Laboratory studies are usually not indicated for isolated anterior or middle hypospadias. Screening for a urinary tract anomaly by renal ultrasonography should be considered in patients with posterior hypospadias and in those with an anomaly of at least one additional organ system. Karyotyping should be performed in patients with cryptorchidism or ambiguous genitalia. Other tests that should be considered include serum electrolytes, 17-hydroxyprogesterone, testosterone, luteinizing hormone, follicle-stimulating hormone, and sex hormone-binding globulin, ultrasonography of the abdomen, human chorionic gonadotropin stimulation tests, and molecular genetic analysis of the androgen receptor gene and the 5α reductase gene. The ordering of endocrine tests should be directed by the history, physical examination, and abnormal laboratory findings. In patients with associated micropenis, a pituitary evaluation followed by a trial of testosterone therapy should be performed [4].

## Therapeutic Principles

The goals of hypospadias surgery are to create a straight penis that is adequate for sexual intercourse, to reposition the urethral meatus to the penile tip to allow the patients to void while standing, to create a neourethra of adequate and uniform caliber, to construct a normal looking penis, and to accomplish the foregoing with as few complications as possible. Surgical correction should also be considered in patients with a distal hypospadias and minimal deformity as the psychological benefit can be substantial. The ideal age for surgical repair in a healthy child is approximately 6–12 months of age [5].

# Hypotension, Hereditary

Manish Suneja, Christie P. Thomas
Division of Nephrology, Department of Internal Medicine, University of Iowa College of Medicine, Iowa City, IA, USA

## Synonyms

Genetic hypotension: Pseudohypoaldosteronism type-1, PAH1; Autosomal recessive pseudohypoaldosteronism (OMIM 264350); Autosomal dominant pseudohypo aldosteronism (OMIM-177735); Congenital adrenal hypoplasia; Congenital adrenal hyperplasia (CAH); 21-Hydroxylase deficiency classical salt wasting (OMIM 201910); 3βHydroxysteroid dehydrogenase deficiency classical (OMIM 201810); Steroidogenic acute regulatory protein deficiency (OMIM 201710); Familial orthostatic hypotensive disorder, Streeten type (OMIM 143850); Congenital dopamine –beta – hydroxylase deficiency (OMIM 223360); Bartter syndromes; Gitelman syndrome

## Prevalence

Rare [1].

## Definition and Characteristics

Hypotension is usually an acute clinical syndrome that follows loss of circulating volume or cardiac disturbances or is associated with endocrine or vasomotor disorders. Hypotension can also be a chronic condition that arises from salt wasting tubulopathies or from autonomic dysfunction. In rare cases, hypotension is one of a constellation of abnormalities that define certain inherited disorders resulting from a specific genetic abnormality. The majority of studies to identify genes that influence blood pressure have focused on hypertensive kindred, but the isolation of genes in familial disorders characterized by hypotension has also contributed to our understanding of blood pressure regulatory pathways in the continuum from low to high blood pressure. There are several genetic diseases where hypotension is a prominent feature and these are discussed in detail elsewhere and include the following:

1. *With sodium wasting*
*with hypokalemia*
   - Bartter Syndrome
   - Gitelman Syndrome

*with hyperkalemia*
   - Pseudohypoaldosteronism type-1 (PHA 1); autosomal recessive
   - Pseudohypoaldosteronism type-1 (PHA 1); autosomal dominant

*with hyperkalemia and ambigous genitalia*
   - Congenital adrenal hypoplasia (AHC)
   - Congenital adrenal hyperplasia (CAH)

2. *Without sodium wasting*
   - Familial orthostatic hypotensive disorder, Streeten type (OHDS)
   - Congenital Dopamine beta hydroxylase defiency (DBH deficiency)

## Genes

The genes involved are:

- PHA 1-AR: Mutation in both copies of the alpha subunit (SCNN1A), the beta subunit (SCNN1B), or the gamma subunit (SCNN1G) of the epithelial sodium channel (ENaC).
- PHA1-AD: Mineralocorticoid receptor gene (*MLR*) NR3C2
- AHC: DAX1, steroidogenic factor (SF1)

**Hypotension, Hereditary. Table 1** Sodium wasting disorders

| Disease | OMIM entry | Gene | Locus | Na wasting + Hyperkalemia | Ambiguous genetalia |

### Molecular and Systemic Pathophysiology

Most genetic disorders leading to hypotension have renal salt wasting in common. The specific pathophysiology depends on the underlying genetic defect (see specific disorders).

### Diagnostic Principles

Diagnostic evaluation for salt wasting includes analysis of serum chemistry for evidence of hyponatremia, hypo or hyperkalemia and metabolic acidosis or alkalosis. Other diagnostic tests include the measurement of urinary sodium and potassium, plasma levels of aldosterone and renin. Diagnostic evaluation for ambiguous genitalia and precocious puberty include the measurement of cortisol, aldosterone and androstenedione as well as precursor hormones in each of the biosynthetic pathways of the adrenal cortex. Definite diagnosis is made by genetic analysis.

### Therapeutic Principles

Treatment aims at counteracting volume depletion and derangements of plasma electrolyte concentrations and the replacement of glucocorticoid aldosterone (or both) as necessary. The use of glucocorticoids may also suppress precursor hormones that cause virilization. Infants with ambiguous genitalia will require surgical evaluation. More details can be found in specific chapters that deal with the specific genetic disease.

## Hypothermia

Hirokazu Sasaki, Tetsuo Yukioka
Department of Emergency and Critical Care Medicine, Tokyo Medical University, Shinjuku, Tokyo, Japan

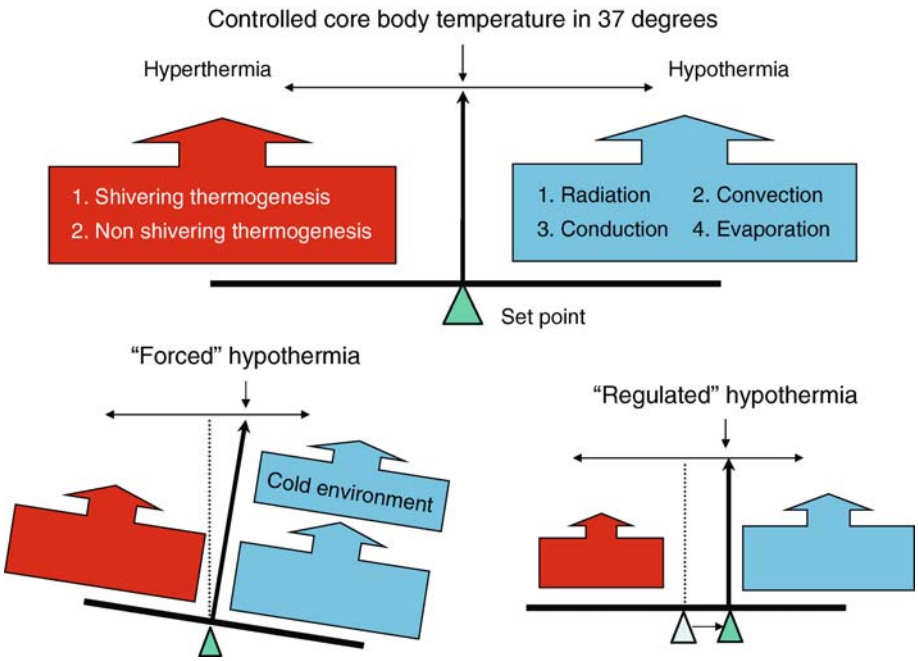
### Synonyms

Accidental hypothermia (AH) [1]; Neurotensin-induced hypothermia; NIH [2]; Endogenous cryogen-induced hypothermia; ECIH [3]; Hypoxia-induced hypothermia; HIH

### Definition and Characteristics

Heat is generated by metabolic processes that occur within the tissues of the body, such as fat and muscle. If exposure to cold continues, the body becomes fatigued and unable to generate sufficient warmth. AH is commonly a result of accidental prolonged exposure of coldness resulting in unconsciousness. AH can be defined as the fall of core body temperature down to below 35°C. It can be classified as mild (core temperature 32.2–35°C), moderate (<32.2–28°C), or severe <28°C. There are two types of hypothermia depending on the set point alteration. AH is a type of hypothermia with a fixed set point of core body temperature. Although counter-regulation increases heat production to keep the core body temperature around the set point, the cold environment forces the decrease in the core body temperature ("forced hypothermia"). The other type, such as NIH, ECIH, and HIH are caused by a downward shift of the set point ("regulated hypothermia") (Fig 1).

In NIH intracerebroventricular administration of the neurotensin is known to elicit hypothermia in rodents. Likewise, in ECIH the injection of urine into rodents results in a reduction of the core body temperature. HIH was originally reported as part of the thermoregulation behavior of single-cell organisms; however HIH takes place in human beings with cellular hypoxia [4].



**Hypothermia. Figure 1** Diagrammatic representation of the heat balance. The explanation of heat balance can be simplifi ed as a balance between the total sources of heat production (shivering and non-shivering thermogenesis) and heat loss (radiation, convection, conduction, and evaporation). When the core body temperature is stable, heat production is equal to heat loss. When heat loss boosted by a cold environment exceeds heat production, the subject suffers so-called "forced" hypothermia. If the set point were changed to less than 37°C, the subject becomes hypothermic by so-called "regulated" hypothermia because heat production is suppressed and heat loss is increased.

## Prevalence

Data on the prevalence of hypothermia is lacking.

## Genes

While there is a paucity of information about genetic aspects of hypothermia, the gene encoding carnitine palmitoyltransferase α deficiency has been reported to affect thermoregulation. A homozygous F383Y mutation of this gene is associated with recurrent episodes of hypothermia, rhabdomyolysis, and disorders of fatty acid metabolism [5].

## Molecular and Systemic Pathophysiology

Neurotensin for NIH is a tridecapeptide isolated from the bovine hypothalamus. It is expressed in various regions of the brain and the gastrointestinal tract. When exogenous neurotensin is administered to the cranial cerebrospinal fluid spaces it produces effects such as hypothermia. The hypothermic effect of neurotensin is thought to be activated mainly by the hypothalamus. NT69L and NT77 are neurotensin analogs that can induce hypothermia. It was reported that NT77 administered after resuscitation from cardiac arrest in rats produced mild hypothermia and improved the neurological outcome compared with that of results from external cooling, i,e, "forced hypothermia."

ECIH is caused by injection (iv or ip) of urine. Urine contains a substance that decreases the core body temperature. This substance, the so-called "endogenous cryogen" (EC), is probably cleared from the plasma by the kidney. Support for the above hypothesis comes from numerous studies that have shown that removal of kidneys results in a fall in core body temperature in both experimental animals and humans. Furthermore, in patients with chronic renal failure hemodialysis normalizes their lowered core body temperature. Moreover, the injection of dialyzed urine had no effect on the thermoregulatory response, suggesting that the EC is dialyzable and urine contains the EC which promotes a regulated decrease in core body temperature.

HIH is an acute reaction regarded as an adaptive response to hypoxia. An animal study showed that survival rates from hemorrhagic shock were ameliorated with mild hypothermia during the shock period. We reported alterations of core body temperature immediately following hemorrhagic shock. As a control, core body temperature was measured in

patients with sudden cardiopulmonary arrest (CPA) in whom there should be no heat generation and no biological adaptive response. Decrease of body temperature of patients with sudden CPA can be regarded as the natural cooling of the body mass. In patients with hemorrhagic shock, the body temperature decreases more than that of patients with CPA in the acute phase, and this could lend credence to the hypothesis that in human beings, as in other animals, faced with cellular hypoxia, the core body temperature tends to decline and the degree of decline is more than that of natural cooling.

### Diagnostic Principles

The symptoms and signs of AH depend on the severity. Mild hypothermia is characterized by shivering, tachycardia, tachypnea, and vasoconstriction. Moderate hypothermia consists of decreased respiratory rate, decreased heart rate with atrial arrhythmia, decreased level of consciousness, and hyporeflexia. ECG shows a J wave in the ST-T segment and shivering ceases. Severe hypothermia results in coma, apnea ventricular arrhythmia and asystole, nonreactive pupils, pulmonary edema and oliguria.

### Therapeutic Principles

Hypothermia patients require warming. Rewarming strategies are divided into passive rewarming and active rewarming. Passive rewarming is the method for managing patients with only external rewarming such as covering the body with warm blankets. Active rewarming is the method of core warming such as giving warm intravenous fluids and assisted circulation in addition to passive warming. Active rewarming is considered necessary for patients with severe hypothermia. We must be aware of complications during rewarming. Hypotension may occur during rewarming, probably as a consequence of peripheral vasodilatation. Afterdrop refers to a drop in core body temperature during rewarming. Afterdrop is thought to occur as a consequence of peripheral vasodilatation and release of cold peripheral blood to the body core.

## Hypothyroidism

Seda Sancak[1], Ralf Paschke[2]
[1]Marmara University Medical School, Istanbul, Turkey
[2]III. Medical Department, University of Leipzig, Leipzig, Germany

### Definition and Characteristics

Hypothyroidism is the most common hormone deficiency [1].

In areas where iodine intake is adequate, the most common causes of primary hypothyroidism are chronic autoimmune thyroiditis, ablative treatment for thyrotoxicosis or nodular goiter [1]. Several drugs (e.g., amiodarone) can cause hypothyroidism by interfering with thyroid hormone production or by provoking thyroid autoimmunity [1].

Central hypothyroidism (CH) arises from an inadequate stimulation by thyrotropin (TSH) of an otherwise normal thyroid gland. This can be the consequence of an anatomic or functional disorder of the pituitary gland, the hypothalamus, or both [2].

In patients with elevated TSH, the distinction between overt and subclinical hypothyroidism is defined by low serum free thyroxine ($T_4$) concentration or free $T_4$ within the reference range, respectively [1].

CH can be diagnosed by low $T_4$ and $T_3$ serum levels together with low, normal or midly elevated TSH levels [2].

### Prevalence

The prevalence of spontaneous hypothyroidism is 3.5% in women and 0.06% in men. The odds ratio of developing hypothyroidism in women with (i) raised serum TSH alone is 8; (ii) positive thyroid peroxidase antibodies (TPO Ab) alone is 8; (iii) both raised serum TSH and positive TPO Ab is 38. The mean age at diagnosis of spontaneous hypothyroidism is 59 years [3].

### Molecular and Systemic Pathophysiology

Clinical hypothyroidism is associated with modulation of calorigenesis and oxygen consumption in most tissues and additional organ-specific effects [1].

$T_3$ effects are mediated via thyroid receptor (TR) regulation of target gene transcription in the nucleus. In addition to the nuclear actions of thyroid hormone, $T_3$ stimulates cellular uptake of aminoacids and glucose, augments calcium-ATPase activity in cardiomyocytes, and alters mitochondrial ATP-generation by non-genomic mechanisms [1].

A decreased expression of the hepatic LDL receptor gene mediated by thyroid hormone regulated SREBP2 (sterol regulatory element binding transcription factor 2) decreases the rate of LDL-cholesterol clearance causing hypercholesterolaemia. Decreased expression of myocardial sarcoplasmic reticulum ATPase and α-myosin heavy chain impairs diastolic and systolic ventricular performance, respectively [1].

## Diagnostic Principles

Hypothyroidism usually presents with nonspecific constitutional symptoms such as cold intolerance, weight gain, constipation, dry skin, bradycardia, hoarseness and neuropsychiatric complaints or hypercholesterolemia, hyponatremia, hyperprolactinemia, hyperhomocysteinemia, hypoglycemia, and elevated creatine phosphokinase. Severe untreated hypothyroidism can lead to heart failure, psychosis, and hypothyroid coma which still has a high mortality [1].

A history for other autoimmune endocrinopathies should be obtained in all patients with autoimmune hypothyroidism. Recent pregnancy may suggest postpartum thyroiditis [1].

CH is usually associated with other pituitary hormone deficiencies including adrenocorticotropic hormone (ACTH), gonadotropins and growth hormone [2].

A thyroid releasing hormone stimulation test to assess thyrotropin responsiveness should also be carried out [1,2]. Pituitary imaging by computed tomography (CT) or magnetic resonance imaging (MRI) should be obtained in case of CH and for the evaluation of extrasellar extension of pituitary tumors [2].

The rare pituitary resistance to thyroid hormone and TSH-secreting pituitary tumors can present with an inappropriately elevated serum TSH. However raised serum free $T_4$ or triiodothyronine, or both, suggest these diagnoses [1].

TSH-secreting pituitary tumors should be suspected: (i) with a disproportionate abundance in serum of free α-subunit relative to TSH; (ii) when serum TSH fails to increase above the basal level in response to TRH or decreases during the administration of TH; (iii) when other members of the family, particularly the parents of the patients, fail to exhibit thyroid test abnormalities [4].

Serum TSH concentrations may also be transiently elevated during recovery from nonthyroidal illness and in painful subacute and postpartum lymphocytic thyroiditis [1].

## Therapeutic Principles

The treatment of choice for hypothyroidism is levothyroxine sodium ($T_4$) [5].

The usual replacement dosage for $T_4$ is 1.8 μg/kg/day although the appropriate dosage may vary among patients. The initial $T_4$ dosage may range from 12.5 μg/day to a full replacement dose based on the age, weight, cardiac status of the patient, the severity and duration of the hypothyroidism [5].

Subclinical hypothyroidism which usually progresses to overt hypothyroidism and which may be associated with hyperlipidemia and atherosclerotic heart disease, is often asymptomatic [1,5]. Therefore treatment is indicated if TSH levels are >10 μIU/mL or in case of TSH levels between 5 and 10 μIU/mL in conjunction with goiter or positive TPO Ab or both [5].

Recent studies have shown a renewed interest in the possible benefits of treatment of hypothyroidism with combinations of $T_4$ and $T_3$. However, there is insufficient evidence to know which patients with hypothyroidism, if any, would be better treated with a combination of $T_4$ plus $T_3$ rather than with $T_4$ alone [5].

Patients with CH should be evaluated by measurements of serum cortisol and assessment of ACTH reserve. if ACTH deficiency is present, cortisol replacement should be initiated before any $T_4$ is given because of the risk of precipitating an adrenal crisis [2].

A normal TSH level of 1–2 mU/L is the goal for an optimal $T_4$ substitution in patients with primary hypothyroidism, while serum free $T_4$ levels in the mid or upper normal range may denote optimal replacement in individuals with central hypothyroidism [1].

Patients should undergo reassessment and therapy should be titrated after an interval of at least 6–8 weeks [5]. Once a stable TSH is achieved, annual examination is appropriate [5].

# Hypothyroidism, Congenital

Hulya Iliksu Gozu[1], Roland Pfäffle[2], Ralf Paschke[3]
[1]Section of Endocrinology and Metabolism, Dr. Lutfi Kirdar Kartal Education and Research Hospital, Istanbul, Turkey
[2]Pediatric Department, University of Leipzig, Leipzig, Germany
[3]Department of Internal Medicine III, University of Leipzig, Leipzig, Germany

## Synonyms

Congenital nongoitrous hypothyroidism; Congenital dyshormonogenesis; Thyrotropin resistance; Congenital central hypothyroidism.

## Definition and Characteristics

Congenital hypothyroidism (CH) refers a group of disorders that have in common a lack of thyroid hormone in the neonatal period. It is usually sporadic, but 2% of cases are inherited. Developmental or functional abnormalities at any level of the hypothalamic-pituitary-thyroid axis can cause CH characterized by common findings including thyroid agenesis, ectopic/hypoplastic thyroid or goiter, large posterior fontanel, noisy breathing, nasal stuffiness, macroglossia, hypothermia, lethargy, hypotonia, bradycardia, poor feeding, delayed growth and skeletal maturation, abdominal distention, umblical hernia, dry and puffy skin, hoarse cry, jaundice, constipation, low serum T4, and high TSH levels [1] (OMIM 218700).

CH may be permanent or transitory. In up to 10% of all cases, it is transient and self-limited. CH is associated with thyroid dysgenesis in 80–85% of cases of permanent primary CH. In these cases, the thyroid gland can be absent (agenesis), ectopically located, and/or severely reduced in size (hypoplasia). In permanent primary cases, 15–20% is due to defects of thyroid hormone synthesis (dyshormonogenesis) associated with an enlarged thyroid. Permanent secondary hypothyroidism resulting from the defects at the level of hypothalamus or pituitary is rarely seen [1,2].

## Prevalence

Permanent primary congenital hypothyroidism is the most common congenital endocrine disorder. It is detected at a rate of 1/3,000 to 1/4,000 newborns with the exceptions of a lower prevalence in African American and an increased prevalence in the Hispanic population. Girls are more often affected than males. Central congenital hypothyroidism occurs at a rate of 1/20,000 to 1/50,000 infants [2–4].

## Genes

The genes that are involved in the pathogenesis of CH and their characteristics are presented in Table 1 [1–5].

## Molecular and Systemic Pathophysiology

CH can be classified as permanent and transient. Transient primary CH can be caused by either iodine deficiency or acute iodine load, maternal therapy with antithyroid drugs, or transplacental transfer of maternal thyrotropin receptor blocking antibodies.

Permanent CH can be classified as secondary (central) or primary (thyroidal) [2,5].

*Primary (Thyroidal) Congenital Hypothyroidism*: The thyroid gland arises from the endodermal pharynx and migrates to its final site. Developmental or functional defects in this process may cause primary CH. The most common etiology of primary CH are defects in the thyroid gland development leading to thyroid dysgenesis (85%), which in turn consists of either thyroid agenesis (40% of cases), failure of the gland to descent normally with or without ectopy (40%), or hypoplasia of an eutopic gland (5%) [1,3]. Defects of thyroid hormone synthesis (dyshormonogenesis) with a thyroid gland in the normal position occur in only 15–20% of the patients [3].

Thyroid gland organogenesis and the migration to its final position depend on several factors, including TSHR, TTF-1, TTF-2, and Pax-8. Germline inactivating mutations in these genes can result in thyroid dysgenesis and CH with or without other congenital malformations [1,3,5]. The Gsα subunit couples to several transmembrane receptors, including the TSH- TRH- PTH- and LH- receptors. Inactivating mutations in GNAS1 result in Albright's hereditary syndrome characterized by multiple congenital malformations with endorgan resistance to multiple hormones, including TSH [1].

Defects in any step of thyroid hormone production can lead to dyshormonogenesis characterized by CH and goiter. The transport of iodide into the thyroid follicular cells is mediated by the $Na^+/I^-$ symporter (NIS). Transport of iodide across the apical membrane of thyroid follicular cells into the colloid space is at least in part mediated by pendrin (PDS). It is then oxidized by hydrogen peroxide (THOX1/THOX2) and bound to tyrosine residues in thyroglobulin (Tg) to form iodothyrosine. After coupling reactions, thyroid hormones are produced. Oxidation, organification, and coupling reactions are catalyzed by thyroid peroxidease (TPO) [1,4,5]. Alterations of any of these factors by loss of function mutations can result in thyroid dyshormonogenesis with different degrees of CH, goiter, and a partial or total organification defect. MCT8 acts as a thyroid hormone transporter across the cell membrane.

**Hypothyroidism, Congenital. Table 1** Names and characteristics of the genes which are involved in the pathogenesis of the CH [1–5] (www.ncbi.nlm.nih.gov/entrez/query.fcgi?CMD = search&DB = omim)

| Gene | Family | Locus of gene | OMIM number | Estimated # of individuals (families) or its frequency | Sites of expression | Function | AR/AD | Phenotype |
|---|---|---|---|---|---|---|---|---|
| **Thyroid dysgenesis and Syndromic CH** | | | | | | | | |
| *TTF-2/Tiff-2 (FOXE-1)* | Forkhead | 9q22.3 | 602617 | 4 individuals (2 families) | Thyroid, hair follicule, testis, foregut endoderm, Rathke, craniopharyngeal ectoderm, kidney, liver (nucleus) | Promotes the migration process or represses differentiation of the thyroid follicular cells until migration has occurred | AR | Bamforth-Lazarus syndrome: CH, athyrosis, developmental delay, cleft plate, choanal atresia, bifid epiglottis, and spiky hair |
| *TTF- 1/Titf-1 (Nkx2.1)* | NKX2 family | 14q13 | 600635 | 9 individuals (one family/four de novo/3?) | Thyroid, forebrain, hypothalamus, basal ganglia, pituitary, the lung and fetus (nucleus and cytoplasm) | For survival and proliferation of primitive thyroid follicular cells and in transcriptional control of the Tg, TPO, and TSHR | AR/AD | CH, choreoathetosis, truncal apraxia, mental retardation, and respiratory distress or benign chorea |
| *PAX-8* | Paired homeodomain transcription factor | 2q12-q14 | 167415 | 21 individuals (6 families/2 de novo) | Thyroid primordium, mid and hindbrain region and developing kidney | For the formation of the follicular cells, stimulates expression of Tg, TPO, NIS | AD | Severe to mild CH, hypoplastic and sometimes ectopic thyroid glands, renal agenesis |
| *GNAS1* | G protein family | 20q13 | 139320 | More than 72 individuals | Ubiquitous; brain, bone, heart, adrenal gland, ovary, testis, thyroid, platelet, lymphocytes, erythrocytes, leukocyte, lymphocyte (membrane) | Mediates signal transduction across cell membranes coupling to TSH, TRH, PTH, LH receptors, ion channels, the AC, and PLC by activating AC | AD | AHO syndrome with PHP1A and PHP1B: short stature, shortened 4–5th metacarpal/metatarsal bones, obesity, round face, cutaneous osteoma, resistance to multiple hormones, intracranial calcification, mental retardation, and PPHP with only phenotypic characteristics |

**Hypothyroidism, Congenital. Table 1** Names and characteristics of the genes which are involved in the pathogenesis of the CH [1–5] (www.ncbi.nlm.nih.gov/entrez/query.fcgi?CMD = search&DB = omim) (Continued)

| Gene | Family | Locus of gene | OMIM number | Estimated # of individuals (families) or its frequency | Sites of expression | Function | AR/AD | Phenotype |
|---|---|---|---|---|---|---|---|---|
| **Thyroid Dysgenesis and Non-Syndromic CH** | | | | | | | | |
| *TSHR* | 7- transmembrane receptor family | 14q31 | 603372 | 21 families | Thyroid, expression starts on the day 14 of embryogenesis after gland migration (membrane) | TSH stimulates growth and function of the thyroid follicular cells, regulates the synthesis and secretion of TH | AR | Varies from euthyroid hyperthyrotropinemia (compound heterozygous) to severe congenital hypothyroidism (homozygous) with thyroid hypoplasia |
| **Dyshormonogenesis and Nonsyndromic CH** | | | | | | | | |
| *NIS* | Solute carrier family 5 | 19p13.2-p12 | 601843 | 60 individuals (35 families) | Thyroid, breast, colon, and ovary tissues (membrane) | Transports iodide across the basolateral plasma membrane of follicular cells | AR | Mild to moderate CH with goiter, no uptake in scan |
| *PDS/SLC26A4* | Solute carrier family | 7q31 | 605646 | 7.5–10 per 100,000 individuals | Thyroid, cochlea and kidney (membrane) | Efflux of iodide at the apical membrane of thyroid follicular cells | AR | PS:CH with goiter, + perchlorate test (partial), sensoryneural deafness, or nonsyndromic deafness |
| *Tg* | Homodimeric glycoprotein | 8q24.2-q24.3 | 188450 | 1 in 40,000 newborns | Thyroid follicular lumen (extra cellular) | Glycoprotein precursor to the TH, important in the synthesis of TH, and storage | AR/AD | Familial goiter: Moderate-severe CH, large goiter, high iodoalbumin in plasma, high iodopeptide in urine, low Tg, high uptake in scan, negative or partial + perchlorate test. ERSD syndrome; CH, goiter, delay in motor and mental development |
| *TPO* | Glycoprotein (enzyme: peroxidase) | 2p25 | 606765 | 1 in 66,000 newborns | Thyroid apical membrane | Responsible for oxidation, organification and coupling reactions | AR | Severe CH, goiter with different size, total + perchlorate test |

Inactivating mutations in this gene cause CH in addition to neurological abnormalities [1].

*Secondary (Central) Congenital Hypothyroidism*: Central CH is caused by disorders in the development and/or function of the hypothalamus, pituitary gland, or both. Recessive mutations in the TSHβ chain or the TRH-receptor can cause isolated hereditary TSH deficiency and thereby CH. Mutations in transcription factors involved in pituitary development and hormone production (such as POU1F1, Prop-1, LHX3, HESX1) can result in various forms of combined pituitary hormone deficiency (CPHD) including TSH deficiency [1,3,5].

## Diagnostic Principles

CH is the major cause of preventable mental retardation. Therefore, early diagnosis and treatment are important to prevent mental retardation and other sequelae.

1. Clinical findings of hypothyroidism should lead to further evaluations.
2. In case of suspected congenital hypothyroidism, serum TSH and FT4 should be measured, because central hypothyroidism is not detected by neonatal (TSH) screening and there still remains a possibility of screening errors. Blood samples already collected for screening additionally should also be re-evaluated.
3. A detailed family and infant history should be taken. This should include a history of possible iodine exposure of the mother or newborn, for example, by iodine-containing desinfectants, which can cause temporary hypothyroidism by the so called Wolff-Chaikoff-effect in newborns.
4. Primarily ultrasonography should be performed to detect ectopic glands, athyreosis, or goiter. $^{99m}$TcO4 (or $123_I$) scintigraphy of the thyroid gland can be postponed, because diagnostic accuracy increases beyond the newborn period and findings would not alter the necessity for immediate treatment! A low uptake by a small-normal shaped thyroid gland however may be indicative for transient hypothyroidism or mutations of the TSHR or PAX-8 genes.
5. Serum thyroglobulin level should be measured. If it is not detectable; thyroid agenesis is most likely. In rare instances, mutations of the thyroglobulin gene can however imitate these findings. If both $^{99m}$TcO4-uptake and serum Tg are undetectable, thyroid agenesis is confirmed. If uptake is undetectable in the presence of detectable serum thyroglobulin levels, transient hypothyroidism or mutations of the TSHR or PAX-8 are more likely.
6. A perchlorate discharge test can be performed if dyshormonogenic CH is suspected. However, it depends on the use of $^{123}$I, which carries a higher exposure to radiation. A positive perchlorate discharge would be indicative for dyshormonogenetic CH. However, an audiometric examination should be performed in all toddlers suspected of dyhormogenic CH to detect deafness early in the case of Pendred's syndrome.
7. Further anomalies that accompany CH should be investigated.
8. The infants with permanent congenital hypothyroidism and their suspected relatives should undergo genetic analysis [1,2,5].

## Therapeutic Principles

Treatment should be initiated as early as possible after hypothyroidism has been confirmed, regardless which etiology could be identified. The treatment of choice is T4. Despite early treatment, up to 10% of these infants are likely to require a special education later on. T4 should be started with doses of 10–15 μg/kg/day. In order to develop normally in severe CH, both early treatment within 1–2 weeks after birth and a high initial T4 dose are required. Initially TSH values are inadequate as a parameter for adequate replacement, because they may remain elevated for several months despite normal FT4 and FT3 levels. Doses decline from 10 to 15 μg/kg/day in toddlers to about 4–5 μg/kg at 5 years of age. The frequency of follow-ups should be every 3 months in the first 2 years, and every 6 months from the age 2 to 6 years. After 6 years, yearly assessment seems to be sufficient until puberty, when thyroid function should again be evaluated twice a year [1,2].

# Hypotrichosis-Osteolysis-Peridontitis-Palmoplantar Keratoderma Syndrome

Maurice A. M. Van Steensel
Department of Dermatology, University Hospital Maastricht, Maastricht, The Netherlands

## Synonyms

HOPP syndrome, MIM 607658

## Definition and Characteristics

HOPP syndrome is a very rare disorder characterized by the co-occurrence of hypotrichosis, acro-osteolysis, peridontitis and palmoplantar keratoderma [1]. The palmar keratoderma shows a highly unusual reticular pattern. The phenotype is illustrated in fig. 1a–d. The syndrome strongly resembles another disorder called Papillon-Lefèvre syndrome and an allelic variant of it, Haim-Munk syndrome.

## Prevalence

The disorder is extremely rare. Three cases are presently known, two in The Netherlands and one in Venezuela.

## Genes

The disorder is probably autosomal dominant, and the undelying genetic defect is unknown.

## Molecular and Systemic Pathophysiology

Unknown. Papillon-Lefèvre syndrome (PLS) and its allelic variant, Haim-Munk syndrome are caused by mutations in the gene coding for cathepsin C (CTSC, EC 3.4.14.1) [2]. CTSC is a dipeptidyl peptidase involved in the activation of several serine proteases in neutrophilic granulocytes, mast cells, monocytic lineage cells and lymphocytes [3]. These proteases are implicated in a wide variety of immune and inflammatory processes, including phagocytic destruction of bacteria and local activation or deactivation of cytokines and other inflammatory mediators. Part of the phenotype of PLS, notably the peridontitis, is probably related to disturbance of immunity against bacteria invading the gums. The skin symptoms indicate that regulation of proteolysis is important for skin homeostasis but the function of CTSC in skin is not yet understood. Interestingly, mutations in cathepsins K and L cause the human disease pycnodysostosis and the furless mutation in mice, respectively [4,5]. The former disorder is characterized, among other symptoms, by dwarfism and acro-osteolysis, the latter by hair loss. Acro-osteolysis is also found in Haim-Munk syndrome, which is allelic to PLS. Apparently, cathepsins are also required for regulation of bone resorption and hair follicle function.

HOPP syndrome shows symptoms found in PLS, pycnodysostosis and furless, suggesting that it, too, may be caused by a mutation in a cathepsin. We did not detect mutations in the CTSC, CTSK or CTSL genes, but it is quite possible that HOPP syndrome is caused either by mutations in a novel cathepsin gene or in one that has a structural or functional relationship with the cathepsins.

## Diagnostic Principles

The cardinal symptoms are reticular or papular palmoplantar keratoderma (Fig. 1), hypotrichosis, peridontitis and acro-osteolysis. X-ray examination of the hands will show resorption of distal phalanges and decreased distal bone density. Severe nail dystrophy in the form of onychogryphosis, meaning claw-like nails, differentiates HOPP from PLS and Main-Munk syndromes. A biopsy of affected skin is seldom helpful and mutation analysis is not yet available, hence the diagnosis is mostly based on clinical judgment.

## Therapeutic Principles

The palmoplantar hyperkeratosis and nail deformities respond well to acitretin 0.5–1 mk/kg/day. The dosage needs to be titrated against the clinical effect with care and the patient's gums need to be monitored carefully during treatment, as the peridontitis may worsen while on acitretin. Regular evaluation of liver enzymes and lipid metabolism is required as is an X-ray examination of the entire vertebral column every two years. In fertile female patients, great care needs to be exercised when prescribing systemic retinoids because of their teratogenicity. Oral contraceptives must be given and a pregnancy excluded before starting retinoid therapy. Should a female patient on oral retinoids decide to have children, the retinoids should be discontinued and the patient should wait for 3 years before becoming pregnant.

Local therapy may also benefit the patient. The hyperkeratosis responds to treatment with retinoids or vitamin D derivatives. The psoriasis-like lesions respond quite well to topical steroids (class 3) and narrowband UV-B. Treatment with anthralins such

**Hypotrichosis-Osteolysis-Peridontitis-Palmoplantar Keratoderma Syndrome. Figure 1** HOPP phenotype. (a) Non-scarring hypotrichosis; (b) Reticular palmar keratoderma; (c) Acro-osteolysis (*arrow*); (d) Plantar hyperkeratosis with punctate pattern.

as dithranol has been attempted once with moderate success. Neutral emollients may be of help in preventing cracking of the plantar hyperkeratoses.

The peridontitis necessitates regular care by an experienced parodontologist. The nail deformities need to be treated as well because the onychogryphosis will lead to considerable disability. Eventually, avulsion of the nails may be required. The osteolysis may respond to methotrexate. Fertile female patients must use oral contraceptives when taking methotrexate and a pregnancy test should be performed before starting therapy.

No treatment is available for the other symptoms.

## Hypovolemia

Rongqian Wu[1,2], Ping Wang[1,2]
[1]Department of Surgery, North Shore University Hospital and Long Island Jewish Medical Center, Manhasset, NY, USA
[2]The Feinstein Institute for Medical Research, Manhasset, NY, USA

### Synonyms

Oligemia; Volume depletion

### Definition and Characteristics

Hypovolemia is a state of an abnormally decreased volume of circulating fluid (plasma) in the body. It may be caused by a rapid and substantial loss of blood or from dehydration due to vomiting, diarrhea, burns, severe environmental fluid losses, or drugs such as diuretics. Lost fluid in patients with dehydration is comprised primarily of plasma rather than whole blood as in the trauma patient. Hypovolemia can be recognized by an elevated pulse, a diminished blood pressure, and the absence of perfusion as assessed through skin signs (skin turning pale) and/or capillary refill on forehead, lips and nail beds. The patient may feel dizzy, faint, nauseated, or very thirsty. Severe hypovolemia leads to hypovolemic shock, which can result in multiple organ failure and death. However, clinical symptoms may not be present until 10–20% of the total whole-blood volume is lost.

### Prevalence

Since there are several different causes for hypovolemia, the prevalence of hypovolemia is difficult to estimate.

### Molecular and Systemic Pathophysiology

If hypovolemia is caused by acute blood loss, the first response is an attempt to form a clot at the site of hemorrhage. Thromboxane $A_2$ is released locally to activate the coagulation cascade and to contract the bleeding vessels. In addition, platelets are activated (also by means of a local thromboxane $A_2$ release) and form an immature clot at the site of injury. The damaged vessel exposes collagen, which subsequently causes fibrin deposition and stabilization of the clot.

Hypovolemia results in the reflexively decreased baroreceptor stimulation from stretch receptors in the large arteries (i.e., the arch of the aorta and the carotid sinuses of the left and right internal carotid arteries), leading to the decreased inhibition of vasoconstrictor centers in the brain stem, and to the increased chemoreceptor stimulation of vasomotor centers. Hypovolemia induces the sympathetic stimulation, leading to the release of epinephrine and norepinephrine. These changes increase vasoconstriction and peripheral arterial resistance. Peripheral vasoconstriction is prominent, while the lack of the response to the sympathetic stimulation of cerebral and coronary vessels, and local autoregulation maintain cardiac and brain blood flow. Hypovolemia increases renin secretion from the juxtaglomerular apparatus in the kidneys. Renin converts angiotensinogen to angiotensin I, which subsequently is converted to angiotensin II by the lungs and liver. Angiotensin II has two major effects: the vasoconstriction of the arteriolar smooth muscle and the stimulation of aldosterone secretion by the adrenal cortex. Aldosterone is responsible for active sodium reabsorption and subsequent water conservation. Decreases in blood pressure (as detected by baroreceptors) and in sodium concentration (as detected by osmoreceptors) increase antidiuretic

hormone (ADH) release from the posterior pituitary gland. ADH indirectly leads to an increased reabsorption of water and salt. All these compensatory mechanisms may mask clinical signs of hypovolemia, leading to delays in treatment [1].

In addition, severe hypovolemia (i.e., hypovolemic shock) can initiate a profound systemic inflammatory process. Diminished perfusion in the mucosal layer of the gut impairs gut barrier function, which may allow the translocation of bacteria and endotoxin. Several studies have demonstrated that many of the inflammatory changes characteristic of hypovolemic shock are secondary to the release and recognition of gut-derived endotoxin [2]. Recently, a body of literature has described other pathways involving the Toll-like receptor 4 (TLR4) in the systemic inflammatory response following hemorrhagic shock [3]. TLR4, the first member in the TLR family to be characterized, was identified as critical for endotoxin recognition. Current evidence indicates that TLR4 can recognize both bacterial endotoxin and multiple endogenous ligands, such as heat shock proteins, heparan sulfate, hyaluronic acid, fibronectin, and high mobility group box 1 (HMGB1). Once TLR4 is activated, an intracellular signaling cascade is initiated which involves both a myeloid differentiation factor 88 (MyD88)-dependent and independent pathway, leading to the upregulation of proinflammatory cytokines and an influx of polymorphonuclear cells (PMN) into tissues, resulting in acute tissue injury [3].

