <sup>130</sup> Several trials have shown that patients with diploid tumors survive longer than those with aneuploid tumors.<sup>130,146,147</sup> Further study is necessary to define the significance of ploidy and that of specific chromosomal alterations within the lung cancer field.<sup>148,149</sup>

### **Epidermal Growth Factor Receptors**

After the identification of the presence and often increased numbers of EGFRs on lung cancer cells, trials have assessed the impact of EGFR expression on survival. In one trial, patients with operable EGFR-positive tumors survived significantly longer than those with EGFR-negative tumors (median survival, 71 and 28 months, respectively). In a second trial, overexpression of EGFR in primary lung tumors was associated with poor survival.<sup>150,151</sup> The presence of EGFR on lung cancer cells is a common finding and may be an important therapeutic target in the future.

### **Blood Group Antigen**

Investigators have reported that the expression of blood group antigen A in tumors of patients with blood group types A and AB was associated with longer survival after surgical therapy than was seen in patients with blood types A and AB who had no blood group antigen A expressed on their tumor cells.<sup>152</sup> This finding has been confirmed in some studies, while others have not been able to show this.<sup>128,129,153,154</sup> This is also true for expression of Lewis<sup>y</sup> antigen.<sup>129,155</sup>

### **Neuroendocrine Markers**

After the observation that tumors with neuroendocrine differentiation, such as small cell lung cancer, are responsive to chemotherapy and the fact that many types of NSCLC contain small cell lung cancer elements, several investigators have looked for evidence of neuroendocrine differentiation in NSCLC. They have done this in the hope of identifying a population of NSCLC patients with enhanced responsiveness to chemotherapy and improved survival. Markers of neuroendocrine differentiation include chromogranin, L-dopa decarboxylase, dense core granules, neuron-specific enolase, and Leu-7.<sup>156</sup> In a group of NSCLC patients treated with a variety of chemotherapeutic agents, neuron-specific enolase, Leu-7, and chromogranin were more commonly expressed in responding patients.<sup>157</sup> In the same study, responding patients with two or more positive markers survived longer. In another study using a monoclonal antibody to define neuroendocrine differentiation, approximately 30% of tumors were positive, and the presence of biopsy specimens containing more than 50% positively staining cells was associated with shortened survival in a multivariable analysis.<sup>158</sup> Although they remain an intriguing and potentially useful area of investigation, neuroendocrine markers cannot be used to select a specific therapy or to determine response or survival in patients with NSCLC.

## Genetic Markers

The intensive study of the role of oncogenes in the pathogenesis of human malignancy has led to an investigation of oncogene activation in lung cancer. In one study, *K-ras point mutations* occurred in almost one-third of human lung adenocarcinomas, while it is less common in squamous cell cancers.<sup>159</sup> In a follow-up study, the same authors found that the presence of K-ras point mutations can define a subgroup of operable NSCLC patients at high risk for relapse and overall shortened survival.<sup>72</sup> This has largely been confirmed by other studies.<sup>73,160,161,162,163,164,165 and 166</sup>

Mutation of the *p53* tumor suppressor gene has been frequently investigated. To date, it has no consistent correlation with prognosis.<sup>126,129,132,167,168</sup> Reduced E-cadherin expression has been associated with unfavorable prognosis in one trial.<sup>163</sup> Plakoglobin expression is also thought to play a role in cell adhesion. Its reduced expression has been shown to be associated with a poor prognosis.<sup>169</sup> Expression of *BCL-2* leads to inhibition of apoptosis. It has been described in approximately 20% of patients and is a favorable prognostic factor.<sup>126,129,170,171</sup> *Fas* expression has been suggested to be associated with a good prognosis in resected stage III disease.<sup>172</sup> Angiogenesis is increasingly recognized as an important factor of tumorigenesis. A variety of end points have been evaluated as angiogenic indicators, including microvessel density or immune staining with anti-factor VIII antibodies. Current evidence supports an adverse prognosis correlating with angiogenesis.<sup>173,174,175,176,177 and 178</sup>

## OCCULT DISEASE

An occult lung cancer is defined as a tumor in a symptom-free patient without radiographic findings. In most instances, this is detected by finding abnormal cells on screening sputum cytologic examination. On occasion, an occult lung cancer may be identified at bronchoscopy that has been performed for other reasons (e.g., screening patients with other aerodigestive tract abnormalities). These occult tumors are usually found at an early stage either as *in situ* disease (Tis) or early T1N0 tumors. A truly occult lung cancer, undetected by radiography and asymptomatic, is almost always found at this early stage of disease. An extremely high proportion (>90%) of such tumors are squamous cell and can be totally cured by surgical removal. In many instances, nonsurgical approaches [e.g., laser ablation, hematoporphyrin ablation, or endobronchial brachytherapy (EBB)] may be employed as curative treatment, especially in noninvasive mucosal tumors.

## LUNG CANCER SCREENING

In the hope that the screening of high-risk population groups by sputum cytology and chest radiograph would improve the identification of early-stage lung cancer, the National Cancer Institute Cooperative Early Lung Cancer Group was formed more than 20 years ago and developed protocols for screening high-risk people (e.g., male cigarette smokers older than 45 years). More than 30,000 male volunteers at three centers were recruited and followed up. One-half underwent intensive screening with four monthly sputum examinations and an annual chest radiograph, and the other one-half composed a control group. Each center had different methods of following up the control group, but initial chest radiographs were performed by all study groups.

The results of this trial demonstrated that lung cancers identified by screening methods were more frequently early-stage tumors (40% vs. 15%). Patients who developed lung cancer during the screening period had an overall 5-year survival of 35%, as compared with 13% in the general population. Despite this, there was no impact on overall survival of the two groups when all deaths were considered.<sup>179,180</sup> It was also found that sputum cytology can identify squamous cell carcinomas and that yearly chest radiographs identify with modest accuracy squamous cell carcinoma and adenocarcinomas. Small cell carcinoma is rarely detected at an early stage no matter what the screening technique.

Other mass screening trials using plain chest radiography performed in Europe have also failed to alter the total death rate in screened versus control groups. All trials demonstrated an improved ability to diagnose lung cancer early. Because these screening interventions fail to alter mortality rates, however, mass screening for lung cancer by chest radiography or sputum cytology (or both) cannot be recommended.

Despite the failure of mass chest x-ray screening, most investigators involved in these studies continue to believe that a person at high risk for developing lung cancer would be prudent to undergo annual chest radiography. Sputum cytology may be worthwhile as an initial screen, limiting further sputum cytology follow-up to those patients demonstrating dysplasia.

### Chest Radiography

Although there are no specific recommendations from cancer agencies, plain posteroanterior and lateral chest radiographs have been used on a yearly basis in high-risk people in an attempt to provide an earlier diagnosis of lung cancer.<sup>181</sup> Important in this approach is the ability to compare previous radiographs with recent films to detect subtle changes. As yet, routine CT scans of high-risk people have not been performed as a mass screening technique, and the impact of digitized chest radiography has not been assessed.