### Diagnostic Principles

A thorough history and physical examination are generally sufficient to diagnose the etiology of hypovolemia. A rapid assessment of the possible source of bleeding is essential when acute hemorrhage is the suspected cause for hemodynamic instability.

### Therapeutic Principles

The therapeutic goals are to restore normovolemia with fluid similar in composition to the lost and to replace ongoing losses. For actively bleeding patients, the main objectives are to stop the source of hemorrhage and to restore circulating blood volume. Minor hypovolemia can usually be corrected via the oral route. More severe hypovolemia requires intravenous therapy. Patients with significant hemorrhage, anemia, or intravascular volume depletion may require blood transfusion or colloid-containing solutions (such as, albumin, dextran). Symptoms and signs can help estimate the degree of volume contraction and should also be monitored to assess the patient's response to treatment. Elderly individuals have less tolerance for hypovolemia compared to the rest of the general population. Aggressive therapy should be instituted early to prevent potential complications, such as myocardial infarction and stroke.

## Hypovolemic Shock

Giora Feuerstein, Robert Ruffolo
Wyeth Research, Discovery Translational Medicine, Collegeville, PA, USA

### Synonyms

Hemorrhagic or hematogenic shock; Oligemic shock

### Definition and Characteristics

Hypovolemic shock is characterized by hypotension, hyperventilation, cold clammy cyanotic skin, and a weak and rapid pulse

### Prevalence

Depends on the cause of blood loss.

### Genes

No particular gene(s) are associated with hypovolemic shock; however, profound genomic perturbations are elicited by hypovolemic shock. Hemophilia, a disease of loss of function of genes associated with coagulation factors VIII and IX, predisposes to bleeding that could lead to sufficient blood loss and hypovolemic shock if unattended.

### Molecular and Systemic Pathophysiology

Hypovolemic shock results from insufficient blood volume for the maintenance of cardiac output, blood pressure, and tissue perfusion. Hypovolemic shock is usually caused by hemorrhage associated with trauma (penetrating or blunt trauma), gastrointestinal bleeds (e.g., peptic ulcers, hepatic varicose veins), bleeding disorders due to coagulation factors deficiency, and drugs that

interfere with blood hemostasis such as anticoagulants (e.g., warfarin, heparin) and antiplatelet agents.

## Diagnostic Principles

The physical examination should always begin with an assessment of the airway, breathing, and circulation. Once these have been evaluated and stabilized, the circulatory system should be evaluated for signs and symptoms of shock. Special attention should be paid to the pulse, respiratory rate, and skin perfusion. Treatment should be aggressive and directed more by response to therapy than by initial classification.

Class I hemorrhage (loss of 0–15%): in the absence of complications, only minimal tachycardia, no changes in BP, pulse pressure, or respiratory rate occur.

Class II hemorrhage (loss of 15–30%): clinical symptoms include tachycardia (rate > 100 beats per minute), tachypnea, decrease in pulse pressure, cool clammy skin, delayed capillary refill, and slight anxiety.

Class III hemorrhage (loss of 30–40%): marked tachypnea and tachycardia, decreased systolic BP, oliguria, and significant changes in mental status, such as confusion or agitation.

Class IV hemorrhage (loss of > 40%): symptoms include marked tachycardia, decreased systolic BP, narrowed pulse pressure, markedly decreased (or no) urinary output, depressed mental status (or loss of consciousness), and cold and pale skin.

## Therapeutic Principles

*Prehospital Care*: Applying direct pressure to site of active bleeding (especially arterial) should be first priority. Ensuring life-saving measures associated with the injury and rapid mobilization to a hospital care for definitive treatment.

*Hospital Care*: Emergency hospital facility exercise the following procedures: (i) maximize oxygen delivery – completed by ensuring adequacy of ventilation, increasing oxygen saturation of the blood, and restoring blood flow, (ii) control further blood loss, and (iii) fluid resuscitation. Fluid resuscitation is performed with an isotonic crystalloid, such as lactated Ringer solution or normal saline. If little improvement is achieved, type O (Rh-negative, preferred) blood should be given. Depending on the cause of bleeding, specific measure to amend the defect is initiated after patient stabilization.

# Hypoxanthine-Guanine Phosphoribosyl Transferase Deficiency

Hyder A. Jinnah, James C. Harris
Johns Hopkins University Medical School, Baltimore, MD, USA

## Synonyms

Lesch-Nyhan disease; Lesch-Nyhan variant; Kelley-Seegmiller syndrome; HPRT deficiency

## Definition and Characteristics

HPRT deficiency is associated with a spectrum of disease severity depending on the amount of residual enzyme function [1–3]. Patients with at least 8% of residual enzyme function have the mildest clinical phenotype, sometimes called Kelley-Seegmiller syndrome (KSS). These patients display evidence of systemic overproduction of uric acid with hyperuricemia, uric acid kidney stones, gouty arthritis and sometimes uric acid tophi. Patients with 1.5–8% of residual enzyme function have all the consequences of uric acid overproduction with additional evidence for neurological impairment. The severity of neurological impairment in this group ranges from only mild clumsiness or dysarthria to severely disabling dystonic motor dysfunction. Patients with <1% of residual enzyme function have the most severe clinical phenotype, known as Lesch-Nyhan disease (LND). These patients display uric acid overproduction, severe motor dysfunction, cognitive impairment and behavioral abnormalities. The behaviors include compulsive or aggressive behaviors and a very high frequency of self-injurious behaviors.

## Prevalence

HPRT deficiency occurs roughly equally in all cultures with an estimated prevalence of 1:380,000 for LND. The partial variants are even rarer. The disorder is inherited in an X-linked recessive manner, so almost all cases are male. Females are encountered only very rarely when the hprt loci on both chromosomes are affected.

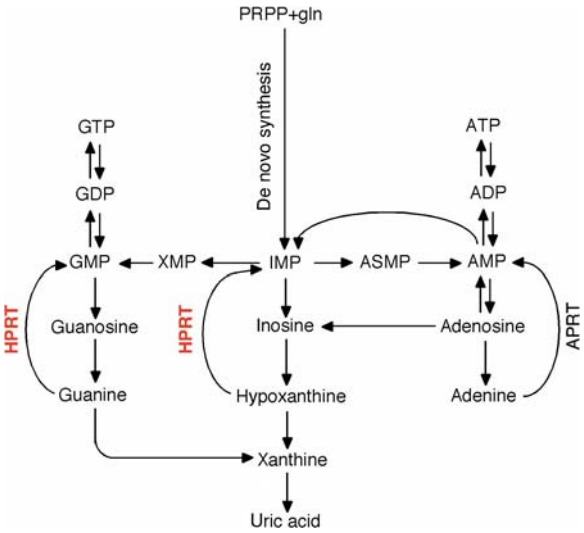
## Genes

HPRT is encoded by a single gene on the X chromosome at Xq26–27. There are no significant polymorphisms in the human genome, but there are non-functional pseudogenes. More than 300 different mutations have been identified, most of which arose as de novo events [4].

## Molecular and Systemic Pathophysiology

HPRT plays a central role in recycling purine bases hypoxanthine and guanine as part of the purine salvage pathway (Fig. 1).

There are two main direct consequences of HPRT deficiency. The first is that the purine bases cannot be re-utilized and they are therefore degraded and excreted as uric acid. The second is the synthesis of purines via the de novo pathway is markedly accelerated. This acceleration occurs presumably because of the accumulation of PRPP, which is a substrate for HPRT as well as the rate-limiting step in purine synthesis. In addition to these two main effects of HPRT deficiency, a number of additional abnormalities have been documented in both purine and pyrimidine metabolism. It is the failure of purine recycling and the augmented synthesis of purines that accounts for the overproduction of uric acid in HPRT deficiency and the poor solubility of uric acid in biological fluids that accounts for many of the overt clinical manifestations. The precipitation of uric acid crystals in the urogenital system accounts for stone formation and nephropathy, while the precipitation of crystals in the joints accounts for gouty arthritis.



**Hypoxanthine-Guanine Phosphoribosyl Transferase Deficiency. Figure 1** Role of HPRT in the metabolism of purines.

Precipitation of uric acid in the subcutaneous tissues produces tophi. The pathophysiology of the neurological and behavioral abnormalities is not well understood. This element of the clinical phenotype seems to be unrelated to the overproduction of uric acid. Instead, a review of the evidence suggests that one or more of the changes in purine metabolism caused by HPRT indirectly causes damage or dysfunction in the dopaminergic pathways of the basal ganglia and that dysfunction of the basal ganglia is responsible for the neurological and behavioral anomalies [5].

## Diagnostic Principles

The clinical diagnosis of full-blown LND where there is evidence for uric acid overproduction with neurobehavioral abnormalities is straightforward. Plasma uric acid values are not sufficient preliminary screening tools for the diagnosis, because of rapid clearance of plasma uric acid by the kidneys in children. A better screen requires measurement of both plasma and urinary uric acid. Definitive diagnosis requires the measurement of HPRT enzyme activity from blood or fibroblasts and/or the demonstration of a pathological mutation in the HPRT gene. Transfusion will mask diagnosis from blood alone. Early clinical recognition before all the features of the disease are fully manifest is more challenging. The literature describes several cases presenting in infancy with renal failure, before the development of other features that make the diagnosis more apparent. The clinical recognition of the partial variants is also challenging, as many present with chronic renal insufficiency with few other clues pointing to the diagnosis. The diagnosis must be considered when gout or uric acid kidney stones occur at a young age.

## Therapeutic Principles

The overproduction of uric acid must be treated with a combination of allopurinol and generous hydration at all times. Some patients also have the urine alkalinized to promote the solubility of purine metabolites. Allopurinol reduces the production of uric acid by inhibiting xanthine oxidase, which metabolizes xanthine and hypoxanthine to uric acid. Allopurinol treatment simultaneously increases urinary concentrations of xanthine and hypoxanthine. Xanthine is even less soluble than uric acid, sometimes resulting in xanthine nephropathy. It is therefore important to avoid over-treating with allopurinol and to assure adequate hydration to continually eliminate all of these purine metabolites. Treatment of the neurobehavioral disturbances is not satisfactory. The severity of the motor disorder can be attenuated by the use of benzodiazepines or baclofen. The behavioral problems require a combination of behavior therapy and medications. No medication has proved consistently effective in

the control of the behavioral abnormalities, but anecdotal experience has suggested benzodiazepines, serotonin uptake inhibitors, atypical neuroleptics, carbamazepine or gabapentin to be helpful.

# Hypoxia

Holger K. Eltzschig[1,2], Almut Grenz[1,3]
[1]Mucosal Inflammation Program, Department of Anesthesiology and Perioperative Medicine, University of Colorado Health Sciences Center, Denver, CO, USA
[2]Department of Anesthesiology and Intensive Care Medicine, Tuebingen University Hospital, Tuebingen, Germany
[3]Department of Pharmacology and Toxicology, Tuebingen University Hospital, Tuebingen, Germany

## Synonyms

Limited oxygen availability

## Definition and Characteristics

Most commonly, tissue hypoxia occurs in the setting of ambient hypoxia (e.g., by inspiration of a hypoxic gas mixture, containing less than 21% of oxygen), attenuated blood flow to an organ (ischemia), attenuated oxygen transport capacity (e.g., anemia, carbon monoxide poisoning) or during impaired cellular oxygen utilization (e.g., cyanide intoxication, sepsis).

## Prevalence

The prevalence of hypoxia is unknown. However, hypoxia is one of the most common characteristics of human diseases, including for example stroke, myocardial infarction, infection or inflammation. Therefore, hypoxia certainly carries a very high prevalence as a pathophysiological aspect of many human diseases.

## Genes

Central to mammalian oxygen homeostasis and adaptation to hypoxia is the transcription factor "hypoxia inducible factor" (HIF). Recently, a family with erythrocytosis and a mutation in the HIF-2A gene, which encodes the HIF-2α protein was described [1]. Functional studies indicate that this mutation leads to stabilization of HIF-2α protein and suggest that wild-type HIF-2α regulates erythropoietin production in adults.

## Molecular and Systemic Pathophysiology

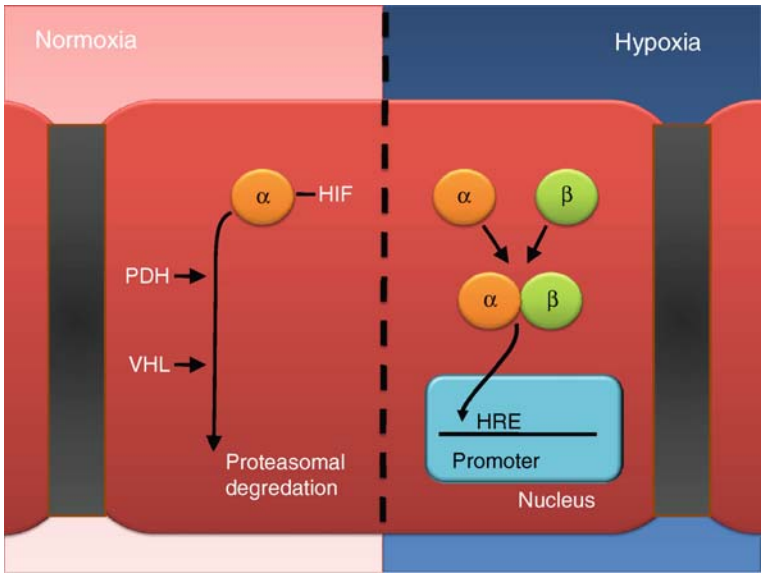
The chemical reduction of oxygen is the primary source of metabolic energy for all eukaryotic cells [2]. Diminished tissue oxygen supply is a common physiologic and pathophysiologic occurrence, and for this reason, mammalian cells have evolved elaborate compensatory mechanisms to cope with hypoxia. Exposure to hypoxia is associated with the induction of a phenotypic disease pattern very similar to acute inflammatory responses. For example, hypoxia exposure is associated with increased vascular permeability, and increased inflammatory cell content in many organs ("inflammatory hypoxia"). Similarly, organ ischemia is associated with increased edema, inflammation and organ dysfunction. At the same time, hypoxia also elicits a cascade of adaptive responses targeted to restore oxygen supply and attenuate inflammation. At the tissue level, hypoxia can emanate from a number of sources. Such events include frank vascular occlusion such as occurs with stroke. Tissue fibrosis and microvascular breakdown associated with chronic inflammation also result in localized tissue hypoxia/ischemia. Alternatively, diminished oxygen delivery to tissues may occur in shock, hypotension or in cases where the oxygen carrying capacity of blood is compromised (e.g., carbon monoxide poisoning). Finally, solid tumors have been demonstrated to form hypoxic cores, and respond accordingly by induction of hypoxia-responsive gene products.

The basic mechanism(s) by which cells "sense" oxygen are not well understood at the molecular level. While significant insight has been gained by the discovery of specific oxygen regulated gene products, many aspects of adaptation to hypoxia currently remain areas of intense investigation. In mammalian oxygen homeostatis, changes in oxygen concentration represent a fundamental physiologic stimulus for transcriptional adaptation. This stimulus elicits both acute (rapid-onset and short-term, e.g., changes in respiratory patterns) and chronic (delayed-onset and long-term, e.g., changes in hypoxia-dependent gene transcription) responses. Intracellular oxygen concentrations are maintained within a very narrow range due to the risk of oxidative damage from excess oxygen (hyperoxia), and of metabolic demise from insufficient oxygen delivery. Whereas acute responses often entail changes in the activity of

pre-existing proteins, chronic responses frequently involve changes in gene expression [2]. Decreased oxygen content in the blood of mammals is sensed by the carotid body, which is located at the bifurcation of the common carotid artery and activates the cardiovascular and respiratory centers in the central nervous system to increase ventilation and cardiac output [2]. Similarly, a limited oxygen availability is also sensed by cells in the liver and kidney (but also by other cells), which respond by producing erythropoietin, which in turn increases red blood cell production, thus enhancing the oxygen-carrying capacity of the blood [2,3]. On a transcriptional level, research work over the past 15 years has provided a central role for the oxygen sensing transcription factor HIF in mammalian oxygen homeostasis. HIF-1, originally discovered as a transcriptional factor responsible for hypoxia-associated transcriptional increases in erythropoetin production is also involved in oxygen sensing by the human carotid body [3].

HIF-1 is composed of two distinguished subunits: constitutively expressed HIF-1β and the oxygen regulated HIF-1α [2,3]. More recently, database searches uncovered the existence of HIF-2α, which is also regulated by oxygen, dimerizes with HIF-1β, and regulates an overlapping but distinct set of target genes [1,3]. During sufficient oxygen availability, HIF-1α and HIF-2α are extremely unstable due to hydroxylation on proline residues, followed by binding of the von Hippel-Lindau (VHL) tumor suppressor protein, leading to proteosomal degradation (Fig. 1) [2,3].

In contrast, hypoxic conditions are associated with inhibition of hydroxylation and attenuated binding of VHL protein, leading to accumulation of HIF-1α and HIF-2α [2,3]. Under hypoxic conditions, hydroxylation is inhibited and the VHL protein does not bind to HIF-1, eventually leading to stabilization of the alpha-subunit, heterodymerization, nuclear translocation, binding to a consensus motif within the promoter region of hypoxia-responsive genes (hypoxia responsive element, HRE) and transcriptional activation (Fig. 1). For example, binding of HIF to consensus domains in the erythropoietin promoter results in the transcriptional induction of HIF-1-bearing gene promoters. Reporter genes containing the erythropoietin enhancer are induced by hypoxia in a variety of cell types. Moreover, HIF-1 is widely expressed and consensus HIF binding sequences (HREs) exist in a number of genes other than that of erythropoietin. In particular, HIF-1 has been found to regulate multiple genes that include HREs in their promoter region, including vascular endothelial growth factor, insulin-like growth factors, their binding proteins (insulin-like growth factor binding proteins) and iron supply regulating genes (e.g., transferring). Thus, the discovery of HIF represented a major advance in the



**Hypoxia. Figure 1** Mechanism of hypoxia inducible factor (HIF) stabilization during hypoxia. With adequate levels of oxygen (normoxia), the HIF−α subunit is hydroxylated via prolyl-hydroxylase (PHD). Hydroxylated HIF−α associates with the vonHippel Lindau protein (VHL) to recruit ubiquitin ligase, wherein the HIF−α subunit is poly-ubiquitylated and targeted for degradation by the proteasome. When levels of oxygen fall below a critical threshold (hypoxia), the lack of PHD substrate (oxygen) results in the accumulation of HIF−α, which then associates with HIF−β. The HIF heterodimer translocates to the nucleus where it is made available to activate HIF-bearing gene promoters.

understanding of gene regulation by hypoxia. Such studies have led to an understanding that induction of HIF responsive genes drives altered cellular metabolism, increased vascular mass and diameter and increased oxygen carrying capacity of the blood; all events which are conducive to an adaptive response to diminished oxygen supply. In addition, recent studies have provided strong evidence for a central role of HIF in transcriptional regulation of infection and inflammation.

## Diagnostic Principles

In a clinical setting, hypoxia is most readily detected using pulse oximetry. For this purpose, a sensor is placed on a thin part of the patient's anatomy, usually a fingertip, earlobe, or the foot of a newborn. Next, a light beam containing both red and infrared wavelengths is passed from one side of the instrument to the other. This technique allows the assessment of changes in absorbance of two wavelengths that are measured – one of the wavelengths representing oxygenated hemoglobin, the other de-oxygenated hemoglobin. Taking advantage of the pulsatile blood flow, the absorbances of arterial blood alone can be determined, excluding venous blood, skin, bone, muscle, or other tissues. Taking into account the ratio of changing absorbance of red and infrared light caused by the difference in color between oxygen-bound (bright red) and oxygen unbound (dark red or blue) hemoglobin, a measure of oxygenation can be determined, which is expressed as a percentage of oxygenated hemoglobin (also called oxygen saturation). In healthy individuals at sea level, this value is usually higher than 95%. During ambient hypoxia (e.g., high-altitude mountaineering) values below 80% or even lower can be observed and are tolerated by acclimatized individuals. At sea level, values below 90% can be indicative of different disease processes (e.g., pulmonary embolism).

In an experimental setting, tissue hypoxia can be studied using histological staining approaches. For example, 2-nitroimidazole dyes are used for this purpose. This class of compounds undergo intracellular metabolism depending on the availability of oxygen within tissue. Current understanding suggests that nitroimidazoles enter viable cells where they undergo a single electron reduction, to form a reactive intermediate species. In the presence of normal oxygen levels, these molecules are immediately re-oxidized, and diffuse out of the cell over time. In the absence of adequate tissue oxygen availability, this process is incomplete and highly reactive forms of reduced nitroimidazole associate with various intracellular proteins, forming adducts that can be localized with antibodies. For example, localization of hypoxia utilizing these 2-nitroimidazole dyes yielded very interesting observations during inflammatory conditions. Such imaging studies demonstrated that cells overlying inflamed mucosal lesions (e.g., during murine colitis) are highly hypoxic. Accumulation of nitroimidazole adducts – particularly in the epithelium – were as intense as those observed in some tumors, suggesting the existence of intense foci of hypoxia within inflamed lesions. Such studies highlight that acute inflammation and hypoxia share a number of similar characteristics.

## Therapeutic Principles

Two therapeutic principles are commonly applied when treating "hypoxia" in a clinical setting: First, elimination of the causative agent and secondly attenuation of hypoxia-associated tissue damage. For example, elimination of the causative agent may include fibrionolysis during a massive pulmonary embolism, treatment of an airway disease or coronary angioplasty during a myocardial infarction to restore blood flow to an ischemic areal of myocardium. If systemic hypoxia is encountered, attenuation of hypoxia-associated tissue damage becomes crucial to maintain intact functions of vital organs such as the kidneys, liver, heart, intestine and particularly the brain. For this purpose, delivery of hyperoxic gas-mixture becomes important (e.g., oxygen delivery via nasal cannula or an oxygen mask). If this is not sufficient to improve oxygen supply to the desired level, tracheal intubation and mechanical ventilation frequently become necessary.

At present, no specific pharmacological approaches are available to increase organ resistance to hypoxia or ischemia. However, ongoing studies are directed towards identifying novel pharmacological approaches that may render tissues more resistant to hypoxia or ischemia. Such pharmacological approaches could be utilized in a prophylactic approach, and given to patients who are at high risk for experiencing hypoxia or ischemia. For example, prophylactic treatment could be given to a patient with known coronary artery disease undergoing major surgery to attenuate the consequences of a potential perioperative myocardial infarction. Secondly, such pharmacological approaches could be utilized in the direct treatment of medical conditions characterized by hypoxia or ischemia. This is an area of very intense investigation. For example, ongoing studies directly test the usefulness of HIF-activators in treating hypoxia or ischemia. As such, a recent study found a critical role for HIF-1 in attenuating myocardial infarct sizes, and extension of these studies suggest HIF-activators in the treatment of acute myocardial ischemia [4]. Other studies investigate the usefulness of HIF-target genes in the treatment of ischemia or hypoxia. For example, a recent study demonstrated that the A2B adenosine receptor – a known HIF-target gene – renders the kidneys more resistant to an ischemic insult [5].

## ICF Syndrome

Stanley M. Gartler[1,2], R. Scott Hansen[1]
[1]Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA, USA
[2]Department of Genome Sciences, University of Washington, Seattle, WA, USA

### Synonyms

Immunodeficiency; Chromosome instability; Facial anomalies

### Definition and Characteristics

The ICF syndrome is a rare autosomal recessive disease characterized by variable immunodeficiency, chromosome instability of the pericentromeric regions of chromosomes 1, 9, and 16, and facial anomalies. Characteristic facial features may include a round face with epicanthus, telecanthus, flat nasal bridge, hypertelorism, up-turned nose, macroglossia, micrognathia, and low- set ears.

### Prevalence

ICF syndrome has to date been described in less than 40 cases. The disease was first reported in 1978 by two groups independently [1,2]. Males and females are equally affected and present with similar phenotypes.

### Genes

The ICF gene was localized to a 9-cM region on chromosome 20q11-q13 by homozygosity mapping. At the same time that the ICF gene was mapped, two DNA methyltransferases were identified in the mouse [3]. A search of the sequence data from human chromosome 20 for the presence of a DNA methyltransferase gene led to the identification of a gene highly homologous to murine Dnmt3b. Mutations of this gene in ICF patients confirmed that DNMT3B was a gene responsible for ICF syndrome [4]. There are several ICF patients in which no DNMT3B

mutation has been found. This observation raises the possibility that the ICF syndrome is genetically heterogeneous, and recent work indicates that the spectrum of hypomethylation defects in these cases is different from that of DNMT3B-positive patients.

A number of different mutations in the DNMT3B gene have been described among ICF patients. It is very likely that most of these mutations will lead to a much reduced, but not complete absence of the methyltransferase (MT3β) activity. From the analysis of gene structure it is predicted that some of the detected mutations are null mutations; that is, they would lead to a protein with no enzymatic activity. None of these have been found as homozygotes. This is expected, since studies in mice have shown that complete deficiency of this enzymatic activity results in embryonic lethality, which presumably would similarly apply to humans. Non-null DNMT3B mutations are likely to be a major factor in ICF patient survival.

## Molecular and Systemic Pathophysiology

DNA methylation is generally known to act as a silencing factor. The primary defects leading to phenotypic consequences in ICF are predicted to result from abnormal escape from transcriptional silencing due to lack of methylation by MT3β. Hypomethylation and escape from silencing in ICF cells have been demonstrated for a small number of genes on the inactive X chromosome and at other loci. None of these genes, however, appear to be likely candidates underlying the ICF phenotype. It is likely that a similar mechanism could be responsible for genes that do play important roles in facial development and the immune system.

Most ICF patients have normal birth weight, but growth retardation may occur due to failure to thrive following infections. Their intelligence is variable with some moderately or severely retarded cases. Many patients die early due to infections, so there is not much information on sexual development. In the few cases followed, puberty appears to be normal. The majority of ICF patients have a T cell defect and often develop respiratory tract infections caused by H. influenzae or S. pnemoniae. Failure to thrive is a common problem with many patients suffering from diarrhea. Agammaglobulinemia with a normal number of B cells is the most common finding in ICF, but the immunodeficiency is quite variable.

## Diagnostic Principles

The most important first step in diagnosis is chromosomal analysis. Without chromosome studies, most patients with the ICF syndrome might be classified as having ►common variable immunodeficiency (CVID). ICF syndrome should be considered for all patients with B cell-positive agammaglobulinemia or CVID without a known gene defect. Diagnosis of ICF syndrome can be made by cytogenetic analysis and analysis of satellite methylation. Direct confirmation of ICF by mutational analysis of the DNMT3B gene can be expected to be obtained in about 70% of cases.

Chromosomal aberrations, including gaps, deletions, isochromosomes, and multiradial figures, of heterochromatic pericentromeric blocks are observed at high frequency in ICF lymphocyte cultures, whereas fibroblasts and lymphoblasts show much fewer aberrant cells. The chromosomal abnormalities seen in ICF lymphocytes are like those found in normal lymphocytes treated with the DNA demethylating agent 5-azacytidine, and it was therefore proposed that ICF patients might have a defect in DNA methylation. Pericentromeric satellites are abnormally hypomethylated in all ICF cells [5] and CpG islands on the inactive X as well as some other CpG rich repetitive elements are also hypomethylated. Genome wide methylation of the ICF genome, however, is generally unaffected, which means that the great majority of methylated sites in the genome are unaffected in the ICF syndrome.

## Therapeutic Principles

At present, most ICF patients receive regular treatment with immunoglobulins, but bone marrow transplantation (BMT) is another option. Two ICF cases have been successfully treated with BMT, and this procedure should be considered in patients suffering from infections and failure to thrive.

# Ichthyosis Congenital

►Lamellar Ichthyosis

## Ichthyosis Simplex

►Ichthyosis Vulgaris

## Ichthyosis Vulgaris

Vinzenz Oji, Heiko Traupe
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Autosomal dominant ichthyosis vulgaris; Ichthyosis simplex

### Definition and Characteristics

Ichthyosis vulgaris (IV) (MIM *146700), the most common form of ichthyosis, is a hereditary disorder of keratinization characterized clinically by light gray scaling, keratosis pilaris, hyperlinearity of the palms ("ichthyosis hand"), heat intolerance and associated atopic manifestations such as atopic dermatitis. The disorder is not present at birth, but usually develops during the first year of life with an improvement often seen during summer and with age. The symmetrical scaling of the skin is most prominent on the extensor surfaces of the extremities and spares the flexural folds varying from barely visible roughness and dryness to marked scaling.

### Prevalence

World-wide occurrence with an estimated prevalence of 1:250–1,000.

### Genes

Gene map locus 1q21–22. Basic defect unknown.

### Molecular and Systemic Pathophysiology

The clinical severity of the disorder correlates with the defective synthesis of filaggrin (FLG) in the epidermis. Filaggrin aggregates keratin intermediate filaments in the lower stratum corneum and is subsequently proteolyzed and metabolized, producing free amino acids that may play a critical role as water-binding compounds in the upper stratum corneum. Profilaggrin, synthesized in the granular layer of the epidermis and a major component of keratohyalin granules, is the high molecular weight precursor of filaggrin. AGL (absence of the granular layer) seen in light microscopy corresponds to the absence or reduction of keratohyalin granules at the ultrastructural level. With the so-called AGL endophenotype, significant linkage of IV to the epidermal differentiation complex on 1q21 (including the FLG-gene) was obtained assuming either a recessive or dominant inheritance model. However, no mutation in the FLG-gene has been found so far. Most probably there are other genetic factors, Mendelian and/or polygenic, rendering individuals susceptible to the development of IV. Biochemical studies in IV keratinocytes have demonstrated a decreased profilaggrin expression resulting from a selectively impaired posttranscriptional control. Profilaggrin mRNA has a shorter half-life compared with that in normal cells. The autosomal recessive mouse mutation flaky tail (ft), which leads to attenuated or absent profilaggrin/filaggrin expression and loss of specific mouse keratohyalin granules, provides a possible animal model for the filaggrin-deficient skin seen in ichthyosis vulgaris with AGL.

### Diagnostic Principles

The diagnosis is based on the above described clinical findings. Cutaneous symptoms are similar to those of X-linked ichthyosis (MIM *308100), which, if necessary, can be ruled out by a normal beta-lipoprotein electrophoresis or steroid sulfatase testing. An outstanding but nonspecific histologic feature of ichthyosis vulgaris is the reduced granular layer of the epidermis with mild orthohyperkeratosis, prominent follicular hyperkeratosis and reduction in the number of the sebaceous glands. Ultrastructural examination reveals crumbly keratohyalin granules.

### Therapeutic Principles

Usually ichthyosis vulgaris responds well to topical ointments supporting skin hydration and containing urea or NaCl or alpha hydroxy acids (e.g., lactic, glycolic or pyruvic acids). Salicylic acid should be avoided because of percutaneous absorption which can cause life threatening toxicity especially in children.

# ICOS Deficiency

Julia Horn[1], Bodo Grimbacher[2]
[1]Division of Rheumatology and Clinical Immunology, University Hospital Freiburg, Freiburg, Germany
[2]Department of Immunology and Molecular Pathology, Royal Free Hospital and University College Medical School, London, UK

## Synonyms

Inducible costimulator deficiency

## Definition and Characteristics

ICOS (inducible costimulator) deficiency was the first described monogenetic cause for ►common variable immunodeficiency (CVID) [1]. ICOS deficiency is an autosomal recessive disorder. Affected patients show an antibody deficiency and are therefore prone to recurrent bacterial infections. They also develop other typical implications of CVID like autoimmune phenomena, follicular nodular hyperplasia, carcinoma and splenomegaly [2].

## Prevalence

ICOS deficiency is a very rare disease. As of 2005, there are nine patients from four different families diagnosed with ICOS deficiency. Over 200 CVID patients worldwide have been screened for ICOS deficiency [3].

## Genes

The ICOS gene is localised on chromosome 2 in a cluster with the costimulatory genes CD28 and CTLA4. ICOS has five exons. The nine patients who suffer from ICOS deficiency all carry the same deletion of exon 2 and exon 3 in ICOS. The SNP analysis of the shared haplotype revealed an identical costimulatory locus among all affected members, suggestive of a founder effect for all four families with ICOS deficiency.

## Molecular and Systemic Pathophysiology

ICOS is a costimulatory molecule exclusively expressed on activated T-cells. The physiological ligand of ICOS is the ICOS ligand, which is expressed on B-cells, dendritic cells and other antigen presenting cells. Human ICOS deficiency causes a severe hypogammaglobulinemia particularly concerning the class-switched isotypes (IgG, IgA, IgE), suggesting a crucial role of human ICOS in the development of secondary antibody responses. Class-switched-recombination takes place in the germinal centers of lymph nodes. ICOS-deficient mice and men show an insufficient formation of germinal centers. In humans an indicator of functional germinal centers is the presence of CD27+ switched memory B-cells in peripheral blood, which may develop to antibody producing plasma cells. Indeed all ICOS patients present with B-lymphopenia and severely reduced numbers of CD27+ switched memory B-cells, suggesting an insufficient function of germinal centers. It remains unclear why ICOS-deficient mice and men do not develop normal germinal centers. It is speculated that the reduced IL-10 production in ICOS-deficient T cells plays a role in impaired germinal centre formation because IL-10 has been shown to support survival of germinal centre B-cells [2].

Another hypothesis is that the defect in GC formation and secondary antibody production in ICOS-deficient humans and mice is primarily due to the impaired development of follicular B helper T-cells. These CD4 + T-cells express the chemokine receptor CXCR5, which mediates their migration to the B-cell follicles where they provide cognate help to B-cells. In ICOS-deficient mice the population of CXCR5+ T helper cells is reduced [4].

IL-17 is another down-regulated cytokine in ICOS-deficient CD4+ T-cells. No role in germinal centre formation has been reported for IL-17. Reduced IL-17 might explain the increased rate of respiratory infections in ICOS-deficient patients as IL17-deficient mice succumb to bacterial pneumonia due to impaired neutrophil recruitment [2].

## Diagnostic Principles

ICOS deficiency may be suspected in patients with the clinical phenotype of CVID and an autosomal recessive familial trait. Adults as well as children may be affected. CVID Type 1 patients with B-lymphopenia and severe reduction of CD27+ switched memory B-cells should be suspected of ICOS deficiency, although it is not specific for ICOS deficiency as 75% of CVID patients are classified as Type 1. The diagnosis of ICOS deficiency can be confirmed by FACS analysis of ICOS surface expression on activated T-cells and by genetic analysis.

### Therapeutic Principles

The treatment of ICOS deficiency is the same as in CVID to prevent recurrent infections. Therefore, therapy consists of intravenous or subcutaneous immunoglobulin replacement therapy and additional antibiotic treatment in case of severe or recurrent infections.

[1]Inherited Cardiovascular Disease Group, The Heart Hospital, University College London Hospitals NHS Trust and Institute of Cardiovascular Science, University College London, London, UK
[2]Imperial College, London, UK

### Synonyms

HCM; Hypertrophic cardiomyopathy; IHSS

### Definition and Characteristics

Genetically inherited heart muscle disease associated with left ventricular hypertrophy (LVH), myocyte disarray, small vessel disease (narrowing of intramural coronary arteries by medial thickening), and fibrosis. Major clinical complications include diastolic dysfunction, left ventricular outflow tract obstruction (~25%), arrhythmia, and sudden cardiac death.

### Prevalence

Prevalence in general adult population estimated at 1 in 500 [1].

### Genes

Often considered a disease of the sarcomere, or contractile apparatus of the cell.

Most common mode of inheritance is autosomal dominant.

Penetrance is incomplete and age-related: 55% from the ages of 10–29, 75% from 30 to 49, and 95% in gene carriers over the age of 50.

Compound-heterozygous, double-heterozygous, and homozygous states are less common but recognized. Phenotype analyses suggest a gene-dose effect [2].

Current estimates suggest ~60% harbor mutations in one of the known disease-causing sarcomeric genes. Significant proportion of remainder may have metabolic disorders or mitochondrial cytopathies that produce cardiac "phenocopies" of hypertrophic cardiomyopathy.

Timely recognition of phenocopies important for four main reasons:

1. May have distinct cardiac profile, with increased incidence of conduction disease and progression to cavity dilation and heart failure
2. May have extra-cardiac features such as skeletal myopathy, renal impairment, and neurological involvement

3. Specific therapies may be available to alter the natural history of the disease (e.g., enzyme replacement in Fabry's disease)
4. Recessive, X-linked, and mitochondrial patterns of inheritance more frequent, with implications for familial assessment [3]

## Molecular and Systemic Pathophysiology

Compromised cellular energetics may be central to the development of HCM and related phenotypes [4]. An aberration at any point along the pathway of ATP synthesis, transfer, regulation, and expenditure may generate a cellular energy deficit (Table 1), which impairs function of the sarcoplasmic reticulum calcium re-uptake pump.

The prolonged cytosolic calcium transient may serve as the signal that ultimately triggers cellular hypertrophy, although the exact pathway remains to be unraveled. Indeed, genetic defects that produce a HCM-like phenotype by an unknown mechanism may turn out to be components of the downstream signaling pathway.

Magnetic resonance spectroscopy of patients with mutations in beta-myosin heavy chain, troponin T, and myosin-binding protein C revealed significant reductions in the cardiac phosphocreatine to ATP ratio, an indicator of myocardial energy status. Equally, the presence of the bioenergetic deficit in nonpenetrant gene carriers without hypertrophy argues against it being a secondary phenomenon. Further validation of the energy compromise hypothesis, however, awaits diagnostic and therapeutic applications [3].

The main clinical manifestations of HCM and their underlying cellular and molecular mechanisms are presented in Table 2 [3].

## Diagnostic Principles

Clinical diagnosis of HCM is based on the 12-lead ECG and echocardiogram.

While an unexplained maximum left ventricular wall thickness of ≥15 mm in any myocardial segment on echocardiography is considered diagnostic in adults, milder degrees of hypertrophy (≥12 mm) have been observed in many gene carriers. LVH may be mild or absent in individuals with Troponin T mutations, in whom ECG findings may be the mainstay of diagnosis.

Autosomal dominant transmission confers a 50:50 chance that the first-degree relatives of a proband with confirmed HCM will be genetically affected. Minor ECG and echocardiographic abnormalities are therefore more likely to represent disease expression in family members than in the general population. Modified diagnostic criteria for familial HCM have been proposed to reflect this [5].

**Idiopathic Hypertrophic Subaortic Stenosis. Table 1** Disease-causing genes in hypertrophic cardiomyopathy and phenocopies

| | Purported mechanism(s) | Examples |
|---|---|---|
| Sarcomeric mutations | ? Ineffective ATP utilization | β-myosin heavy chain ,α-tropomyosin, troponin T, troponin I, myosin binding protein-C, regulatory myosin light chain, essential myosin light chain, cardiac actin, titin, α-cardiac myosin heavy chain, troponin C |
| Metabolic diseases | ? Reduced substrate for ATP synthesis | Glycogen storage diseases<br>Phosphorylase B kinase deficiency<br>CD36 & carnitine deficiencies |
| | ? Reduced activity of respiratory chain enzymes | Anderson-Fabry disease |
| | ? Impaired regulation of ATP | AMP kinase |
| Mitochondrial cytopathies | ? Interference with ATP synthesis | MELAS, MERRF, LHON<br>Friedreich's ataxia (deficiency of frataxin, which is a key activator of mitochondrial energy conversion) |
| | ? Interference with ATP transport | Senger's syndrome |
| Syndromic HCM | Dysregulated RAS-MAPK signalling | PTPN11, RAF1 (Noonan's and LEOPARD syndromes) |

Abbreviations: MELAS= mitochondrial encephalomyopathy, lactic acidosis, stroke-like episodes; MERRF= myoclonic epilepsy and ragged red fibers; LHON = Leber's hereditary optic neuropathy.

**Idiopathic Hypertrophic Subaortic Stenosis. Table 2** Major clinical manifestations of HCM and underlying pathophysiology

| | |
|---|---|
| Diastolic dysfunction | Myocyte disarray, cellular energy deficit, and altered affinity of mutant sarcomeric proteins for calcium ions may impair calcium uptake and active isovolumetric relaxation.<br>Hypertrophy and interstitial fibrosis reduce compliance and passive relaxation. |
| Ischemia | Changes in coronary microcirculation<br>Capillary-mass mismatch |
| Left ventricular outflow tract obstruction | Systolic anterior movement of the mitral valve resulting from structural abnormalities of the valvular apparatus and a flow-drag effect |
| Inappropriate vasodilator response during exercise | Excess stimulation of left ventricular mechanoreceptors by abnormal wall strain (? due perhaps to myocyte disarray and fibrosis)<br>Exaggerated sensitivity of arterial baroreceptors<br>Raised levels of natriuretic peptides |
| Arrhythmia | Substrate: myocyte disarray and fibrosis<br>Triggers: ischemia, left ventricular outflow tract obstruction, vascular instability, cellular energy depletion |
| Wall thinning (up to 60%)<br>Cavity dilation and systolic impairment (<5%) | Ischemia, compromised energetics, injury from abnormal hemodynamic loading lead to progressive myocyte loss and replacement fibrosis |

After references [1,3].

## Therapeutic Principles

Exertional dyspnoea and chest pain consequent to diastolic dysfunction and/or ischemia may respond to β-blockers or calcium channel blockers.

β-blockers may alleviate exertional left ventricular outflow tract obstruction; disopyramide is more effective for a resting gradient. Alcohol septal ablation and septal myectomy are available options if pharmacological therapy fails.

A small but important minority of HCM patients are at risk of sudden death and may benefit from implantation of a cardioverter-defibrillator. Key predictors of increased risk are a family history of premature sudden death, nonsustained ventricular tachycardia, unexplained syncope, a maximum wall thickness ≥30 mm, and failure of the systolic blood pressure to increase appropriately during exercise [6].

## IgA Nephropathy

Kar Neng Lai
Department of Medicine, The University of Hong Kong, People's Republic of China

### Synonyms

Berger's disease; Benign recurrent hematuria syndrome; IgAN

### Definition and Characteristics

Mesangial proliferative glomerulonephritis with predominant mesangial IgA deposition leading to terminal renal failure in 30% of patients over 30 years. Recurrence of IgAN in allograft due to primary defect in IgA molecule.

### Prevalence

Highest amongst Asia-Pacific rim, followed by Mediterranean and Australasia accounting for 30%, 20% and 15% of primary glomerulonephritis in adult.

### Genes

Familial clustering with a linked locus at 6q22–23 in 60% of families of Italian or Caucasian ethnicity. Increased co-transmission of the 2093C and 2180T alleles supports genetic variation in Megsin conferring susceptibility to IgAN.

### Molecular and Systemic Pathophysiology

The initiating event in the pathogenesis of IgAN is the mesangial deposition of IgA, which is predominantly polymeric IgA of the IgA1 subclass (pIgA1). Three key factors contribute to the development of IgAN, and the extent to which each is operational decides the severity, tempo, and eventual clinical outcome of the individual patient:

1. Synthesis, release, and persistence in the circulation of pIgA1 with characteristics that favor mesangial deposition;
2. The "reactivity" of the glomerular mesangium as judged by:
   - its susceptibility to mesangial deposition
   - its capacity to mount an inflammatory response to that deposition.
3. The tendency of the kidney to respond to injury by mounting a response that favors progressive renal injury rather than resolution of inflammation without ongoing glomerulosclerosis and particularly, tubulointerstitial atrophy and fibrosis.

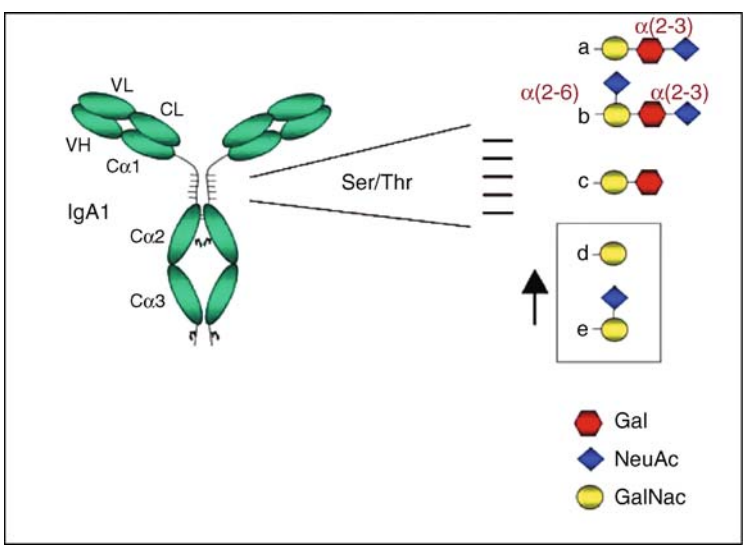
Although mesangial IgA deposition and the initiation by IgA of glomerular inflammation are specific to IgAN, mechanisms of IgA deposition remain uncertain. Known IgA receptors do not participate in the binding of pIgA1 and electrostatic charge of the IgA molecule affects the binding. The subsequent renal injury followed either by resolution or progressive sclerosis are originally thought to be generic, not differing substantially from those seen in other forms of chronic glomerulonephritis. However, most recent investigation shows IgA does not bind to renal tubular cells despite mesangial deposition. The tubulointerstitial injuries are mediated through a glomerulo-tubular crosstalk involving

TNF-α, interleukin 6, and angiotensin II (AngII) as well as proteinuria.

A number of abnormalities in circulating IgA and its production are reported in IgAN. However, patient cohorts are heterogeneous with respect to these abnormalities, supporting the notion that more than one pathogenic mechanism may result in the production of pathogenic circulating IgA. An increased plasma IgA level is not sufficient per se to produce mesangial IgA deposits. It is likely that patients with IgAN must produce a pool of circulating IgA molecules with special characteristics that particularly promote mesangial deposition. However, there is no evidence that IgAN is driven by circulating IgA autoantibodies that bind specifically to glomerular antigens. No single pathogenic antigen has been identified to induce specific IgA autoantibodies

There is now growing evidence supporting abnormal O-glycosylation of the hinge region of IgA1 is involved in the pathogenesis of IgAN (Fig. 1). The abnormality takes the form of reduced galactosylation of the IgA1 hinge region O-glycans, leading to increased frequency of truncated O-glycans. Data on sialylation of the IgA1 O-glycans in IgAN remain conflicting, with increased and decreased O-sialylation being reported. Other than plasma IgA1, IgA1 eluted from isolated glomeruli have now identified the same O-glycosylation abnormalities in mesangial IgA1, strongly implicating altered glycosylation in the mechanisms of IgA deposition. The functional effects of altered IgA1 hinge region O-glycosylation remain uncertain. Under in vitro setting, aberrantly glycosylated IgA1 have an increased tendency both to self-aggregate and to form antigen-antibody complexes with IgG antibodies directed against IgA1 hinge epitopes, favoring the generation of macromolecular aggregates of pIgA1 and IgA immune complexes. In addition, IgA1 molecules that lack terminal sialic acid and galactose units have increased in vitro affinity for the extracellular matrix components fibronectin and type IV collagen. A functional abnormality of the specific glycosyltransferases responsible for the O-glycosylation of IgA1 has been proposed as a mechanism for altered O-glycosylation in IgAN. β 1,3-Galactosyltransferase is the key enzyme, catalyzing the addition of galactose to O-linked glycans. So far, no overt defect in the activity of this enzyme has been found in bone marrow B cells in IgAN.

IgA from patients with IgAN exerts pathophysiologic effects on target cells such as the mesangial or tubular epithelial cells. Under in vitro setting, mesangial cells incubated with aggregated IgA elicited a dose-dependent increase in calcium flux. Cultured mesangial cells conditioned with pIgA or aggregated IgA expressed



**IgA Nephropathy. Figure 1** The microheterogeneity of the O-glycans at the hinge region of IgA1 molecule. *O*-glycans are presented as (a) trisaccharides, (b) tetrasaccharides, (c,e) disaccharides, and (d) morosaccharides. *N*-acetylgalactosamine (*circle*) is β1,3-linked to galactose (*hexagon*). Sialic acid (*diamond*) has a α2,6-linkage to GalNac, and α2,3-linkage to Gal residues. Abnormal IgA1 in IgAN patients possess an increased proportion (↑) of the terminal as either (d) GalNac or (e) GalNac–NeuAc glycan structures. Abbreviations: Cα, constant region of IgA; CL, constant light chain region; VL, variable light chain region; VH, variable heavy chain region; the Ser/Thr-rich hinge region glycosylation sites are indicated by small bars. (Modified from: Monterio RC et al. (2002) Pathogenic significance of IgA receptor interactions in IgA nephropathy. Trends Mol Med 8:464–468. With permission).

more $\alpha_v$ receptor per cell than those incubated with unconditioned medium suggesting IgA, especially the polymeric form, may play a role in modulating the cell-matrix interaction in IgAN. Other in vitro studies revealed binding of IgA to mesangial cells led to increased expression of NFκB, c-jun, interleukin 6, interleukin 8, MCP-1, TNF-α, and Ang II. The enhanced production of interleukin 8 may lead to the renal accumulation of neutrophils in IgAN.

An altered glomerular expression of AngII type 1 receptor (ATR1) suggesting a regulatory response to high intra-renal AngII concentration in IgAN. Tubular expression of ATR1 and AngII type 2 receptor (ATR2) was increased in IgAN. In vitro culture experiment show that the up-regulation of these receptors is not due to the direct effect of IgA but the indirect effect following IgA deposition on human mesangial cell. AngII production is up-regulated leading to inflammation and apoptosis via the ATR1 and ATR2 respectively. The initial interaction between AngII and ATR1 activates both PKC and MAPK pathways leading to inflammatory responses. This early ATR1-dependent event is followed by up-regulation of ATR2 expression and continued AngII release. In vitro studies suggest appropriate control of AngII receptor activities may ameliorate tubulointerstitial injury in IgAN.

### Diagnostic Principles

Microscopic or macrosopic hematuria. Raised plasma IgA in 30–50% of patients. Renal biopsy is needed for definitive diagnosis.

### Therapeutic Principles

Pharmacological therapy includes renin-angiotensin system blockade. AngII modulates inflammatory and hemodynamic effects renal cells. Low protein diet reduces glomerulosclerosis. Other treatment such as corticosteroid and mycophenolate mofetil provides encouraging results in selected groups of patients and requires further confirmation with randomized clinical trials. In vitro studies show mycophenolate mofetil suppresses activated lymphocytes and reduces binding of polymeric IgA to mesangial cells.

## IgA-Pemphigus

Silke Hofmann, Leena Bruckner-Tuderman
Department of Dermatology, University Medical Center, Freiburg, Germany

### Synonyms

Intercellular IgA dermatosis; IgA pemphigus foliaceus; IgA herpetiform pemphigus; Intraepidermal IgA pustulosis; Intercellular IgA vesiculopustular dermatosis

### Definition and Characteristics

Autoimmune intraepidermal bullous disease associated with circulating and tissue-bound IgA autoantibodies against keratinocyte surface proteins. Patients present with pruriginous flaccid vesicles or pustules and neutrophilic infiltrates in the epidermis. Mucous membrane involvement is rarely present. Clinically and histologically, two types of IgA-pemphigus may be differentiated: subcorneal pustular dermatosis (SPD) type and intraepidermal neutrophilic (IEN) type [1].

### Prevalence

The prevalence and incidence are not known; since its first description in 1979, more than 70 cases have been described in the literature. IgA-pemphigus affects women more frequently and typically occurs in middle-aged or elderly persons.

### Molecular and Systemic Pathophysiology

IgA antibodies in sera from patients with IgA-pemphigus have been shown to bind to cell surface antigens on skin explant cultures before the induction of intraepidermal acantholysis. These experiments suggested a pathogenic role of the IgA autoantibodies, which belong mainly to the $IgA_1$ subclass.

In SPD-type of IgA-pemphigus, autoantibodies are directed against the desmosomal cadherin desmocollin 1 (105–115 kDa) as revealed by cDNA transfection and living cell immunofluorescence. These findings were confirmed by postembedding immunoelectron microscopy showing that SPD-type sera target the extracellular domain of desmocollins. In contrast, the autoantigen of the IEN-type of IgA pemphigus is localized in the

intercellular space between desmosomes suggesting that the autoantigen is a nondesmosomal transmembranous protein [2].

### Diagnostic Principles

Histology shows IEN pustules located in the subcorneal layers of the epidermis (SPD-type) or in the lower epidermis (IEN-type). Intercellular IgA deposits are always present in lesional tissue. Indirect immunofluorescence may be positive on normal human skin or transfected COS-7 cells expressing human desmocollins (SPD-type). Some patients have additional autoantibodies against desmogleins.

### Therapeutic Principles

Dapsone is the drug of choice in the treatment of IgA pemphigus. Alternative treatments include prednisolone, etretinate, acitretin, isotretinoin, colchicine, methotrexate, and cyclophosphamide. Furthermore, plasmapheresis or PUVA therapy may help to achieve good control of IgA-pemphigus.

## IGF1R Gene Defect

Peter E. H. Schwarz, Jiang Li
Medical Clinic III, Medical Faculty Carl-Gustav-Carus, Technical University Dresden, Dresden, Germany

### Synonyms

EC 2.7.10.1 defect; Insulin-like growth factor I receptor defect; IGF-I receptor defect; CD221 antigen defect

### Definition and Characteristics

Autosomal dominant defect in insulin-like growth factor I receptor. The insulin-like growth factor 1 (IGF-1) receptor is a transmembrane receptor that is activated by IGF-1 and by the related growth factor IGF-II. It belongs to the large class of tyrosine kinase receptors. This receptor mediates the effects of IGF-1, which is a polypeptide protein hormone similar in molecular structure to insulin. Clinical features of the gene defect include intrauterine growth retardation (IUGR), microcephaly, micrognathia, renal anomalies, lung hypoplasia, and delayed growth and development.

### Prevalence

IGF-I receptor defect is rare.

### Genes

IGF1R (MIM 147370) is located on chromosome 15q26.3. It contains 21 exons and spans about 100 kb [1]. Its 5-prime flanking and untranslated region is GC-rich and contains numerous potential SP1 and AP2 binding sites as well as a thyroid response element, but no TATA or CCAAT elements [2].

### Molecular and Systemic Pathophysiology

Two alpha subunits and two beta subunits make up the IGF-1R. The beta subunits pass through the cellular membrane and are linked by disulfide bonds. IGF1R is activated by IGF-1 and by the related growth factor IGF-II. It belongs to the large class of tyrosine kinase receptors. This receptor mediates the effects of IGF-1, which is a polypeptide protein hormone similar in

molecular structure to insulin. IGF-1 plays an important role in growth and continues to have anabolic effects in adults – meaning that it can induce hypertrophy of skeletal muscle and other target tissues.

The IGF-1R is implicated in several cancers, most notably breast cancer. It is highly overexpressed in most malignant tissues where it functions as an anti-apoptotic agent by enhancing cell survival. In some instances its anti-apoptotic properties allow cancerous cells to resist the cytotoxic properties of chemotherapeutic drugs or radiotherapy. It is further implicated in breast cancer by increasing the metastatic potential of the original tumor by inferring the ability to promote vascularization.

### Diagnostic Principles

The diagnosis is made by genetic analysis.

### Therapeutic Principles

Monoclonal antibodies (MABs) can be used to block IGF-1 binding to the IGF1R and so to inhibit cancer cell growth [3]. Due to the similarity of the structures of IGF-1R and the insulin receptor, especially in the regions of the ATP binding site and tyrosine kinase regions, synthesizing selective inhibitors of IGF-1R is difficult. Prominent in current research are two main classes of inhibitor: tyrphostins such as AG538 and AG1024 and Pyrrolo[2,3-d]-pyrimidine derivatives such as NVP-AEW541, which show far greater (100-fold) selectivity towards IFG-1R over insulin receptor.

## Synonyms

Joseph's syndrome

## Definition and Characteristics

Iminoglycinuria is an autosomal recessive disorder of amino acid transport in the kidney and to some extent in the intestine. It is defined as an increased excretion of glycine, proline and hydroxyproline in the urine. The disorder is caused by reduced capacity to transport glycine, proline and hydroxyproline across the apical membrane in the kidney and in some cases also in the intestine. The disorder was first described Joseph et al. and is therefore sometimes referred to as Joseph's syndrome [1]. Although some early reports mentioned pathological findings, later studies found that the disorder is a benign anomaly of amino acid absorption [2]. Iminoglycinuria is regularly observed in newborns. The condition ceases after about 6 months when kidney reabsorption has matured. Differences in inheritance are observed in iminoglycinuria. All homozygotes are characterized by renal excretion of glycine, proline and hydroxyproline. Heterozygotes are normal in some pedigrees whereas in others hyperglycinuria is observed. In the few cases that were investigated most individuals would have normal intestinal transport, but some individuals with intestinal transport defects have been reported [2]. As a result it is assumed that iminoglycinuria is a complex disorder involving more than one allele.

## Prevalence

About 1:15,000 in Caucasians.

## Genes

No genes have been reported as yet, which harbor mutations in iminoglycinuria. Since the renal physiology is fairly well understood, a number of candidate genes have been identified, which are involved in glycine and proline transport in kidney and intestine.

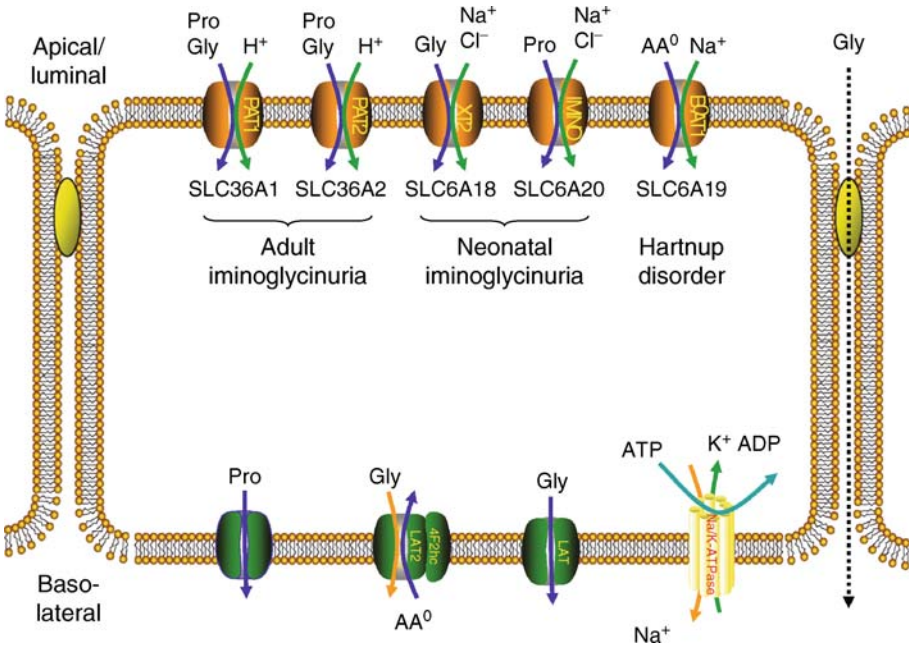
- The proline and glycine transporter PAT1 (SLC36A1, 5q33.1)
- The proline and glycine transporter PAT2 (SLC36A2, 5q33.1)
- The proline-specific transporter IMINO (SLC6A20, 3p21.31)
- The putative glycine transporter XT2 (SLC6A18, 5p15.33)

## Molecular and Systemic Pathophysiology

Iminoglycinuria is thought to be caused by mutations in apical proline, hydroxyproline and glycine transporters (Fig. 1). Hydroxyproline and proline share the same transporters, in the following proline will stand for both amino acids. Reabsorption of proline and glycine in the kidney is a complex process involving at least five different transport proteins (Fig. 1).

Both proline and glycine are substrates of the general neutral amino acid transporter B0AT1 (SLC6A19). Mutations in this transporter cause Hartnup disorder (see the corresponding chapter in this Handbook), which is unrelated to iminoglycinuria. The remaining transporters for proline and glycine are the proton amino acid transporters PAT1 (SLC36A1) and PAT2 (SLC36A2), the IMINO transporter (SLC6A20) and XT2 (SLC6A18). Physiological studies have provided evidence for a common proton-driven glycine and proline transporter, sometimes referred to as the Imino acid carrier. In the intestine this transporter has been identified as the proton-amino acid transporter PAT1 [3]. A second isoform with similar properties has been described (PAT2) but the level and pattern of expression of the two isoforms in kidney remains unknown. In addition separate high-affinity transporters for glycine and proline have been described in the kidney. The molecular correlate of the proline-specific transporter is the IMINO transporter [4]. To date the best candidate for the glycine-specific transporter is XT2 (SLC6A18). XT2 belongs to the amino acid transporter (II) branch of the neurotransmitter transporter family (SLC6). Extensive studies have failed to show any transport activity for XT2. However, an slc6a18 deficient mouse displays isolated glycinuria and appears to lack a high-affinity transporter for glycine [5].

Iminoglycinuria is a common observation in newborns. Hyperiminoaciduria ceases after about 3 months, hyperglycinuria disappears after 6 months. It is thought that at birth the common transporter for glycine and proline (most likely PAT1/2) is expressed, whereas the two specific transporters (most likely IMINO and XT2) are lacking. Development of renal reabsorption then involves increased expression of IMINO followed



**Iminoglycinuria. Figure 1** Transporters involved in glycine and proline transport in kidney and intestine. Glycine and proline are accepted by five different transport systems, four of which are proposed to be involved in iminoglycinuria. A lack of XT2 and IMINO is thought to cause neonatal iminoglycinuria, whereas adult iminoglycinuria is most likely caused by mutations in PAT1 or PAT2. The phenotype could be modified by mutations in IMINO and XT2. Release of proline and glycine across the basolateral membrane is not well characterized but could involve L-type amino acid transporters. Paracellular transport appears to be significant in the case of glycine.

by the expression of XT2. As a result iminoglycinuria could result from mutations in IMINO and XT2 as well as from mutations in the common transporter(s). This is supported by phenotype variations in pedigrees with iminoglycinuria [2]. All homozygotes are characterized by renal iminoglycinuria. Some pedigrees have an intestinal transport defect, whereas others do not. Heterozygotes are either normal or show glycinuria. Mutations in the proposed candidates can explain the phenotype variability.

## Diagnostic Principles

Proline clearance in iminoglycinuria is about 10 ml $min^{-1}$ $1.73m^{-2}$ (normal 0–0.03). Glycine clearance is about 20 ml $min^{-1}$ $1.73m^{-2}$ (normal < 10). The disorder is diagnosed by increased amounts of glycine, proline and hydroxyproline in the urine persisting for more than 6 months after birth.

## Therapeutic Principles

The disorder is considered to be benign. No treatment is required.

# Immotile Cilia Syndrome

Wallace F. Marshall
Department of Biochemistry & Biophysics, University of California, San Francisco, CA, USA

## Synonyms

Primary ciliary dyskinesia; PCD; Kartagener's syndrome

## Definition and Characteristics

Patients with immotile cilia syndrome (OMIM 242650) suffer from recurrent respiratory tract infections and bronchiectasis due to an inability to effectively clear mucus from the airway. Other mucus-related symptoms include chronic nasal congestion, chronic sinusitis, and middle ear infections. Approximately 50% of patients have dextrocardia or situs inversus, in which case the disease is called Kartagener's syndrome (OMIM 244400). In some cases hydrocephalus also accompanies immotile cilia syndrome.

## Prevalence

1:15,000

## Genes

Disease-causing mutations have been reported in DNAI1 (found in 10% of patients), DNAH5, and DNAH11 encoding protein subunits of the outer dynein arms that drive ciliary movement [1].

## Molecular and Systemic Pathophysiology

Cilia are found in almost all cells of the body and play active roles in physiological sensing and motility [2]. The pathophysiology of immotile cilia syndrome reflects the functions of ciliary motility in physiology and development of different tissues (Table 1).

Cilia play an active role in clearing mucus from airway and sinuses, and also drive flows of cerebrospinal fluid in the brain. Defects in these flows leads to the symptoms that are reported for immotile cilia syndrome. The bronchiectasis and sinusitis seen with immotile cilia syndrome are an obvious consequence of reduced mucus clearance and flow rates due to loss of ciliary motility. Situs inversus reflects a role of cilia-driven flow of extraembryonic fluid in the initial left/right symmetry breaking in mammalian embryogenesis.

The lack of ciliary motility can in many instances be traced back to specific structural defects [3]. These defects generally fall into one of four classes: defects in dynein arms, defects in radial spokes, defects in central pair, or defects in orientation. The most frequent defect seen in patients is missing or abnormal dynein arms [1]. Dynein arms are motor complexes that provide the motile bending force of the cilium. Cilia contain several different types of dynein arms, classed broadly into outer arms and inner arms based on their position in the cross section of the cilium. Within these two classes there are several different dynein motor isoforms as well as a number of regulatory subunits. Defects in specific classes or isoforms can yield slightly different defects in ciliary motility, thus representing potentially different variants of immotile cilia syndrome. Such differences are currently being characterized. Most patients (60–70%) have defective outer dynein arms [4] although the reason why such mutants should be relatively more prevalent is not understood, and may simply reflect a founder effect.

The activity of the dynein arms is coordinated by a complex machinery consisting of a central pair of microtubules that runs up the middle of the cilium, which is then linked to the inner dynein arms by protein complexes called radial spokes. Defects in either the spokes or the central pair can lead to defective motility even though the dynein arms themselves are perfectly intact. When central pair microtubules are missing, it is often observed that one of the outer doublet microtubules is displaced into the center of the cilium, a condition known as "ciliary transposition." Central pair defects often result in a circular ciliary beat pattern, but with a frequency comparable to that seen in normal patients. PCD resulting from central pair defects is generally NOT associated with situs inversus, possibly because the node cilia that are critical for determining situs normally lack the central pair and tend to move with a circular type of beat.

**Immotile Cilia Syndrome. Table 1** Tissue-specific symptoms associated with immotile cilia

| Symptom | Tissue affected |
|---|---|
| Bronchiectasis | Airway |
| Chronic sinusitis | Sinuses |
| Hydrocephalus | Ependyma |
| Situs inversus | Embryonic node |
| Male infertility | Sperm |
| Reduced female fertility | Oviduct |

## Diagnostic Principles

The most precise diagnosis involves a combination of video microscopy-based analysis of ciliary beating frequency and pattern, ultrastructural examination by electron microscopy, and measurements of nitric oxide production which is reduced in PCD patients [1,4].

## Therapeutic Principles

The most serious symptoms of immotile cilia syndrome all have to do with reduced efficiency of mucus clearance. Reduced mucus clearance is also a symptom in cystic fibrosis (CF) although in that case the defect is due to changes in the mucus itself rather than ciliary function. Nevertheless, the same types of palliative remedies used to treat CF currently constitute the

standard of care for immotile cilia patients suffering from mucus clearance-related symptoms.

►Kartagener Syndrome

# Immune Deficiency, Primary

Elana Lavine, Chaim M. Roifman
Division of Immunology and Allergy, The Hospital for Sick Children, Toronto, ON, Canada

## Definition and Characteristics

A primary immune deficiency is typically revealed by resulting infection. However, an increased prevalence of autoimmune disease and malignancy are also manifestations of underlying immune dysfunction. Defects in antibody synthesis and/or function, cell mediated immunity, complement and phagocytosis can be observed. With each type of defect, an individual is predisposed to infections that capitalize on the breach in immunity created by the defect [1].

Defective function of phagocytic cells, an ancient feature of the immune system, classically manifests as an infant with delayed umbilical cord separation and cutaneous abscesses. Impaired function of the complement system frees encapsulated organisms, resulting in meningitis and septicaemia. Defective humoral immunity allows pyogenic organisms to infect sinopulmonary mucosa, causing sinusitis, otitis media, pneumonia, and ultimately bronchiectatic change in lower airways. Defective cell mediated immunity allows infection with ubiquitous Pneumocystis carinii and Candida albicans and typically presents in early infancy with pneumonitis, oral thrush and chronic diarrhea [2].

A "pure" humoral immunodeficiency, i.e. X-linked (Bruton's) agammaglobulinemia, is associated with intact cell mediated immunity, while severe combined immunodeficiencies (SCID) create more sweeping deficiencies in global immune function. Chronic mucocutaneous candidiasis (CMCC) predisposes to Candida infection of skin and mucosal membranes. Interleukin-1 receptor associated kinase-4 (IRAK-4) deficiency is an example of an immunodeficiency of the innate immune system, which predisposes patients to severe invasive bacterial infections. Common variable immunodeficiency labels individuals with a spectrum of low antibodies, a predisposition to autoimmunity and increased risk of malignancy.

## Prevalence

One in 500 individuals has selective IgA deficiency, which is largely asymptomatic. Excluding this entity, overall prevalence of primary immune deficiency is estimated at 1:50,000–1:100,000.

## Genes

Mutations in a number of genes may play causative roles in immune dysfunction; illustrative examples are listed herein. SCID may be caused by mutations in genes such as ADA, RAG1, RAG2, Artemis, CD3δ, CD3ξ, CD45, IL-7Rα, IL-2Rγ and ZAP70. The timing of each gene's expression in the sequence of T-lymphocyte maturation determines the ultimate number and type of cells that will develop despite the mutation, helping to characterize the nature of the SCID [3]. Agammaglobulinemia can be caused by mutations in the BTK gene among others. CMCC may be related to mutations in AIRE. WHIM syndrome (warts, hypogammaglobulinemia, frequent infections and myelokathexis) has been linked to mutations in CXCR4.

## Molecular and Systemic Pathophysiology

Much has been learned from the study of the thymus, a specialized gland that reaches the anterior mediastinum by the eighth week of gestation and receives a population of lymphoid stem cells by the tenth week. Further maturation of glandular architecture and these resident T (thymus)-lymphocytes characterizes the remainder of the in utero development. Normal processes include genetic rearrangement of the T-cell receptor chains in order to create distinct lineages of functional cells that can recognize foreign antigens. In SCID, this process is abnormal and yields a dysplastic thymus with aberrations in both lymphocyte populations and non-lymphoid elements such as Hassall's corpuscles. Biopsy of thymic tissue may reveal features characteristic of a particular form of SCID, as the various genetic aberrations can block maturation of thymus tissue or thymocytes at different stages of differentiation [4].

## Diagnostic Principles

Diagnosis begins with the clinical assessment, where symptoms, signs and the patient's age may suggest the nature of the immune deficit. The clinician must bear in mind that immunodeficiency will not always present in a typical manner. Humoral immunity can be assessed through quantitative measurement of immunoglobulins G, A and M. Immunoglobulin function is best assessed through measurement of specific protein and polysaccharide antibodies to known exposures, most commonly through vaccinations, such as tetanus, measles, mumps, rubella, diphtheria, pneumococcus and varicella. Cell mediated immunity is reflected in numbers of lymphocytes, their relative distribution among B- and T-lymphocytes and their subsets (i.e. CD4+, CD8+, etc). Furthermore, the repertoire of T-lymphocytes can be assessed through quantification of the T-cell receptor variable beta chain, revealing any oligoclonality. Their function can be assessed through responses to both mitogens, which stimulate lymphocytes, and selected antigens, which rely on such processes as immunological memory. Newer testing methods such as T-lymphocyte receptor excision circle measurement (TREC) can actually quantify thymic output. Other specific tests (neutrophil burst or oxidation indices, measurement of enzymes such as adenosine deaminase, skeletal imaging, etc) may be indicated on a case-by-case basis.

## Therapeutic Principles

The most severe phenotypes, including SCID, require reconstitution of the immune system with human stem cell transplantation from peripheral blood, bone marrow or umbilical cord sources. Less severe phenotypes may require only the replacement of absent antibodies with pooled human immune globulin administered on a regular basis, most commonly via the intravenous route. Antibiotic prophylaxis helps to reduce the incidence of bacterial or PCP infection in a variety of immunodeficiencies.

# Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-linked Syndrome

Makoto Miyara, Shimon Sakaguchi
Department of Experimental Pathology, Institute for Frontier Medical Sciences, Kyoto University, Kyoto, Japan

## Synonyms

IPEX syndrome; X-linked autoimmunity-allergic dysregulation syndrome; XLAAD; IDDM-secretory diarrhea syndrome; DMSD; Autoimmunity-immunodeficiency syndrome, X-linked; Diarrhea, polyendocrinopathy, fatal infection syndrome, X-linked; Enteropathy, autoimmune, with hemolytic anemia and polyendocrinopathy; Polyendocrinopathy, immune dysfunction, and diarrhea, X-linked; XPID; Diabetes mellitus, congenital insulin-dependent, with fatal secretory diarrhea; IPEX

## Definition and Characteristics

The immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX) is a rare systemic autoimmune and inflammatory disorder caused by mutations of the FOXP3 gene. The main characteristics of IPEX are a high incidence of autoimmune disease (in particular type 1 diabetes), inflammatory bowel disease, and severe allergy including allergic dermatitis and food allergy. The FoxP3 protein is a transcription factor that is indispensable for the development and the function of the naturally occurring $CD4^+CD25^+$ regulatory T cell (Treg) population, which constitutes 5–10% of peripheral $CD4^+$ T cells in normal healthy individuals and engages in the maintenance of immunologic self-tolerance and immune homeostasis. Similar to IPEX, the absence of expression or the loss of function of the FOXP3 gene in mice, for example in Foxp3 mutant Scurfy mice, results in the development of a fatal autoimmune/inflammatory disease that is characterized by lymphoadenopathy, massive lymphocytic infiltration in the liver and the skin, and severe wasting disease [1].

## Prevalence

IPEX is an extremely rare disease which usually occurs in young male patients (X linked disease).

## Genes

The locus of the FOXP3 gene is Xp11.23-q13.3. Foxp3 is a 431 amino acid protein which has three functional

domains including the zing finger domain, the leucin zipper domain and the winged-helix/forkhead DNA binding domain. Splice-site mutations and point mutations in these functional domains of Foxp3 have been described. IPEX disease can also be secondary to the absence of FoxP3 expression due to mutations in the promoter regions of the FOXP3 gene.

### Molecular and Systemic Pathophysiology

FoxP3, like other members of the forkhead box protein family, has the ability to homodimerize through their leucin zipper domain and controls many genes by binding to promoter regions of many genes, including the IL-2 gene, through their zing finger and FKH domains. FoxP3 also forms transcription complexes with other transcriptions factors such as NFAT and AML1/Runx1. FoxP3 is a key controller of the development and function of natural $CD4^{+}CD25^{+}$ Tregs, which actively suppress aberrant or excessive immune responses harmful to the host. This mechanism of Treg-mediated self-tolerance, called dominant self-tolerance, is best exemplified in mothers of IPEX patients: the mothers, who are heterozygous for mutated FoxP3 genes on X-chromosome, are completely healthy because residual Tregs expressing the normal FOXP3 allele, are sufficient to dominantly control self-reactive T cells. In IPEX patients, who are usually male children, lack of FoxP3 or expression of anomalous FoxP3 results in the absence or dysfunction of Tregs. This leads to uncontrolled activation and expansion of T cells reactive with self-antigens, innocuous environmental substances, or commensal bacteria in the intestine, hence autoimmune disease, allergy, and inflammatory bowel disease, respectively.

### Diagnostic Principles

The disease is manifested in the peri- or neonatal period or in infancy. Frequent initial clinical features include diarrhea, type I diabetes mellitus, eczematous atopic dermatitis, poor feeding, ileus, anemia, thrombocythemia, hypothyroidism and lymphadenopathy. Polyarthritis, asthma, ulcerative colitis, glomerulonephritis can accompany the disease. Growth retardation, cachexia and sepsis usually secondary to catheter infection, are seen as complications of the disease. Main causes of death are diarrhea or malnutrition, sepsis, type I diabetes or its complications, hemorrhage, pneumonitis or respiratory failure [2]. Laboratory findings are related to type I diabetes, enteropathy, hypothyroidism and cytopenia [2].

Diagnosis of IPEX is based on the identification of the IPEX clinical syndrome and above all the identification of a mutation in the FOXP3 gene or in its promoter region.

### Therapeutic Principles

In addition to supportive measures (insulin injections, parenteral nutrition, red cell and/or platelet transfusion), immunosuppression is proposed to control systemic autoimmunity and inflammation but is only partially effective and does not prevent fatal outcome. Allogeneic bone marrow transplantation has proved effective [3], especially after conditioning with alemtuzumab, fludarabine and melphalan [4].

[2]Department of Immunology and Molecular Pathology, Royal Free Hospital and University College Medical School, London, UK
[3]Section of Clinical Immunology and Infectious Diseases, Medical Department, Rikshospitalet University Hospital, Oslo, Norway

### Synonyms

Common variable hypogammaglobulinemia; Acquired hypogammaglobulinemia; Late onset immunoglobulin deficiency; CVID

### Definition and Characteristics

Common variable immunodeficiency (CVID, Mendelian Inheritance in Man #240,500) comprises a heterogeneous group of diseases characterized by a significant hypogammaglobulinemia of unknown cause, failure to produce specific antibodies after immunizations and susceptibility to bacterial infections, predominantly caused by encapsulated bacteria.

Most cases of CVID are sporadic, but in about 10% a positive family history can be observed. Most of the CVID families (~80%) show an autosomal dominant trait, while about 20% are autosomal recessive.

Over 98% of the patients present with recurrent bronchitis, sinusitis, otitis and pneumonia and chronic pulmonary damage is the major complication of CVID. Autoimmune phenomena are present in about 25% of patients with CVID – autoimmune thrombocytopenic purpura (AITP) and autoimmune hemolytic anemia (AIHA) being the most common. Lymphoproliferative disorders such as generalized lymphadenopathy and/or splenomegaly are present in up to 30% of patients with CVID and there is an increased risk of the development of gastrointestinal and lymphoid malignancies, especially non-Hodgkin's lymphoma.

### Prevalence

The prevalence of CVID is estimated as 1:25,000 among Caucasians to 1:100,000 in the Japanese population and affects men and women equally. While some patients are diagnosed with CVID in early childhood, the major peak of onset lies between the second and third decades of life, frequently with several years delay between onset of symptoms and a definite diagnosis.

### Genes

So far, four monogenic defects associated with CVID have been identified, ICOS deficiency, TACI deficiency, BAFF-R deficiency and CD19 deficiency. The incidence of TACI deficiency among patients with CVID is estimated to be 8%. Unlike TACI deficiency, all other defects seem to be very rare.

Furthermore, family studies suggest the presence of at least two susceptibility loci within the major histocompatibility complex on chromosome 6. More recent linkage studies identified additional loci for CVID on chromosomes 16q and 4p. However, there is considerable variation in the clinical presentation in patients with similar genotype. Thus, epigenetic and other factors substantially influence the clinical appearance of CVID.

### Molecular and Systemic Pathophysiology

While the underlying immunologic defects causing CVID are by definition unknown, a broad range of disturbed functions in almost all parts of the innate and adaptive immune system have been described in patients with CVID.

T-cell defects include decreased activation and proliferation, impaired cytokine production and altered expression of activation induced surface molecules such as CD40L, L-selectin and attractin, suggesting some

abnormalities in the TCR signaling. In particular, T-cells in a subgroup of CVID patients seem to have increased activity of the cyclic adenosine monophosphate/protein kinase AI (cAMP/PKAI) system, which affects both proliferative capacity and cytokine secretion and may be caused by increased systemic inflammation in CVID. A large-scale gene expression analysis of T-cells in CVID has been published, showing a predominance of senescent, effector memory T-cells.