### Computed Tomography Scans

Most recently, two reports of screening using low-dose spiral CT scans have been reported. In a long-term Japanese study, a significant number of very early primary tumors have been identified using this technique, with significantly improved 5-year survival outcome in treated patients. In a more recent U.S. study, the use of low-dose spiral CT scans has confirmed the ability to discover extremely early lung cancers, with a prevalence rate of 30 per 1000 (vs. 3000 to 4000 with plain chest radiographs). These provocative studies have suggested that screening for lung cancer using low-dose, low-cost spiral CT scans is worthwhile in identifying early tumors and, it is hoped, in improving the outcome of patients with lung cancer by virtue of earlier detection. Although the exact cost of this type of mass screening program cannot be estimated in relation to finances or the investigation of other abnormalities identified at the time of CT scan (23% of individuals in the American study had other noncalcified benign nodules requiring investigation), this approach is worthy of further study. Whether the discovery of early treatable cancers ultimately affects the overall long-term mortality in a mass screening population will have to be determined prospectively. However, the 5-year survival of screen-detected stage I lung cancer falls from near 70% to less than 20% if left untreated, suggesting a significant benefit for earlier treatment.<sup>182,183,184 and 185</sup>

### Sputum Cytology

The routine use of annual sputum examination for cytologic assessment is not cost-effective in the detection of early lung cancer. Dysplastic changes identified at sputum cytology, however, should be followed up. Severe dysplasia indicates a significant chance of ultimately developing lung cancer.<sup>186</sup> These patients should be followed up extremely closely.<sup>187</sup> As noted, Tockman et al.<sup>95,96 and 97</sup> have developed a monoclonal antibody that may improve the yearly detection rate of lung cancer using specific monoclonal antibodies.

### Bronchoscopy

Bronchoscopy certainly can identify early mucosal changes suggestive of lung cancer. Tis and T1N0 proximal tumors (usually squamous cell) can be identified with relative ease using flexible bronchoscopy. The improved acuity of video equipment will probably further increase this yield.<sup>188</sup> However, many early lesions can be missed. Hematoporphyrins are preferentially taken up by rapidly dividing cells and, by using hematoporphyrin excitation by specific wavelengths (630 or 410 nm) of light, a characteristic fluorescence occurs in tissue containing the hematoporphyrin sensitizer. This technique can be used to detect these occult neoplasms but has the disadvantages of false-positive results (due to fluorescence of cellular atypia or metaplasia), hematoporphyrin light sensitivity, and limited availability. Only two or three centers have pursued this diagnostic approach.<sup>189,190</sup>

A new approach exploits spectral differences of autofluorescence in dysplastic and malignant cells without using drugs. This technique, called *lung imaging fluorescent endoscopy*, has been shown to identify early cellular changes and is being investigated for the detection and localization of early lung cancer,<sup>191,192</sup> especially proximal squamous cell tumors.

## MANAGEMENT

The management of occult lung cancer depends on the stage of disease at diagnosis. Because most of these tumors are early but invasive T1N0 carcinomas, many

are treated by surgical excision. Whenever surgery is contraindicated, curative radiotherapy is indicated. With proximal early-stage tumors, the role of brachytherapy alone or to augment the total dose is unknown, but curative treatment can be applied in this fashion.

In patients who have carcinoma *in situ*, hematoporphyrin or neodymium–yttrium aluminum garnet laser destruction of lesions can be used. Hayata et al.<sup>194</sup> found that early lesions should be less than 1 cm<sup>2</sup> in total surface area. Only a complete endobronchial response to such therapy is acceptable. After such a response, local recurrences are rare. Cortese et al.<sup>193</sup> recently reported using photodynamic therapy (PDT) in 21 carefully selected patients with superficial T1N0 lesions, all of which were squamous cell lung cancers. Using PDT, a complete response was identified in 15 of 21 patients at the Mayo Clinic; ultimately, 9 patients were spared an operation, 12 had recurrent disease after treatment, and 6 had complete responses. Recommendations for primary treatment with PDT in minimal occult tumors await further definition.<sup>194,195</sup> Only those patients who have had complete responses should be maintained on this type of treatment protocol, and they should be closely monitored with follow-up bronchoscopies. Whenever possible, surgical treatment is indicated for invasive T1N0 tumors and for all lesions persisting after nonsurgical (e.g., phototherapy, laser destruction, radiotherapy) treatment.

## CHEMOPREVENTION

No chemopreventive strategy has been proven effective for NSCLC, either for at-risk people (i.e., smokers or individuals with occupational exposures) or for patients with treated lung cancer who have an increased risk of second primary tumors. No definite link between the dietary intake of carotenoids, vitamins C and E, or selenium and the pathogenesis of lung cancer has yet been established. Chemoprevention trials of carotene, retinol, and the combinations of folic acid plus vitamin B<sup>12</sup> and carotene plus retinol in lung cancer have failed to demonstrate a chemopreventive effect. In two studies, an adverse risk was associated with carotene use.<sup>47,53</sup>

Recent insights into the biology of lung cancer and cellular differentiation suggest several new lines of research in this area. The most relevant to the chemoprevention of lung cancer appears to be the use of derivatives of retinoic acid, particularly 13- *cis* retinoic acid. This agent has been demonstrated to control leukoplakia (a premalignant epithelial lesion)<sup>196</sup> and to prevent second primary cancers in head and neck cancer patients after treatment of their primary tumors.<sup>197</sup> The association of specific chromosomal deletions, inactivation or loss of tumor suppressor genes, and mutation of specific protooncogenes may allow better definition of people at risk for second lung cancers and development of specific interventions for each genetic event. A nationwide trial in the United States is assessing the value of this association. Early unpublished results appear to be negative.

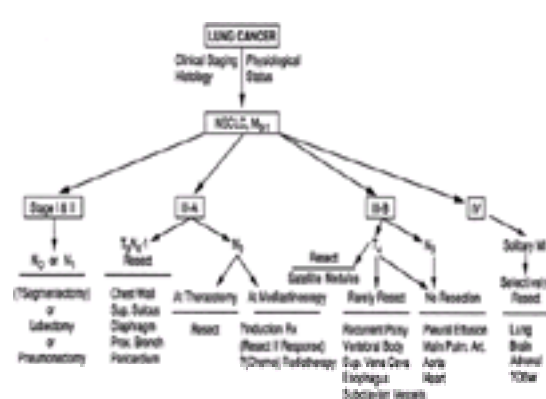

## OVERVIEW OF INVASIVE LUNG CANCER MANAGEMENT: TREATMENT MODALITIES

Surgery and radiotherapy have been used independently to obtain local control of the primary tumor and regional lymphatic drainage. Until recently, chemotherapy had been used in an attempt to prolong symptom-free life in patients with metastatic disease. In the last 20 years, however, combined-modality therapies have become much more prevalent and have spurred intensive investigation. All three modalities are now used as primary therapy and, in combination, have been employed to improve disease-free intervals and ultimate survival.

Historically, surgery has provided the best chance of cure in the management of NSCLC when the tumor can be completely resected. Whenever surgery is not an option because of the inability of the patient to tolerate this approach, primary radiotherapy has been offered for patients with limited locoregional disease. Effective chemotherapy in the management of NSCLC is the last modality to be introduced. Although as a single modality chemotherapy rarely provides a total cure in the management of lung cancer, complete responses do occur with locoregional disease and in patients with metastatic disease. Long-term survival occasionally is possible. This section describes these three treatment modalities and, in general terms, their application. The newer forms of systemic therapy (e.g., biologic therapy) also are discussed.

## SURGERY

In NSCLC, when the tumor is limited to the hemithorax and can be totally encompassed by excision, surgery provides the best chance for cure ( Fig. 31.2-12). In stage I and stage II disease, when the tumor has not extended beyond the bronchopulmonary lymph nodes, a complete excision is almost always possible. Controversy arises in the management of N2 disease. Ipsilateral (N2) mediastinal lymph node involvement, despite being potentially resectable, remains a contentious issue when indications for surgery are discussed. Whenever a complete excision occurs, the patient is afforded a chance of cure. In clinical staging, it is imperative that the surgeon assess whether the tumor and its involved nodes can be completely removed at operation. N2 disease identified preoperatively (clinical staging), either by imaging studies or mediastinoscopy, affords a much poorer prognosis (<10% 5-year survival rate) than occult N2 disease (30% 5-year survival rate) discovered only at the time of surgery.

**FIGURE 31.2-12.** Schema for operability at the various stages of non–small cell lung cancer (NSCLC). See text for details. Chemo, chemotherapy; Prox. Bronch, proximal bronchus; Pulm. Art., pulmonary artery; Rx, therapy; Sup., superior.

Except for a few special circumstances, stage IIIB disease, by virtue of incontrovertible evidence of contralateral lymph node spread (N3) or primary tumor invasion of vital structures (T4), denotes inoperability, with a small likelihood of success after surgical excision. Similarly, lung cancer that has metastasized to distant organs is usually beyond the realm of surgical excision. There has been success, however, in removing the primary tumor as well as a solitary metastatic focus. In selected patients, this affords long-term disease-free control. Surgical approaches are frequently used to palliate symptoms.

### Patient Selection

The preoperative assessment of patients considered for surgical treatment of lung cancer includes clinical staging of the disease to assess its resectability, assessment of the cardiopulmonary reserve of the patient to determine whether the intended pulmonary resection is possible, and assessment of the patient with regard to the perioperative risk of the procedure. Traditionally, patients are suitable candidates for pneumonectomy if the predicted forced expiratory volume in 1 second (FEV<sub>1</sub>) after pneumonectomy is greater than 1.2 L, the patient does not suffer from hypercapnia, and cor pulmonale is not present.<sup>198,199 and 200</sup> Pulmonary function studies best suited to assess these parameters include spirometry, arterial blood gases, diffusion capacity measurements of oxygen uptake with exercise (mVO<sub>2</sub>) and, when indicated, ventilation-perfusion scans to estimate the proportions of functioning pulmonary tissue required to be excised.<sup>201</sup> Patients undergoing lobectomy or smaller resection require similar postoperative pulmonary function parameters.<sup>202,203</sup> Prospective analyses, however, have failed to show differences in pulmonary function studies, including FEV<sub>1</sub>, after lobectomy or smaller resection.<sup>204,205</sup> The amount of functioning pulmonary tissue removed by lobectomy or smaller resection rarely interferes with ultimate recovery and function and may actually improve pulmonary function,<sup>206</sup> as it does with volume-reduction operations for emphysema.

A more important factor in preoperative assessment is the ability of the patient to tolerate a general anesthetic and the rigors of the early postoperative period. To prevent postoperative cardiopulmonary complications and decrease the chance of other major postoperative problems, care must be taken to determine accurately

the patient's cardiopulmonary status before operation. In the hope of ultimately improving the estimate of these risks,  $m\dot{V}O_2$ , cardiac radionuclide studies, and echocardiography have been introduced. The ability of patients to perform the necessary pulmonary toilet (e.g., coughing, deep breathing) after such procedures requires intensive preoperative instruction and a period of rehabilitation when necessary. Pulmonary complications increase remarkably when the  $FEV_1$ -forced vital capacity ( $FEV_1/FVC$ ) ratio is below 75% of predicted, indicating significant airway obstruction.  $FEV_1/FVC$  ratios of less than 50% of predicted lead to significant postoperative morbidity and mortality. Similarly, it appears that an  $m\dot{V}O_2$  of less than 15 increases morbidity and an  $m\dot{V}O_2$  of less than 10 leads to significant morbidity and mortality. However, the exact risk for any single patient cannot be estimated. No single test is absolutely predictive. Clinical judgment is extremely important.

### Postoperative Care

A major insult to cardiopulmonary reserve reflected by thoracotomy and pulmonary resection demands that patients undergoing such procedures receive assiduous care and monitoring in the postoperative period. This is best served by a 24- to 48-hour period in a monitored setting. With newer forms of pain control (epidural narcotic analgesia, patient-controlled analgesia, intrathoracic analgesia), the potential for less morbidity after pulmonary resection may be realized.

### Surgical Procedures

Until 50 years ago, pneumonectomy was considered the surgical excision of choice in managing all lung cancers.<sup>207</sup> Presently, when complete excision can be obtained by lobectomy, thus sparing functioning lung, this is the preferred resection method, with what appears to be an equal opportunity for long-term success.<sup>208</sup> In the last 20 years, there has been a resurgence of interest in smaller resections and lung-conserving operations. Jensek<sup>209</sup> has been the major proponent of segmentectomy for T1–2N0 peripheral tumors. Survival after such a limited resection and the morbidity and mortality of the operation appeared at least equivalent to lobectomy in retrospective analyses.<sup>210</sup> Newer information, however, suggests that locoregional recurrence is increased and survival is decreased when less than a lobectomy is performed.

In proximally situated tumors (T3) for which a pneumonectomy may be required for total excision, lung-conserving operations using bronchoplastic procedures to preserve uninvolved lobes (e.g., sleeve lobectomy) have results equivalent to the more extensive pneumonectomy and should be employed when possible. Even when the proximal pulmonary artery is involved, vascular sleeve resections can be used to preserve pulmonary function ( Fig. 31.2-13).

**FIGURE 31.2-13.** Bronchoplastic and bronchovascular sleeve resections to preserve pulmonary function. **A:** Right upper lobe sleeve resection. **B:** Left upper lobe sleeve resection. **C:** Left upper lobe bronchovascular sleeve resection.

With improved surgical and anesthetic technique and perioperative care, the postoperative mortality rate for surgical resections has decreased remarkably during the last 50 years. Today, pneumonectomy can be performed with a mortality rate of less than 6%, lobectomy with less than 3%, and smaller resections with 1% mortality or less. These mortality figures are significantly affected by the age of the patient, stage of the disease, and extent of resection.<sup>211</sup>

The most common complications after resectional surgery are not technical failures of the operation but cardiopulmonary problems, especially supraventricular arrhythmias and respiratory failure. Improved preoperative assessment and postoperative care to identify high-risk patients and to decrease these complications will ultimately lead to lessened operative risks for the patient ( Table 31.2-7).<sup>212</sup>

	Mortality Rate (%)	Complication Rate (%)
<b>TYPE OF RESECTION</b>		
Segment or wedge	1.5	10.4
Lobectomy	2.0	15
Pneumonectomy	6.2	15
<b>AGE (Y)</b>		
<50	1.3	8
50-59	1.3	10.7
60-69	4.1	13.0
70-79	7	24.5
≥80	8.1	30
<b>PULMONARY FUNCTION</b>		
$FEV_1 < 1.2$	NS	22
$FEV_1 1.3-2.0$	NS	14
$FEV_1 \geq 2$	NS	14
<b>DISEASE STAGE</b>		
I	NS	10.0
II	NS	11.0
III	NS	18.0

$FEV_1$ , forced expiratory volume in 1 second; NS, not stated.

### RADIOTHERAPY

Radiotherapy is used for the treatment of NSCLC in various ways. In unresectable disease, it is the primary modality for the cure of tumor. In the postoperative setting, it is used as an adjuvant treatment to improve local control. Radiotherapy is also frequently used for the palliation of advanced and metastatic lung cancer.

The vast bulk of radiotherapy for NSCLC is delivered via external-beam radiotherapy, either through a radioactive source, such as cobalt 60, or more commonly via a linear accelerator. Newer techniques, such as three-dimensional conformal radiotherapy (3D-CRT) and intensity-modulated radiotherapy, are essentially improved techniques to deliver external-beam radiotherapy more accurately and with fewer side effects. This allows for a higher dose of radiation to be delivered safely. Brachytherapy is another treatment modality that is used for both curative and palliative intent. Alterations in dose fractionation, such as hyperfractionation, are attempts to take advantage of the biologic behavior of tumors and normal tissue to optimize repair of radiation damage and limit tumor repopulation.