On the B-cell side, several studies have suggested intrinsic B-cell defects leading to impaired terminal differentiation into plasma cells, reduced somatic hypermutations, an impaired up-regulation of CD86 and CD70 and a disturbed development of class switched memory B-cells *in vivo*. Disturbed activation, differentiation and function in monocyte derived dendritic cells (MdDC) have also been reported.

## Diagnostic Principles

CVID is a diagnosis of exclusion. Thus, any other cause for hypogammaglobulinemia needs to be ruled out. Among these, the most important conditions are loss of gamma globulins *via* the intestine or urine, hematological malignancies, viral infections or drug induced loss of B-cell function. Analyses of lymphocyte function *in vitro* and *in vivo*, including the analysis of specific antibody responses after vaccination and immunophenotyping of T- and B-cells may strengthen the diagnosis and indicate subgroups of CVID.

To monitor the progression of pulmonary disease, chest radiographs, computer tomography (CT) scans and lung function testing should be performed regularly. Ultrasound and/or CT examination of the abdomen may be necessary to assess additional complications of CVID, such as enlarged abdominal lymph nodes, spleen and liver pathology or granulomas. Gastroscopy with evaluation of possible Helicobacter pylori and Giardia lamblia infections and for the exclusion of any malignancy may also be needed.

## Therapeutic Principles

The therapeutic basis in CVID is immunoglobulin replacement therapy, using pooled human immunoglobulin, usually administered intravenously or subcutaneously. To reduce long-term pulmonary sequelae, microbiological sampling and targeted antibiotic treatment is necessary. About 30% of CVID patients develop bronchiectasis and may profit from lung physiotherapy and other measures improving mucus clearance. The frequently occurring cytopenias require particular awareness and specific treatment such as splenectomy may be indicated. Moreover, concurrent autoimmune disorders or malignant disease will require specific treatment.

# Immunodeficiency, Severe Combined with Jak3 Deficiency

Marcus D. Säemann
Department of Internal Medicine III, Division of Nephrology and Dialysis, Medical University of Vienna, Vienna, Austria

## Synonyms

T-B + NK-SCID; SCID

## Definition and Characteristics

Autosomal recessive defect of Jak3 leading to a profound immunodeficiency due to absence and profound defect specifically in T-lymphocytes and natural killer (NK) cells.

## Prevalence

Seven to fourteen percent of heritable SCID, whereby the prevalence of SCID is estimated to be 0.11/100,000, 0.47/100,000, or 0.045/100,000 in Australia, Switzerland, and Norway.

## Genes

The JAK3 gene is localized on chromosome 19p13.1 comprising 23 exons. The majority of all known Jak3 mutations significantly reduce Jak3 protein expression. An interesting minority revealing the functionality of Jak3 affects catalytically active kinase domain. The kinase domain is flanked by the enzymatically inactive pseudokinase domain and some patient-derived mutations within this domain have been shown to destroy the whole kinase activity of Jak3 indicating an essential regulatory role of this domain. Finally, mutations in the amino-terminus of Jak3 which is shared by all Jaks (FERM, band for point one ezrin, radixin, moesin)

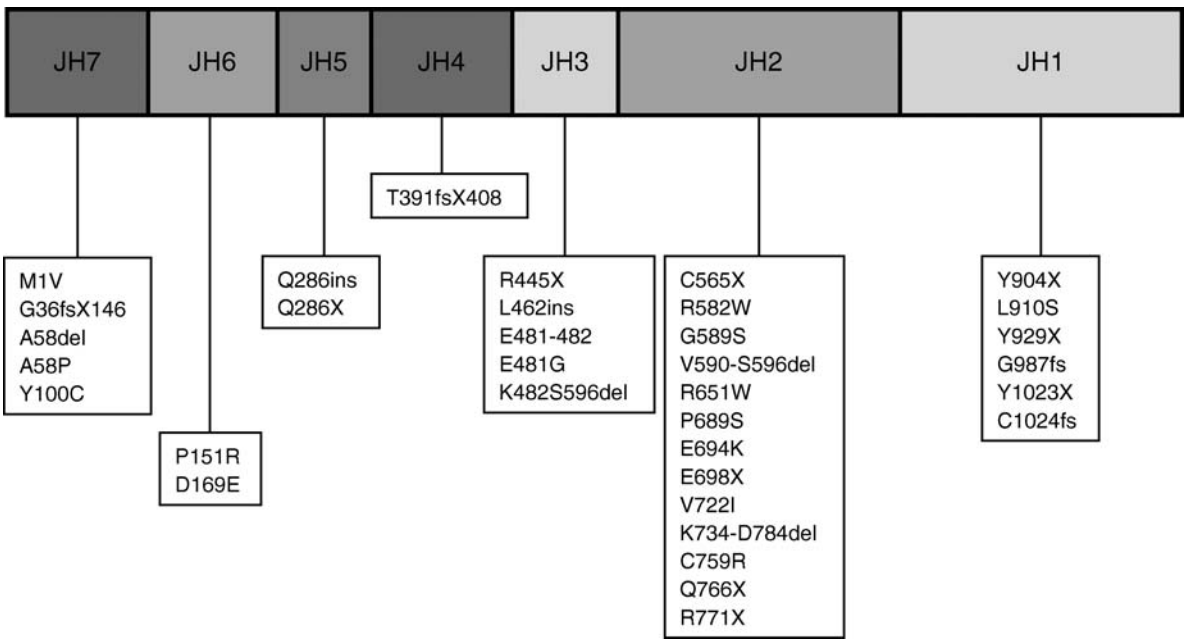
containing a distinct domain necessary for binding to the cγ chain and also enhancing kinase activity also lead to SCID.

## Molecular and Systemic Pathophysiology

Jak3 is a protein tyrosine kinase serving an essential role for various cytokines including IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 receptors that all share the common γ (cγ) chain, but each of them is engaging a specific α chain of cytokine receptors [1]. Each of these cytokines activates Jak3 after receptor binding, which is necessary to promote cell-cycle progression as well as to prevent programmed cell death of lymphocytes. Hence loss of function of Jak3 was demonstrated to be essential for T-cell development and function, since patients with a JAK3 deficiency display a severe lymphopenia at birth characterized by only scarce amounts of T-cells and NK-cells [2]. The described sites of mutation in Jak3-deicient SCID are shown in Fig. 1, whereby the seven Janus homology (JH) domains are depicted and JH1 designates the carboxy-terminal tyrosine kinase domain and JH2 the pseudokinase domain JH5-JH7 has homology to the FERM domain. The immune abnormalities associated with Jak3 deficiency were mimicked with the generation of Jak3-knockout mice which resembled the human phenotype of Jak3 deficiency as well as a deficiency of the cγ chain receptor such as small thymi, and severely reduced numbers of T-cells and NK cells. Of note, mice results differed from humans with respect to a defective B-cell function that was not observed in humans pointing to a species-specific cytokine usage. Interestingly, treatment of Jak3-deficient patients with bone-marrow transplantation demonstrates that indeed JAK3 is essential only for distinct immunocompetent cells and no pathophysiological alterations in other organ compartments. These findings have led to the development of novel immunosuppressive compounds specifically targeting Jak3 promising an immune cell-specific treatment approach to treat transplant rejection or autoimmunity.

## Diagnostic Principles

The manifestation of severe lymphopenia at birth points to the presence of SCID. Likewise a significantly increased incidence of severe infections especially viral infections due to the lack of NK cells and a variety of opportunistic infections immediately after birth will make SCID more likely. Hence further subset analysis will reveal T-B + NK-cells often with supranormal or significantly increased B-cell numbers. To complete the diagnosis a specific molecular defect should be obtained also with regard to genetic counseling and early or prenatal diagnosis in relatives of the affected individuals [3]. As the most robust assay, generation of EBV lines from the patient with the subsequent detection of Jak3 protein expression has been established [4]. Finally, Jak3 deficiency must be confirmed at the genetic level, whereby the lack of genetic hot spots forces one to sequence the complete coding region and adjacent intronic sequences.



**Immunodeficiency, Severe Combined with Jak3 Deficiency. Figure 1** Schematic structure of Jak3 and identified mutations.

## Therapeutic Principles

Due to the absence of T-lymphocytes and NK cells, Jak3 deficiency is a lethal disorder. Therefore, affected patients require a hematopoietic stem cell transplant that is the treatment of choice for Jak3-SCID and optimal results may be expected with HLA-matched siblings [5].

# Impaired Intestinal Absorption of Histidine

►Histidinuria

# Impetigo

Cord Sunderkötter
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Pyoderma

## Definition and Characteristics

Contagious superficial infection of the skin caused by Staph aureus or Streptococci pyogenes.

## Prevalence

Frequent in children, or under bad socioeconomic conditions with poor hygiene or overcrowding. In temperate climates, staphylococcal impetigo is more common than streptococcal impetigo. Endemic outbreaks occur in preschool or school children especially during late summer. Impetigo accounts for ~10% of all skin problems in children [1].

## Molecular and Systemic Pathophysiology

There needs to be (i) colonization or infection with Staph aureus or Streptococci pyogenes and (ii) additionally minor trauma of the skin. The latter happens more readily in fragile skin of small children. Because of minor trauma and lesion in the epidermis, Staph aureus or Streptococci pyogenes gain entry into skin. Among eliciting Streptococci pyogenes, those of Lancefield group A are commonly encountered in lesions, but group C and group G Streptococci have also been detected as causative agents. Among *Staph aureus*, group II phage types predominate in bullous and nonbullous impetigo.

Their repertoire of degrading enzymes leads to further discontinuation of the epidermis and elicitation of an inflammatory reaction with recruitment of an inflammatory infiltrate.

Bullous impetigo is caused when Staph aureus express the gene for exfoliative toxin A or B (ETA or ETB). These exotoxins are both serine proteases that in the skin exclusively cleave desmoglein 1, a transmembrane glycoprotein of desmosomes belonging to the cadherin gene superfamily [2–4]. This attack on a structurally critical peptide of the desmosome causes dysfunction of the desmosome, subsequently loss of adherence between keratinocytes and formation of the characteristic blister below the stratum corneum. Since much of the barrier function of epidermis resides in the stratum corneum, this is an efficient mechanism of Staph aureus to spread in the cleavage plane right under the stratum corneum.

The gene for ETA (eta) is located on the chromosome, whereas that for ETB is located on a large plasmid. Only relatively few clinical isolates produce ETA, as the eta gene is acquired by phages and horizontal gene transfer.

## Diagnostic Principles

Clinical hallmark in initial nonbullous impetigo is a thin-walled vesicle on erythematous ground that, however, ruptures rapidly and extends peripherally while the roof of the blisters and the exuding serum leave honey-colored brownish-yellow crusts. Sites of predilection are exposed areas such as face and extremities. In bullous impetigo, the bullae usually become larger before they rupture. The subsequent events are similar as in nonbullous impetigo.

Complications include so-called poststreptococcal acute glomerulonephritis when there was infection by

Streptococci pyogenes with nephritogenic potential such as Streptococci pyogenes M-49. In contrast, rheumatic fever is not a sequela of streptococcal impetigo.

Diagnosis can be made clinically, but should be completed by microbiological analysis.

### Therapeutic Principles

(i) Elimination or avoidance of eliciting factors; (ii) antimicrobial treatment depending on extent of impetigo; in limited impetigo, local antiseptics are sufficient (local antibiotics must not be used); if infection spreads, if there is lymphadenopathy or suspicion of endemic outbreak with nephritogenic Streptococci pyogenes, systemic antibiotics should be used. while penicillin is sufficient to treat streptococcal impetigo, a penicillinase-resistant penicillin should be chosen for staphylogene impetigo, at best according to resistogram. In case of bullous impetigo caused by ETA-producing Staph aureus, clindamycine is recommended as it interferes with production of the toxin [5].

## Impingement Syndrome

Eiji Itoi
Department of Orthopedic Surgery, Tohoku University School of Medicine, Sendai, Japan

### Definition and Characteristics

The term “impingement syndrome” was first used by Neer in 1972. Anterior acromioplasty was effective in cases with bursitis and partial tears of the rotator cuff. Later, he classified the impingement syndrome into three stages: stage I, edema and hemorrhage; stage II, fibrosis and tendinitis; and stage III, tendon rupture. He speculated that mechanical stress on the rotator cuff caused inflammation, bleeding, swelling, and eventually a tear of the rotator cuff tendon. Thus, he used the term “impingement syndrome” in the broad sense including a cuff tear. However, his theory of impingement has never been proven in the clinical cases. These days, the term “impingement syndrome” is usually used to refer to a clinical condition, in which the impingement sign and test are positive without rotator cuff tears.

### Prevalence

Impingement syndrome is the major cause of painful shoulder.

### Molecular and Systemic Pathophysiology

Pathophysiology of “impingement syndrome” is thought to be subacromial bursitis, rotator cuff tendinitis, tendinopathy, or combination of these caused by the mechanical stress between the undersurface of the acromion and the rotator cuff tendon. Histological examination of impingement syndrome revealed hyaline degeneration of the tendon and increased number of apoptotic tendon cells [1]. Recent studies have shown that various cytokines are related to inflammation of the bursa observed in shoulders with impingement syndrome and rotator cuff tears: these cytokines include IL-1 [2,3,4], IL-6 [4], TNF-alfa [3,4], MMP-1, MMP-9, COX-1, COX-2 [4], TGF-beta, bFGF [3], and VEGF [5]. These studies indicate that various cytokines are related to proliferation and inflammation of the synovium, and also related to pain observed in patients with rotator cuff diseases including impingement syndrome.

### Diagnostic Principles

Impingement sign and impingement test are positive as physical examinations. Imaging modalities reveal thickening of the supraspinatus tendon, which is in contact with the undersurface of the acromion.

### Therapeutic Principles

In most cases, NSAIDs and subacromial injection of steroid are effective. If conservative treatment is not effective, acromioplasty is indicated. After acromioplasty, the symptoms are relieved and the tendon thickness gradually returns to normal.

## Synonyms

Hereditary inclusion body myopathy; HIBM; "Quadriceps sparing" myopathy; QSM; Inclusion body myopathy 2; IBM2; OMIM #600737; Distal myopathy with rimmed vacuoles; DMRV; Nonaka myopathy; NM; #OMIM 605820; Autosomal dominant inclusion body myopathy; Inclusion body myopathy 3; IBM3; OMIM #605637

Related conditions, not described in detail:

- Inclusion body myopathy with early onset Paget disease and frontotemporal dementia (IBMPFD), OMIM #167320
- Welander distal myopathy (WDM), OMIM #604454
- Tibial muscular myopathy, Udd myopathy, OMIM #600334

## Definition and Characteristics

Hereditary inclusion body myopathies (HIBMs) are represented by progressive, clinically and genetically distinct autosomal recessive and dominant neuromuscular disorders. The term HIBM was designated to take into account that all the hereditary disorders summarized herein share skeletal muscle pathomorphological similarities with sporadic inclusion body myositis (SIBM) except for the presence of significant inflammation [1].

Molecular genetic advances will define new and unique entities out of this "pool" of disorders, called HIBMs.

*Autosomal Recessive Forms*: "Quadriceps Sparing" myopathy (QSM): Recessively inherited HIBM with quadriceps sparing was first described in Jews of Persian descent and reflects the "prototype" of HIBM. Therefore, the term HIBM is often used for QSM. Onset is in the third decade of life. Several atypical phenotypes of this myopathy have been identified, including cases with major quadriceps involvement. QSM therefore may become an obsolete term. QSM/HIBM has also been documented in populations other than Jewish-Persian [2,3].

Distal myopathy with rimmed vacuoles (DMRV): This form is prevalent in the Japanese population, with onset in early adulthood in distal leg muscles, accentuated in the tibialis anterior muscle and often sparing of the quadriceps femoris muscles [3].

Due to the fact that DMRV maps to the same region as QSM/HIBM they are regarded as allelic disorders [3].

*Autosomal Dominant Forms*: An autosomal dominant HIBM was first described in a Swedish family (SF HIBM). Clinical characteristics included congenital joint contractures and slowly progressive, proximal muscle weakness and ophthalmoplegia. Deterioration of muscle function became manifest in the third to fifth decade of life [4].

## Prevalence

HIBMs are rare autosomal recessive or dominant disorders with ethnic related clusters.

## Genes

*QSM/HIBM*: caused by mutations in the gene encoding UDP-N-acetylglucosamine 2-epimerase/N-acetylmannosamine kinase (GNE). Most common homozygous GNE mutation in QSM: M712T [2,3].

*DMRV*: allelic with QSM/HIBM and caused by homozygous or compound-heterozygous mutations in

the GNE gene. Most common mutation in DMRV: V572L [3].
*SF HIBM*: linkage indicated that the locus maps to the region 17p13.1–17p11.2 colocalizing to the myosin heavy chain (MYHC) region. A missense mutation Glu706Lys could be detected in the MYHC2A gene in the SF HIBM [4].

### Molecular and Systemic Pathophysiology

*QSM/HIBM and DMRV*: The GNE gene encodes a bifunctional enzyme known to regulate and initiate biosynthesis of sialic acid. [2,3]. In cases with HIBM due to GNE mutations, a hyposialyzation of neutral cell adhesion molecule could be demonstrated [5].

*SF HIBM*: The missense mutation Glu706Lys in the highly conserved region of the motor domain of the MYHC2A gene may result in conformational changes, which at least lead to a dysfunctional myosin [4].

### Diagnostic Principles

The coincidence of a progressive muscular disorder with proximal and/or distal pareses or the typical QSM-pattern, lack of significant inflammation, rimmed vacuoles and filamentous inclusions within skeletal muscle biopsy specimens (and exclusion of a primary neurogenic dysfunction with rimmed vacuoles, for example post-polio syndrome), as well as a family history revealing a genetic origin are highly suggestive for HIBM. Detection of one of the actually identified mutations confirms the diagnosis.

### Therapeutic Principles

No standardized therapy is available.

## Incontinentia Pigmenti

Vinzenz Oji, Heiko Traupe
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Bloch-Sulzberger syndrome; Bloch-Sulzberger pigment dermatosis

### Definition and Characteristics

Incontinentia pigmenti (IP; MIM *308300) is an uncommon X-linked dominant genodermatosis/multisystemic disorder which is usually lethal in males in utero. The clinical course is highly variable. Affected females develop four sequential cutaneous stages (inflammatory/vesicular, verrucous, hyperpigmented and hypopigmented/atrophic), which mostly start within the first two weeks of life and resolve in early adulthood. Involvement of teeth, nails and hair is common [1]. Ophthalmic manifestations and/or complications in the central nervous system occur in about 10–20%.

### Prevalence

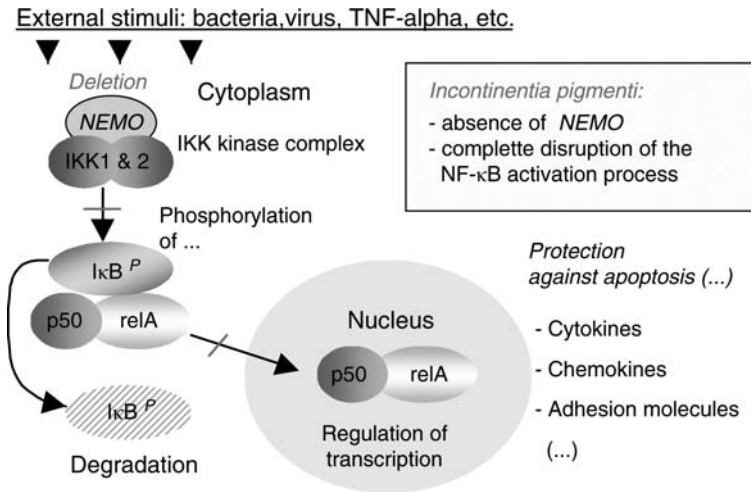
Unknown. Hundreds of cases are reported in the world literature.

### Genes

Mutations at Xq28 in the 23-kb NEMO (NF-κB essential modulator) gene, also known as IKK-γ (IκB kinase-γ) gene, result in IP [2]. The deletion of exon 4–10 caused by a special genomic rearrangement accounts for up to 80–85% of all cases [3]. The gene possessing a second, incomplete copy close by is located between the glucose-6-phoshpate dehydrogenate (G6PD) gene and factor VIII locus.

### Molecular and Systemic Pathophysiology

NEMO/IKKγ is required for the activation of the transcription factor NF-κB, which is kept inactive in the cytoplasm through association with inhibitory proteins



**Incontinentia Pigmenti. Figure 1** Overview of the NF-κB (p50/relA) activation process and its disruption in IP.

of the IκB family: IκBα, IκBβ or IκBε (Fig. 1). As, initiated by phosphorylation, IκB proteins become degraded through IKK kinase, free NF-κB (heterodimers of p50 and p65/relA subunits) enters the nucleus and activates the transcription of various target/cytokine genes, which are involved in many immune, inflammatory and anti-apoptotic pathways. IKK kinase consists of two related catalytic subunits (IKKα/IKK1 and IKKβ/IKK2) and NEMO, which acts as an essential structural and regulatory subunit of this complex. NF-κB is stimulated by cytokines such as TNF-α or IL-1, viral double-stranded RNA or bacterial endotoxins, but in the absence of intact NEMO, as it is the case in IKKγ negative IP cells, the IKK kinase complex is unresponsive to external stimuli. As a result NF-κB remains inhibited rendering IP cells highly sensitive to TNF-induced apoptosis. IP skin lesions follow a linear pattern along the lines of Blaschko reflecting somatic mosaicism of X-chromosome inactivation. It is assumed that toxins of the stressed IKKγ negative keratinocytes activate cytokine synthesis in neighboring IKKγ positive cells leading to an amplification loop of inflammatory reaction and apoptosis of IP-cells. Successively cells expressing the mutated X-chromosome are selectively eliminated around time of birth and later, explaining the different stages of the disorder. NEMO/IKKγ-deficient mice models exist and show striking similarities to the human IP phenotype [4,5].

## Diagnostic Principles

Diagnosis is established using the cutaneous signs of the described clinical stages considering especially the typical linear efflorescence pattern. It might be obvious in a new-born having developed the classic rash but can be easily overlooked in an adult with faded lesions. Histopathologic characteristics (dyskeratotic keratinocytes, dermal eosinophilia, dermal melanin deposited in melanophages ∼ pigment incontinence) can establish the diagnosis of IP. Furthermore, diagnosis can be confirmed by NEMO-DNA analysis.

## Therapeutic Principles

There is no specific treatment for IP. Blisters should be left intact and treated with antiseptic ointments to avoid possible bacterial superinfections. Meticulous dental care is often required. Early ophthalmologic consultation including follow-ups and, as the case may be, treatment with photocoagulation or vitreoretinal surgery should be initiated in order to prevent progressing retinopathy. Complete neuropediatric examination is warranted for all newly diagnosed IP infants.

## Definition and Characteristics

Involuntary inability to conceive.

## Prevalence

8.4% of women between 15 and 44 years of age in the US.

## Genes

Defective GNRHR (chromosome band 4q21) leads to impaired response to gonadotropin-releasing hormone stimulation; defective HESX1 (chromosome band 3p21), PROP1 (chromosome band 5q35), FSHβ (chromosome band 11p13), FSHR (chromosome band 2p21-p16), LHR (chromosome band 2p21) lead to disorders of anterior pituitary; defective X chromosomal anomalies, deletions of several chromosome X loci (POF1, Xq26.2-q28; POF2, Xq13.3-q21.1); CYP17 gene (chromosome 10); GALT gene; FOXL2 gene (chromosome band 3q23); FMRI gene (chromosome band Xq27.3); AIRE gene (chromosome band 21q22.3); GNAS gene (chromosome band 20q13.1) lead to disorders of the ovary.

## Molecular and Systemic Pathophysiology

*Disorders of the Hypothalamic Pituitary-Gonadal Axis*: Disorders of Hypothalamus: Gonadotropin-releasing hormone (GnRH) from the hypothalamus regulates the production of the gonadotropins follicle stimulation hormone (FSH) and luteinizing hormone (LH) from the pituitary.

Disorders of GnRH function (hypogonadotropic hypogonadism) can result from functional hypothalamic dysfunction (anorexia nervosa, exercise, stress), failure developmental migration of the GnRH-releasing neurons to the fetal hypothalamus (Kallmann syndrome), and mutations in the GnRH receptor (GNRHR), with impaired gonadotropin response to GnRH stimulation [1].

*Disorders of Anterior Pituitary*: Abnormalities of gonadotropin release and action include the idiopathic and acquired hypopituitarism (neoplasms, after surgery, irradiation, infarction, infection, or trauma), empty sella syndrome, hyperprolactinemia (GnRH secretion inhibition by increased hypothalamic dopamine) and loss-of-function mutations in transcription factors, gonadotropin and gonadotropin-receptor genes. Mutations in the genes that regulate anterior pituitary development (homeobox gene expressed in ES cells (HESX1), Prophet of Pit-1 (PROP1)) have already been described. Mutations in the FSH β-subunit gene are extremely rare and seem to interfere with the efficient combination of the α- and β-subunit to form intact FSH. No α-subunit mutations have so far been described. Complete and partially inactivating mutations in the FSH receptor (FSHR) gene have been observed in the extracellular domain of the receptor leading to reduced receptor binding to FSH. Inactivating mutations in the LH receptor (LHR) with impaired signal transduction activity of LH have been reported in women with anovulatory infertility [2].

*Disorders of the Ovary*: The causes of premature ovarian failure include ovarian dysgenesis (Turner syndrome), defective germ cell migration, trisomy X, inherited enzymatic defects (17α-hydroxylase deficiency, galactosemia). Ovarian dysgenesis involves structural alterations in or absence of an X chromosome. The excess of chromosome X can be associated with accelerated atresia or decreased numbers of germ cells. An abnormal follicular development is observed in the 17α-hydroxylase deficiency, whereas in galactosemia (galactose-1-phosphate uridyltransferase (GALT) deficiency), the abnormal metabolite interferes with gonadotropin postreceptor activity. Others

gene mutations associated with premature ovarian failure include mutations in the forkhead transcription factor gene (FOXL2) in the blepharophimosis/ptosis/epicanthus inversus syndrome, the fragile X mental retardation gene (FMRI), the autoimmune regulator 1 gene (AIRE) in autoimmune polyendocrinopathy syndrome type 1, and guanine nucleotide-binding protein α-simulating activity polypeptide 1 (GNAS) in pseudohypoparathyroidism [1,3]. A common ovarian disorder includes chronic anovulation resulting from inappropriate ovarian-pituitary feedback in polycystic ovary syndrome.

*Others Causes of Female Infertility*: Vaginal and cervical disorders (excessive vaginal acidity, inadequate cervical mucus production, Chlamydia trachomatis, and Ureaplasma urealyticum infections); uterine abnormalities (leiomyomas, intrauterine synechiae, chronic endometritis), tubal damage (secondary to infection, endometriosis, intraabdominal surgery), endometriosis (through embryonic implantation failure in the endometrium and increased levels of cytokines, growth factors and macrophages in the peritoneal fluid with toxic effect on sperm function and embryo survival) [4].

## Diagnostic Principles

Assessment of ovulation – basal body temperature, serum progesterone, estradiol and FSH levels, endometrial biopsy, TSH, prolactin, circulating androgens measurements; assessment of uterine cavity and fallopian tubes – hysteroscopy, pelvic and transvaginal ultrasonography, hysterosalpingography; assessment of cervical factors – postcoital test, bacteriological examination. Karyotyping and genetic analysis of known mutations [5].

## Therapeutic Principles

Where possible, the underlying cause is eliminated. In addition, expectance management, administration of the nonsteroidal estrogen antagonist clomiphen citrate, intrauterine insemination, or *in vitro* fertilization may be employed depending on the condition.

# Infertility, Immune-mediated

Karen Buckingham[1,2], Larry Chamley[1,2]
[1]Department of Obstetrics and Gynecology, University of Auckland, Auckland, New Zealand
[2]Fertility Plus, Greenlane Clinical Centre, Auckland, New Zealand

I

## Definition and Characteristics

Infertility, the inability to conceive within one year of unprotected intercourse, is estimated to affect up to 1 in 6 couples of reproductive age [1]. There are three well-investigated entities in which the immune system may induce infertility:

1. Antisperm antibodies (ASA) – antibodies that bind to sperm and may be present in the reproductive tract fluids or blood of either males or females.
2. Autoimmune premature ovarian failure (aPOF) – the cessation of ovarian function in women before the age of 40, characterized by the development of amenorrhoea, infertility, sex steroid deficiency and elevated gonadotrophin levels.
3. The antiphospholipid syndrome (APS) – characterized by vascular thrombosis (arterial or venous), and/or pregnancy morbidity in association with medium to high titers of antibodies to certain plasma proteins that are often bound to anionic phospholipids (antiphospholipid antibodies (aPL)). The aPL include anticardiolipin antibodies, antiphosphatidyl serine antibodies, lupus anticoagulant and antibodies reactive with β2-glycoprotein a phospholipid-binding protein. Some researchers include antibodies reactive with other phospholipids such as phosphatidyl choline but there is little evidence that these additional antibodies have significant diagnostic value.

## Prevalence

Antisperm antibodies are found in ~10% of infertile couples, however as they are also present in 1–2.5% of fertile men and 4% of fertile women, they do not always cause sterility [2]. Premature ovarian failure affects 1% of women; while it has a multicausal aetiology, autoimmune mechanisms may account for up to

30% of cases [3]. Antiphospholipid antibodies are found in ~10–15% of infertile women compared with a prevalence of 1–2% in the normal population [4].

## Molecular and Systemic Pathophysiology

Antisperm antibodies can potentially adversely affect any of the processes involved in sperm transport in the female reproductive tract or fertilization but they do not usually affect sperm production. IgA class antibodies in cervical mucus have been shown to be particularly inhibitory to sperm migration in cervical mucus.

In POF, the mechanism by which ovarian autoimmunity is initiated is unknown. Antibodies to ovarian antigens may form as a result of structural damage to the ovary or through exposure to a virus or other agent similar in structure to components of ovarian tissue. Alternatively, a basic failure in immune regulation might develop, leading to loss of "self tolerance" [5]. Ultimately, follicle depletion and fibrosis occurs resulting in ovarian failure.

Antiphospholipid antibodies cause recurrent miscarriage and stillbirths and are statistically associated with infertility, particularly in women with recurrent in vitro fertilization failure in retrospective studies. However, it is unclear whether antiphospholipid antibodies cause infertility as the presence of these antibodies does not predict poor IVF outcome.

## Diagnostic Principles

Antisperm antibodies are most often detected using agglutination assays such as the immunobead test (IBT) or the mixed agglutination reaction (MAR). These can be direct tests in which antisperm antibodies (from the male partner) bound to sperm are identified or indirect tests in which antisperm antibodies in reproductive fluids or blood are allowed to bind to donor sperm, then detected by IBT or MAR. Most antisperm antibodies are IgG or IgA class antibodies.

At present, no validated serum antibody marker exists to identify women who have an autoimmune mechanism for their premature ovarian failure. Ultrasound examination of the ovaries is not helpful in making the diagnosis. Similarly, ovarian biopsy to detect autoimmune oophoritis is not recommended because of the potential risks of surgery and the lack of effective treatments.

Lupus anticoagulant is detected by coagulation assays such as the activated partial thromboplastin time (APTT), Kaolin clotting time (KCT) and the dilute Russell viper venom time (DRVVT), then confirmed with a neutralizing test such as the platelet neutralization procedure (PNP). Anticardiolipin antibodies and antiphosphatidyl serine antibodies are detected by ELISA but should be confirmed to persist for at least six weeks (but preferably 12 weeks) by a repeat test, before a diagnosis is made.

## Therapeutic Principles

Several approaches to reducing the level of antisperm antibodies or their effects on sperm have been investigated, including sperm washing and immunosuppressive therapy. However, the development of intracytoplasmic sperm injection (ISCI), in which a single sperm is injected directly into an oocyte, has largely superseded these other treatments.

Whilst patients with a diagnosis of premature ovarian failure have a small chance of spontaneous pregnancy (5–10%), there are no clinically proven treatments to restore fertility at present. The suggestion that immunosuppression with corticosteroids may reverse some cases of ovarian failure remains to be proven [3]. Assisted reproductive technology with use of donor oocytes offers definitive management of infertility.

In women with antiphospholipid antibodies and recurrent miscarriage, treatment with heparin and low dose aspirin may be beneficial, but this treatment is not justified in women with antiphospholipid antibodies whose sole clinical presentation is infertility.

# Infertility, Male

Alberto Ferlin, Carlo Foresta
Department of Histology, Microbiology and Medical Biotechnologies, Section of Clinical Pathology and Centre for Male Gamete Cryopreservation, University of Padova, Padova, Italy

## Synonyms

Male subfertility; Male sterility

## Definition and Characteristics

Infertility is the inability of a sexually active couple to achieve pregnancy despite unprotected intercourse for a period of greater than 12 months. The primary problem resides exclusively in the male partner in 30–40% of infertile couples, and in an additional 15–20% problems reside in both the male and the female partner [1,2]. Male infertility is commonly classified on the basis of semen analysis, however complete absence of possibility of natural conception (sterility) is found only when sperm are completely absent (azoospermia, found in approximately 15–20% of infertile men) or there is lack of ejaculation. Minor degrees of fertility impairment are usually associated with abnormal semen quality, such as reduced number of sperm (oligozoospermia), reduced motility of sperm (asthenozoospermia), higher number of abnormally shaped sperm (teratozoospermia), or a combination of defects (oligo-astheno-teratozoospermia). However 10–20% of infertile men show apparent normozoospermia (unexplained or idiopathic infertility). Many causes can lead to or are associated with male infertility, including endocrine diseases, infections, varicocele, cryptorchidism, anti-sperm antibody, systemic diseases, obstruction or absence of vas deferens, and genetic alterations [1,2].

## Prevalence

The proportion of couples seeking medical treatment for infertility is 10–20% in western countries [1,2]. A male factor is present in about half of the cases.

## Genes

Genetic abnormalities are present in about 10–15% of male infertile subjects [3].

Chromosome abnormalities (above all the 47, XXY Klinefelter syndrome) and Y chromosome long arm microdeletions are found in 10–15% of non-obstructive azoospermic and severely oligozoospermic men [4].

Mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene (7q31.2) are found in 60–70% of patients with congenital bilateral absence of the vas deferens.

Mutations in the androgen receptor (AR) gene (Xq11-q12) cause a variety of defects known collectively as androgen insensitivity syndrome.

Mutations in the Insulin-like 3 (INSL3) gene (19p13.2) or its receptor Relaxin family peptide 2 (RXFP2) gene (13q13.1) are associated with abnormalities in testis descent (cryptorchidism).

Mutations in different genes might cause hypogonadotropic hypogonadism (HH). The phenotype of HH and anosmia is called Kallmann syndrome and is caused by mutations in the KAL1 gene (Xp22.3) or autosomal genes.

## Molecular and Systemic Pathophysiology

Pathophysiology of male infertility can be classified as pre-testicular, testicular or post-testicular. Pre-testicular etiologies cause alterations in the pituitary-testicular axis, usually evidenced as HH. The absent stimulation of spermatogenesis by the follicle stimulating hormone (FSH) and of testosterone production by the luteinizing hormone (LH) cause infertility and hypogonadism. In these cases, systemic manifestations of low testosterone concentrations may be present.

Chromosomal alterations cause meiotic disturbances and/or loss of spermatogenesis genes. Y chromosome microdeletions cause the loss of many genes necessary for spermatogenesis with reduction of germ cells in the testis (hypospermatogenesis) and/or meiotic alterations. The most severe forms cause the complete disappearance of the spermatogenic component, a condition known as Sertoli cell-only syndrome.

Mutations in the AR gene cause absent (complete forms) or reduced (partial forms) activity of the androgen receptor in response to its ligand, testosterone. In mildest forms only spermatogenesis may be affected. More severe forms exhibit other clinical manifestations of androgen insensitivity, such as cryptorchidism, hypospadia, gynecomastia, reduced androgenicity.

Mutations in the CFTR gene cause a post-testicular form of infertility due to congenital absence of one or both vas deferens. In these cases, testicular function and spermatogenesis are normal, but signs of mild form of cystic fibrosis may be present depending on the severity of the mutation.

Mutations in INSL3 and RXFP2 genes may be responsible for alterations in testicular descent during the fetal life (unilateral or bilateral cryptorchidism), thus rendering the testes more susceptible to spermatogenic impairment and testicular cancer.

## Diagnostic Principles

Initial evaluation should include a complete history and physical exam with particular emphasis to the reproductive tract and testicular volume. Semen analysis, repeated at least twice at a distance of 3 months, is the main exam, but it should not be evaluated without information on testicular and epididymal ultrasounds and reproductive hormone (FSH, LH, testosterone, oestradiol and prolactin) concentrations (Table 1). Semen analysis should include sperm culture and antisperm antibody determination. In cases of azoospermia and severe oligozoospermia, analysis of the spermatogenic process by open biopsy (histology) or fine needle aspiration (cytology) allows a better diagnosis. Non obstructive azoospermia

I

**Infertility, Male. Table 1** Normal values of semen parameters and nomenclature for normal and pathological findings in semen analysis according to World Health Organization

| | |
|---|---|
| Volume | >2ml |
| pH | 7.2–8.0 |
| Sperm concentration | >20 × $10^6$ spermatozoa/mL |
| Total sperm count | >40 × $10^6$ spermatozoa/ejaculate |
| Motility | >50% with forward progression (categories A and B)<br>or >25% with rapid progression (category A) within 60 min of ejaculation |
| Morphology | >30% with normal forms |
| Vitality | >75% live |
| Normozoospermia | Normal ejaculate |
| Oligozoospermia | Sperm concentration <20 × $10^6$/ml or <40 × $10^6$/ejaculate |
| Asthenozoospermia | <50% spermatozoa with forward progression (categories A and B) or <25% spermatozoa with category A movement |
| Teratozoospermia | <30% spermatozoa with normal morphology |
| Oligo-astheno-terato-zoospermia | Alterations of all three variables (combination of only two prefixes may also be used) |
| Azoospermia | No spermatozoa in the ejaculate |
| Aspermia | No ejaculate |

and severe oligozoospermia should be analyses for karyotype, Y chromosome long arm microdeletions, and possibly AR gene mutations. Cases with absence of vas deferens should be analyzed for CFTR gene mutations. Cases with history of cryptorchidism should be analyzed for INSL3 and RXFP2 gene mutations. Cases with HH and anosmia should be analyzed for KAL1 gene mutations.

### Therapeutic Principles

Men with HH are candidates for gonadotropin therapy. Men with oligozoospermia and normal levels of gonadotropins could be treated with FSH. Men with obstructive azoospermia could undergo to surgical correction. When few sperm are present in the ejaculate, or when only sperm from the testis or epididymis could be recovered, or when previous therapeutic option did not determined pregnancy, or when unexplained infertility is present, assisted reproduction techniques represent the best choice.

### Definition and Characteristics

Inflammation is in principle a beneficial host immune response to cellular injury. It is typically characterized by five classic clinical signs: heat, redness, swelling, pain, and loss of function. Although a principly beneficial response, overwhelming or prolonged inflammation can be detrimental to the host, contributing to the pathogenesis of a large, unrelated group of human diseases, including allergic diseases, autoimmune diseases, infectious diseases, myopathies, autoinflammatory diseases and cancer. In autoimmune diseases, the specific adaptive immune system erroneously causes lymphocyte reactivity, including elaboration of antibodies directed against self. In parallel with autoimmune

diseases, the concept of autoinflammatory diseases (e.g., Muckle-Wells syndrome (MWS)), has emerged recently as disorders characterized by seemingly unprovoked inflammation. These conditions are primarily caused by dysregulation of the innate immune system without primary involvement of T-lymphocytes or specific (auto)antibodies.

## Prevalence

The prevalence of inflammation varies considerably between continents and races, and the disease to which it is linked. Each year more than 30 billion tablets of nonsteroidal anti-inflammatory drugs (NSAIDs) are sold over the counter in the United States. These numbers reflect an enormous dependency on anti-inflammatory drugs. In contrast to the high prevalence of autoimmune diseases such as rheumatoid arthritis (about 1% of the U.S. population), autoinflammatory diseases are very rare disorders.