The maximum tolerated dose of radiotherapy to the thorax has yet to be established. Standard therapy for unresected disease in this country and Europe has consisted of 60 to 65 Gy over approximately 6 weeks. When patients receiving 65 Gy without chemotherapy were carefully evaluated for local tumor control, only 15% were free of disease after treatment.<sup>213</sup> Radiation resistance to the dose levels typically used represents a major factor contributing to the high incidence of local failure. Higher doses appear to be required for improved local control.<sup>214</sup> A phase I-II dose escalation protocol<sup>215</sup> of hyperfractionated radiotherapy established that a dose of 79.2 Gy can be safely delivered. Currently, dose escalation protocols are under way at many institutions to investigate the upper limits of dose that can be tolerated. Doses as high as 102.9 Gy for small tumors and 81 Gy for large tumors have been delivered safely.<sup>216,217 and 218</sup>

### External-Beam Radiotherapy

External-beam radiotherapy is generally delivered via high-energy photon beams generated by a linear accelerator. The challenge in delivering radiotherapy is the balancing of toxicity to the lung, spinal cord, esophagus, and other thoracic structures. To avoid an excessive dose of radiation to the lung, treatment is given from opposed anterior and posterior beams. These beams typically include the spinal cord, and the dose that can be delivered this way is limited. Therefore, oblique treatment fields are used to avoid the spinal cord. However, these fields treat more lung and expose the patient to an increased risk of radiation pneumonitis.

When a patient is simulated for radiotherapy, the treatment field encompasses the tumor with enough margin to account for tumor motion, patient movement, and set-up error. The tumor can be demarcated by many methods. The most straightforward is observing the tumor under fluoroscopy and on plain films during simulation. This has the advantage of helping to determine tumor motion. However, this method might lead to underestimation of tumor dimensions because of inadequate imaging technique and disease not discernible on plain films. Therefore, CT images should be used to help to localize tumor. With the advent of CT-based simulation, tumors can be outlined in the axial plane of consecutive images. A representation of the tumor in three dimensions can then be placed on a digitally reconstructed radiograph. Recently, new imaging modalities, such as [<sup>18</sup>F]fluorodeoxyglucose-PET scanning, have been used to help to define tumor volumes.<sup>219</sup> The treatment field should be verified on the treatment machine prior to the initiation of radiotherapy. Treatment fields should also be checked weekly so that adjustments can be made.

Acute side effects occurring during the course of radiotherapy are organ-specific and related to the fractionation scheme, total dose, and use of sequential or concomitant chemotherapy or radiosensitizers. They typically manifest in the second to third week of treatment. A significant concern of combined therapy is the increased toxicity, which may outweigh the benefit from both modalities.

Delayed acute radiation toxicity can occur 1 to 3 months after completing treatment but has been known to occur as late as 6 months after completion of treatment. Organs at risk include normal lung, esophagus, spinal cord, and heart. Radiation factors, including fraction size, overall treatment time, radiation dose, and volume of normal organ treated, contribute to acute delayed toxicity for conventional fractionation with radiotherapy. Similarly, the use of concurrent chemotherapy, as well as novel fractionation regimens, can lower the threshold for delayed tissue reactions.<sup>220</sup>

**PULMONARY TOXICITY.** Animal models have demonstrated increased vascular permeability after thoracic irradiation.<sup>221</sup> Alveolar surfactant levels also increase after thoracic irradiation and, owing to increased vascular permeability, are detectable in the serum.<sup>222</sup> This endothelial injury may lead to an inflammatory response, causing the clinical syndrome of radiation pneumonitis. Elevated serum levels of transforming growth factor- $\beta$ , a growth factor known to stimulate connective tissue formation, has been demonstrated in patients developing lung toxicity.<sup>223</sup> Radiation-induced clinical pneumonitis represents the most commonly observed delayed acute reaction, usually occurring between 1 and 3 months after completion. Patients with pneumonitis typically present with shortness of breath on exertion, tachypnea, tachycardia, fever, and nonproductive cough. Chest radiography often reveals an infiltrate within the irradiated volume.<sup>224</sup> These symptoms can mimic an upper respiratory infection, which must be ruled out before embarking on specific treatment related to alleviating pneumonitis. Recurrence or spread of tumor must be considered in the differential diagnosis. Although the effects of radiation pneumonitis are usually self-limiting, it is a potentially life-threatening process. The use of corticosteroids (prednisone) in a starting dose of 1 mg/kg/d, followed by a carefully controlled slow taper, usually resolves most clinical symptoms of pneumonitis. Corticosteroids, however, appear to reduce the ability of alveolar macrophages to release tumor necrosis factor in response to infectious agents, which can lead to recurrent respiratory tract infections in patients treated chronically with these drugs.<sup>225</sup>

Enhancement of radiation damage by chemotherapy in terms of acute and late effects appears to be maximum with concurrent treatment, with a tendency for damage to decline as the interval between drug and radiation is increased.<sup>226,227</sup> Roach et al.<sup>228</sup> analyzed radiotherapy parameters in 24 combined-modality trials completed before 1994, involving more than 1911 patients with both small cell lung cancer and NSCLC, to determine potential risk factors for radiation pneumonitis when radiation is combined with chemotherapy. Multiple fractionation schemes, total doses, and fraction sizes, along with several chemotherapeutic regimens, were used. The overall incidence of pneumonitis was 7.8%. Factors associated with a higher risk included fraction size higher than 2.67 Gy and total dose. Twice-daily radiation, however, appeared to reduce the risk expected if the same total daily dose were given as a single fraction. Based on this analysis, high dose per fraction when combined with chemotherapy should be avoided.

Late radiation injury is related primarily to the dose per fraction and total dose. Most patients who develop clinical pneumonitis eventually become asymptomatic, although nearly all ultimately develop the radiologic evidence of pulmonary fibrosis in the region of the previous pneumonitis. The degree of late pulmonary toxicity and fibrosis is directly proportional to the volume of normal lung irradiated and the total dose delivered, as well as the fraction size. It is not clear whether chemotherapy actually modifies the latency period for the development of late pulmonary reactions or increases the actual incidence. For most patients, pulmonary fibrosis is an expected and unavoidable consequence of high-dose irradiation. For patients presenting with preexisting compromised pulmonary function, however, and for patients who develop severe clinical pneumonitis, a distortion of the pulmonary architecture by fibrosis can have a major impact on the quality of life and functional status.

**ESOPHAGEAL TOXICITY.** Since the esophagus has a central location, it is exposed to high-dose radiation during the treatment of most NSCLCs and can be a major dose-limiting factor. Radiation may induce acute esophagitis during the course of therapy. Histologic changes occur during the first week of treatment,<sup>229</sup> although clinical symptoms typically begin during the second through fourth weeks of treatment. Esophagitis presents with mild to severe swallowing difficulty requiring diet modification and nonnarcotic or narcotic analgesics, depending on severity. It is caused by an inflammatory response of the esophageal mucosa.<sup>229</sup>

Chemotherapy and radiosensitizers appear to accelerate the onset and severity of symptoms. In a randomized prospective intergroup trial, the rate of grade 3 or worse esophagitis increased from 1.3% to 65% with the addition of concurrent cisplatin and etoposide to 50.4 Gy thoracic radiation.<sup>230</sup> When used concurrently with carboplatin and paclitaxel, the grade 3 or 4 esophageal toxicity has been reported to be approximately 25%.<sup>229</sup> Agents such as 5-fluorouracil, doxorubicin, cisplatin, and mitomycin also enhance radiation-induced esophageal toxicity.<sup>168,169</sup> and <sup>170,231,232</sup> and <sup>233</sup> Acute esophagitis generally resolves shortly after the completion of radiotherapy, with few patients progressing to chronic esophagitis. The rare patient with chronic esophagitis may require dilatation to relieve stricture formation.

Hyperfractionated treatment has also been shown to increase toxicity. When 60 Gy given via accelerated hyperfractionation was compared to standard fractionation, the grade 3 or worse acute esophageal toxicity increased from 9% to 35% ( $P = .0017$ ).<sup>234</sup>

**CUTANEOUS TOXICITY.** With the use of megavoltage equipment, treatment rarely causes an acute reaction to the skin, such as erythema or moist desquamation. Moist desquamation can occur in the supraclavicular region after a course of high-dose radiotherapy, owing to the sloping surface of the chest at the level of the thoracic inlet. The addition of chemotherapy or sensitizers may also enhance the effects of radiotherapy on the skin.

**NEUROTOXICITY.** A transient myelopathic syndrome (Lhermitte's syndrome) can occur during the first 6 months after therapy and is manifested by dysesthesias and paresthesias affecting the upper extremities and shoulder girdles on flexion of the neck.<sup>235</sup> It is related to the total radiation dose, dose per fraction, and length of spinal cord irradiated. Lhermitte's syndrome is self-limiting and does not appear to be related to the development of late radiation myelitis.<sup>236</sup>

The spinal cord can tolerate conventionally fractionated radiotherapy doses in the range of 45 to 50 Gy, and the radiation oncologist should strive to maintain the maximal spinal cord dose at or below this level. In some cases, depending on the volume of spinal cord treated and the dose per fraction, the tolerance has been reported to be as high as 60 Gy; in selected cases in which the tumor is paraspinal, it may be appropriate to treat a small portion of the cord to this dose with the patient's understanding of potential toxicity.<sup>237</sup> Chemotherapy can reduce the tolerance threshold of this organ. There has been a concern that altered fractionation might lead to increased myelitis. Jeremic et al.<sup>238</sup> have reported no cases of radiation myelitis in 158 patients who lived at least 1 year after receiving hyperfractionated radiotherapy in fraction sizes of 1.2 Gy per day to a total dose of 50.4 Gy. Once it develops, radiation-induced transverse myelitis is irreversible.

**CARDIAC TOXICITY.** Radiation injury to the heart is usually manifested as pericarditis, although other complications, such as myocardial ischemia and chronic pericardial effusions, can occur. The tolerance for the entire heart is approximately 40 Gy; up to one-third of the heart can tolerate approximately 60 Gy.<sup>239</sup>

### **Three-Dimensional Conformal Radiotherapy**

3D-CRT represents an approach to improve the local outcome of radiotherapy in NSCLC.<sup>239a,239b</sup> The major aim of this method is to decrease the risk of underdosing or missing portions of the tumor. In addition, owing to the improved ability to conform the high radiation dose to the target, considerable amounts of normal lung, esophagus, and heart can be effectively excluded from the high-radiation-dose regions. This provides a potential for increasing the tumor dose to levels beyond those feasible with conventional radiotherapy, with a concomitant decrease in the normal tissue complication probability. Single-institution and cooperative group studies of

dose escalation are under way <sup>216,217</sup> and <sup>218</sup> to evaluate the efficacy of this strategy.

3D-CRT is accomplished using CT to aid in treatment planning. A clinical tumor volume (CTV) is defined in the axial plane of the CT images. A margin is subsequently added to the CTV to generate the planning target volume. This margin compensates for tumor motion during treatment caused by breathing, patient movement, and set-up error. The treatment beams are subsequently constructed using the beam's-eye-view technique.

The use of 3D-CRT also allows investigators to predict more accurately the toxicity of a given course of radiotherapy. The normal tissue complication probability is an estimate of clinical toxicity based on the dose delivered to the volume of normal lung. It has been shown to correlate with incidence of radiation pneumonitis. Other institutions use either the mean lung dose <sup>240</sup> or the dose that a given volume of lung receives as a determinant of lung toxicity. For example, in the Radiation Therapy Oncology Group (RTOG) dose escalation protocol, the volume of lung receiving 20 Gy is used as a guide as to what dose to deliver. <sup>216</sup>

### **Intensity-Modulated Radiotherapy**

Intensity-modulated radiotherapy represents a new approach to radiotherapy wherein the beam within the treatment field is dynamically changed during treatment to give more radiotherapy to areas with tumor and less to areas with normal tissue. <sup>241</sup> Its use is being investigated.

### **Gated Radiotherapy**

Motion of the tumor and of the lung itself during the delivery of each treatment appears to affect the outcome of radiotherapy in inoperable NSCLC. Lung tumors have been shown to move substantially during quiet breathing, causing inaccuracies in treatment delivery. <sup>242,243</sup> Underdosage of the CTV may result if the tumor target moves outside the treatment volume during the administration of radiotherapy. To compensate for this motion, a large margin is usually used, consequently increasing the amount of normal lung tissue in the high-dose volume and limiting the amount of radiation that can be delivered.

To overcome this, techniques have been developed to keep the tumor still during radiotherapy. Two distinct techniques have been used to reduce the effect of respiratory motion. The first involves confining the radiation delivery to a specified phase in the breathing cycle by gating the linear accelerator while the patient breathes freely. Breathing is monitored with devices that trigger radiation delivery during specific phases of the patient's respiratory cycle. <sup>244</sup> The use of gated treatments has been evaluated <sup>244,245,246</sup> and <sup>247</sup> and offers the advantage of allowing patients to breathe freely while the radiation beam is turned on and off. In the second approach, breathing is controlled either voluntarily by the patient <sup>248</sup> or by using an occlusion valve. <sup>249</sup> This technique is less challenging to perform, since it involves no modification to the treatment machine, but it is not suitable for all patients.

### **Stereotactic Radiotherapy**

Stereotactic radiotherapy and stereotactic radiosurgery have been shown to be effective in treating brain metastases. Stereotactic radiotherapy is a technique by which a high dose of radiation is delivered to a small, well-circumscribed lesion with minimal dose to surrounding structures. This technique has been applied to lung tumors with good local control. <sup>250</sup> It will be applicable only in a small subset of patients with very early, small tumors and must be considered investigational at this time.

### **Neutron Therapy**

Fast neutrons have been examined as a potential modality to improve the results of therapy for NSCLC. The biologic properties of neutrons differ from conventional photon energies, possessing advantages of high-linear-energy transfer. This high-linear-energy transfer can lead to a number of biologic effects, including greater relative biologic effectiveness, reduced oxygen enhancement ratio, less sublethal and potentially lethal damage repair, and less cell cycle specificity than photons. <sup>251</sup>

A randomized trial of 200 patients was performed using modern neutrons to a dose of 20.4 neutron Gy as compared to 66 Gy of standard photons. <sup>252</sup> It showed no difference in overall survival between the two groups. Grade 3 or worse radiation pneumonitis occurred in 11% and 24% of the patients in the photon and neutron groups, respectively. Therefore, unless a specific group of patients who might benefit from neutron therapy can be identified, it is unclear whether this modality is useful for patients with NSCLC.

### **Brachytherapy**

**INTRAOPERATIVE INTERSTITIAL BRACHYTHERAPY AND RADIOTHERAPY.** Intraoperative interstitial brachytherapy has been applied in the curative and palliative treatment of NSCLC. Implantation of radioactive sources offers an advantage over external irradiation because of the limited penetrability from source to prescription point, resulting in rapid dose fall-off and sparing of surrounding normal tissues.