## Genes

Several genetic loci have been associated with an increased risk of specific inflammatory diseases [1]. In contrast to most inflammatory diseases that are multifactorial, some monogenic hereditary autoinflammatory diseases (e.g., MWS) have recently been shown to be associated with mutations in a gene (NALP3) that encodes a protein that is involved in the processing of pro-IL-1β [2].

## Molecular and Systemic Pathophysiology

Inflammation occurs in two phases giving rise to acute and chronic inflammation, respectively. The acute response to tissue injury occurs in the microcirculation at the site of injury. Within several minutes, chemical mediators released at the site of injury cause relaxation of arteriolar smooth muscle, vasodilation, and increased capillary permeability. Protein-rich fluid then exudes from capillaries into the interstitial space. This fluid contains many of the components of plasma, including fibrinogen, kinins, complement-derived peptides, and immunoglobulins that mediate the inflammatory response. Leukocytes, platelets, and red blood cells in injured vessels become sticky and adhere to the endothelial cell surfaces. Polymorphonuclear leukocytes such as neutrophils are the first cells to infiltrate the site of injury. Basophils and eosinophils are more prevalent in allergic reactions or parasitic infections. As the inflammatory process continues, macrophages predominate, actively removing damaged cells or tissue. Different mediators (e.g. histamine, serotonin, leukotrienes, prostaglandins, nitric oxide and cytokines such as TNF and IL-1) that are derived from injured tissue cells or recruited white blood cells modulate the activity and function of other cells to coordinate and control the inflammatory response at the local and systemic level. If the cause of injury is eliminated, acute inflammation may be followed by a period of tissue repair. Failure to terminate the inflammatory response when no longer needed results in chronic inflammation, cellular destruction, and attempts to heal the inflamed tissue, which include angiogenesis and fibrosis. One intrinsic mechanism employed to terminate inflammation is the short half-life of inflammatory mediators *in vivo*. Active mechanisms which serve to terminate inflammation include TGF-β, IL-10 and lipoxins. Inflammation also induces high systemic levels of acute-phase proteins. In acute inflammation, these proteins prove beneficial, however in chronic inflammation they can contribute to amyloidosis. When inflammation overwhelms the host, systemic inflammatory response syndrome is diagnosed.

## Diagnostic Principles

Besides fever and the local symptoms, such as edema, pain, reddish, histopathologic examination of the infiltration of white blood cells in the injured tissue is the gold standard for diagnosis of inflammation. Leukocytosis (15,000 cells/ml) is often seen during inflammation induced by infection. A high amount (1–10mg/dl) of C reactive protein (CRP) or an increased erythrocyte sedimentation rate (ESR) also corresponds to increased non-specific inflammation in the body. CRP levels become elevated within 6 h of the start of inflammation. ESR levels increase about a week after the start of inflammation.

## Therapeutic Principles

- NSAIDs or COX-2 specific inhibitors
- Analgesics
- Corticosteroids or glucocorticoids
- DMARDs (Disease-modifying anti-rheumatic drugs) such as methotrexate
- Biologic response modifiers (BRMs) such as etanercept, infliximab and adalimumab (target = TNF; [3]) or anakinra (target = IL-1; [4])

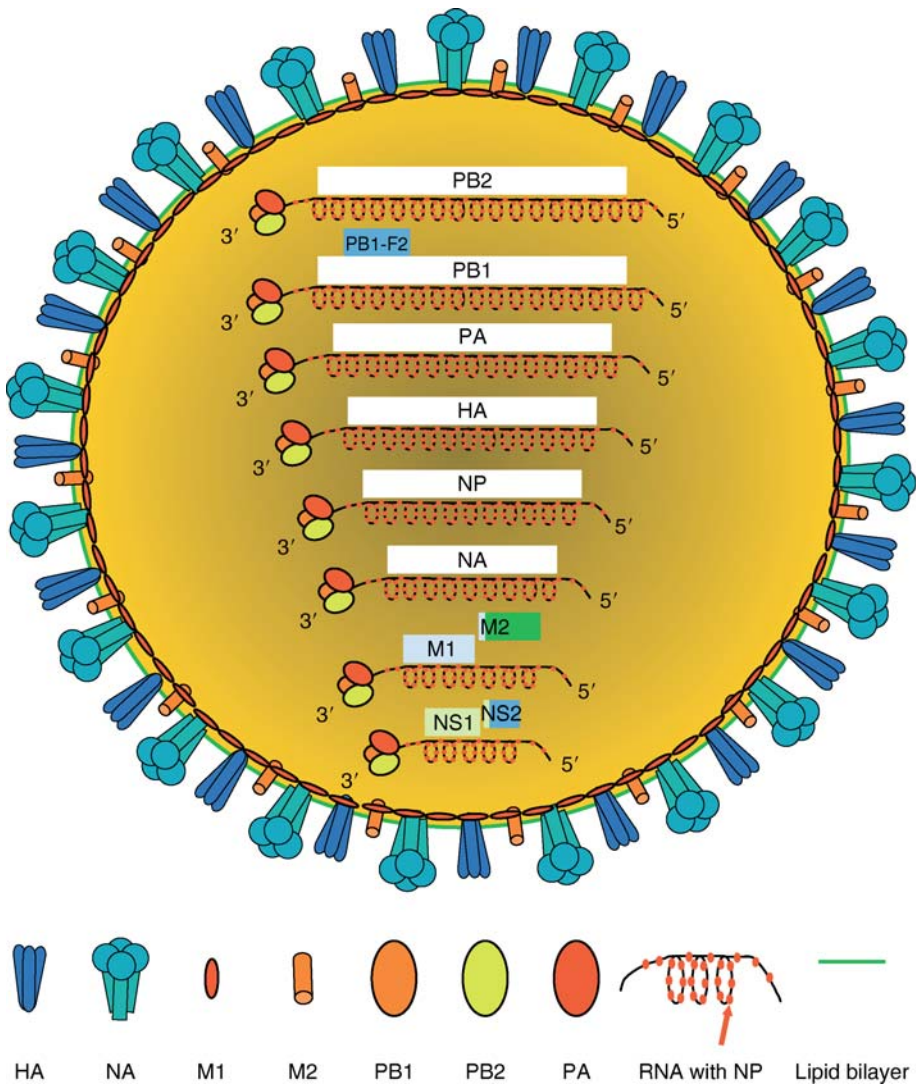
## Synonyms

Flu virus infection

## Definition and Characteristics

Influenza virus belongs to the virus family Orthomyxoviridae and is defined by its helical symmetry with 80–120 nm in diameter although filamentous forms have been observed. The viral envelope encloses several ribonucleoprotein (RNP) complexes consisting of viral proteins and viral single-stranded (ss) RNA segments of antisense orientation (Fig. 1). Within the Orthomyxoviridae, five virus genera have been described (Influenza A virus (IAV), Influenza B virus (IBV), Influenza C virus (ICV), Thogotovirus, Isavirus).



**Influenza. Figure 1** Scheme of influenza A virus (IAV) particle. The viral envelope contains the viral glycoproteins hemagglutinin (HA) and neuramindase (NA) as homotrimers and homotetramers, respectively. The ion channel protein M2 is an integral part of and the matrixprotein M1 is associated with the viral envelope. The ribonucleoprotein (RNP) complex localized in the core of the viral particle consists of at least four viral proteins (PB1, PB2, PA, NP) and the viral RNA. Six RNA segments encode single proteins. RNA segments 2 (PB1, PB1-F2), 7 (M1, M2), and 8 (NS1, NS2) encode two viral proteins each. Transcribed RNA of genome segments 7 and 8 are spliced during the viral replication resulting in two coding mRNAs with identical protein sequences at the very N-terminus of each protein.

## Prevalence

IAV has been isolated from a broad variety of mammals including humans and from birds. The natural reservoir for IAV is the water bird population. IAV infections are an example for a zoonotic disease and also interspecies-transmissible disease. IBV is almost exclusively a human pathogen, but was also isolated from seals. Very similarly, ICV has been isolated mainly from humans and occasionally from pigs. Thogotovirus was isolated from mammals including humans and it belongs to the arthropodically born diseases. Isavirus was isolated from fish only. For humans, IAV, IBV, and ICV are of importance. The zoonotic character of IAV is of greatest concern for human health. Two pandemics (1957 (H2/N2), 1968 H3/N2)) were probably caused by introduction of genomic segments from wild bird IAV into the background of already circulating human IAV. The most deadly pandemic (1918, H1/N1) was probably caused by a bird IAV adapted to humans. The adapter function of swine during this process has been discussed. More recently, a direct infection of humans with IAV from birds has been described (H9/N2: H7/N7; H5/N1). The latter is currently of greatest concern because it may have the potential to become a pandemic threat due to its high pathogenicity causing a mortality of ~50% in humans.

## Genes

The genome of IAV and IBV consists of eight RNA segments encoding 11 proteins. ICV has seven segments, which code for nine proteins. The viral proteins (e.g., for IAV, Fig. 1) regulate and facilitate viral replication (PB1, PB2, PA, NP, NS1), support viral morphogenesis (M1), or act as an integral part (M2) of the viral envelope as an ion channel for transport of hydrogen ions inducing endosomal acidification, which leads to a morphological alteration of the receptor-binding protein. In addition, proteins interact with host responses either counteracting the innate immune response (NS1) or inducing apoptosis (PB1-F2). The glycoproteins embedded in the viral envelope are responsible for receptor binding and entry into the cell. IAV and IBV code for two glycoproteins (hemagglutinin (H), neuraminidase (N)), and ICV codes for one glycoprotein (hemagglutinin-esterase, HE). They represent the major inducers of the adaptive immune response and are important for differentiation between the different virus genera. The glycoproteins within each genus of IBV and ICV are antigenically very similar. In contrast, for IAV 16 H- and nine N-subtypes have been described. The precursor H is cleaved by cellular proteases into two disulfide-linked polypeptides (HA1, HA2). HA1 is the receptor-binding protein whereas HA2 facilitates membrane fusion inducing the release of the uncoated virus into the cytoplasm. N cleaves the terminal sialyl residues from oligosaccharides of both cell and virus glycoproteins supporting dissemination of viruses. H, N, and M2 are able to induce neutralizing antibodies. For IBV and ICV, only one subtype for each glycoprotein has been described.

## Molecular and Systemic Pathophysiology

The acute influenza virus infection affects the respiratory tract in the nose, throat, and lung. Later the epithelial cells in the trachea and bronchi are affected. In addition, acute encephalitis and encephalopathy have been described. In both clinical pictures, the acute onset of clinical signs is likely caused by a cytokine storm induced by viral infection. Production and accumulation of proinflammatory cytokines (e.g., TNF-alpha) seems to play a key role. In addition, the contractility of airway smooth muscle cells is reduced, supporting the observed bronchoconstriction during infection.

## Diagnostic Principles

It is difficult to differentiate between influenza virus infection and other infections causing the common cold by clinical signs in an early stage of infection. IAV and IBV virus infections are characterized, besides the initial symptoms of common cold, by a fast onset of severe clinical symptoms (headache, rapidly increasing body temperature, chills, joint aches, muscle pain, fatigue) and can cause mortality in humans. Clinical signs after ICV infection are slighter and comparable to common cold. Diagnosis can be made by observation of clinical signs if an appropriate epidemiological situation is given. Laboratory diagnostic methods are available. The diagnosis and differentiation of influenza virus infections can be performed by antigen detection using commercial tests, RT-PCR and virus isolation.

## Therapeutic Principles

The use of vaccines (inactivated: IAV, IBV: attenuated: IAV) is effective within 2 weeks after application. Annual revaccination due to the antigenic changes of the field virus is needed. Target groups for vaccinations are people older than 65 years, younger than 2 years or immunocompromised persons. For diseased persons, symptomatic therapy (antipyretics, analgetics, cough suppressants, expectorants) is predominant. The use of neuraminidase inhibitors (zanamivir, oseltamir) and M2 ion channel blocker (amantadine, rimantadine) will not prevent infection but can reduce duration and severity of influenza virus infection. These drugs should be given within 24–48 h after onset of clinical symptoms. They are approved for prophylaxis, but side effects have been observed. Drug-resistant forms of IAV have been described.

## Synonyms

AIED; Immune mediated hearing loss

## Definition and Characteristics

Presentation is idiopathic, bilateral, rapidly progressive sensorineural hearing loss. The involvement of the second ear may occur 1 month to 1 year after the presentation of the first ear. AIED may occur as an organ-specific disease involving only the inner ear or it may occur in association with systemic autoimmune disease. It responds positively to high-dose corticosteroids.

## Prevalence

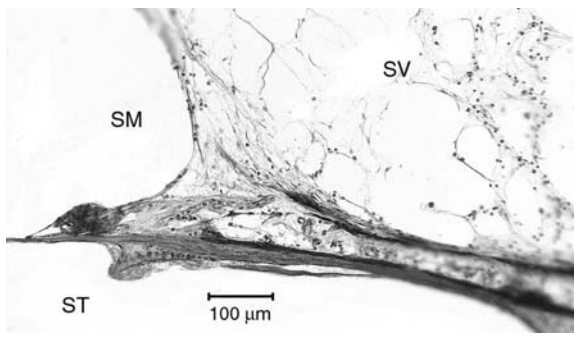
The prevalence is unknown, but it is relatively rare. It occurs in all age ranges, but middle age is the most common.

## Molecular and Systemic Pathophysiology

As the name suggests, the pathophysiology is assumed to be an autoimmune response to inner ear antigens. The presence of inflammation in any tissue results in some tissue destruction by leukocytes, but when this occurs within the inner ear, which has no capability of repairing its epithelial cells, there is induction of the only repair process available, fibrosis and osteoneogenesis. Histopathology supports this hypothesis [1]. Several different molecular weight antigens have been suggested as possible auto-antigens with a 68 kD antigen receiving the most attention [2]. Most recently, a 68 kD antigen has been identified as a choline-transporter-like protein-2 [3] (Fig. 1).

## Diagnostic Principles

The diagnosis is problematic, however in any case of idiopathic, bilateral, rapidly progressive sensorineural hearing loss an autoimmune mechanism should be suspected. There is no generally accepted set of



**Inner Ear Disease, Autoimmune.**
**Figure 1** Photomicrograph of an H&E stained, celloidin section of a human temporal bone from an individual with suspected autoimmune hearing loss and ulcerative colitis. The scala vestibuli (SV) of the second turn contains leukocytes and inflammatory matrix. SM, scala media, ST, scala tympani. diagnostic criteria; nor is there a definitive diagnostic test, although several antibody assays and the lymphocyte transformation test have been reported in clinical use [4]. The presence of inflammatory cells in the inner ear can not be determined with current imaging tools. Confirmation of the diagnosis is positive response to prolonged high dose corticosteroids.

### Therapeutic Principles

High dose prednisone is the first therapeutic approach. It is common to start with 60 mg/day for a month or a lower dose for longer term. If hearing is restored with this treatment, the drug is tapered slowly. Unfortunately, relapse is common and the need for a second prednisone trial may be necessary. In experimental animal models of sterile labyrinthitis the only successful strategies for reduction of hearing loss have been those that reduce the number of inflammatory cells from entering the cochlea. Blockage of intracellular adhesion molecules with intravenous injection of antibodies to ICAM-1 and blockage of TNF-alpha activity with the drug, etanercept, a TNF-receptor blocker (Immunex, Inc. Seattle, WA) [5], both reduced inflammation and hearing loss in guinea pigs. The first presumably acted by reducing the number of extravasated leukocytes and the second by blocking the signal that recruits leukocytes from the circulation.

## Insulin-like Growth Factor-I Gene Deletion

Cecilia Camacho-Hübner, Katie A. Woods, Adrian J. L. Clark, Martin O. Savage
Pediatric Endocrinology Section, Department of Endocrinology, St. Bartholomew's Hospital, London, UK

### Synonyms

Growth; Growth hormone; IGF-I system; IGF-I; Insulin insensitivity; IGF

### Definition and Characteristics

Insulin-like growth factor-I (IGF-I) deficiency is a clinical condition usually associated with severe postnatal growth failure and characterized by a combination of auxological, clinical and metabolic abnormalities caused by decreased IGF-I biologic action [1]. IGF-I deficiency can result from a defect in the IGF-I gene or in its promoter or can be secondary to disorders in growth hormone (GH) synthesis and action, in the type 1 IGF receptor or in the IGF-binding proteins (IGFBPs) Differential diagnosis of JGF deficiency (modified from [1]):

1. GH deficiency
2. GH insensitivity
   - Primary GHI: due to GH receptor abnormalities/post-receptor defects
   - Secondary GHI: due to malnutrition, liver disease, chronic disease
3. Primary IGF-I deficiency due to an IGF-I gene defect
4. Defects of IGF transport/clearance
5. IGF resistance

### Prevalence

Complete IGF-1 deletion is a rare condition.

### Genes

A great deal has been learned about the genetic causes of IGF-I deficiency over the past decades. By 1996 many patients with GH receptor (GHR) mutations had been identified. These patients presented with either the clinical phenotype of classical Laron syndrome [2] or with atypical clinical features, the latter associated sometimes with milder biochemical abnormality [2].

The development of IGF knockout models have provided clear evidence on the important role of circulating and locally produced IGF-I in both fetal and postnatal growth and development [3].

**Insulin-like Growth Factor-I Gene Deletion. Table 1** Biochemical assessment at baseline and during IGF-I therapy

| Peptide | Baseline | IGF-I therapy (80 µg/kg/day) | Reference range |
|---|---|---|---|
| IGF-I (ng/ml) | Undetectable | 421 ng/ml | 39–537 |
| IGF-II (ng/ml) | 1,044 | 756 | 420–852 |
| IGFBP-3 (mg/L) | 5.8 | 4.7 | 2.03–5.96 |
| IGFBP-2 (ng/ml) | 73 | 194 | 145–625 |
| IGFBP-1 (ng/ml) | 4.7 | 26.8 | 35.6 ± 8.8 (mean ± SD) |
| ALS (mg/L) | 46.3 | 30 | 15–34 |
| Insulin (mU/L) | 28.9 | 12 | 8–18 |

Modified from [5].

## Molecular and Systemic Pathophysiology

IGF-I, in concomitant with many other growth factors, exerts physiologic effects virtually in every organ and tissue during fetal and postnatal life [4].

The most important clinical features include severe intrauterine growth retardation and postnatal growth failure. Throughout infancy and childhood severe growth failure continues. Additional features of the disease include sensorineural deafness, dysmorphic features not seen in patients with classical Laron syndrome, micrognathia, a low hairline and severe microcephaly.

The first patient described had bilateral clinodactyly and a single palmar crease in the left hand. At that time he was in early puberty with Tanner stage 2 genitalia, Tanner stage 1 pubic hair and testicular volume of 4 ml bilaterally. A neurologic examination showed severe bilateral hearing loss and mild myopia. The rest of his physical examination was normal.

He had no history of hypoglycaemia or any other metabolic disorder.

## Diagnostic Principles

The results of the initial biochemical assessment of the GH-IGF-I axis of a patient with IGF-deletion are summarized in Table 1.

In addition to GH hypersecretion the patient had marked hyperinsulinaemia with fasting euglycaemia.

## Therapeutic Principles

The cloning of the IGF-I gene [6] and peptide characterization also led to the development of recombinant IGF-I (rhIGF-I) that has been used therapeutically from the late 1980's. Since then rhIGF-I has been safely used in the treatment of patients with classical and atypical Laron syndrome. This treatment was also used in the patient with an IGF-I gene deletion described by our group. An improvement of insulin sensitivity index while the patient was receiving IGF-I treatment was observed.

# Insulin-like Growth Factor-I Gene Deletion and Growth Retardation

Cecilia Camacho-Hübner, Katie Woods, Adrian Clark, Martin O. Savage
Department of Endocrinology, St. Bartholomew's Hospital, London, UK

## Synonyms

Primary IGF-I deficiency

## Definition and Characteristics

Primary IGF-I deficiency, caused by a partial homozygous deletion of the IGF-I gene [1] leads to severe intrauterine growth retardation and severe postnatal

growth failure associated with sensorineural deafness, developmental delay, severe microcephaly, normal myelination and marked hyperinsulinemia with fasting euglycemia.

## Prevalence

To date only one patient with molecular abnormalities of the IGF-I gene has been reported [2,3].

## Genes

Primary IGF-1 deficiency is caused by a defect of the gene encoding the Insulin-like growth factor (IGF)-I, which is localised on chromosome 12q22–q24.1 [4,5]. The IGF-I gene and its mRNAs are complex in structure and expression [6]. In humans the single copy gene encompasses at least 90 kb of chromosomal DNA. It contains two promoters and at least six exons that are variably expressed in IGF-I mRNAs that encode two protein precursors [6]. All of the mature peptide coding sequence is present in the distal part of exon 3 and exon 4. A schematic representation of the structure of the gene is depicted in Fig. 1.

## Molecular and Systemic Pathophysiology

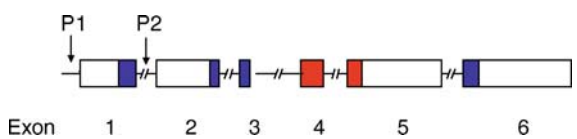
The insulin-like growth factor (IGF) system [7], composed of two ligands, their receptors and regulatory proteins (acid-labile subunit and IGF-binding proteins) play a central role in the regulation of growth and development in mammals.

In addition to its key role in the stimulation of cellular proliferation and growth, IGF-I has important effects on carbohydrate, protein and bone metabolism [7].

Laboratory findings in patients with IGF-1 deficiency include GH hypersecretion, absent serum IGF-I levels, elevated serum IGF-II, IGF-binding protein-5 (IGFBP-5) and acid labile subunit (ALS) and normal IGFBP-3 [8].

## Diagnostic Principles

Screening of the IGF-I gene for mutation or deletions should be performed in patients presenting with severe intrauterine growth retardation and severe postnatal growth failure, associated with the following biochemical features: elevated GH secretion, undetectable serum IGF-I levels and normal or elevated IGFBP-3 and ALS concentrations. Glucose regulation should also be investigated in patients with severe IGF-I deficiency.



**Insulin-like Growth Factor-I Gene Deletion and Growth Retardation. Figure 1** Schematic representation of the human IGF-I gene. The exons are indicated as boxes numbered 1–6. The shaded boxes of the exons represent the protein encoding regions. P1 and P2 are promoters of the IGF-I gene.

## Therapeutic Principles

The disorder may be treated with IGF1 administration [9], which leads to significant increase in growth velocity. However the overall clinical response may remain modest. Some contributing factors for this clinical response may be the timing of rhIGF-I treatment, severe intrauterine growth retardation and severe short stature associated with dysmorphic features [8]. Furthermore, treatment with rhIGF-I given systemically may not completely replace the local response of target tissues to locally produced IGF-I.

### Synonyms

Insulin producing tumor; Pancreatic ß-cell tumor

### Definition and Characteristics

Insulinomas are rare neuroendocrine tumors of pancreatic islet cells that retain the ability to produce and secrete insulin. In contrast to normally differentiated ß-cells, insulinoma cells fail to suppress insulin secretion in response to decreasing blood glucose. This dysregulated insulin secretion manifests clinically as fasting hypoglycemia. The diagnosis of insulinoma is established by demonstrating inappropriately high insulin levels with coincident hypoglycemia during a supervised fast. Localization of insulinomas is challenging due to their small size but should be attempted to maximize the chance for successful surgical resection and avoid risks associated with re-operation. In the majority of cases, successful surgical resection leads to lifelong cure.

### Prevalence

An estimated 2–4 insulinoma cases are diagnosed per million person per year. Though rare, insulinomas are the most frequently observed pancreatic neuroendocrine tumors; accounting for 70% of these.

### Genes

Insulinomas occurring in the setting of the familial multiple endocrine neoplasia type I syndrome [(MEN-1) (5–10% of all insulinomas)] are associated with loss of function of menin; the 610-amino-acid protein of the tumor suppressor gene MEN1 located on chromosome 11q13. Germline mutation and insulinoma-cell specific deletion that results in biallelic loss of MEN1 leads to the development of insulinomas. Tissue specific deletion can be recognized by demonstrating loss of heterozygosity (LOH) at the 11q13 location in these tumors. The exact molecular mechanism(s) by which functional loss of menin results in tumor formation has (have) not been fully elucidated.

Less is known about the genetic events linked to sporadic insulinoma development. Monoclonal tumors are hypothesized to arise from less aggressive oligo/polyclonal precursor lesions. Studies using comparative genomic hybridization (CGH) for genome wide analysis of pancreatic neuroendocrine tumors (PET) suggest a role of genomic instability in tumor initiation and progression. These studies have revealed non-randomly distributed genomic alterations in the form of regional chromosomal gains (e.g., 4pq, 5q, 7pq, 9q, 12q, 14q, 17pq and 20q) and losses (e.g., 1p, 3p, 6q, 10pq, 11q, Y and X) in PET. The type and number of chromosomal anomalies correlates with tumor size and malignant potential. The observation that chromosomal losses occur more frequently than gains in PET suggests involvement of a tumor suppressor pathway. Insulinomas, in keeping with their benign nature, tend to exhibit a lower number of genomic alterations. The most frequently observed alteration in 62 recently reported sporadic insulinomas was a 9q gain [1]. Malignant insulinomas, in this and other studies, exhibited significantly more chromosomal alterations than benign insulinomas suggesting a role for genomic instability in progression of the disease. LOH studies, using PCR amplification of microsatellite markers, have confirmed and added to the findings of CGH. Mutations in oncogenes [e.g., KRAS (12p12.1), MYC (8q24.21), SRC (20q12-q13) or DCC (18q21.3)] and tumor suppressor genes [e.g., TP53 (17p13.1), CDKN2A4

(9p21), PTEN (10q23.3), SMAD4 (18q21.1)] common to many gastro-intestinal adenocarcinomas, are infrequently observed in benign insulinomas. Finally, deletion and somatic mutations in the MEN1 gene have been reported in 5/12 (41%) and 2/12 (17%) cases of sporadic insulinomas respectively; suggesting a role for this tumor suppressor gene in a subset of patients [2]. Few studies have evaluated the role of epigenetic modifications on the development of these tumors. Taken together these studies highlight the complex genetic mechanisms that give rise to insulin producing tumors. Oncogenesis, as suggested by an animal model of insulinoma [3], likely involves cooperation between both proliferative (e.g., c-Myc) and anti-apoptotic (e.g., Bcl-$X_L$) signals.

## Molecular and Systemic Pathophysiology

Though genetic alterations likely account for tumor initiation and progression, systemic pathophysiology results from the fact that these tumors produce and release insulin inappropriately. Insulinoma cells fail to suppress insulin secretion in response to decreasing plasma glucose concentration. The relative insulin excess in relation to glucose leads to hypoglycemia.

Insulin secretion in normal ß-cells is a tightly regulated process that ensures hormone release appropriate for need. Key steps in the stimulus-secretion coupling process include: glucose uptake by the low affinity glucose transporter GLUT2; glucose metabolism by the rate limiting, high $K_m$, glucokinase enzyme (GCK); increase in cellular ATP/ADP concentration; closure of ATP-sensitive potassium channels (SUR1/Kir6.2) and opening of voltage-gated calcium channels leading to release of primed insulin granules. Though mutations in mediators of these steps [e.g., ABBC8 (SUR1), KCNJ11 (Kir6.2), glutamate dehydrogenase and GCK] have been implicated in cases of hyperinsulinism of infancy, their role in human insulinomas has not been studied.

Clinical, ultrastructural and molecular studies of human insulinomas suggest that defects in: insulin biosynthesis; processing; storage and secretion contribute to the pathophysiology of the disease. About ninety percent of patients with insulinomas were demonstrated to have elevated plasma proinsulin levels; defined as a proinsulin level >25% that of total immunoreactive insulin. This observation suggests a disordered processing of proinsulin and implicates the insulin secretory pathway in the pathophysiology of the disease. Histochemical and ultrastructural studies [4] are consistent with this notion and have shown that insulinomas contain lower insulin concentration, higher proinsulin concentration and a variable number of atypical appearing secretory granules when compared to normal ß-cells. More recently, contribution of insulin biosynthesis to the pathophysiology of these tumors has been suggested by a report demonstrating overexpression of an insulin mRNA splice variant associated with increased insulin translation efficiency in nine human insulinomas [5]. Insulin secretion in insulinoma cells, does not follow the regulated insulin secretory pathway of normal ß-cells. The critical molecular determinant along the pathway that leads to dysregulated secretion remains to be identified.

## Diagnostic Principles

The most useful and practical approach to make the diagnosis of insulinoma is the 48-h supervised fast. This test was shown to have a diagnostic sensitivity of 95%. Demonstration of abnormal insulin suppression along with symptomatic fasting hypoglycemia during the fast establishes the diagnosis of insulinoma. A plasma insulin level that fails to suppress to <6 µU/mL at the time of hypoglycemia is strongly suggestive of the presence of an insulin secreting tumor. In contrast, a suppressed plasma insulin level favors another etiology. In rare cases, plasma insulin levels in patients harboring an insulinoma does suppress to <5 µU/mL with hypoglycemia. In such cases, an elevated fasting plasma proinsulin level predicts the presence of an insulinoma. Tumors in these patients are presumed to have retained some glucose sensing ability. Furthermore, the plasma insulin cutoff value from newer more specific insulin assays is expected to be lower than the 6µU/mL value established using a less specific radioimmunoassay. Plasma c-peptide levels and sulfonylurea/meglitinide drug screens are obtained during the fast to exclude the diagnosis of factitious hypoglycemia.

## Therapeutic Principles

Tumor localization followed by surgical enucleation will result in lifelong cure in close to 90% of patients. Though localization of these tumors can be challenging because of their small size (most are <2 cm); blind distal pancreatectomies are not recommended as they pose considerable risk to the patient and are unlikely to result in cure. If conventional imaging studies fail to localize the tumor, invasive pre-operative localization procedures (e.g., intra-arterial calcium stimulation with hepatic venous sampling for insulin, endoscopic ultrasound) should be considered as these modalities can regionalize/localize 80–90% of tumors. Knowledge of tumor location before surgery may: influence surgical approach; improve intra-operative localization and maximize the chance for cure. Prior to surgery, oral or intravenous carbohydrates are administered to prevent hypoglycemia. Medical therapy, in the form of diazoxide, is reserved for metastatic disease, cases in which the tumor cannot be localized or when surgery is not a therapeutic option.

## Synonyms

Interrupted aortic arch; Atretic aortic arch; Discontinuous aortic arch; Congenital absence of the aortic arch; IAA

## Definition and Characteristics

Interrupted aortic arch (IAA) was first described by Steidele in the 1778. This disease was uniformly fatal until surgical repair became available. IAA may be defined as a complete loss of luminal communication between the ascending and descending aorta; this may occur at various levels in the aortic arch. Abbott's 1936 classification to define different types of IAA was modified by Celoria and Patton in 1959, and this revised classification has remained in effect since. Three types of IAA are identified: type A, type B, and type C, each with subtypes depending on the origin and/or course of the subclavian arteries. Before describing the different types of IAA, one should understand the normal anatomy of the aortic arch. The right innominate artery is the first branch off the proximal aortic arch; this divides into the right subclavian artery and right common carotid artery, The next branch is the left common carotid artery, and the last branch off the aortic arch is the left subclavian artery. In type A, the arch discontinuity is distal to left subclavian artery. Type B is discontinuity between the left common carotid artery and the left subclavian artery. In type C, the discontinuity is between the right innominate artery and the left common carotid artery. The interruption can occur both with left and right aortic arches.

Type B interruption is the most common [1], comprising approximately 52% of all interrupted aortic arch cases. Type A interruption comprises 44% of cases.

Type C interruption is least common and occurs with a frequency of 4% of cases.

IAA is not usually seen as an isolated lesion. It is almost certainly associated with a patent ductus arteriosus which establishes continuity between the main pulmonary artery and the descending aorta. A ventricular septal defect (VSD) is present in 50% of patients with type A interruption, and close to 80% of cases with type B defects. Aortic stenosis, both subvalvar and valvar, truncus arteriosus, double outlet right ventricle (Taussig-Bing anomaly), single ventricle, transposition of the great arteries, and aorto-pulmonary septal defects are also commonly found in association with interrupted arch. The ventricular septal defect is usually a posteriorly malaligned defect in the conal septum. The subvalvar aortic stenosis appears to be related to the posterior malalignment of the conal septum, causing left ventricular outflow tract obstruction.

## Prevalence

Congenital heart disease occurs with a frequency of 0.8% of all live births. IAA comprises less than 1% of all congenital heart disease.

## Genes

There is no known Mendelian genetic inheritance pattern described for IAA. There is a strong association with DiGeorge's syndrome, chromosome 22q11 microdeletion. This is most commonly seen in the type B interruption. In one series, 43% of patients with DiGeorge's syndrome had type B interruption, and 68% of patients with type B interruption had DiGeoge's syndrome. This association must be considered anytime a patient has hypocalcemia in association with a cardiac defect, and care must be taken to only give irradiated blood products in the event the status of the patient is unknown. While the chromosomal abnormality is most common with type B IAA, it is also reported in occasional cases with type A and type C interruptions.

## Molecular and Systemic Pathophysiology

There are two theories as to the development of IAA. The first is based on formation and regression of the paired aortic arches, and the second based on altered hemodynamic pattern in utero.

The paired aortic arches connect distally to form the descending aorta, and connect proximally with the aortic sac, which is connected to the truncus arteriosus, to form the ascending aorta. Through a series of formations and regressions from apoptosis, the embryonic arch system develops into that of the adult pattern. Abnormal involution of the aortic arch at different locations will result in different types of interrupted aortic arch.

The second theory is based on altered flow hemodynamics in utero. The posteriorly malaligned VSD shunts blood away from the left ventricular outflow tract, thus less flow is delivered to the aortic arch. Because of the decrease in flow, the distal arch is hypoperfused and that segment becomes hypoplastic, and eventually atrophy of the hypoperfused segment ensues.

## Diagnostic Principles

The diagnosis of interrupted arch can be made by fetal echocardiography, but is one of the more difficult diagnoses to make in utero. In the immediate neonatal period, the patient is asymptomatic, and remains so until ductal constriction ensues or pulmonary vascular resistance drops. Even though the lower half of the body is supplied by the right ventricle by way of the patent ductus arteriosus, there is no deferential cyanosis (upper extremity pink, lower extremity cyanotic) because of shunting of oxygenated blood into the right ventricle and pulmonary artery across the VSD. There is no blood pressure differential in the setting of an unrestricted PDA. As the PDA constricts, the blood flow to the descending aorta is compromised and cardiovascular collapse becomes apparent from metabolic acidosis and pulmonary edema. Diagnosis rests on clinical intuition and is usually confirmed by two dimensional echocardiography [2]. Cardiac catheterization is rarely necessary to establish a diagnosis. Chest radiography shows cardiomegaly and increased pulmonary blood flow or pulmonary edema. Electrocardiogram may show right, left or bi-ventricular hypertrophy. The corrected QTc may be prolonged due to hypocalcaemia, if the patient has DiGeoge's syndrome. Three-dimensional reconstruction from MRI clearly defines the anatomy although such is not usually required in the newborn period.

## Therapeutic Principles

If left untreated, interrupted aortic arch is fatal within the first week or two of life. Prior to the advent of Prostaglandin $E_1$ ($PGE_1$), these patients would present in severe cardiovascular collapse with renal and hepatic dysfunction, and would have to undergo surgical intervention under suboptimal conditions. Since the advent of $PGE_1$, the neonates are started on $PGE_1$ infusion and stabilized prior to surgical intervention, allowing a return to normalcy of end organ function. Ductal patency is maintained with prostaglandin infusion, inotropic support may need to be initiated, and electrolyte abnormalities should be corrected.

Surgical correction is aimed at a complete primary correction with arch repair and closure of the VSD. Samson performed the first repair of IAA in 1955,

and the first repair in a neonate was performed by Sirak in 1968. Of the several options available, direct anastomosis with patch augmentation is preferable [3]. The use of interposition grafts should be avoided as they will not grow with the baby. The mortality is high and the higher risk is seen with associated complex heart disease and poor condition at presentation. In cases with severe left ventricular outflow tract obstruction/hypoplasia, Norwood or Damus-Kaye-Stencil approaches may become necessary. Re-intervention is required in 28% patients [3]. With recurrence of aortic arch obstruction, balloon angioplasty or stent implantation may become necessary [4,5]. The prognosis has improved during the last decade because of advances in neonatal, medical, anesthetic and surgical management of these sick babies.

## Synonyms

Diffuse parenchymal lung disease; Diffuse interstitial lung disease; Interstitial pneumonia; Interstitial pneumonitis; Interstitial lung disease; ILD

## Definition and Characteristics

Interstitial lung disease (ILD) is a term given to a heterogeneous group of inflammatory and scarring processes that damage the interstitium, including the space between the epithelial and endothelial basement membranes. ILD generally involves both lungs and occurs in an acute, subacute or chronic manner. Patients with ILD have symptoms of dyspnea, hypoxemia, restrictive ventilatory defect, and the presence of bilateral diffuse pulmonary infiltrates on chest roentgenograms. ILD is sometimes caused by occupational and environmental exposures, drug reactions, collagen vascular diseases, granulomatous diseases, etc. However, idiopathic interstitial pneumonias (IIPs) are the most common and important.

In 1969, IIPs were classified into five types by Liebow and Carrington, and a new American Thoracic Society/European Respiratory Society classification was proposed in 2002 [1]. This new classification includes the following clinico-radiologic-pathologic entities in the order of relative frequency: idiopathic pulmonary fibrosis (IPF)/cryptogenic fibrosing alveolitis (CFA), nonspecific interstitial pneumonia (NSIP), cryptogenic organizing pneumonia (COP), acute interstitial pneumonia (AIP), respiratory bronchiolitis-associated interstitial lung disease (RB-ILD), desquamative interstitial pneumonia (DIP), and lymphocytic interstitial pneumonia (LIP). The major objectives of this classification are to establish a uniform set of definitions and criteria for the diagnosis of IIPs.

## Prevalence

In a population-based study in Bernalillo County, New Mexico, the prevalence of ILD was 81.9 per 100,000 in males and 67.2 per 100,000 in females, and its incidence was 31.5 per 100,000 per year in males and 26.1 per 100,000 per year in females [2]. On the other hand, IPF showed a prevalence of 3–20 per 100,000, an incidence of 7–11 per 100,000 per year, and a mortality of 0.03–1.3 per 100,000 [3].

## Genes

No strong associations between genetic polymorphisms and IIPs have yet been demonstrated. However, genes and gene polymorphisms of surfactant protein C, tumor necrosis factor, interleukin-1 receptor antagonist, etc., have been evaluated in sporadic IPF.

## Molecular and Systemic Pathophysiology

Six common types of IIPs are described:

*Usual interstitial pneumonia (UIP, IPF/CFA)*: The key histological feature is a patchy and temporally varied fibrosis with little inflammation presenting a heterogenous appearance; fibroblastic foci are the hallmark of UIP (Fig. 1). Pulmonary function tests show reduced vital capacity and impaired gas exchange, and these functions gradually deteriorate.

*NSIP*: NSIP consists of three subgroups: group I, primarily with interstitial inflammation; group II, with both inflammation and fibrosis; and group III, primarily with fibrosis [4]. The lung is typically uniformly involved, but the distribution of the lesions is often patchy. In group I, mild to moderate chronic interstitial inflammation with lymphocytes and a few plasma cells are observed. In group III, dense or loose interstitial fibrosis is present in varying degrees and the connective tissues are temporarily homogeneous.

*COP*: Excessive proliferation of granulation tissue occurs with chronic inflammation in the surrounding alveoli.