Indications for implantation include unresectable or incompletely resected tumors found at thoracotomy: hilar tumors adherent to major vasculature with no clearance for safe dissection; attachment of tumors to mediastinal structures, such as the trachea, pericardium, or esophagus; extensive tumor involvement of the chest wall, spine, or paravertebral tissue when a complete resection is not possible; and recurrent or metastatic endobronchial lesions. <sup>253</sup>

For curative techniques, the selection of radioactive sources depends on the tumor location and the amount of gross disease left after surgery. In circumstances in which more than 1 cm of tumor is left behind, a permanent volume implant is usually required. The area to be implanted is determined, and its dimensions are measured. A nomogram is applied to determine the number of radioactive sources (<sup>125</sup>I or <sup>103</sup>Pd) needed and the proper spacing of the needles, which in turn are based on the strength of the sources and the average dimension of the tumor volume. Hollow needles are inserted into the tumor, and radioactive sources are permanently implanted. For close and positive margins or in the presence of a minimal plaque of residual gross disease, either a permanent planar or temporary interstitial implant may be used. For situations requiring permanent placement of radioactive sources, <sup>125</sup>I seeds encapsulated in Vicryl or <sup>103</sup>Pd seeds can either be directly sutured onto the area at risk or sewn into a premeasured Dexon or Vicryl mesh, which in turn is sutured onto the target area. A similar technique employing <sup>125</sup>I embedded in a Gelfoam plaque has been described. <sup>254</sup> Both techniques allow implantation of radioactive seeds in areas that are near vital structures that cannot be directly sutured. <sup>255</sup>

Temporary implants use <sup>192</sup>Ir or <sup>125</sup>I at either a low- or a high-dose-rate method of delivering radiation using afterloading catheters. Temporary implants have been advocated for tumors invading the chest wall, superior sulcus, mediastinum, and paravertebral regions when a complete resection is not certain. In general, the catheters are spaced 1 cm apart, with a 1-cm margin around the defined target, and exit out the chest wall. The patient is then loaded with radioactive sources (<sup>125</sup>I or <sup>192</sup>Ir) approximately 4 or 5 days after surgery to allow for proper wound healing.

**INTRALUMINAL BRACHYTHERAPY.** Intraluminal brachytherapy or EBB is generally used as a palliative treatment for obstructive recurrent tumors causing such symptoms as dyspnea and hemoptysis. This treatment directly introduces a high-activity <sup>192</sup>Ir source directly into the lumen of the tracheal or bronchial airway. Flexible bronchoscopic guidance is used to localize the tumor and to position a catheter beyond the site of disease. Patients are generally treated under a combination of monitored intravenous sedation and the application of local anesthesia to the larynx and trachea. The radioactive <sup>192</sup>Ir source is then introduced into the catheter and positioned. Treatment lasts only a couple of minutes, owing to the high activity of the source. High-dose-rate intraluminal brachytherapy has largely replaced both direct interstitial implantation of <sup>125</sup>I seeds into endobronchial tumors and low-dose-rate endobronchial irradiation. <sup>256</sup>

Side effects after intraluminal brachytherapy include massive hemoptysis, fistula formation, chronic mucosal sloughing, and airway edema. <sup>257</sup> Langendijk et al. <sup>258</sup> examined risk factors for massive hemoptysis. The highest complication rate occurred in patients receiving EBB for recurrent tumor (43%) or combination external-beam therapy and EBB (25%). They also found that patients receiving a single fraction of 15 Gy prescribed to 1 cm had a 50% rate of massive hemoptysis, whereas patients receiving 7.5 Gy × 2 or 10 Gy in a single fraction had an 11% rate. Hennequin et al. <sup>259</sup> theorized that most massive hemoptysis is from disease progression and not treatment toxicity. They reported a 7% risk of massive hemoptysis and concluded that all but one case had evidence of tumor progression. They also reported an 8.7% rate of radiation bronchitis. The risk factors for toxicity in their series included palliative intent of treatment and the length of bronchus treated.

### **Intraoperative Radiotherapy**

Experience with the use of intraoperative radiotherapy for NSCLC is limited. This modality does not appear to show a significant benefit over external-beam irradiation alone or in combination with chemotherapy. The technique involves the modification of a linear accelerator through the attachment of an intraoperative cone for electron-beam treatment.<sup>260</sup> Both the optimal dose and threshold tolerance of mediastinal structures are unknown; however, one fraction is generally delivered intraoperatively at a dose of 10 to 20 Gy. The published results are conflicting. With no reported phase III trials, this modality must be considered experimental.

## CHEMOTHERAPY

### General Principles

Chemotherapy for patients with NSCLC has been under investigation for several decades. Conceptually, it has evolved from the administration in the palliative care setting to its integration into combined-modality curative therapy settings in patients with locoregionally advanced disease.

Currently, chemotherapy as a single-treatment modality can be considered standard therapy for most patients with stage IV disease or stage IIIB disease due to pleural effusion or positive scalene lymph nodes.<sup>261,262,263,264</sup> and <sup>265</sup> In these settings, prolongation of survival time and amelioration of clinical symptoms are the goals of therapy. It has been conclusively demonstrated in randomized clinical trials that chemotherapy prolongs median survival times as compared with “best supportive care” and also increases quality of life (discussed later in [Stage IV Disease](#)).

In patients with locoregionally advanced disease (stage IIIA or IIIB), traditional therapy has consisted of surgery and postoperative radiotherapy (PORT) or radiotherapy alone for patients with unresectable disease. In these patients, chemotherapy is now used as a component of multimodality therapy.<sup>266,267</sup> and <sup>268</sup> Therapy is given with curative intent, and it is hoped that the integration of chemotherapy will lead not only to an increased overall median survival time but to an increase in the percentage of (cured) patients surviving for long periods (discussed later in [“Unresectable” Stage IIIA and IIIB Non–Small Cell Lung Cancer](#)).

Strategies in this setting have included classic adjuvant chemotherapy in patients with fully resected disease and induction (or “neoadjuvant”) chemotherapy whereby a specified number of chemotherapy cycles are administered prior to definitive local therapy with surgery, radiotherapy, or both. The simultaneous use of chemotherapy and radiotherapy (concomitant chemoradiotherapy) has also been intensively investigated. In theory, adjuvant and induction chemotherapy are aimed at improving systemic control of occult microscopic metastatic disease. Decreasing the size (downstaging) of the locoregional tumor burden may also be observed with induction chemotherapy. The delay of radiotherapy to allow for administration of induction chemotherapy has been of theoretic concern, since this could lead to the proliferation of clonogenic tumor cells in an unresponsive tumor.<sup>269</sup> Concomitant chemoradiotherapy may also result in systemic antitumor activity.<sup>270</sup> However, this will be realized only if systemically active doses and schedules of the drugs are administered. In clinical practice, the latter has been challenging, since radiation-related toxicities are usually increased in the presence of chemotherapy (i.e., esophagitis and radiation pneumonitis). Therefore, the primary goal of concomitant chemoradiotherapy may be to enhance the antitumor activity of radiation and increase locoregional control (radiation sensitization or enhancement).<sup>270</sup>

It has been conclusively demonstrated that induction chemotherapy followed by radiotherapy prolongs the median survival time in patients with unresectable stage III disease when compared with radiotherapy alone.<sup>213,271,272</sup> and <sup>273</sup> Encouraging data also exist to support the administration of combination chemotherapy with concomitant radiotherapy.<sup>274,275</sup> The use of induction chemotherapy in the surgical setting (stage IIIA)<sup>276,277</sup> or with simultaneous radiotherapy<sup>274</sup> remains investigational. Also, the use of adjuvant chemotherapy in patients with resected stage I, stage II, or stage IIIA disease is considered experimental.

### Selection of Specific Drugs

Most patients with NSCLC present with metastatic (stage IV) disease at initial diagnosis. There is no known curative therapy for these patients. The treatment goals are, therefore, broadly defined to maximize survival time and maintain acceptable quality of life. Because metastatic NSCLC is a systemic disease, its therapy is logically based on the use of systemic therapy. Additional local therapy is used to palliate specific sites of disease.

Most traditional drugs have at best moderate single-agent activity in NSCLC.<sup>261,263,264</sup> and <sup>265,270,278,279,280</sup> and <sup>281</sup> It has been generally accepted that a single agent should have a response rate of approximately 15% for the drug to be considered active.<sup>261,262,263,264</sup> and <sup>265</sup> This guideline is compromised by the fact that, historically, not all drugs have been studied in rigorously designed and conducted phase II or phase III trials. For example, rigorous testing during the 1990s suggested response rates for cisplatin or carboplatin of only approximately 10%.

Throughout the 1970s and 1980s, only six drugs were thought to have sufficient single-agent activity in NSCLC. Complete responses to single-agent therapy were exceedingly rare. Furthermore, the response duration was short, on average 2 to 3 months. Median survival trials were 6 to 8 months, with no long-term survivors.

Combination chemotherapy was investigated in an attempt to increase response rates.<sup>261,262,263,264</sup> and <sup>265,270,282</sup> Generally, higher responses were reported, but it remained unclear whether a more pronounced impact on survival was also achieved. One of the earliest combination chemotherapy regimens was the regimen consisting of cyclophosphamide, doxorubicin (Adriamycin), methotrexate, and procarbazine (CAMP). In a single-institution study, a response rate of 26% was noted.<sup>283</sup>

Subsequent clinical trials incorporated cisplatin, which was thought by many investigators to be the most active single agent in NSCLC in the 1980s.<sup>144,282,284</sup> Among the most frequently used combinations were the regimens of cisplatin and etoposide, cisplatin and vinblastine, or (in Europe) cisplatin and vindesine or teniposide.<sup>282,285,286</sup> and <sup>287</sup> Three-drug combinations incorporating ifosfamide,<sup>288,289</sup> mitomycin C,<sup>286,290</sup> or leucovorin<sup>291,292</sup> were also investigated ([Table 31.2-8](#)).

Drug Regimen	Dose	Reference (No.)
CAMP	1000 mg/m <sup>2</sup> cyclophosphamide, 40 mg/m <sup>2</sup> doxorubicin, 15 mg/m <sup>2</sup> methotrexate, 100 mg/m <sup>2</sup> procarbazine	283
EP	100 mg/m <sup>2</sup> etoposide, 100 mg/m <sup>2</sup> cisplatin	144,282
EPV	100 mg/m <sup>2</sup> etoposide, 100 mg/m <sup>2</sup> cisplatin, 3 mg/m <sup>2</sup> vinorelbine	285
EPV	100 mg/m <sup>2</sup> etoposide, 100 mg/m <sup>2</sup> cisplatin, 3 mg/m <sup>2</sup> vindesine	286
EPV	100 mg/m <sup>2</sup> etoposide, 100 mg/m <sup>2</sup> cisplatin, 3 mg/m <sup>2</sup> teniposide	287
EPV	100 mg/m <sup>2</sup> etoposide, 100 mg/m <sup>2</sup> cisplatin, 3 mg/m <sup>2</sup> ifosfamide	288
EPV	100 mg/m <sup>2</sup> etoposide, 100 mg/m <sup>2</sup> cisplatin, 3 mg/m <sup>2</sup> mitomycin C	289
EPV	100 mg/m <sup>2</sup> etoposide, 100 mg/m <sup>2</sup> cisplatin, 3 mg/m <sup>2</sup> leucovorin	291
EPV	100 mg/m <sup>2</sup> etoposide, 100 mg/m <sup>2</sup> cisplatin, 3 mg/m <sup>2</sup> irinotecan	292

**TABLE 31.2-8.** Combination Chemotherapy Regimens for Non–Small Cell Lung Cancer

Most of these regimens have in common the combination of cisplatin with a vinca alkaloid or etoposide. They were based on the incorporation of drugs with known single-agent activity, unlike earlier combinations, such as CAMP. Phase II studies of these regimens frequently resulted in response rates of 30% to 50%, suggesting higher activity than the first-generation combination regimens.<sup>265</sup> Because cisplatin is logistically difficult to administer and can result in severe toxicity, direct comparisons of cisplatin-based regimens with non–cisplatin-containing combinations were performed. Although some studies reported increased response rates with a cisplatin-containing regimen, there was no consistent increase in survival. Only three studies reported superior survival with cisplatin.<sup>293</sup>

Another question of interest was whether there exists a dose-response curve for cisplatin's activity in NSCLC. One early study suggested an increase in response rate when increasing the cisplatin dose from 60 to 120 mg/m<sup>2</sup>.<sup>294</sup> A second study, however, did not support this observation.<sup>282</sup> The Southwestern Oncology Group (SWOG) initiated a three-arm comparison of cisplatin administered at 100 mg/m<sup>2</sup> versus 200 mg/m<sup>2</sup> per cycle versus a third arm of high-dose cisplatin and mitomycin based on promising phase II data for high-dose cisplatin.<sup>284</sup> The response rates for the three arms were 12%, 14%, and 27%, respectively, and median survival times

were not statistically different at 5 to 7 months.<sup>295</sup> This study discounted the possibility that increasing the cisplatin dose beyond 100 mg/m<sup>2</sup> results in significantly higher activity. Currently, most clinical trials use doses of 75 or 80 mg/m<sup>2</sup> every 3 weeks.

The Eastern Cooperative Oncology Group (ECOG) conducted several comparative studies attempting to identify the most active combination in treating NSCLC. In one such study, a first-generation regimen (CAMP) was compared with three cisplatin-containing regimens, including the combination of mitomycin C, vinblastine, and cisplatin (platinum), or MVP.<sup>296</sup> Although the MVP regimen produced the highest numeric response rate at 31%, the median survival time ranged from 4.5 months (for MVP) to 6.5 months and was not significantly different among the four regimens. In another five-arm study, single-agent carboplatin or iproplatin followed by MVP chemotherapy at the time of first progression was compared with first-line MVP and two other cisplatin-based regimens.<sup>297</sup> Patients treated with initial carboplatin had the longest median survival time; first-line MVP again resulted in the highest response rate but in a lower median survival time (23 weeks, versus 32 weeks for initial carboplatin). Carboplatin and cisplatin are now considered to be of equal activity in NSCLC, with single-agent response rates of approximately 10% and a different spectrum of clinical toxicities.

### **New Drugs**

During the decade of the 1990s, several new drugs with single activity in NSCLC were identified. These include the taxanes, paclitaxel, and docetaxel; the antimetabolite gemcitabine; the topoisomerase I inhibitor irinotecan; and the vinca alkaloid vinorelbine.<sup>261,262,263,264</sup> and <sup>265</sup> The introduction of these agents into clinical practice generated much enthusiasm, since they are usually tolerated better than cisplatin, have reproducible single-agent activity of 15% to 25% and, in some cases, have novel intracellular targets. Current standard regimens for stage IV disease and most clinical trials in earlier-stage disease involving chemotherapy are focused on combinations including these drugs and are discussed further in the stage-specific segments.

### **BIOLOGIC THERAPY**

Investigators have evaluated both nonspecific and specific means to stimulate the immune system of patients with NSCLC.<sup>298</sup> Despite this effort and the proven ability to modulate immunologic end points, no immunologic agent or approach has been shown to induce regressions or improve survival in epithelial lung cancer patients. As with all other forms of systemic therapy for this illness, immunotherapy remains an investigational approach. Patients should be treated only as part of formal protocols. In addition, because cytotoxic chemotherapy given as initial treatment for metastatic NSCLC can reliably induce regressions and prolong survival, inclusion of chemotherapeutic drugs in the overall treatment plan should be discussed.