*AIP*: The main histologic feature of AIP is diffuse alveolar damage. In the exudative phase, there is edema, hyaline membrane and interstitial inflammation; in the organizing phase, loose organizing fibrosis within alveolar septa and proliferation of type II pneumocytes.

*RB-ILD*: Dusty brown macrophages are observed predominantly in the respiratory bronchioles, alveolar ducts and peribronchiolar alveolar spaces, and mild peribronchiolar fibrosis is also seen. It usually occurs in current and heavy smokers.

## Diagnostic Principles

Close communication between the clinician, radiologist and pathologist is critical to achieving a correct diagnosis in patients with IIP. Adequate clinical information and high-resolution computerized tomography (HRCT) scans are indicated for all patients to assure diagnostic accuracy. A surgical lung biopsy is necessary for making decision about therapy except in cases with a typical clinical-radiological picture of UIP/IPF, and it is better to perform the biopsy before the end-stage of ILD and indeed before initiation of treatment. Transbronchial lung biopsies are not useful in the diagnosis of most cases, and bronchoalveolar lavage is not always required to access IIPs.

## Therapeutic Principles

Accurate diagnosis is essential to adequate treatment. In particular, IPF/UIP, which is often resistant to various drugs including corticosteroids and immunosuppressive agents, should be distinguished from other forms of IIPs.

# Interstitial Nephritis

Bernd Hohenstein, Christian P. M. Hugo
Department of Nephrology and Hypertension, University Erlangen-Nuremberg, Erlangen, Germany

## Synonyms

AIN; Acute interstitial nephritis

## Definition and Characteristics

Interstitial nephritis is widely used as a synonym for acute interstitial nephritis (AIN). This disease is characterized by an immunological reaction following the exposure to various drugs, bacterial antigens, as well as in association with autoimmune disorders, sarcoidosis and the tubulointerstitial nephritis and uveitis syndrome. In contrast, chronic interstitial nephritis is a histologic entity defined by tubulointerstitial injury, macrophage and lymphocytic infiltration including progressive interstitial fibrosis. Hereby, the chronic interstitial inflammatory process may be caused either by progression of acute interstitial nephritis, chronic exposure to other agents such as heavy metals or analgesics, or by systemic immune disorders, hematologic diseases, glomerulonephritides, or chronic obstruction.

Among patients with acute interstitial nephritis, drug (especially antibiotics) induced cases are most common (70%), followed by infection associated cases (15%) as well as cases associated with immunologic disorders (5–10%). Table 1 depicts the most common drugs responsible for AIN. Other causes are rare.

## Prevalence

Approximately 1–3% of all biopsies, up to 15% of cases with acute renal failure.

## Genes

So far, a genetic component has not been identified.

## Molecular and Systemic Pathophysiology

Depending on the underlying agent, either cell- or antibody-mediated mechanisms can be involved in the pathogenesis of AIN. Extrarenal antigens may contribute to renal injury by various mechanisms such as cross-reactivity, precipitation in the tubulointerstitium, a mimicry with renal antigens or nonspecific binding to renal structures as a "planted antigen." The deposition of immune complexes may result in complement activation and subsequent cytokine release and invasion of inflammatory cells. However, immunofluorescence staining of the kidney in AIN is typically negative. In most cases, interstitial edema and a prominent interstitial inflammatory infiltrate containing mainly T cells and monocytes, less frequently also eosinophils and plasma cells, indicate a predominantly cell-mediated injury [1].

## Diagnostic Principles

Besides laboratory signs of acute renal failure (rise in plasma creatinine and BUN), patients present with rather nonspecific symptoms of acute renal failure including oliguria, macroscopic pyuria and hematuria. By ultrasound, kidneys are normal or mildly enlarged, with enhanced echogenicity of the renal cortex (comparable or higher than the liver). Clinical examination may demonstrate flank pain (approx. one third of patients), but usually absence of hypertension and edema.

The urinary sediment usually demonstrates white blood cells, white cell casts and red blood cells. Due to these findings, a bacterial infection needs to be excluded and the specific staining for eosinophils in

the urinary sediment may add to the further differentiation (but has a low sensitivity). Proteinuria is typically mild or absent (usually less than 1 g/day). In the presence of proteinuria, urinary protein differentiation reveals a predominantly tubular excretion pattern, e.g., with loss of alpha-1 microglobulin. Onset of disease relates with the underlying cause, ranging from several days up to several weeks. However, in 80% of all patients, symptoms of AIN develop within 3 weeks after exposure to the immunological antigen. Due to the allergic component of AIN, patients may additionally present with allergic symptoms such as rash and fever as well as eosinophilia and an increase in serum IgE. However, presence of all these symptoms together is rare (less than 10%).

Due to the predominant tubular injury, disorders such as Fanconi syndrome or renal tubular acidosis can be found in some cases.

Past medical history and laboratory findings usually lead to renal biopsy as the only way to make a definitive (histological) diagnosis.

### Therapeutic Principles

The primary therapeutic step is the removal of the disease inducing agent and the prevention of re-exposure. If necessary, renal replacement therapy should be used to overcome clinical symptoms of acute kidney injury.

Several small uncontrolled and retrospective studies evaluated a 4 week treatment with prednisolone at a dose of 1 mg/kg body-weight/day, but failed to demonstrate beneficial effects [2]. Upon this, in other studies patients receiving corticosteroids tended to have more severe alterations of renal function [3].

A recent, multicenter retrospective study among patients with drug-induced acute interstitial nephritis (by antibiotics and NSAIDS) compared 52 patients with steroid treatment with nine patients who did not receive steroid treatment [4]. In this so far largest study, patients without steroid treatment had a significantly increased risk to remain on chronic dialysis and the delay of treatment also demonstrated an adverse effect on renal recovery (as indicated by the final serum creatinine). Nevertheless, within the treatment group only 50% of all patients had a complete recovery of renal function.

# Intestinal Lymphangiectasia

Sema Uguralp
Department of Pediatric Surgery, Turgut Ozal Medical Center, Inonu University, Malatya, Turkey

## Synonyms

Waldmann disease; Idiopathic hypoproteinemia; Hypercatabolic protein-losing enteropathy; Primary (congenital) intestinal lymphangiectasia; Familial dysproteinemia; Familial hypoproteinemia with lymphangiectatic enteropathy; Intestinal lymphangiectasis; Lymhangiectatic protein-losing enteropathy; Neonatal lymphedema due to exudative enteropathy; Secondary intestinal lymphangiectasia

## Definition and Characteristics

Intestinal lymphangiectasia (IL) is a disease category rather than a single entity. It is characterized by dilated lymphatic vessels in the lamina propria of the small intestine with leakage of lymph into the intestine and consequent protein-losing enteropathy (i.e., hypoproteinemia, edema, steatorrhea).

IL may be congenital (present from birth) due to malformation of the lymphatic system, or it may be acquired in association with another disease. Primary (congenital) intestinal lymphangiectasia (PIL) was originally described in 1961 by Waldmann et al. [1]. Lymphatic channels are hypoplastic or obstructed, resulting in dilatation of the proximal channels. PIL often have extraintestinal lymphatic abnormalities. It may be associated with different syndromes such as Hennekam syndrome, Urioste syndrome, Noonan's syndrome, and Turner's syndrome [2]. PIL may be associated with aplasia cutis congenita.

Secondary (acquired) intestinal lymphangiectasia can develop in a variety of diseases in which lymphatic flow is obstructed due to cardiac failure, pericarditis, intestinal lymphoma, inflammatory bowel diseases, and other conditions.

## Prevalence

The prevalence is unknown. Two of 48 cases with chronic diarrhea in Saudi Arabia, 2 of 27 children with chronic diarrhea in Malaysia, and 1 of 92 children with protracted diarrhea in Kuwait had IL. In 2,250 endoscopic examinations of the upper gastrointestinal tract IL had been found in 48 cases histologically.

## Genes

Different genetic abnormalities have been defined according to associated syndrome. Waldmann disease and Noonan's syndrome have autosomal dominant inheritance. Hennekam syndrome and Urioste syndromes have autosomal recessive transmission. Turner's syndrome has 45X0 chromosome anomaly. 22q11 microdeletion and exudative enteropathy due to abdominal lymphatic dysplasia had been reported in a case of velocardiofacial syndrome.

## Molecular and Systemic Pathophysiology

The histopathology consists of dilatation of the lymphatics in the mucosa, lamina propria, and submucosa of the small bowel and mesentery. Lacteals are lymph vessels in the intestinal tract designed to absorb nutritional fats. When there is high pressure within the lymph vessels, the tender lacteals burst and instead of absorbing fats, the lymph inside, its cells, fats, and precious proteins are lost. The intestine may be able to reabsorb some of these valuable substances at other sites but if the inflammatory intestinal disease that started the problem in the first place is widespread, the balance may have shifted to nutritional loss rather than gain. The loss of lymphocyte and immunoglobulin into the intestine also causes lymphopenia and hypogammaglobulinemia. This leads to immunologic abnormalities, including anergy and impaired allograft rejection. In addition to the loss of other serum components (e.g., lipids), iron and certain trace metals may also be affected [3].

## Diagnostic Principles

PIL is a disease that usually affects children and young adults. Nearly all reported patients had their first symptoms within the first three decades of life. Symptoms consist of failure to thrive, general or peripheral edema, abdominal pain, nausea, vomiting, chronic diarrhea with or without steatorrhea, and chylous ascites.

The diagnosis is suggested by hypoalbuminemia, lymphopenia and low immunoglobulin levels, elevated fecal $\alpha_1$-antitrypsin, and elevated fecal fat content.

A small bowel barium study shows uniform dilatation of the bowel, hyperflocculation of barium, symmetric thickening of mucosal folds throughout the small intestine. Computed tomography is useful in demonstrating the pathologic characteristics and the anatomic distribution of the involvement [4].

Endoscopically, a small intestinal biopsy shows marked dilatation of the lymph vessels of the mucosa and submucosa, with no evidence of inflammation [5]. When IL is due to a focal abnormality, multiple intestinal biopsies and serial sections are indicated if this diagnosis is suspected.

## Therapeutic Principles

The medical treatment methods are high-protein and low-fat diet with added medium-chain triglycerides

(MCT). MCTs bypass the enteric lymphatics. Octreotids and antiplasmin therapy have been reported to decrease intestinal protein losses. Surgical management consists of resection of the involved small intestinal segment.

# Intestinal Lymphangiectasis

►Intestinal Lymphangiectasia

# Intestinal Malrotation

Ralf Kubitz, Dieter Häussinger
Clinic for Gastroentorology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

Intestinal malrotation

## Definition and Characteristics

During embryogenesis, the gut rotates around the superior mesenteric artery (SMA) to fit into the abdominal cavity. Disturbances of this process result in partial or complete intestinal malrotation. One third to two thirds of patients with this condition have other associated intestinal anomalies such as an omphalozele, defects of the diaphragm, intestinal atresia, Meckel's diverticulum, or mesenteric cysts.

## Prevalence

Symptomatic intestinal malrotation occurs approximately in 1 of 6,000 births. Asymptomatic intestinal malrotation occurs 12–30 times more often. Within the first year of life, 80–90% of symptomatic cases need surgical treatment.

## Genes

Familial occurrence of intestinal malrotation has been described in the literature [1,2,3,4]. These case reports suggests a mono- or oligogenetic background of intestinal malrotation, however, no responsible single gene has been identified in humans yet. Animal models suggest that genes of the retinoic acid signaling such as retinaldehyde dehydrogenase (RALDH2) or retinoic acid hydroxylase (CYP26A1) may significantly control left–right asymmetry of the gut tube [5].

## Molecular and Systemic Pathophysiology

During normal development, the duodenojejunal junction rotates around the SMA in a counterclockwise direction (looking from anterior to posterior). This rotation guides the duodenum below and behind the SMA. The ileocecal junction completes the reciprocal turn, thus directing the colon above the SMA. The sense of rotation is governed by disparate growing speeds of the gut segments and by the space requirements of other abdominal organs, especially the liver. When rotation is complete, the gut gets fixed to the posterior abdominal wall at the duodenojejunal junction (ligament of Treitz) and at the ascending and descending colon. The complete small bowel (jejunum and ileum) adheres to the mobile mesenterium; the corresponding mesenteric base spans from the ligament of Treitz (left upper quadrant) to the ileocecal junction (right lower quadrant). In intestinal malrotation, the mesenteric base is shortened and disorientated, which increases the risk of intestinal distortion (volvulus). The most frequent type of malrotation is associated with a tethering of the cecum to the right abdominal wall by a peritoneal strand, which is called "Ladd's band" (named after William E. Ladd, who wrote a crucial article about surgical treatment of malrotation in 1936) [6]. Ladd's band crosses the duodenum and may cause significant compression of the duodenum and acute upper GI obstruction. Other forms of malrotation result in malposition of the duodenum and colon with respect to the SMA (duodenum in front or colon behind of the SMA).

## Diagnostic Principles

Main appearances of symptomatic malrotation are intestinal obstruction and ischemia. Obstruction due to intestinal malrotation should be considered in young children with bile-stained vomitus or acute duodenal obstruction. A hazardous complication is a volvulus,

leading to intestinal ischemia. Sequelae are an acute abdomen with abdominal distension, hematemesis, hematochezia, peritonitis, and shock. More than half of the patients with intestinal malrotation present with a volvulus within the first month of life. In older children with malrotation, only 10–15% experience a volvulus.

Older children with malrotation may become symptomatic with recurrent abdominal pain, vomiting, and diarrhea. Consecutive malabsorption and failure to thrive may also be indicative for malrotation.

On a plain X-ray film the "double-bubble" sign (air bubble in stomach and in duodenum) may indicate malrotation. Upper GI contrast X-ray films may reveal a misplaced duodenum with a coiled appearance.

A barium enema may demonstrate an obstruction of the transverse colon; however, the position of the cecum is very mobile and therefore is an unreliable sign of malrotation.

Abdominal ultrasound signs of malrotation are (i) an abnormal position of the superior mesenteric vein (anterior or leftsided in relation to the SMA), (ii) a dilated duodenum, or (iii) twisted mesenteric vessels ("whirlpool" sign of volvulus).

## Therapeutic Principles

Symptomatic malrotation is managed surgically with the Ladd procedure [1,7]. This includes the untwisting of distorted bowel, the disconnection of the Ladd bands, the release of the mesenteric base (from adhesions between duodenum and colon), and the exclusion of associated intestinal stenosis (in newborns). Routinely an appendectomy is performed. Further surgical procedures depend on the degree of intestinal ischemia. Resection of necrotic bowel may result in short bowel syndrome.

# Intestinal Obstruction

►Intestinal Obstruction, Functional

# Intestinal Obstruction, Functional

Thomas Frieling
Medical Clinic II, Helios Klinikum Krefeld, Krefeld, Germany

## Synonyms

Intestinal obstruction; Functional intestinal obstruction; Intestinal pseudo-obstruction; Pseudo-obstruction; Congenital pseudo-obstruction; Megacystis microcolon hypoperistalsis syndrome

## Definition and Characteristics

Intestinal pseudo-obstruction is a rare, severe, and disabling disorder with a mortality rate of 25% per 2 years in congenital forms [1]. Intestinal pseudo-obstruction comprises a heterogeneous group of gastrointestinal nerve and muscle disorders with a similar phenotype. The disorder is characterized by repetitive episodes or continuous symptoms and signs of bowel obstruction, including radiographic documentation of dilated bowel with air-fluid levels, in the absence of a fixed, lumen-occluding lesion. However, there are cases without or only intermittent bowel dilation. Pseudo-obstruction represents the most severe form of motility disorder and may be considered an insufficiency of the intestinal pump. Pseudo-obstruction may be congenital or acquired, primary or secondary. Any segment of the gastrointestinal tract may be involved, and symptoms reflect this heterogeneity. In children, the most common symptoms are nausea, vomiting, abdominal distension, and constipation. Dysphagia, abdominal pain, and diarrhea seem to be more common in adults. However, no sign or symptom is pathognomonic of pseudo-obstruction and the clinical presentation may mimic that of many other gastrointestinal disorders. Intestinal pseudo-obstruction may not be limited to impaired gastrointestinal motility and may present as dilated bladder (megacystis) with impaired neuromuscular function, malrotation, or autonomic nervous system dysfunction, especially vagal dysfunction.

## Prevalence

Epidemiological data on pseudo-obstruction are not available yet. However, from data obtained from

the American Pseudo-obstruction and Hirschsprung's Society, the prevalence of pseudo-obstruction suggests that approximately 100 infants are born every year in the United States with congenital pseudo-obstruction. In adults, the condition is even more prevalent, including many forms of pseudo-obstruction caused by systemic diseases. In most children, pseudo-obstruction is sporadic or nonfamilial [2].

## Molecular and Systemic Pathophysiology

Among the most common causes of adult pseudo-obstruction are scleroderma and other connective tissue disorders, diabetes, use of narcotics or drugs with anticholinergic properties, hypothyroidism, paraneoplastic syndromes, amyloidosis, and radiation enteritis. Other causes of pseudo-obstruction may include DNA viral infections (cytomegalovirus, herpes zoster, and Epstein-Barr virus), autoimmune myositis, prenatal exposure to alcohol, and immune response against occult neoplasms (e.g., small cell lung carcinoma). Mitochondrial disorders may cause pseudo-obstruction, mostly as a part of a syndrome known as mitochondrial neurogastrointestinal encephalomyopathy (MNGIE). Acquired aganglionosis may be caused by a T cell-mediated inflammatory response against enteric neurons, leading to enteric ganglionitis and subsequent loss of colonic and intestinal neurons and pseudo-obstruction. The study of other discrete forms of pseudo-obstruction (achalasia, hypertrophic pyloric stenosis, and Hirschsprung's disease) have suggested altered inhibitory neurotransmission as the major underlying pathomechanism. Nitric oxide (NO) and vasoactive intestinal polypeptide (VIP) are among the most important neurotransmitters. In all these conditions there is a loss of nitrergic and VIP-containing neurons with consecutive sustained contraction in affected segments. The interstitial cells of Cajal (ICC) are considered the pacemaker cells of the gut because their network generates the slow waves of depolarization of the gut smooth musculature. There have been reports of altered ICC in these disorders and of delayed maturation of ICC contributing of pseudo-obstruction occurring in neonates. In addition, mutations in the RET proto-oncogene have been associated with long-segment aganglionosis and are also found in multiple endocrine neoplasia types 2A and 2B and in papillary and medullary thyroid carcinoma. Abnormal endothelin-B receptor genes and endothelin three genes have been detected in shorter forms of the disease and are found in type 2 Waardenburg syndrome.

## Diagnostic Principles

The two most important elements for diagnosing pseudo-obstruction are suspecting the diagnosis and excluding mechanical obstruction. Many patients undergo several laparotomies before the diagnosis of pseudo-obstruction is made. This makes it even more difficult to distinguish subsequent pseudo-obstructive crisis from mechanical obstructions caused by adhesions. It is, therefore, crucial to carefully collect patient history and perform clinical examination together with endoscopy and radiology (abdominal radiograph, contrast radiology with water soluble material, computed tomography, MRT) to detect the various causes of intestinal obstruction. These are muscle disorders, postoperative ileus, autoimmune diseases (SLE, scleroderma, dermatomyositis, polymyositis, and celiac disease), malignoma, chemotherapeutic side effects, paraneoplastic syndrome (ganglioneuroblastoma and small cell carcinoma), multiple myeloma, sickle cell disease, infectious or post-infectious causes (Chagas disease, cytomegalovirus, herpes zoster, Epstein Barr virus, and Kawasaki disease), endocrine disorders (diabetes mellitus, hypoparathyroidism, hypothyroidism), mitochondrial cytopathies, fetal alcohol syndrome, jellyfish envenomation, drug effects (diltiazem, nifedipine, and phenylephrine eye drops), Ehlers-Danlos syndrome, eosinophilic gastroenteritis, angioedema, Crohn's disease, intestinal carcinoma or lymphoma, and radiation injury. Patients' history may provide hints that the patient does not have mechanical obstruction such as intermittent or long-standing symptoms, positive family history, extraintestinal symptoms (urinary symptoms), coexistence of vomiting, abdominal distension and constipation, no symptom free intervals, weight loss, autonomic nervous system dysfunction (postural dizziness, sweating abnormalities), history of several nondiagnostic laparotomies, and radiological studies not consistent with mechanical obstruction. Antroduodenal manometry is one key investigation in pseudo-obstruction, because antroduodenal motility is always abnormal in patients with pseudo-obstruction. In neuropathy, contractions have normal amplitude and are uncoordinated, leading to nonperistaltic activity. Abnormal or even absent phase III of the migrating motor complex (MMC) may occur during fasting. An impaired or even absent motor response to food may occur in both visceral neuropathy and extrinsic autonomic neuropathy. In myopathy, there is hypomotiltiy with either coordinated, persistently low-amplitude contractions or absence of contractions in advanced disease. Nonpropagated, prolonged contractions during the postprandial period (cluster contractions) are suspicious of mechanical obstruction. A higher motor activity and the presence of phase III of the MMC are associated with better outcome. Antroduodenal manometry may also be used to rule out generalized motility disorder in chronic obstipated patients considered for colectomy. If the entire gastrointestinal tract is diseased, removal of the colon or creation of an ileostomy is not likely to

improve symptoms. Transit studies (radio-opaque marker, scintigraphic studies, gastric emptying studies and electrogastrography (EGG)) identify the site of functional obstruction and add further information. For example, normal gastric emptying for solids greatly reduces the likelihood of gastroduodenal dysmotility and the presence of pseudo-obstruction. Full-thickness biopsies allow the study of both muscle and nerves. The pathologist´s routine staining (H&E) is not adequate for studying the enteric nervous system (ENS). Biopsies should be done for routine light microscopy (formalin), for electron microscopy (glutaraldehyde), and for enzyme histochemistry (snap-frozen). Pathology studies should be performed in referral laboratories on whole mount tissue preparations with histochemistry and immunohistochemistry staining for neuropeptides.

### Therapeutic Principles

Treatment of intestinal obstruction should be directed to the underlying mechanisms. However, intestinal pseudo-obstruction continues to be a life-threatening disease with one third of death of newborns in the first year of life. Dietary measures including the use of frequent, small liquid meals low in fat and fibers may help patients with gastroparesis. The effect of prokinetic drugs (cisapride, metoclopramide, erythromycin, domperidone, misoprostol, octreotide, tegaserod, and neostigmine) might be beneficial in some cases. Abnormal motility increases the risk of bacterial overgrowth which by itself causes further impairing of gastrointestinal motility by mucosal inflammation. Therefore, treatment with antibiotics (amoxicillin, clavulanic acid, cotrimoxazole, and metronidazole) often with antifungal drugs (nystatin and fluconazole) may improve motility. Multidisciplinary treatment should include behavioral or relaxation therapy and the use of nonnarcotic medicines. Bowel decompression through gastrostomy, jejunostomy, and loop enterostomy to decrease bowel distension and to improve gastrointestinal motility often represents the most beneficial intervention in patients with pseudo-obstruction. Gastrostomy and jejunostomy feedings should always be attempted before considering parenteral nutrition. Surgical bypass of diseased segments may be beneficial for carefully selected patients in whom the disease is limited to an isolated segment of the bowel. Electrical stimulation via implanted electrodes may help to support gastric or intestinal pacemaker activity. However, their effect in pseudo-obstruction has not been proved yet. Therefore, small bowel transplantation is the only definitive cure for patients with pseudo-obstruction. This should be considered in patients receiving total parenteral nutrition with frequent septic episodes, limited intravenous access for nutritional support, thromboembolic disease, and cholestatic liver disease.

## Intestinal Pseudo-Obstruction

►Intestinal Obstruction, Functional
►Ogilvie's Syndrome

## Intestinal Pseudo-Obstruction, Chronic

Marcus Schmitt
Gastroenterology, Hepatology and Infectiology, UKD, Heinrich-Heine-University, Duesseldorf, Germany

### Synonyms

CIPO, Chronic intestinal pseudo-obstruction; Chronic idiopathic intestinal pseudo-obstruction, CIIP

### Definition and Characteristics

Chronic intestinal pseudo-obstruction is a syndrome mimicking mechanical bowel obstruction of the small or large bowel in the absence of an anatomic obstruction, that stops the flow of intestinal contents. CIPO is divided into neuropathic and myopathic forms. Each of these forms can occur as a hereditary or sporadic form. Furthermore chronic intestinal pseudoobstruction secondary to a systemic disease like diabetes mellitus, lupus erythematodes, amyloidosis, Chagas disease, myxedema, Duchenne muscular dystrophy must be mentioned.

### Prevalence

The prevalence of chronic colonic pseudo-obstruction is unknown, no exact data exist about incidence and male/female ratio.

## Molecular and Systemic Pathophysiology

Gastrointestinal motor function is a complex sequence controlled by an extrinsic nerve supply from the brain and spinal cord, the plexi within the wall of the intestine (the so called enteric brain) and the effects of locally released transmitters, altering the excitability of the intestinal smooth muscles. Therefore chronic intestinal pseudo-obstruction may be divided into three systems of origin: the enteric nervous system, the extrinsic nervous system and the system of smooth muscles. Patients with chronic pseudo-obstruction or with slow transit constipation show a reduced density of the interstitial cells of Cajal (ICC). These cells are the pacemakers of the intestine coordinating intrinsic and extrinsic neuronal function.

In most cases chronic intestinal pseudoobstruction is due to a systemic disease affecting neuromuscular function. Neuropathic disorders include amyloidosis, diabetes mellitus, Chagas disease and paraneoplastic syndromes; Duchenne muscular dystrophy and scleroderma are examples of myopathic process. Combinations of neuropathic and myopathic etiologies also occur in scleroderma and amyloidosis.

Nevertheless several genetic disorders were identified leading to recurrent or chronic intestinal pseudo-obstruction (primary forms of CIPO) [1].

One genetic form results from qualitative abnormalities of the enteric ganglia and nerve fibers, suggesting the presence of a differentiation defect. Autosomal recessive inheritance was suggested by Tanner et al. (1976) [2] for this type of defect occurring as a syndrome presenting with short small bowel, malrotation, and pyloric hypertrophy associated with morphologic defects of argyrophil neurons in the myenteric plexus.

Auricchio et al [3] described a family in which the disorder appeared to be segregating as an X-linked recessive trait and in which they were able to map the disease locus (symbolized CIIPX by them) to Xq28. The microsatellite marker DXYS154, located in the distal part of Xq28, showed no recombination with a maximum lod score of 2.32. Multipoint analysis excluded linkage with markers spanning other regions of the X chromosome. On the basis of analysis of recombinants, Auricchio concluded that the critical region for the disease gene is limited by DXS15 toward the centromere and by the pseudoautosomal boundary toward the telomere. Auricchio raised the intriguing hypothesis that CIIPX may represent an additional susceptibility locus in Hirschsprung disease. (Hirschsprung disease is the most common form of neuronal intestinal pseudoobstruction.) A higher penetrance of Hirschsprung disease has been observed in males compared to females in the case of both RET and EDNRB mutations [4].

Among a variety of disorders forms of MNGIE (Myopathy and external ophthalmoplegia; Neuropathy; Gastro-Intestinal; Encephalopathy) should be mentioned: 100% of these patients have a visceral neuropathy due to affected Thymidine phosphorylase. Genetic characteristic: Chromosome 22q13.32-qter; recessive. Most common are missense mutations furthermore insertions, deletions or splice acceptor change in intron occur.

## Diagnostic Principles

Diagnosis is based on radiology, assessment of the nutritional status, dysmotility testing by transition time and intestinal manometry. Intestinal manometry differentiates myopathical disorders from neuropathic disorders.

Clinical signs may be acute, recurrent, or chronic and impress like an ileus as abdominal distension, constipation, heartburn/regurguítation, fullness, abdominal pain and nausea and vomiting. Other signs are anorexia, weight loss, diarrhea, alternating bowel habits. Lab findings: serum electrolytes and albumin concentration showing disbalances, acidosis and nutritional state.

## Therapeutic Principles

General therapeutic recommendations are based predominantly upon clinical experience.

*Drugs*: Maintenance of an adequate nutritional state by oral and/or enteral nutritional support is essential. Enteral nutrition is typically used for neuropathic disorders, while parenteral nutrition may be necessary for patients with severe usually myopathic pseudo-obstruction.

Stimulation of an organized intestinal propulsion by prokinetic drugs. Prokinetic agents, particularly erythromycin and cisapride, may be useful for acute and chronic therapy of intestinal pseudo-obstruction. Responding patients may maintain body weight and are off parenteral nutrition. The combination of a prokinetic agent with an antiemetic medication for symptom relief is successful.

Antibiotics in a rotating regimen are recommended against confirmed bacterial overgrowth.

*Surgery*: Case reports have suggested a possible role for percutaneous endoscopic colostomy, but experience is limited. Unnecessary laparotomies should be strictly avoided because they may lead to adhesions and markedly complicate the clinical course.

For children, however, intestinal transplantation may be life-saving. Furthermore, the introduction of sirolimus to the immunosuppressive regimen appears to have improved the outcome of isolated small bowel transplantation.

[2]MonashHeart, Monash Medical Centre, Melbourne, VIC, Australia

## Synonyms

Atrial septal defect; ASD; Patent foramen ovale; PFO; Ventricular septal defect; VSD

## Definition and Characteristics

Intra-cardiac shunts may occur at the level of the atrial septum (ASD; PFO), or at the ventricular septum (VSD). Extra-cardiac shunts (not discussed here) can occur between the aorta and pulmonary artery (e.g., patent ductus arteriosus) or between any systemic artery and vein (e.g., A-V fistula).

There are three types of ASD's: secundum, primum and sinus venosus. Secundum defects occur in the area of the fossa ovalis and account for 75% of all ASD's. They result from deficient growth of the secundum septum or excessive absorption of the primum septum. They are more common in females and can occur in association with other cardiac anomalies (e.g., Ebstein's anomaly or in combination with mitral stenosis [►Lutembacher's syndrome]). Primum ASD's (15%) occur, if the primum septum does not fuse with endocardial cushions resulting in a defect at the base of the interatrial septum. They are usually associated with VSD and anomalies of the AV valves. Sinus venosus defects (10%) are due to overriding of the interatrial septum by either the superior or inferior vena cava. They are usually associated with partial anomalous drainage of the right upper lobe pulmonary veins into the right atrium. The commonest VSD defect is membranous (70%). Other VSD defects include muscular portion of the septum (20%), below the aortic valve (5%) and near the junction of the AV valves (5%). A PFO is a flaplike opening as a result of failure of fusion of the septum primum and secundum after birth. They may be associated with atrial septal aneurysm and Chiari networks.

## Prevalence

ASD occurs in 1 per 2,000; VSD in 0.5 per 1,000 adults and PFO in 25–30% of normal adult hearts.

## Molecular and Systemic Pathophysiology

ASD's and VSD's result in intra-cardiac shunting of blood, the direction and magnitude of which are determined by the size of the defect and the relative compliance of the pulmonary and systemic circulations (Table 1). ASD's and VSD's usually result in left to right shunting but large defects (in particular large VSD's) may result in elevation of the pulmonary vascular resistance such that it equals or exceeds the systemic vascular resistance in which case bidirectional or right to left shunting may occur resulting in cyanosis. VSD's but not ASD's are prone to infections (endocarditis). Small ASD's and VSD's are generally asymptomatic. A large ASD may cause fatigue, dyspnea on exertion, supraventricular arrhythmias, right heart failure, paradoxical embolism or recurrent pulmonary infections. Depending on pulmonary vascular resistance large VSD's may lead to either left heart failure or pulmonary hypertension and right heart failure. The vast majority of PFO's are asymptomatic and of no hemodynamic consequence. Persistent or transient elevation of right atrial pressure may lead to right to left shunting and rarely paradoxical embolism and cryptogenic stroke. Left to right shunting does not occur with a PFO.

## Diagnostic Principles

Electrocardiographically ASDs often have a right axis deviation and incomplete right bundle-branch block. Left axis deviation occurs with ostium primum. VSD's generally have a normal ECG if the defect is small. A large VSD may show left atrial and left ventricular enlargement. If pulmonary hypertension ensues there maybe right axis deviation with right atrial and ventricular enlargement. PFO's generally have a normal ECG. The chest x-ray in a significant ASD or VSD may show

**Intra-cardiac Shunts. Table 1** Cardiac shunt types and their associated characteristics, diagnostic and therapeutic modalities

| Cardiac shunt | Types | Prevalence | Symptoms | Diagnosis | Therapy |
|---|---|---|---|---|---|
| ASD | Secundum; primum; sinus venosus | 1 in 2,000 | *Small*: asymptomatic: *large*: fatigue, dyspnea, supraventricular arrhythmia, right heart failure, paradoxical embolism | ECG<br>CXR<br>Transthoracic or transoesophageal echocardiography<br>Cardiac catheterization | Percutaneous or surgical closure |
| VSD | Membranous; muscular; infra-aortic valve; atrial-ventricular valves | 0.5 per 1,000 | *Small*: asymptomatic; *large*: left heart failure, pulmonary hypertension with right heart failure | ECG<br>CXR<br>Transthoracic or transoesophageal echocardiography<br>Cardiac catheterization | Surgical or percutaneous closure |
| PFO | | 25–30% | Paradoxical embolism, cryptogenic stroke | ECG<br>Transoesophageal echocardiography with contrast injection | Medical therapy for secondary prevention of stroke; surgical or percutaneous closure |

features of pulmonary plethora or more rarely pulmonary hypertension with enlargement of the proximal pulmonary arteries, rapid tapering of the peripheral pulmonary arteries and oligemic lung fields. Transthoracic and transoesophageal echocardiography are the modalities of choice to confirm the presence, location, magnitude and shunt direction of ASD's or VSD's, as well as assessment of chamber enlargements and other cardiac abnormalities. PFO can generally only be definitively diagnosed with transoesophageal echocardiography augmented by valsalva maneuver and contrast injection. Cardiac catheterization can confirm the presence and location of ASD's and VSD's, determine the magnitude of shunting and the pulmonary vascular resistance.

### Therapeutic Principles

ASD closure can be performed either percutaneously using a closure device or surgically. VSD closure is generally performed surgically but small defects may be closed percutaneously. If the ratio of pulmonary to systemic vascular resistance exceeds 0.7, the surgical risk for ASD or VSD closure is high. Therapeutic options for secondary stroke prevention in patients with PFO include therapy with anti-platelet agents or anticoagulation, and surgical or percutaneous closure of the defect.

# Intussusception

Alexander K. C. Leung[1], Andrew L. Wong[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Department of Surgery, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Intussusception involves the invagination of a proximal segment of bowel (the intussusceptum) into a more distal segment (the intussuscipiens) (Fig. 1).

More than 80% of cases of intussusception are ileocolic [1]. Typical presenting features include colicky abdominal pain, irritability, lethargy, vomiting, and passage of "currant-jelly" stool [1]. Children with intussusception sometimes also have fever and diarrhea, which may create diagnostic confusion and delay. The pathognomonic sign is an elongated mass in the right upper quadrant or epigastrium with a feeling of emptiness in right lower quadrant (Dance sign) [1]. If the intussusception has traveled far enough, its apex may be felt, especially on bimanual rectal examination.

## Prevalence

Intussusception occurs most frequently in infants between the ages of 5 and 12 months. The incidence is reported to be between 0.3 and 2.5 cases per 1,000 live births in North America, Europe and Australia [2]. The male to female ratio is approximately 3:2 [1]. Intussusception is slightly more common in white than in black children [1].

**Intussusception. Figure 1** Intraoperative finding of a 3-year-old boy with intussusception. Note the invagination of the intussusceptum into the intussuscipiens.

## Molecular and Systemic Pathophysiology

Most cases are idiopathic. Some experts believe that hypertrophy of Peyer patches from an antecedent viral infection may be responsible. Intussusception has been associated with the use of antibiotics and a rotavirus vaccine (RotaSheild®) [3,4]. Recognizable pathologic lead points for intussusception are found in about 2–10% of cases [1]. The most common is a Meckel diverticulum, followed by intestinal polyp, duplication, and appendix. During the invagination, the mesentery is dragged along into the distal lumen and the mesenteric blood vessels are compressed between the layers of the intussusceptum. This results in venous congestion leading to an outpouring of mucous and blood from the intussusceptum. If reduction of the intussusception does not occur in time, the ischemia may lead to gangrene and perforation of the bowel [5].

## Diagnostic Principles

Plain abdominal radiographs may show dilated loops of intestine, air-fluid levels, paucity of air in the right lower quadrant, minimal faucal content, and a soft tissue mass in the right or mid abdomen. Abdominal ultrasonography is a sensitive noninvasive diagnostic tool and is very reliable in experienced hands. The diagnostic findings include a tubular mass ("sandwich" or "pseudokidney" sign) in longitudinal views and a target appearance ("doughnut" sign) in transverse views [1]. If doubt remains, the diagnosis can be confirmed by radiography with barium or air insufflation; both procedures are diagnostic as well as therapeutic. A barium enema shows a filling defect or cupping in the head of barium, where its advance is obstructed by the intussusceptum. An air enema, however, is the procedure of choice as it is safer, less expensive, and easier to perform than a barium enema and involves less radiation exposure.

## Therapeutic Principles

The reduction rate with an air or barium enema is approximately 80%. The bowel perforation rate ranges from 0.1–0.2% to 0.5–2.5% for air enema and barium enema, respectively. For air enema, air pressure must be monitored during air reduction; the maximum is 110 mm Hg in children and 80 mm Hg in infants. Both types of reduction should be attempted only under controlled conditions. Evidence of peritonitis, intestinal perforation, shock, advancing sepsis, and possible gangrenous bowel precludes pneumatic or hydrostatic reduction. Unsuccessful pneumatic or hydrostatic reduction, shock, peritonitis, intestinal perforation, and demonstration of a pathologic lead point are indications for laparotomy. Preoperative measures include nasogastric decompression and administration of intravenous fluids and broad-spectrum antibiotics. Reduction can usually be

accomplished be gentle distal pressure, which milks the intestine out of the intussuscipiens. Pulling out the intussusceptum should never be attempted. An appendectomy is performed after reduction, because the blood supply to the appendix is often compromised. Bowel resection is indicated if the bowel is nonviable, a pathologic lead point is found, or the reduction is unsuccessful. A primary end-to-end anastomosis can usually be performed after the resection.

# Inv Dup(15)

Alessandra Baumer, Albert Schinzel
Institute of Medical Genetics, University of Zurich, Schwerzenbach, Switzerland

## Synonyms

Inv dup(15)(q13); Partial tetrasomy 15(pter-q13); Additional marker chromosome 15

## Definition and Characteristics

The additional inversion duplication chromosome 15 with breakpoint at 15q13 is one of the most frequent marker chromosomes in humans. Characteristic features include severe mental retardation, untreatable epilepsy and lack of a specific dysmorphic phenotype.

## Prevalence

The disorder occurs in ~1/50,000 live births.

## Genes

A number of genes at 15q11-q13 may be involved in the disorder, including the imprinted genes E6-associated protein ubiquitin-protein ligase gene: UBE3A (MIM: 601623); Small nuclear ribonucleoprotein polypeptide N: SNRPN (MIM: 182279).

## Molecular and Systemic Pathophysiology

The genetic basis of the origin and mechanism of formation is a segment at 15q13 with specific repeats. Rearrangements between the homologues or between chromatids may result in different chromosome aberrations, particularly the Prader-Willi and Angelman syndrome due to (paternal and maternal, respectively) deletion, a tandem duplication of segment 15q11.2-q13 and the additional inv dup(15)(q13) chromosome resulting in tetrasomy for segment 15pter-q13 [1]. The aberration almost invariably stems from an initial trisomy 15 due to maternal meiotic nondisjunction and subsequent inversion duplication formation [2]. The impact of triplication of known genes within the critical segment, e.g., SNRPN and UBE3A on the phenotype is not understood. Since in all so far investigated cases the extra chromosome was of maternal origin, it seems possible that paternal triplication of this region is lethal in utero.

## Diagnostic Principles

The main criteria for the clinical diagnosis are presence of an extra chromosome in the karyotype, which by molecular cytogenetic techniques can be shown to be a mirror-symmetric inv dup(15)(q13), and a nonspecific phenotype associated with severe to profound mental retardation associated with personality disorders (hyperactivity, aggressivity, self-mutilation, autistic features) and untreatable seizures. Dysmorphic signs may include: downslanting palpebral fissures, epicanthic folds, high palate, clinodactyly of little fingers and partial 2/3 syndactyly of toes.

The molecular diagnosis of inv dup(15) is based on the analysis of the methylation status at SNRP(N) or microsatellite analysis. Quantitative, or semi quantitative, evaluations are needed for both methods since a dosage difference between the paternal alleles is expected (e.g., for the methylation test at SNRPN): depending on the parental origin of the inv dup(15) the results will show either an excess of paternal alleles or of maternal alleles (i.e., in the SNRPN methylation test, either PCR products representing the non-methylated or the methylated alleles, respectively) [3].

## Therapeutic Principles

No therapy is available. Severe seizures may be treated with anticonvulsive drugs. Physiotherapy and ergotherapy are recommended.

# Inv Dup Del (8p)

Orsetta Zuffardi[1], Roberto Ciccone[1], Roberto Giorda[2]
[1]Genetica Medica, Università di Pavia, Pavia, Italy
[2]Molecular Biology Laboratory, E. Medea Scientific Institute, Bosisio Parini, Lecco, Italy

## Synonyms

8p Inverted duplication; 8p Mirror duplication

## Definition and Characteristics

Early studies on patients with the inv dup del (8p) showed that this rearrangement is characterized by an inverted duplication associated with a deletion of the distal portion of 8p (8p23.2-pter). Further molecular studies [1] demonstrated that in all cases there is a normal region ("single copy region") between the deletion and the duplication region. At variance with the deleted and single copy regions that always have the same size of about 7 and 3.5 Mb, respectively, the duplicated region ranges in different subjects from about 10 Mb to the centromere. In the latter case, the abnormal chromosome 8 ends with an inactive centromere detectable by FISH with an alphoid probe (Fig. 1a).

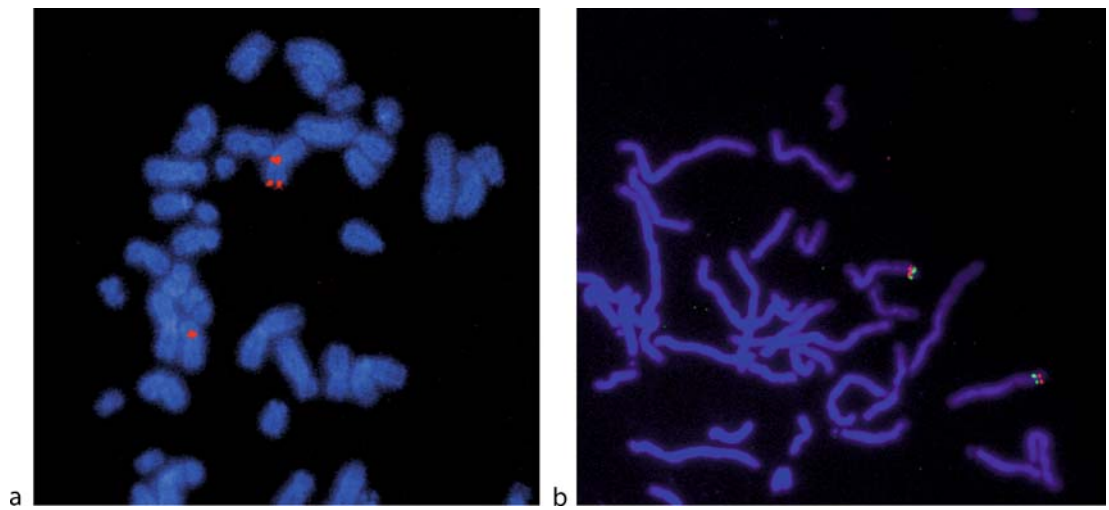
## Prevalence

The recurrent inv dup del(8p) rearrangement has an estimated frequency of around 1:10,000–20,000 newborns. In all cases, parents have an apparently normal karyotype.

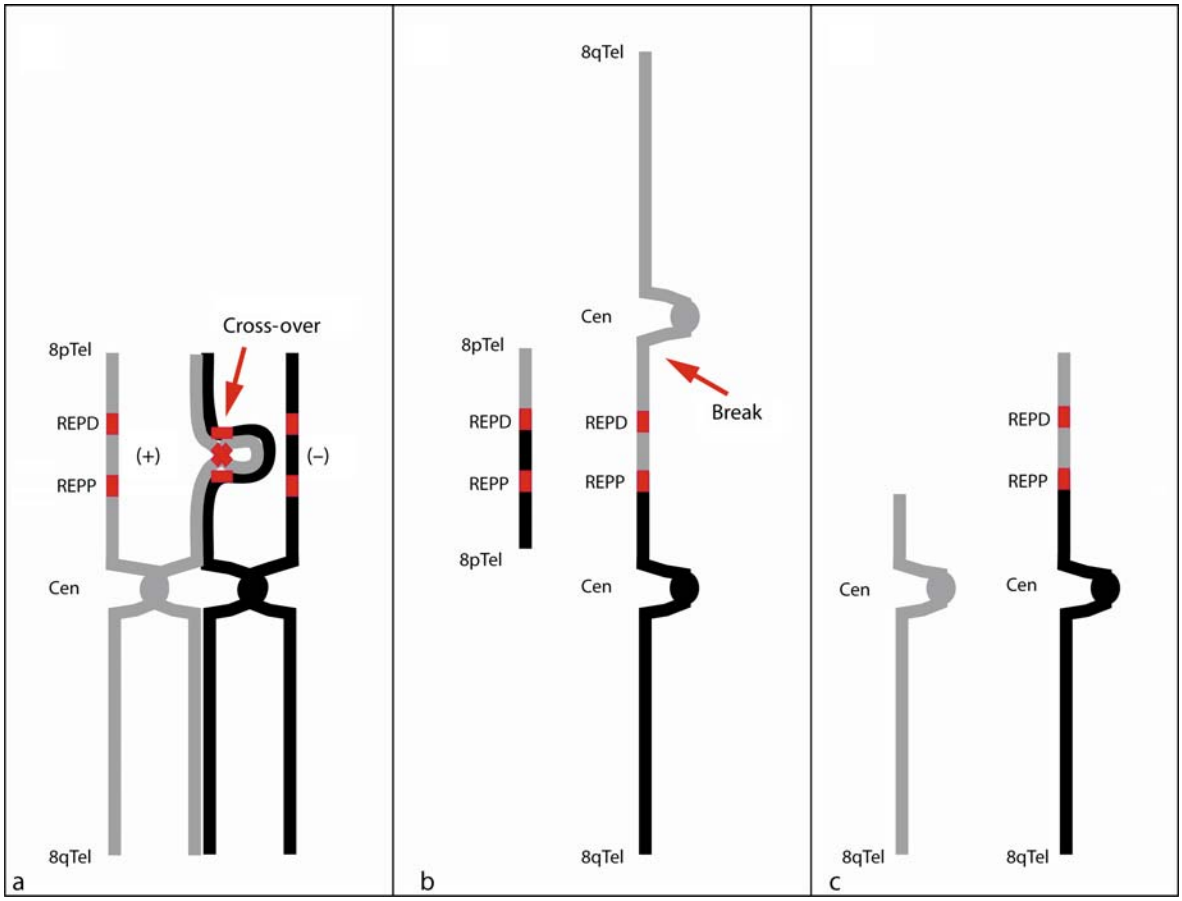
## Genes

We hypothesize that the inv dup del(8p) was not the first product of the meiotic parental recombination. Rather, an abnormal meiotic recombination (Fig. 2a) would initially lead to the formation of a dicentric chromosome with the two duplicated regions separated by a single copy region and a distal 8p23.2 deleted region (Fig. 2b); the breakage of the dicentric chromosome 8qter-8p23.1::8p23.1-8qter would then lead to the formation of an inv dup del(8p) and of a chromosome 8 deleted for part of its short arm (8p-) (Fig. 2c).

The finding of fetuses and patients carrying del(8p)/inv dup del(8p) mosaicisms [2] indeed suggests that the dicentric chromosome may be inherited by the zygote and that it might persist as such in the early postzygotic stages, then undergo diverse breakages in different cells leading to either deleted or duplicated



**Inv Dup Del (8p). Figure 1** (a) FISH with the alphoid probe specific for chromosome 8 showing a second hybridization signal on the tip of the inv dup del chromosome; (b) Dual-color FISH with probes RP11-399J23 (green) and RP11-589N15 (red) showing the heterozygous paracentric inversion at 8p23.1.



**Inv Dup Del (8p). Figure 2** Mechanism of inv dup del(8p) formation. (a) Abnormal meiotic pairing between chromosomes 8 in a subject heterozygous (+/–) for the REPD/REPP inversion and non-allelic homologous recombination between the LCRs leads to the formation (b) of an acentric der(8p) and a dicentric 8qter-8p23.1::8p23.1-8qter chromosome. Breakage of the dicentric chromosome leads to the creation (c) of 8p- and inv dup del(8p) chromosomes. The REPD and REPP LCRs are indicated by red boxes. The recombination and breakage locations are shown by arrows.

abnormal chromosomes. The fact that the original inv dup del(8p) originated from a dicentric chromosome led us to hypothesize that the reciprocal analphoid chromosome (Fig. 2b) might be present in some subjects, provided that it had acquired a neocentromere. From a literature review we were able to identify two such cases where the analphoid chromosome was a supernumerary marker in mosaic with a normal cell line [3].

Molecular definition of this marker (+der(8p)) demonstrated that it was exactly the reciprocal of the dicentric chromosome 8 and that both rearrangements were mediated by a pair of highly homologous olfactory receptor (OR)-containing low copy repeats (LCRs) mapping to 8p23.1 and lying at a distance of about 3.5 Mb [3]. Thus, the rearrangement originated as a classical genomic disorder [4] mediated by non-allelic homologous recombination between two segmental duplications constituted by the LCRs. The rearrangements, as demonstrated by microsatellite analysis of the trios, were of maternal origin in 29 of the 30 cases we analyzed. They originated through interchromosomal recombination in 19 cases, through interchromatidic recombination in seven cases; in four cases we could not determine the chromosomal origin ([1] and our unpublished data). Comparison of the two OR-containing LCR sequences having a size of 1.1 Mb (distal repeat, REPD) and 0.8 Mb (proximal repeat, REPD) revealed that the two repeats show strong relative identity with complex direct and inverted orientations.

## Molecular and Systemic Pathophysiology

According to classical cytogenetics, the production of two reciprocal rearrangements, one dicentric and

the other acentric, could only result following a crossover within a paracentric inversion. We studied the apparently normal chromosomes 8 in the parents who transmitted the abnormal 8 (18 cases with inv dup del(8p) and one case with +der(8p)) by fluorescent *in situ* hybridization and discovered that a heterozygous paracentric inversion with the same breakpoints of the dicentric and acentric chromosomes was present in all of them (Fig. 1b). Population studies revealed that the 8p23 inversion is present in the heterozygous state in 26% of the Europeans [3] and in 39% of the Japanese [5]. Thus, the inversion represents a genomic polymorphism that, in the heterozygous state, renders misalignment and abnormal recombination more likely, just as it occurs in cytogenetically identifiable inversions. In other words, the inversion makes an individual susceptible to the formation of a *de novo* chromosome rearrangement (inv dup del (8p) and +der(8p)).

An unexpected finding is that all subjects with either inv dup del(8p) or +der(8p) are single cases in their families, although all mothers who transmitted the anomalous chromosome are carriers of the inversion and, therefore, one would anticipate a recurrence of the event. However, if we consider the analphoid chromosome, the occurrence of a neocentromere is a rare event. Thus most of the zygotes containing a +der (8p) will lose it very soon, thus acquiring a normal chromosome complement. As to the dicentric chromosome, it seems very likely that most of the deleted chromosomes 8 derived by its breakage will not be compatible with embryonic development, resulting in premature termination of the pregnancy. Moreover, we may assume that if in the dicentric the inactivation, and ensuing stabilization, of one centromere occurs very early the resulting embryo will be trisomic for an almost entire chromosome 8. It has been clearly demonstrated that survival of trisomy 8 is possible when the aneuploid cell line arises relatively late in development. Thus, embryos with trisomy 8 owing to the presence of a dicentric chromosome are expected to be prematurely aborted. Because no evidence of increased spontaneous abortion has been found in mothers of inv dup del(8p) subjects, we postulate that trisomy 8 results in preclinical abortion.

## Diagnostic Principles

The inv dup del(8p) is diagnosed by conventional cytogenetics analysis. The confirmation of the rearrangement must be done by FISH with probes distal to REPD that are expected to be deleted and probes proximal to REPP that are expected to be duplicated. Genome-wide arrays may also be used to confirm the rearrangements.

## Therapeutic Principles

No therapy available.

## Iodine Deficiency and Excess

Elio Roti
Istituto di Endocrinologia, University of Milano, Milan, Italy

### Definition and Characteristics

Iodine is a trace element, essential for thyroid hormone synthesis. In adults, the recommended daily iodine intake is 150 µg. Iodine excess may induce both hypothyroidism and hyperthyroidism. Approximately 1 mg/day, the smallest amount of iodide administered to euthyroid subjects with adequate iodine intake, may induce thyroid dysfunction. Excess iodine may be due to treatment with antiseptic containing iodine, radiology contrast agents and amiodarone. All these substances release large amounts of iodine. In patients with iodine-deficient goiter thyroid dysfunction may occur also following the intake of small amounts of iodine, such as following iodine prophylaxis.

### Prevalence

The prevalence of iodide-induced hypothyroidism in subjects with normal thyroid function is very rare. In contrast the prevalence of iodide-induced hypothyroidism is very frequent in subjects with underlying thyroid diseases. The prevalence of iodide-induced hyperthyroidism has been estimated to increase 1.7% after iodine prophylaxis. In subjects with adequate iodine intake, this is a rare phenomenon.

### Molecular and Systemic Pathophysiology

Iodide-induced hypothyroidism occurs mainly in euthyroid subjects with underlying thyroid diseases such as, Hashimoto's thyroiditis, after a previous episode of subacute thyroiditis, post-partum thyroiditis, transitory episodes of thyroid dysfunction induced by amiodarone, and interferon, in euthyroid subjects previously treated for Graves' disease, and in the newborn. In these conditions, the thyroid fails to escape the inhibitory effect of iodide on the organification of iodine, the so-called acute Wolff-Chaikoff effect. It has been proposed that iodopeptides are formed temporarily to inhibit thyroid peroxidase mRNA and proteins synthesis and, therefore, thyroglobulin iodination. In general, iodide-induced hypothyroidism is a temporary phenomenon, and thyroid resumes normal function after iodine excess withdrawal [1–3].

Iodide-induced hyperthyroidism is not a single entity. It may occur in patients affected by iodine-deficient goiter when exposed to excess iodine. In these patients, the presence of autonomous thyroid function induces an increased synthesis and release of thyroid hormones. Iodide-induced hyperthyroidism has been reported in euthyroid subjects previously treated for Graves' disease. In these patients, iodine excess may trigger the appearance of circulating anti-TSH antibodies and, therefore, hyperthyroidism. Occasionally, iodide-induced hyperthyroidism has been observed in euthyroid subjects with previous episode of thyroid dysfunction induced by amiodarone and interferon and in subjects without any underlying thyroid disease [4].

### Diagnostic Principles

A positive history of excess iodine intake is required for both iodine-induced hypothyroidism and hyperthyroidism. Elevated serum TSH concentrations are diagnostic for the presence of hypothyroidism. Suppressed serum TSH and elevated FT4 and FT3 concentrations are diagnostic for hyperthyroidism. In both conditions, radioactive thyroid iodine uptake is usually absent; however, normal and exceptionally elevated values have also been observed. Urinary iodine concentrations are increased in these pathological conditions.

### Therapeutic Principles

Iodide-induced hypothyroidism disappears after iodine withdrawal. Levo-thyroxine is necessary when hypothyroidism is permanent. Iodine-induced hyperthyroidism is rarely corrected by iodine withdrawal; therefore, antithyroid treatment with methimazole and propylthiouracil is required. In some cases, thyroidectomy and radioactive iodine treatment may be necessary.

# Iodine-related Disease States

Klaus Schümann[1], Josef Köhrle[2]
[1]Technical University Munich, Munich, Germany
[2]EnForCé, Charité, University Hospital, Berlin, Germany

## Definition and Characteristics

Iodine is an essential trace element for humans. It is part of the thyroid hormones T3 and T4 which influence growth, development, energy metabolism, and thermoregulation as well as many metabolic reactions.

## Prevalence

Less than 2% of the German population had an adequate iodine intake in 1996 and 30–50% of German adults had an increased thyroid volume. More recently, German children seem almost adequately supplied with iodine due to increasing use of iodinated salt in households, commercial food, and bakery products [1,2].

## Molecular and Systemic Pathophysiology

*Homeostasis*: Iodine is well absorbed in the small intestine. Its status, thus, depends on iodine intake (WHO recommendation: 20 μg I/kg body weight), which is high in populations with ample sea-fish and seafood consumption, e.g., in Japan. Iodine accumulates in the thyroid gland. This is due to Na/K-ATPase-driven active transport via a specific Na/I symporter (NIS) in the basolateral plasma membrane of the thyrocyte. NIS is a highly glycosylated 618-amino acid intrinsic membrane protein, mutations of which (e.g., T354P) cause human congenital hypothyroidism. Moreover, NIS is blocked by goitrogens inducing thyroidal growth (e.g., thiocyanate, isothiocyanate, and goitrin in brassica vegetables and cassava, Kojic acid used to ferment soy products, chlorate, and nitrate) [3]. Iodine export from the thyreocyte is mediated by the iodide channel protein Pendrin and the apical iodide transporter. Iodine is oxidized by thyroperoxidase (TPO), a hemoprotein at the extracellular surface of the thyrocytes apical membrane. The oxidation step requires $H_2O_2$, the availability of which is geared to the demand by regulated expression of thyroxidase (ThOx), an NADPH-dependent oxidative flavoprotein. TPO also mediates oxidative coupling of mono- and diiodotyrosine residues of thyroglobulin to 3,3′,5-triiodo-L-thyronine (=T3) and 3,3′-5,5′-tetraiodo-L-thyronine (T4). This process is also inhibited by goitrogens [3]. In addition, bromide may block TPO function, and copper chelation reduces its expression via the redox-regulated transcription factor Pax 8. During the process of hormone biosynthesis, the tyrosine residues remain bound in the polypeptide chain of thyreoglobulin that is synthesized and excreted by the thyreocyte into the follicular lumen forming the thyrocolloid. Iodinated thyreoglobulin is subsequently taken up by the thyreocyte via pinocytosis upon thyrotropin (TSH) stimulation under hormonal regulation. It is degraded in secondary lysosomes by cathepsins to release T3 and T4 which, in turn, are excreted into the circulation by still unknown efflux mechanisms [4].

T3 and T4 are bound to thyroxine-binding globulin (TBG), transthyretin (TTR), and albumin in the plasma. T4 is a preform of T3 with a half-life of 7 days. It is deiodinated by two seleno-enzymes, the type I and type II iodothyronine-5′-deiodase, to form the bioactive hormone T3 (half-life 1 day). T3 exhibits hormonal function via T3 receptors (TRα1, TRβ1, TRβ2) in mitochondria and nuclei, where it regulates the expression of T3-dependent genes and proteins [4].

A high percentage of total iodine body content (~10–20 mg) is stored in thyroid tissue; some is stored in hepatic lysosomes, nuclei, and mitochondria of other organs which, however, cannot accumulate high concentrations of iodine because of the lack of TPO. NIS is expressed in salivary and breast glands as well as in some intestinal cells. Macrophages and leukocytes partly iodinate bacterial proteins after NADPH-dependent oxidation in phargosomes, which increases antigenicity of these proteins. T4 and T3 are inactivated by 5-deiodase type III or by glucuronidation or sulfation of iodothyronines in 4′-position. Ninety percent of body iodine is excreted with the urine.

*Thyroidal Autoregulation*: Thyroidal sensitivity to thyrotrophin (synonym: thyroid stimulating hormone = TSH) depends on the thyreocyte's iodine content. TSH is synthesized in the hypophysis after stimulation by the hypothalamic thyrotrophin-releasing hormone (TRH) which, in turn, is stimulated by T3/T4 deficiency. TSH acts via a G-protein coupled receptor in the thyreocyte's basolateral membrane. This protein consists of 398 amino acids, forms 7 transmembranous domains and 1 intracellular domain. It is encoded by a 60-kb gene and stimulates T3 and T4 synthesis as well as the secretion and expression of thyroglobulin, TPO, and THOx via the cAMP cascade. Signal transduction can be blocked by fluoride. The TSH receptor is target of autoantibodies in autoimmune thyroid disorders which preferentially affect women. Iodinated lipids (δ-iodolactone, α-iodohexadekane) reduce NIS expression and inactivate TPO, resulting in reduced iodide uptake into the thyreocyte. This effect named after Wolff-Chaikoff is used to limit thyroidal uptake of radioactive iodide after accidental exposure [4].

*Iodine Deficiency*: Severe iodine deficiency in adolescents and adults can lead to myxedema and

myxedematous coma. To compensate for chronic iodine deficiency, TSH stimulates thyroidal growth leading to goiter formation, which may compress trachea and esophagus. Moreover, TSH overstimulation during chronic iodine deficiency may produce autonomous thyroidal tissue ("hot" nodules or disseminated tissue), that is it is no longer under TSH regulation and produces T3/T4 continuously and at high rates. Thus, if iodine intake increases, e.g., with pharmaceuticals such as iodinated X-ray contrast media or the iodine-rich antiarrhythmic drug Amiodaron®, autonomous T3/T4 synthesis may lead to hyperthyroidism or even thyrotoxicosis. Moreover, iodine deficiency increases the risk for adenoma and cancer as well as for abortion, foetal malformation, stillbirth, and neonatal cretinism [1,4].

## Diagnostic Principles

Urinary iodine concentration is the most frequently used parameter in epidemiological studies while serum iodine concentration is more reliable to determine individual iodine status. The colorimetric cer-asenite method, HPLC, and neutron activation are used for iodine determination. Thyroidal dysfunction can be located by pertechnate-$^{99}$m scintigraphy. T4 and T3 serum concentrations are determined by enzyme- or radioimmunoassays, serum TSH by immunoradiochemical or chemoluminiscence methods, if necessary after TRH stimulation [5].

## Therapeutic Principles

In deficiency, iodine has to be supplemented. On an epidemiological scale, this can be achieved by consumption of iodinated salt, which contains 15–25 mg I/kg as $KIO_3$ and which can be stored for longer periods than after KI fortification. Iodine tablets should be used for individual supplementation, in particular during pregnancy and lactation under control of thyroid status [2,4].

# Iron Deficiency

Klaus Schümann[1], Günter Weiss[2]
[1]Technical University Munich, Munich, Germany
[2]Department of Internal Medicine I, Medical University, Innsbruck, Austria

## Definition and Characteristics

Reduced body iron content due to deficient dietary iron absorption, increased iron demand during growth and pregnancy, or after iron losses via bleeding [1].

## Prevalence

World wide iron-deficiency affects ~2 billion people [2]. The prevalence of iron-deficiency anaemia in children and women of childbearing age in developing countries is 30–60%, ~50% of all anemias being due to iron-deficiency. In industrialised countries, the prevalence is much lower, e.g., 0.2% and 2.6% in US adult males and females, respectively [3].

## Genes

Signals orchestrating gene expression of the involved proteins encompas modŭlation of transcription, mRNA stability, translation and post-translational modifications as sketched above [4]. Our understanding of these processes and their interaction with e.g. inflammation and with the genes involved in ►Hemochromatosis, hereditary evolves rapidly.

## Molecular and Systemic Pathophysiology

Approximately 60% of body iron is bound in erythrocyte haemoglobin, ~13% function in myoglobin and iron-dependent enzymes and 20–30% is storage iron. Accordingly, iron deficiency leads to hypochromic, microcytic anaemia, impaired muscular $O_2$-utilisation and decreased cytochrome C-dependent cellular ATP production. These changes reduce physical and intellectual work capacity. Moreover, iron-deficiency impairs electron transfer and proper myelinisation of the white matter. Lack of the iron-dependent amino acid monoxygenases disturbs neuronal transmitter metabolism. Psychomotoric development and cognitive performance are reduced in children that were anaemic at an age of 12–18 months. Lack of iron-dependent ribonucleotide-reductase may impair DNA-synthesis and, thus, cellular immune response, function of organs with rapid cell turn-over, and may lead to reduced birth weight and increased perinatal mortality [1].

Malabsorption (short bowel syndrome, sprue), atrophic gastritis with reduced acid production and gastrectomy reduce iron absorption. Moreover, nonhaem-iron absorption varies by a factor of 10 depending on food ligands in the lumen. Such ligands either inhibit absorption by tight binding (e.g., phytates in rice, maize, or grains; polyphenols and tannins in tea and coffee) or promote it by preventing the formation of non-absorbable iron hydroxides (e.g., ascorbate, citrate and fumarate in fruits; amino acids (e.g., cysteine) and oligopeptides resulting from meat digestion). Vegetarian food staples in the Third World such as rice, corn and cereals are rich in inhibitory ligands [5]. This explains the high prevalence of iron-deficiency anaemia. The absorption of haem-iron from meat, fish, and poultry is much less affected by dietary components with the exception of calcium. Iron losses via bleeding due to chronic parasite infection (e.g., hook worms) may add to iron-deficiency [1,3].

To compensate for reduced iron availability nonhaem-iron absorption increases from 10 to 20% in iron deficiency. Iron deprivation increases iron uptake from the intestinal lumen by increased expression of the Divalent Metal Transporter 1 (DMT-1), as regulated by the Iron Regulating Element/Iron-Regulatory-Protein (IRE/IRP) mechanism. DMT-1 is a trans-membrane protein and mediates proton-coupled uptake of divalent metals from the lumen, such as Fe(II). Dcytb, a membrane-bound homologue of cytochrome b561, reduces Fe(III) to the divalent state and is usually in sufficient abundance, though it expression increases in iron-deficiency and hypoxia. Little is know on Fe-shuttling through the enterocytes. Haem-iron uptake from the intestinal lumen was proposed to be mediated by a haem carrier protein (HCP1) which, however, also seems to mediate folate transport. Haem is degraded in the enterocyte by a microsomal haem-oxygenase (HO-1) and its iron enters the cytosolic non-haem iron pool. Iron export from the enterocytes is mediated by ferroportin, the expression of which is regulated by the IRE/IRP motive and increases in iron deficiency. Moreover, decreased hepatic hepcidin production under iron-limiting conditions goes along with lacking inhibition of ferroportin function and increases intestinal iron absorption. Copper-dependent hephaestin oxidizes Fe(II) to Fe(III) in the basolateral membrane so that it can bind to transferrin and enter cells via the transferrin receptor (TfR). TfR-expression, in turn, increases in iron-deficient cells as mediated by the IRE/IRP mechanism to improve cellular iron supply [1].

## Diagnostic Principles

Anaemia is quantified by haemoglobin determination and erythrocyte counts. Reduced iron stores go along with low serum ferritin concentration (<12 µg/L) and transferrin (Tf)-saturation (<15%). Serum ferritin

indicates the size of iron stores. Moreover, is an acute phase protein reacting to cytokines and, therefore, requiring adequate control for inflammatory interference (e.g., CRP, leukocytes). Circulating Transferrin Receptor (TfR) indicates iron-deficient erythropoiesis, i.e., insufficient iron-delivery to the bone marrow. It increases in iron-deficiency (>6 ng/dL). Plasma iron, Tf-saturation, free and total iron binding capacity show high circadian and day-to-day variations. Iron-deficiency of unexplained cause may be due to occult blood losses (e.g., gastric ulcers, colonic carcinoma) which require careful diagnosis [1].

### Therapeutic Principles

After identification of underlying pathologic conditions and specific therapy (e.g., peptic ulcer, bleeding colonic carcinoma, parasites, myoma of the uterus) iron deficiency is cured by replacing iron losses by oral or parenteral iron supplementation. In the third world iron intake can be increased by food iron fortification [1,4]. Pharmaceutical iron supplementation should be controlled by monitoring increments in haemoglobin- and serum ferritin-concentrations.

## Iron Intoxication, Acute

Klaus Schümann[1], Günter Weiss[2]
[1]Technical University Munich, Munich, Germany
[2]Department of Internal Medicine I, Medical University, Innsbruck, Austria

### Definition and Characteristics

Acute excessive intake of pharmaceutical iron preparations with severe pathological damage.

### Prevalence

Intoxication associated with excessive iron intake is a common cause of poisoning death in children and occurs in ~0.1% of patients exposed to oral iron preparations [1].

### Molecular and Systemic Pathophysiology

Ingestion of an acute overdose of pharmaceutical iron preparations causes mucosal lesion in stomach and intestine due to direct coagulating effects. Excessively absorbed iron leads to capillary leakage, heart failure and shock. It causes hepatocellular necrosis, coagulopathies, and hepatic failure [1] most likely by direct iron mediated catalysis of hydroxyl radical formation and iron-induced lipid peroxidation. Oral iron at doses of 180–300 mg Fe/kg b.wt. can be fatal; at doses below 10–20 mg Fe/kg b.wt. it causes no acute toxicity.

### Diagnostic Principles

History of acute iron intake, serum iron >500 μg Fe/100 ml, pink urine after application of the chelator desferrioxamin [1].

### Therapeutic Principles

Introduction of desferrioxamin, a parenterally applied iron chelator as a therapeutic principle, reduced the mortality rate from >50% to <2%. In children, this treatment is combined with bowel irrigation and gastric lavage at doses over 50 mg Fe/kg as well as management of shock, coagulopathy and organ failure [2,3].

Irritable bowel disease; Functional bowel disease; Irritable colon; Nervous bowel; Spastic bowel; Spastic colitis

## Definition and Characteristics

The irritable bowel syndrome is defined on the basis of the recently modified Rome III criteria (2006) as the presence of recurrent abdominal pain or discomfort that cannot be explained by structural or biochemical abnormalities at least 3 days per month during the previous 3 months and that is associated with two or more of the following features: pain is relieved with defecation, its onset is associated with a change in the frequency of bowel movements (diarrhea or constipation), or a change in stool form or appearance (loose, watery, pellet like) [1]. Supporting symptoms include the following: altered stool frequency, altered stool form, altered stool passage (straining and/or urgency), mucorrhea, abdominal bloating, or subjective distention.

## Prevalence

In the USA, population-based studies estimate the prevalence of irritable bowel syndrome at 15% and the incidence at 1–2% per year. Of people with irritable bowel syndrome, approximately 25% seek medical care [1,2]. An estimated 20–50% of gastroenterology referrals relate to this symptom complex.

## Genes

A single genetic defect has not been reported to date but twin studies indicate that genetic factors play an important role in the development of irritable bowel syndrome. Some pharmacogenetic studies suggested a possible genetic polymorphism in the gene encoding for activity of the serotonin transporter protein (SERT), but a recently published meta-analysis (eight studies) showed no association [3].

## Molecular and Systemic Pathophysiology

The cause of irritable bowel syndrome is unknown, though pathophysiology includes altered gastrointestinal motility, visceral hyperalgesia, psychosocial factors, and an imbalance in neurotransmitters [1,2,4]. Altered gastrointestinal motility of the small intestine during fasting, such as loss of the migrating motor complex and the presence of both discrete, clustered contractions and prolonged, propagated contractions, has been described in patients with the irritable bowel syndrome [2]. Recently, microscopic inflammation has been documented in some patients. This concept is groundbreaking in irritable bowel syndrome that had previously been considered to have no demonstrable pathologic alterations. Both colonic inflammation and small bowel inflammation have been discovered in a subset of patients with irritable bowel syndrome as well as in patients with inception of irritable bowel syndrome after infectious enteritis (postinfectious). Laparoscopic full-thickness jejunal biopsy samples revealed infiltration of lymphocytes into the myenteric plexus and intraepithelial lymphocytes in a subset of patients. Neuronal degeneration of the myenteric plexus was also present in some patients. Patients with postinfectious irritable bowel syndrome may have increased numbers of colonic mucosal lymphocytes and enteroendocrine cells. Enteroendocrine cells in postinfectious irritable bowel syndrome appear to secrete high levels of serotonin, increasing colonic secretion, and possibly leading to diarrhea. After food ingestion, there is release of serotonin produced in enteroendocrine mucosa cells and the enteric nervous system, and increased levels are observed especially in irritable bowel syndrome with predominant diarrhea. This biogenic amine is inactivated by the SERT, which belongs to the family of solute carrier family 6 (neurotransmitter transporter, serotonin), member 4 (SLC6A4) transporters [5]. In one study, messenger RNA for SERT and tryptophan hydroxylase protein levels in rectal mucosa were found to be decreased in patients with irritable bowel syndrome. This led to the hypotheses that diarrhea results from the failure to inactivate serotonin and activation of receptors for serotonin that accelerate transit (5-$HT_4$ receptors) and that constipation in inflammatory bowel syndrome results from downregulation of the receptor secondary to failure to inactivate the serotonin [5]. Serotoninergic 5-$HT_3$ receptor antagonists are used to treat IBS-D while 5-$HT_4$ receptor agonists are used to treat constipation-predominant irritable bowel syndrome (IBD-C). Another finding of a recent study is that the protein p11 (calpactin 1 light chain or annexin II ligand), which is a member of the S100 EF-hand (helix–loop–helix) protein family, which share a $Ca^{++}$ binding motif, increased the localization of 5-$HT_{1B}$ receptors to the cell surface [5]. These inhibitory receptors are important because their desensitization is thought to underlie the effect of selective serotonin reuptake inhibitors in depression. Moreover, p11 expression was reduced in humans and in animal models of depression and p11 knockout mice had features of depression. P11's

role in the intestine is unknown, but in sensory nerves it increases surface expression of Nav1.8, TRVP, and TASK, all ion channels important in neural excitability. Increased surface expression of these receptors might contribute to visceral hypersensitivity, one of the most consistent findings in irritable bowel syndrome [4,5].

### Diagnostic Principles

A meticulous history is the key to diagnosis. The Rome criteria provide the construct upon which questions are based. In the majority of cases, there are no abnormalities on physical examination or laboratory testing and there are no findings of a structural disorder. Endoscopy is directed for many patients to determine inflammation or distal obstruction. Esophagogastroduodenoscopy with biopsy is indicated for a patient with persistent dyspepsia or if weight loss or symptoms suggest malabsorption or if celiac disease is a concern. Colonoscopy is indicated for patients with warning signs such as bleeding, anemia, chronic diarrhea, older age, history of colon polyps, cancer in the patient, or first-degree relatives or constitutional symptoms such as weight loss or anorexia. A screening colonoscopy should be performed according to published guidelines [1,2].

### Therapeutic Principles

The treatment of irritable bowel syndrome is notoriously unsatisfactory. None of the currently available drugs has been subjected to controlled trials conducted to modern standards [1,2]. Patients generally seek dietary advice, but specific diets or elimination diets have not been proven effective [1]. Fiber supplementation may improve symptoms of constipation and diarrhea. Individualize the treatment because few patients experience exacerbated bloating and distention with high-fiber diets. Caffeine avoidance may limit anxiety and symptom exacerbation. Lactose and/or fructose should be limited or avoided in patients with these contributing disorders. The selection of pharmacologic treatment remains symptom directed. The symptom-guided treatment of the irritable bowel syndrome includes anticholinergics, antidiarrheals, tricyclic antidepressants, prokinetics, serotonin (5-HT3) receptor antagonists, chloride-channel activators, and bulk-forming laxatives.

## Isolated FSH Deficiency

Christy T. Oswalt, Christian A. Koch
Division of Endocrinology, Diabetes and Metabolism, University of Mississippi Medical Center, Jackson, MS, USA

### Synonyms

Congenital FSH deficiency; Selective FSH beta chain deficiency; FSH beta subunit deficiency

### Definition and Characteristics

Women with isolated FSH deficiency present with delayed puberty, partial or no breast development, primary amenorrhea, infertility, with or without eunuchoid body habitus. Ovarian follicles remain in the antral stage unless treated. Ovulation may be induced with exogenous FSH.

Men with FSH deficiency present with delayed puberty, various degrees of ineffective spermatogenesis, and small, soft testes. Phenotype is milder in the Tyr76X mutation compared to the Cys51Gly and Val61X mutations [1].

### Prevalence

Rare; autosomal recessive transmission.

### Genes

The FSH beta subunit gene is on the short arm of chromosome 11 and contains three exons encoding 111 amino acids. Four mutations in exon 3 have been described.

Cys51Gly: Codon 51 missense mutation causing the substitution of glycine for cysteine.

Val61X: Codon 61 frame-shift mutation due to a 2 bp deletion altering amino acids 61–86 followed by a premature stop codon truncating amino acids 87–111.

Tyr76X: Codon 76 nonsense mutation causing the production of a truncated protein missing amino acids 76–111.

Cys82Arg: Codon 82 homozygous nonsense mutation causing the substitution of cysteine for arginine.

### Molecular and Systemic Pathophysiology

FSH is a pituitary glycoprotein necessary for pubertal development and fertility in men and women. In women, FSH is necessary for follicular growth, estrogen production via granulosa cell aromatase expression, and oocyte maturation. Granulosa cells divide and differentiate with FSH stimulation.

In men, FSH stimulates Sertoli cell proliferation and spermatogenesis and may play a role in androgen production.

FSH is a heterodimer composed of an alpha and a beta subunit. The structure is stabilized by formation of intramolecular disulfide bonds allowing the beta subunit to wrap around the alpha subunit. This seat belt region includes amino acids 84–104. Tyr76X and Val61X mutations are missing this region. All mutations identified cause disruption of the disulfide bonds preventing stabilization and dimer formation needed for receptor binding. The determinant loop involved in FSH receptor specificity requires amino acids 87–94 which are not present in the Tyr76X and Val61X mutations. Cys82Arg mutation prevents the formation of the first intramolecular disulfide bond. In the Val61X mutation the last five cysteine residues are not produced

preventing the formation of the Cys20-Cys104 disulfide bond that wraps around the alpha subunit for stabilization [2–5].

### Diagnostic Principles

- Undetectable FSH
- Elevated LH
- Elevated GnRH-stimulated LH
- Undetectable GnRH-stimulated FSH
- Low estradiol
- Normal androgens
- Sequencing of the FSH beta subunit gene

### Therapeutic Principles

Ovulation can be induced with exogenous FSH.

### Synonyms

Congenital sucrase-isomaltase deficiency; CSID; Congenital sucrose-isomaltose malabsorption; Disaccharide intolerance I; Sucrose intolerance, congenital; SI deficiency

### Definition and Characteristics

Human expression of the sucrase–isomaltase (SI) complex (E.C.3.2.1.10, E.C.3.2.1.48) is confined to the small intestine enterocytic apical brush border membrane. SI displays α-d-glucosidase activity and catalyzes the lumenal digestion of dietary starch and major disaccharides including sucrose and isomaltose, which is a prerequisite for proper carbohydrate absorption [1].

In congenital SI deficiency (CSID), the sucrase activity is strongly decreased whereas the isomaltase activity varies from absent to normal. Patients present with osmotic-fermentative diarrhea, abdominal pain, and cramps upon the ingestion of di- and oligosaccharides. Symptoms are heterogenous and in part dependent on feeding practice. Typically, infants 2–16 weeks after birth come to attention, but also a form late in onset and symptomatic in adults was reported. A secondary loss of SI activity may occur in Crohn's disease and in the course of aging.

### Prevalence

CSID results from autosomal recessive gene defects. The exact prevalence of CSID is unknown and only a few hundred cases have been reported until today. In Caucasian adults, the prevalence is about 0.2%. In indigenous Greenlanders, prevalence may be up to 5%. Heterozygotes with decreased sucrase activity and normal small-bowel morphology represent 2–9% of European Americans [2].