Several trials have tested nonspecific agents to enhance immune response. After observations that patients who survive an empyema after lung cancer surgery appear to have prolonged survival,<sup>299</sup> McKneally et al.<sup>300</sup> tested the usefulness of intrapleural bacille Calmette-Guérin (BCG) in stage I NSCLC and found fewer recurrences and deaths in treated patients than in comparable controls. Confirmatory prospective randomized trials have failed to confirm this result and, in fact, demonstrated a decrease in disease-free interval for patients given BCG.<sup>301</sup> Levamisole has also been tested as a nonspecific immunopotentiator in epithelial lung cancer patients, with no evidence of benefit.<sup>302,303</sup>

The combination of BCG and levamisole as adjuvant therapy has been compared to cyclophosphamide, doxorubicin, and cisplatin (CAP) chemotherapy in patients with completely resected stage II and III adenocarcinoma and large cell carcinoma.<sup>304</sup> This trial showed an improvement in both disease-free survival and overall survival among patients randomly assigned to receive CAP chemotherapy. The accumulated data demonstrate that no nonspecific immunostimulating agent tested has been shown to improve symptoms, response, or survival in NSCLC.

Interferons have been tested alone and in combination in patients with epithelial lung cancer. Trials of human leukocyte interferon<sup>305</sup> and recombinant interferon- $\alpha$ <sup>306</sup> or interferon- $\beta$ <sup>307</sup> have not shown sufficient activity to warrant either use or further study for this indication. The combination of interferon- $\alpha$  and - $\beta$  given with cisplatin plus etoposide has been compared with the same chemotherapy given alone.<sup>308</sup> No improvement in response or survival and enhanced hematologic toxicity were observed in the combination chemotherapy plus interferon arm of this study. Preclinical data, however, demonstrated additive effects or synergy when interferon was combined with cytotoxic agents, such as fluorouracil or cisplatin, in several tumor types.<sup>309</sup> A therapeutic clinical benefit has not been established.<sup>310,311</sup> and <sup>312</sup> At present, there is no evidence that interferon- $\alpha$ , - $\beta$ , or - $\gamma$ , given alone or in combination with chemotherapy, can influence the natural history of NSCLC. The use of interferon for this indication remains investigational.

Phase I and phase II trials of interleukins have failed to reveal any significant effect.<sup>313</sup> Current investigations are focused on a possible role for monoclonal antibodies to the EGFR (e.g., IMclone C225) or the Her2/neu antibody herceptin.

## **SPECIFICS OF LUNG CANCER MANAGEMENT**

### **LOCALIZED "RESECTABLE" (STAGES I, II, AND IIIA) DISEASE**

When disease is localized to the lung or includes only regional draining lymphatic channels, treatment of the primary disease and these regional lymphatics employs a surgical or radiotherapeutic approach. However, despite lack of evidence of distant metastatic disease at initial staging, patients fail most frequently after treatment because of distant recurrences that indicate that despite primary control, micrometastatic disease was probably present at the time of initial treatment. For this reason, even with disease that can be completely resected, combined-modality treatments are being investigated with fervor to eliminate these presumed micrometastatic foci at the time of initial therapy.

#### **Primary Surgery**

Stage I and II lung cancer denotes disease limited to the hemithorax, with tumor extension no farther than the adjacent resectable structures peripherally (T3) or hilar nodes proximally (N1). In these cases, whenever possible, surgical excision is the treatment of choice.

In most instances, lobectomy is the resection procedure required. When the primary tumor or lymph node involvement extends to the proximal bronchus or proximal pulmonary artery (T3) or cross the major fissure such that a complete resection is only possible by pneumonectomy, this more extensive procedure should be performed. When resectable adjacent structures are involved, an *en bloc* resection of the involved area together with the pulmonary resection is necessary.

The role of mediastinal lymphadenectomy as part of the surgical procedure when hilar or mediastinal nodes are uninvolved is debated. The proponents of complete ipsilateral or bilateral mediastinal lymphadenectomy argue that complete removal of mediastinal lymph nodes improves survival. Certainly, this dissection provides the best possible surgical staging by removing all draining lymph nodes, which can then be analyzed pathologically for metastatic involvement. At minimum, for accurate final surgical and pathologic staging, lymph node sampling of all draining areas should be performed at the time of surgical resection,<sup>314,315</sup> and all lymph nodes involved or suspected to be involved with tumor should be removed. A small randomized trial comparing mediastinal lymphadenectomy to mediastinoscopy plus intraoperative lymph node sampling showed no difference in survival, locoregional recurrence, or accuracy of the two staging procedures as applied to stage I or II lung cancer.<sup>316</sup> A larger phase III trial is under way in North America to address this issue.

In peripheral T1N0 tumors, the role of lesser resection (segmentectomy, wedge excision, or precision cautery dissection) has yet to be fully defined. A randomized trial conducted by the Lung Cancer Study Group (LCSG)<sup>205</sup> showed that after long-term follow-up, the locoregional recurrence rate with limited resection was threefold greater than with lobectomy (15% vs. 5%), and mortality, morbidity, and pulmonary function were equal in both arms. There was a marginally significant long-term survival benefit for lobectomy. For this reason, it is recommended that limited resection be reserved for compromise situations in which the surgeon feels that lobectomy is contraindicated and a complete excision can be performed by a smaller resection (Table 31.2-9). As well, an analysis by the Rush-Presbyterian group also suggests that locoregional recurrence rate after segmentectomy is much higher than that after lobectomy. The value of segmentectomy in preserving lung function in otherwise normal individuals has been questioned. A recent analysis suggests that lobectomy and segmentectomy result in identical pulmonary function 1 year after the surgery.<sup>205,317,318</sup> Except in a few centers, lesser resections (e.g., segmentectomy, wedge excision, precision cautery dissection) have been reserved for situations in which, because of poor cardiopulmonary reserve, it is thought that the patient cannot tolerate a lobectomy. In these situations, this "compromised resection" is certainly indicated, although the risks of locoregional recurrence are higher.

Study	Patients	Estimated 5-Y Survival Rate (%)	Operative Mortality Rate (%)	Local Recurrence Rate (%)
Yam <sup>205</sup>	56	52	1	12
Naruke <sup>315</sup>	113	71	44	44
Naruke <sup>316</sup>	164	63	3	3
Lung Cancer Study Group <sup>28</sup>	123	71	1	15

**TABLE 31.2-9.** Results of Limited Pulmonary Resection Performed as an Intentional Procedure, Mainly for T1N0 Tumors

In the LCSG trial, there appeared to be no difference in locoregional recurrence rates whether the tumor measured 1, 2, or 3 cm. However, some surgeons do advocate that for very early tumors (1 cm or less) a lesser resection is justified without the need to perform a lobectomy. However, studies have demonstrated that even in these very early tumors, lymphatic permeation may have occurred within that lobe,<sup>205,317,318</sup> and the patient would have been better served by a formal lobectomy. The exact role of lesser resections in these very small (often CT-detected) tumors (0.5 to 1 cm) has yet to be defined. This will be important in managing CT-screening-identified subcentimeter nodules.

After surgical resection for stage I and II lung cancer, the 5-year survival rate without recurrence exceeds 50% in stage I and 35% in stage II disease. In completely resected T1N0 tumors, 5-year survival rates exceed 70%. Approximately 25% of patients are tumor-free at death, suggesting that surgical resection in T1N0 lung cancer renders 80% of patients tumor-free.

### T3N0 Tumors

Tumors that invade the chest wall, the diaphragm, the mediastinal pleura, or the pericardium or are situated within 2 cm of the carina constitute the designation of T3. At the Japan National Cancer Center, Naruke et al.<sup>315</sup> reported an overall 5-year survival rate of 26% in 327 patients with this stage of disease. At Memorial Sloan-Kettering Cancer Center (MSKCC), 77 patients with completely resected tumor had a 42% 5-year survival rate, but 48 patients with incomplete resections did not survive beyond 2.5 years. From the literature, it appears that approximately 40% of patients with completely resected T3N0 lesions survive at least 5 years.