### Molecular and Systemic Pathophysiology

The heterodimeric SI complex originates from a single polypeptide, which becomes *N*-glycosylated to a high mannose precursor (pro-SI; MW, 210 kDa) in the endoplasmic reticulum (ER). Under normal conditions, the protein passes the ER quality control for correct

folding and then enters the Golgi compartment for further processing the *N*-linked glycans and additional O-glycosylation. The mature SI (MW, 245 kDa) is then directly targeted to the apical membrane, where it projects the active sites into the intestinal lumen. In situ cleavage by lumenal trypsin finally produces the sucrase and the isomaltase subunit (MW, 145 and 151 kDa, respectively), which remain associated by non-covalent interactions with membrane anchoring by the isomaltase subunit only.

In CSID, amino acid substitutions in the SI account for perturbations of intracellular pro-SI transport and glycosylation, missorting to the basolateral membrane or into the intestinal lumen, intracellular degradation, or functional inactivation. The first discovered and most extensively investigated CSID-associated mutation (A/C at nucleotide 3298) encodes the substitution of glutamine$^{1098}$ by prolin (Q1098P) in the sucrase subunit [3]. $SI_{Q1098P}$ accumulates within the ER/cis-Golgi intermediate compartment and the cis-Golgi, which for the first time indicated quality control of protein folding operating beyond the ER. It was suggested [4] that the (Q1098P) substitution destroys the structure of a neighbored phenylalanine cluster ($F_{1093}$-x-$F_{1095}$-x-x-x-$F_{1099}$), leading to exposure of a retention signal. Of interest, $SI_{Q1098P}$ recovered correct folding, trafficking to the plasma membrane, and normal enzymatic activity at 25°C but not at 37°C in a cell culture model. It was suggested that at the permissive temperature (25°C) sequential binding of pro-$SI_{Q1098P}$ to the molecular chaperons BiP (heavy chain binding protein) and calnexin and its cycling between ER and the cis-Golgi is restored, which allows correct processing, folding, and membrane trafficking of the mutant protein. Further CSID-associated SI amino acid substitutions include Q117R, L620P, and C635R ([2] and references therein).

## Diagnostic Principles

The diagnosis of CSID is based on the patient's presentation with osmotic-fermentative diarrhea elicited by dietary sucrose and starch dextrins. The diagnosis is corroborated by an oral tolerance test with sucrose or isomaltose, respectively, a breath hydrogen test and SI activity determination in small intestinal biopsies.

## Therapeutic Principles

Treatment in the first years of life consists of the elimination of sucrose, glucose polymers, and starch from the diet. Restriction of starch is usually unnecessary after 2–3 years of age. Enzyme replacement therapy by ingestion of bakers' yeast (Saccharomyces cerevisiae) preparations may be an effective treatment option [5].

# Isosexual Precocious Puberty

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Sexual precocity

## Definition and Characteristics

Isosexual precocious puberty is defined as the appearance of any sign of secondary sexual characteristics before the age of 9 years in boys, and before the age of 6 and 7 years in black and white girls, respectively [1]. Common findings in girls with isosexual precocity include rapid linear growth, development of breasts, feminine body contours, pubic and axillary hair, and menses. The reproductive life is usually normal and menopause may be delayed rather than premature [2]. In boys, isosexual precocity is marked by rapid linear growth, testicular and penile enlargement, development of a masculine build, acne, deepening of voice, and growth of pubic and axillary hair. Spermatogenesis has been observed as early as 5 or 6 years of age and nocturnal emissions can occur [2]. In both boys and girls, there is increased growth in height and weight and osseous maturation. The accelerated osseous maturation results in early epiphyseal closure, so that the ultimate height is less than it would have been otherwise. Dental development corresponds to the chronologic age. Intellectual and psychosexual developments are consonant with age and not with stage of sexual development [2].

## Prevalence

The incidence in the USA is approximately 0.01 to 0.05% per year [3]. The condition is more common among blacks than whites [3]. The female to male ratio is 4 to 10:1 [3].

## Genes

Potential candidate genes for central precocious puberty include the GnRH receptor gene, GRP54 receptor gene, the genes that encode the gonadotropins, the leptin gene, and the leptin receptor gene [4]. Mutations of the LH receptor can result in increased testosterone production by the Leydig cells despite low LH levels and the syndrome of familial male-limited precocious puberty (testotoxicosis) [5].

## Molecular and Systemic Pathophysiology

The causes of isosexual precocious puberty are listed below. True and central precocious puberty accounts for 80% of patients with precocious puberty. Central precocious puberty is due to premature reactivation of the hypothalamic-pituitary-gonadal axis. The onset of puberty is partially genetically determined (75%) and partially environmentally determined (25%) [4]. Pseudoprecocious puberty results from autonomous gonadal or adrenal secretion of sex hormone independent of pituitary gonadotropin stimulation or from iatrogenic administration of sex hormones [1].

Aetiologic classification of isosexual precocious puberty (Adapted from [2]):

*True and complete precocious puberty*:

- Idiopathic (sporadic or familial)
- Organic lesions of the central nervous system
  - Congenital (aqueductal stenosis, septo-optic dysplasia, empty sella syndrome)
  - Acquired (tumors, post-inflammatory, hydrocephalus, trauma, cranial irradiation)
- Part of a specific syndrome (neurofibromatosis, tuberous sclerosis, Sturge-Weber syndrome, Silver-Russell syndrome, Tay-Sachs disease, Kabuki make-up syndrome)
- Miscellaneous (hypothyroidism, Addison's disease, treated congenital adrenal hyperplasia, chronic renal failure)

*Incomplete precocious puberty (dissociated puberty)*:

- Premature thelarche
- Premature pubarche

*Pseudoprecocious puberty*:

- Ovarian or testicular tumors
- Testotoxicosis
- Adrenal hyperplasia or tumors
- Gonadotropin-producing tumors of nonendocrine sites (hepatoma, choriocarcinoma, teratoma)
- Exogenous estrogens
- Part of a specific syndrome (McCune-Albright syndrome, tuberous sclerosis)

## Diagnostic Principles

An estimation of the bone age may help to determine the child's growth potential. In addition, significantly advanced bone age is often seen in patients with true precocious puberty, adrenal or gonadal neoplasms, and congenital adrenal hyperplasia. Bone age is modestly advanced in patients with premature pubarche, compatible with chronologic age in children with premature thelarche, and retarded in patients with precocious puberty associated with hypothyroidism [2]. Skull roentgenograms are useful for assessing changes in the sella turcica, the presence of intracranial calcifications, and evidence of increased intracranial pressure. Computed tomographic or magnetic resonance imaging scans of the head is indicated in all children with true precocious puberty. Pelvic ultrasonography can help in the diagnosis of an ovarian tumor. When a metastatic hCG-producing tumor is suspected, a chest roentgenogram and a liver scan can be helpful. The initial endocrine assessment should include assays of serum FSH, LH, and estradiol or testosterone. True precocious puberty is characterized by increased basal gonadotropin and estradiol or testosterone levels, both of which are appropriate for the stage of sexual development. On the other hand, basal gonadotropin levels are low in precocious pseudopuberty, while the serum estradiol or testosterone level is usually greatly increased. The pubertal gonadotropin secretory response to GnRH is helpful in differentiating true and complete isosexual precocity from pseudoprecocious puberty, in which the response is suppressed. LH and FSH levels are normal in patients with premature thelarche and premature pubarche. Markedly elevated LH levels should suggest the presence of an hCG-secreting tumor. Levels of plasma 17-hydroxyprogesterone and its urinary metabolite, pregnanetriol, are elevated in the common forms of congenital adrenal hyperplasia, as well as in some adrenal tumors. The dexamethasone suppression test will differentiate a tumor from congenital adrenal hyperplasia. Adrenal tumors usually cause an elevation of 17-ketosteriods that are not suppressible by dexamethasone. Somatomedin-C levels are significantly elevated for age in children with precocious puberty and are similar to the levels observed during normal puberty.

## Therapeutic Principles

Treatment should be directed toward the underlying cause, if at all possible. GnRH agonists are the treatment of choice for true precocious puberty [1,3]. GnRH agonists bind to GnRH receptors on gonadotrophs with subsequent desensitization of gonadotrophs to GnRH

[1,3]. Treatment of central precocious puberty is indicated if the pubertal maturation has an early onset, if the skeletal age is advancing more rapidly than height age, or if there is significant psychosocial disturbances [2].

# Isovaleric Acidemia

Du Toit Loots
Department of Nutrition, School of Physiology, Nutrition and Consumer's Science, North-West University, Potchefstroom, South Africa

## Synonyms

Isovaleryl CoA dehydrogenase deficiency; Isovaleryl CoA carboxylase deficiency; Isovaleric acidemia; Isovalericacidemia; IVA

## Definition and Characteristics

An autosomal recessive genetic disorder of the enzyme isovaleryl-CoA dehydrogenase in leucine metabolism [1,2].

## Prevalence

The estimated prevalence in the general population of Europe is 1/100,000.

## Genes

The gene for isovaleryl-CoA dehydrogenase is assigned to human chromosome 15q14-15q [2].

## Molecular and Systemic Pathophysiology

Isovaleric acid accumulates due to a defect in the enzyme isovaleryl-CoA dehydrogenase. This metabolite is formed by deacylation of the enzyme's primary substrate, isovaleryl-CoA. The majority of isovaleric acid is converted by the action of glycine-*N*-acylase, to the non-toxic excreted metabolite, isovalerylglycine. A large number of additional isovaleryl-CoA metabolites have also been identified in the urine of these patients. These include: 3- and 4-hydroxyisovaleric acid (by ω-1 and ω-oxidation of isovaleric acid respectively), methylsuccinic acid (by oxidation of 4-hydroxyisovaleric acid), methylfumaric acid (by dehydrogenation of methylsuccinic acid), 3-hydroxyisoheptanoic acid (by condensing isovaleryl-CoA and acetyl-CoA by 3-oxothiolase) and alloisoleucine [1–3]. Additionally, isovaleryl-conjugates of glucuronide, carnitine, alanine, sarcosine, α-aminobutyric acid, aspartic acid, serine, phenylalanine, threonine, valine, leucine, tyrosine, asparagine, histidine, lysine and tryptophan and N-acetyl-conjugates of threonine, valine, glycine, β-alanine, α-alanine, tyrosine and tryptophan are also detected in varying amounts in the urine of these patients [1,2].

The implications of these metabolites on the isovaleric acidemia patient are still unknown. Isovaleric acid is, however, a known inhibitor of succinate:CoA ligase in the tricarboxylic acid cycle and further inhibits liver mitochondrial oxygen consumption with glutamic, 2-oxoglutyric and succinic acids. Isovaleric acid is additionally thought to cause neutropenia by inhibition of poietic progenitor cell proliferation in bone marrow [2].

## Diagnostic Principles

Clinical symptoms include feeding difficulty, vomiting, listlessness, lethargy, coma, dehydration, ketosis, hyperammonaemia, tachypnea, neutropenia, thrombopenia and hypocalcemia [1–3]. A foul odor of "sweaty feet" due to elevated isovaleric acid is common [2]. Diagnosis is made on the basis of the clinical symptoms and excretion of isovalerylglycine and 3 hydroxyisovaleric acid in addition to one or more of the above mentioned excreted metabolites [1].

## Therapeutic Principles

Treatment of these patients during acute episodes entails glucose and bicarbonate infusion. Leucine or protein restricted diets are followed in combination to glycine and L-carnitine supplementation in order to prevent the accumulation of isovaleryl CoA [2].

## Jacobsen Syndrome

Iris Bartels
Institute of Human Genetics, University Goettingen, Goettingen, Germany

### Synonyms

11q terminal deletion disorder; Partial 11q monosomy syndrome; Distal 11q monosomy; JBS

### Definition and Characteristics

Jacobsen syndrome (JBS), primarily described in 1973, is defined by the cytogenetic proof of a constitutional deletion of the distal part of chromosome 11q (Fig. 1). It is a multisystemic genetic disorder with phenotypic heterogeneity characterized by the following frequent clinical features [1]: neonatal thrombocytopenia of Paris-Trousseau type, psychomotor delay, mild to severe mental retardation, growth retardation, craniofacial dysmorphism (trigonocephaly, hypertelorism, ptosis) and congenital heart defect. The heart malformations are most often ventricular septal defect, hypoplastic left heart and aortic coarctation, respectively. Less frequent features include pylorus stenosis, epicanthal folds, high palate, abnormal retinal findings, coloboma of the iris, recurrent ear infections and undescendent testis in boys, respectively. Short stature is frequently associated with low IGF-1 levels.

With increasing age platelet counts tend to increase to near normal, but platelet dysfunction persists. The most common causes of morbidity and mortality in these children are heart malformations and bleeding. Approximately 25% of the children die before the age of two years. To date, very little is known about the adult-onset disorders in this syndrome.

### Prevalence

1 in 100,000 life births or less; male to female ratio 0.53 [1].

### Genes

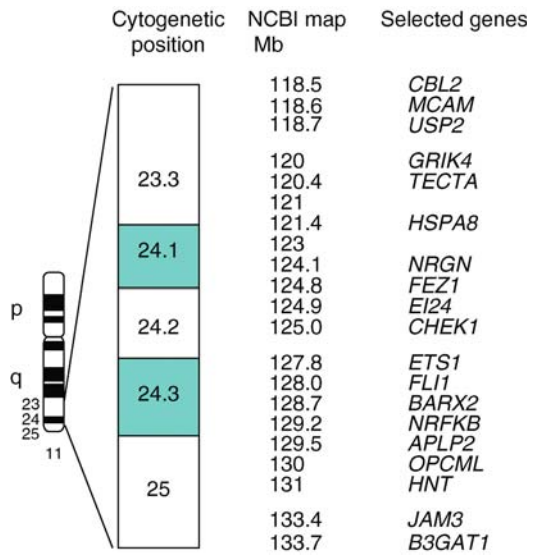
JBS is an autosomal dominant inheritable contiguous gene disorder. The deletion is variable in size and spans <7–20 Mb corresponding to chromosomal bands q25, q24 and q23. According to the extent of the deletion hemizygosity affects less than 100 to approximately 250 genes. Most deletions are terminal and de novo. In a few families a structural rearrangement segregates and is associated with an elevated risk for the disease in children of balanced carriers.

### Molecular and Systemic Pathophysiology

The function of the majority of genes commonly deleted in JBS is not known. There seems to be a strong, but not a complete correlation between cognitive function and deletion size [1]. Approaches to define the minimal deleted regions and candidate genes for the individual symptoms so far revealed inconsistent results. There is a significant variability in the range of features even in patients with similar deletion size.

The FLI1 gene alone encoding for an ets domain transcription factor essential for megakaryopoesis has been implicated as a cause for thrombocytopenia [2]. The JAM3 gene is expressed during cardiogenesis and was assumed as a candidate for hypoplastic left heart and other left-sided obstructive lesions [3]. However, other genes located more centromerically are postulated to be responsible for conotruncal heart defects in JBS. Therefore, the phenotypic variability observed in JBS unlikely results from the deletion size alone.

Only few adult patients are reported. Malignancy is a potential concern in patients who reach adulthood. Patients may have an increased risk of developing neoplasias and altered tumor progression, because several tumor suppressor genes are commonly deleted in JBS patients. The region includes at least three tumor suppressor genes, namely CHK1, BARX2 and OPCML. Hemizygosity for OPCML is known to predispose to ovarian cancer in female patients.



**Jacobsen Syndrome. Figure 1** Selected genes located in the distal part of chromosome 11 commonly deleted in Jacobsen syndrome according to the NCBI map (http:www.ncbi.nlm.nih.gov; build 36).

There is evidence that a small subgroup of the deletions may originate from breakage at a folate sensitive fragile site FRA11B in 11q23.3 [4]. In some patients with breakpoints in FRA11B one parent carries an expansion of the CCG trinucleotide repeat at this site. From the theoretical point of view the fragile site in 11q23.3 may predispose to offspring with JBS – in this subgroup of deletions. However, most breakpoints occur distal to FRA11B.

## Diagnostic Principles

Chromosome analysis at the 500 band-level allows for the detection of deletions extending approximately 3 Mb. Conventional cytogenetics does not provide sufficient resolution to precisely determine the size of the deletion. Fluorescent in situ hybridization, quantitative PCR, and polymorphic marker analysis allow for a precise mapping of the breakpoints and the extent of the deletion. Genomic microarray technologies provide another powerful tool to detect and quantify the deletion.

## Therapeutic Principles

There is no specific causal therapy of the underlying genetic abnormality. The two most common causes of morbidity in these children are neonatal thrombocytopenia and congenital heart anomalies. Both, heart defects and craniofacial anomalies frequently need corrective surgery. Abnormal platelet function persists life long in nearly all patients. Therefore, prolonged bleeding time is possible and has to be considered when surgical intervention is indicated [5]. Proactive platelet transfusions may reduce bleeding risk. Any medication that impairs platelet function should be avoided.

Early intervention programs may help to support the children's developmental capacities individually. Therefore neurological, hematological, ophtalmological baseline evaluation, periodic hearing testing and appropriate therapeutic interventions are recommended.

►Pachyonychia Congenita

# Jansen's Metaphyseal Chondrodysplasia

Frank Beier
CIHR Group in Skeletal Development and Remodeling, Department of Physiology and Pharmacology, University of Western Ontario, London, ON, Canada

## Synonyms

Metaphyseal chondrodysplasia; Murk Jansen Type; Metaphyseal dysostosis

## Definition and Characteristics

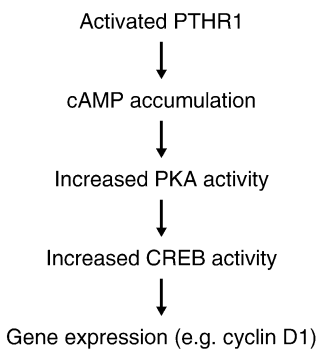
Dominant disease characterized by severe dwarfism and skeletal defects, often with hypercalcemia and other changes in mineral metabolism [1,2].

## Prevalence
Very rare.

## Genes
PTHR1 (parathyroid hormone receptor 1) on chromosome 3 (3p22p21.1). Most cases are caused by sporadic mutations.

## Molecular and Systemic Pathophysiology
PTHR1 encodes the receptor for both parathyroid hormone (PTH) and PTH-related peptide (PTHrP) [2]. Point mutations in PTHR1 (in particular H223R and T410P) result in the constitutive, ligand-independent activation of the receptor [3,4]. This causes increased accumulation of cyclic AMP and the activation of downstream signaling molecules such as protein kinase A and the transcription factor CREB (cAMP response element binding protein), ultimately leading to changes in gene expression ([4,5]; Fig. 1). In growth plate chondrocytes, this results in a delay in hypertrophic differentiation, giving rise to severely reduced final height and bone deformities [2]. Altered PTHR1 signaling causes additional systemic defects in mineral metabolism, including osteopenia, ►Hypercalcemia, ►Hypophosphatemia, ►Hypercalciuria and ►Hyperphosphaturia.

## Diagnostic Principles
Jansen's metaphyseal chondrodysplasia is diagnosed using a combination of radiography and analyses of laboratory markers (e.g., measurement of calcium, phosphate, cyclicAMP, Vitamin D, alkaline phosphatase activity, PTH and PTHrP levels etc.). One hallmark is hypercalcemia with suppressed PTH and PTHrP levels.



**Jansen's Metaphyseal Chondrodysplasia. Figure 1**
Activating mutations in PTHR1 result in the ligand-independent accumulation of cyclic AMP (cAMP), leading to activation of protein kinase A (PKA) and cAMP response element binding protein (CREB) and ultimately to changes in the expression of CREB target genes such as the cyclin D1 gene.

## Therapeutic Principles
Supportive treatment.

# Jaundice

►Hyperbilirubinemia

# Jaundice, Hepatocellular

Peter L. M. Jansen
Department of Gastroenterology and Hepatology, Academic Medical Center, Amsterdam, The Netherlands

## Synonyms
Parenchymatous cholestasis; Intrahepatic jaundice

## Definition and Characteristics
Viral, autoimmune, drug or alcohol-induced hepatitis is characterized by jaundice with elevation of both unconjugated and conjugated bilirubin in serum. As in extrahepatic obstruction, the urine in these patients can be dark-stained whilst the stool may be pale. The degree of cholestasis in these diseases may be highly variable with severe cholestasis marked by elevations of conjugated bilirubin and alkaline phosphatase in acute viral hepatitis A to mixed unconjugated and conjugated hyperbilirubinemia with extreme elevations of serum ASAT and ALAT activities in autoimmune hepatitis. Chronic viral hepatitis may present without jaundice.

## Prevalence

Viral hepatitis C and B are among the most common infectious diseases worldwide. Drug-induced and autoimmune diseases are rare. PBC and PSC are also rare but PBC may be clustered in some industrialized areas.

## Genes

In most cases hepatocellular jaundice is due to viral, autoimmune or toxic liver disease.

## Molecular and Systemic Pathophysiology

Parenchymatous liver disease is a collection of diseases caused by different agents. The pathophysiology of jaundice, in any of these diseases, is complex and incompletely understood. Since the hepatic uptake, metabolism and secretion from liver to bile of bilirubin and bile salts is mediated by enzymes and transport-proteins, it is likely that inflammation-induced regulatory changes of enzyme and transport-protein expression are underlying mechanisms for jaundice and cholestasis in parenchymatous liver disease. It should be pointed out that jaundice and cholestasis are not identical terms. Jaundice means a yellow discoloration of skin and mucous membranes while cholestasis means stasis of bile. Jaundice often is the consequence of cholestasis. Mild degrees of cholestasis may occur without jaundice. Elevation of serum bile acids is a more sensitive indicator of cholestasis than sxerum bilirubin but measuring serum conjugated bilirubin with high-performance liquid chromatography approaches the sensitivity of serum bile acids as a sign of cholestasis. In clinical practice this is rarely done.

Bile flow is supported by the action of transport proteins in the basolateral and canalicular domain of the hepatocyte plasma membrane (see Fig. 1 in the chapter ►Jaundice, Obstructive). These proteins mediate the hepatic uptake and secretion of bile salts and non-bile salt organic anions. The $Na^+$/taurocholate cotransporting polypeptide (NTCP; SLC10A1) is the major bile salt uptake system and OATP-C (SLC21A6) is the main transporter of non-bile acid organic anions including bilirubin. This latter protein also transports bile salts but in a sodium-independent manner. OATP-B (SLC21A9) and OATP8 (SLC21A8) represent additional basolateral transport proteins with an uptake function. The human bile salt export pump (BSEP, ABCB11) in the canalicular domain of the hepatocyte membrane mediates the ATP-dependent transport of bile acids. MRP2 mediates the canalicular secretion of bilirubin glucuronides and numerous other organic anions [1].

Endotoxin administration to rats profoundly influences the expression of transport proteins in the liver. Although in humans the exact mechanism underlying changes of transporter expression in parenchymatous liver disease is not known, cytokines are likely involved. In rats, endotoxin administration causes a decreased expression of Ntcp protein and mRNA [2]. Ntcp, and some of the organic anion transporters (Oatp's) are under the transcriptional control of hepatocyte nuclear factor 1α (HNF1α) and the heterodimer retinoid X receptor:retinoic acid receptor (RXR:RAR). Endotoxin and interleukin-1β down-regulate HNF1α as well as RXR:RAR nuclear binding activity and this likely presents a mechanism for cytokine-induced down-regulation of hepatic uptake transport proteins [3]. Endotoxin and cytokines not only affect hepatic uptake but also hepatic secretion. In rats there is a sharp down-regulation of canalicular Mrp2 expression while the bile salt export pump is relatively less affected [4]. Up-regulation of Mrp3 and Mrp4 in the basolateral membrane of hepatocytes most likely serves as an escape mechanism. Under normal conditions Mrp3 is hardly expressed in the liver but during cholestasis its expression is greatly increased [5]. Mrp3 and Mrp4 mediate transport of bile salts and sulfated bile salts from liver to blood.

## Diagnostic Principles

Hepatitis A is the most frequent cause of acute icterus in children and adolescents. Therefore it is often just called "jaundice." Acute and chronic hepatitis B or C in usually occurs in high-risk groups. In Asia and Africa hepatitis B is often transmitted from mother to child and may be anicteric. Also chronic hepatitis C is usually anicteric and is detected by serological tests. Suspicion is raised in symptomatic and asymptomatic patients with elevated serum levels of liver enzymes (ASAT, ALAT). Drug- and alcohol-induced hepatitis is suspected on basis of a temporal relation with a toxic agent. Jaundice is also the hallmark of some forms of liver cirrhosis such as primary biliary cirrhosis and primary sclerosing cholangitis. Jaundice in primary biliary cirrhosis is a rather late sign. Disproportionally elevated serum levels of conjugated bilirubin are seen in patients with sepsis.

## Therapeutic Principles

Viral hepatitis is treated with antiviral drugs. For drug- and alcohol-induced hepatitis, stopping the offending agent is first choice. Jaundiced patients with primary biliary cirrhosis are usually well under way to become candidates for liver transplantation. Jaundice in patients with primary sclerosing cholangitis may be caused by fibrotic bile duct strictures. These can sometimes be managed endoscopically. Very often however these patients have to be transplanted.

# Jaundice, Neonatal

Peter L. M. Jansen
Department of Gastroenterology and Hepatology, Academic Medical Center, Amsterdam, The Netherlands

## Synonyms

Physiological jaundice of the newborn; Icterus neonatorum

## Definition and Characteristics

Physiological rise of serum bilirubin between the second and eighth day of life (<100 μmol/l).

## Prevalence

Frequent. In Mediterranean countries with a high incidence of hemoglobinopathies (e.g. Greece), neonatal jaundiced may be more severe.

## Molecular and Systemic Pathophysiology

About 60% of normal term newborns develop neonatal jaundice, hence the name "physiological jaundice of the newborn." Bilirubin production in the neonate is increased due to a short red cell life-span. At the same time the capacity of the liver to conjugate bilirubin is not yet fully developed. In contrast to current dogma, no relation was found between fetal hemoglobin and neonatal jaundice [1]. Entero-hepatic cycling of bilirubin may play a role. In the gut, conjugated bilirubin is hydrolyzed by intestinal beta-glucuronidase but, due to the lack of microflora, in neonates it is not metabolized to urobilinogen. Part of the deconjugated bilirubin is reabsorbed and added to the pool of unconjugated bilirubin in the circulation.

Bilirubin is conjugated in the liver by the enzyme UGT1A1, a member of the UDP-glucuronosyltransferase family. These enzymes are under transcriptional control of the nuclear hormone receptors, CAR (constitutive androstane receptor) and PXR (nuclear pregnane X-receptor) [2,3]. In neonatal mice, CAR expression is low. It is only fully expressed 2 weeks after birth. CAR deficiency may thus be a factor in the development of neonatal jaundice. This also explains why phenobarbital is not useful in the treatment of neonatal jaundice. Phenobarbital is only a weak CAR agonist. More potent and non-toxic CAR agonists need to be developed since they may prevent untoward elevations of serum bilirubin in the newborn.

In premature newborns serum bilirubin rises faster and to a higher level than in full-term infants. Other factors that contribute to the severity of neonatal jaundice are hemolysis, due to ABO- or rhesus-antagonism, and Gilbert syndrome. Infants with the Gilbert syndrome have increased neonatal bilirubin levels [4] and may develop prolonged jaundice (>14 days of life) while being breast-fed. The combination of Gilbert syndrome, ABO antagonism or hemoglobinopathies, like glucose-6-phosphate dehydrogenase deficiency, is associated with prolonged and elevated levels of serum bilirubin [5].

## Diagnostic Principles

Serum bilirubin levels are monitored by blood tests or the transcutaneous luminometer. Total serum bilirubin is mainly bound to albumin and is not a good measure of bilirubin toxicity. It is the unbound fraction of unconjugated bilirubin that is neurotoxic and this may cause kernicterus. Certain drugs (e.g. sulfonamides) that displace bilirubin from albumin increase the risk for kernicterus. Therefore, total serum bilirubin values are not absolutely predictive for the risk at kernicterus, unbound bilirubin would be more predictive but there is no good test to determine the unbound fraction.

## Therapeutic Principles

Phototherapy is the first choice treatment. In healthy term newborns phototherapy should be started if serum bilirubin rises above 260 μmol/l at 24–48 h after birth; above 310 μmol/l at 48–72 h; and above 340 μmol/l at more than 72 h after birth. Exchange transfusion should be given if phototherapy fails and the serum bilirubin is above 340 μmol/l, 24–48 h after birth; above 430 μmol/l, 48–72 h and more than 72 h after birth. If the serum

bilirubin is above 430 μmol/l, 24–48 h after birth or above 510 μmol/l, 48 h after birth and thereafter, exchange transfusion should be combined with intense phototherapy. These are recommendations (1994) by the American Academy of Pediatrics (www.aap.org). Epidemiological studies revealed that the administration of phototherapy in newborns is not optimal, it is not used when it should be and sometimes it is used inappropriately.

Tin-mesoporphyrin reduces bilirubin production by inhibiting heme-oxygenase. It has been used to prevent jaundice in glucose-6-phosphate dehydrogenase-deficient infants. Agar, cholestyramine and calcium phosphate interrupt the enterohepatic cycle of unconjugated bilirubin but the effect of these drugs has not been convincing.

# Jaundice, Obstructive

Peter L. M. Jansen
Department of Gastroenterology and Hepatology, Academic Medical Center, Amsterdam, The Netherlands

## Synonyms

Extrahepatic cholestasis; Extrahepatic jaundice

## Definition and Characteristics

Patients with extrahepatic obstruction are jaundiced. Obstruction caused by a tumor of the pancreatic head, papilla of Vater, or cholangiocarcinoma characteristically causes "silent" (painless) icterus with a palpable mass that either may be a distended gallbladder or the tumor. Primary sclerosing cholangitis is a chronic disease characterized by periductular fibrosis affecting the intermediate intrahepatic and larger extrahepatic bile ducts.

Colicky pain is a sign of bile duct obstruction caused by gallstones. Patients with chronic cholestasis, as in primary sclerosing cholangitis, often complain of pruritus (itching).

Laboratory tests in painless as well as in painful obstructive jaundice show elevated serum levels of conjugated bilirubin, alkaline phosphatase, and gamma-glutamyltransferase. Serum bile acids are also elevated but are not usually measured. The transaminases, ASAT and ALAT, may be elevated in case of acute obstruction. About 50% of patients with primary sclerosing cholangitis have anti-neutrophil cytoplasmic antibodies.

## Prevalence

Gallstone disease is the most frequent disease of the hepatobiliary system. Pancreas carcinoma is mainly a disease of the older age group. Primary sclerosing cholangitis usually appears in the third decade of life and affects males and females equally, and 70% of patients also have inflammatory bowel disease.

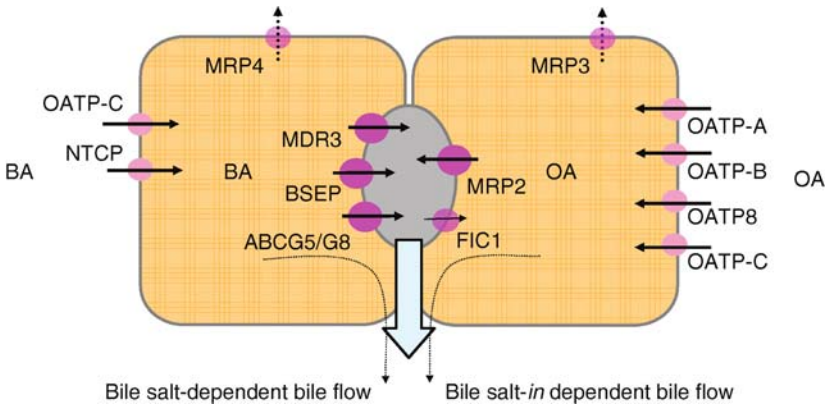
## Genes

Heterozygosity for an ABCG8 mutation (D19H) is associated with gallstone disease (the gene is located on chromosome 2p21) [1]. In heterozygotes for MDR3 (ABCB4) mutations there is a high incidence of intrahepatic microlithiasis [2]. This is probably caused by low biliary secretion of phosphatidylcholine, hence the name "low phospholipid-associated cholelithiasis" (LPAC). Although in the Western world most gallstones are cholesterol stones, patients with hemoglobinopathies may develop bilirubin stones.

## Molecular and Systemic Pathophysiology

Bile acids are the main organic solutes in bile. Their secretion represents the major driving force for bile formation. In addition to the bile acid-dependent bile flow, there is a bile acid-independent component of bile flow. Bile flow is supported by the action of transport proteins in the basolateral and canalicular domain of the hepatocyte plasma membrane (Fig. 1).

These proteins mediate the hepatic uptake and secretion of bile acids and non-bile salt organic anions. The $Na^+$/taurocholate cotransporting polypeptide (NTCP; SLC10A1) is the major bile salt uptake system, and



**Jaundice, Obstructive. Figure 1** Human hepatobiliary transport proteins involved in bile formation, secretion, and reabsorption: Transporter proteins located in the basolateral membrane are responsible for hepatic uptake of bile acids (NTCP, OATPs), bulky organic anions, uncharged compounds (OATPs), and cations (OATPs, OCT1). Transporter proteins located in the canalicular membrane are responsible for the biliary secretion of bile acids, phosphatidylcholine, cholesterol, and glutathione, and the excretion of drugs and toxins. These are the bile salt export pump BSEP (ABCB11); the cholesterol transporter ABCG5/G8; the phosphatidylcholine translocator MDR3 (ABCB4); the multispecific organic anion transporter MRP2 (ABCC2); and the multidrug transporter MDR1 (ABCB1). The organic anion transporters MRP3 (ABCC3) and MRP4 (ABCC4) are present at very low levels in normal human liver but their expression is strongly increased during cholestasis. Both MRP3 and MRP4 are able to transport bile acid conjugates out of the hepatocyte. FIC1 (ATP8B1) has been characterized as an aminophospholipid translocase and functions as a stabilizer of the bile salt exposed membranes surrounding the bile canaliculi and small bile ducts. BA, bile acids; OA, organic anions.

OATP-C (SLC21A6) is the main transporter of non-bile acid organic anions including bilirubin. This latter protein also transports bile acids but in a sodium-independent manner. OATP-B and OATP8 represent additional basolateral transport proteins with an uptake function. The human bile salt export pump (BSEP, ABCB11) in the canalicular domain of the hepatocyte membrane mediates the ATP-dependent transport of bile acids.

When bile flow is blocked as a result of extrahepatic obstruction, bile acids accumulate in the liver and blood. Kupffer cells are activated during cholestasis and produce cytokines such as TNFα and the interleukins 1 and 6. Under these conditions, enzymes of the cytochrome P-450 system in the liver are induced that mediate the hydroxylation of bile acids to compounds that can be conjugated to glucuronides and sulfates. These conjugates are substrates to the basolateral transporters MRP3 (ABCC3) and MRP4 (ABCC4). These proteins are hardly expressed under control conditions but are upregulated during cholestasis. It is postulated that these proteins play a role to alleviate the toxic cellular overload when transport through canaliculus and bile ducts is impaired. Also, in the kidney, transport proteins are induced. For instance, MRP2 in the proximal tubuli helps to eliminate bile acids and other anionic conjugates from the body. Renal MRP2 is induced during cholestasis.

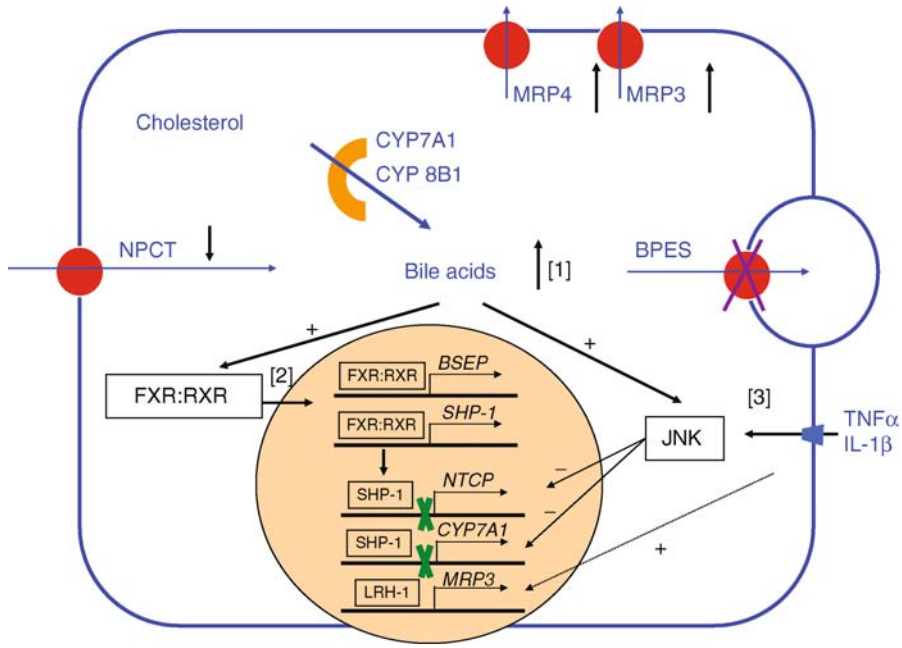
Nuclear hormone receptors have been identified as important transcription factors in these regulatory adaptations. The *BSEP* gene is under the transcriptional control of FXR (farnesoid X-receptor) (Fig. 2) [3].

Chenodeoxycholic acid and cholic acid bind and activate FXR. Subsequently, FXR forms a heterodimer with RXR (retinoid X-receptor) and translocates to the nucleus where it stimulates the transcription of the BSEP and SHP-1 (small heterodimer protein-1) genes. SHP-1 antagonizes and thus downregulates the transcription of CYP7A1, CYP8B1, and NTCP [4].

The expression of NTCP in human cholestatic liver disease is decreased [5]. Downregulation of the NTCP and CYP genes reduces the entry and the de novo synthesis of bile acids. This regulation most probably serves a cytoprotective function. This is particularly important in case of bile duct obstruction when BSEP, via FXR-stimulated expression of its gene, remains active and keeps transporting bile acids into the bile canaliculus despite the downstream obstruction. An increased intrabiliary pressure leads to disruption of tight-junctions and to parenchymal damage. Upregulation of MRP3 and 4 in the basolateral membranes of hepatocytes constitutes an escape route for bile acids and other metabolites.

## Diagnostic Principles

Jaundiced patients are easily recognized by the color of their eyes and skin. In case of obstructive jaundice, the stools are pale. The urine is darkened by the presence of bile pigments (mainly bilirubin conjugates).



**Jaundice, Obstructive. Figure 2** Gene regulation by bile acids. Bile acids are taken up in the liver by NTCP and secreted into bile by canalicular BSEP. When BSEP activity is reduced, the intracellular bile acid concentration increases. Bile acids [1] serve as ligands for FXR, which forms a heterodimer with RXR and translocates to the nucleus [2]. The heterodimer activates the transcription of the BSEP and SHP-1 genes. SHP-1 antagonizes the expression of the bile acid biosynthetic enzymes CYP7A1 and CYP8B1 and the transporter NTCP. In addition, Kupffer cells produce TNF-α and interleukin-1β during cholestasis and via the c-Jun N-terminal kinase-dependent (JNK) pathway [3] they reduce the expression of NTCP and CYP7A1. Thus, at increasing bile salt concentrations, de novo synthesis is reduced, uptake is impaired, and secretion, either across the canalicular or basolateral membrane, is stimulated. As a consequence, the intracellular bile salt concentration remains controlled and limited. Studies in mice revealed that upon extrahepatic bile duct obstruction, Bsep activity is maintained. As a result of undiminished bile salt transport, the intrabiliary pressure increases, the tight junctions become leaky, and bile acids leak back into the liver tissue and to the blood. However, MRP3 and MRP4 expression at the basolateral membrane is enhanced. These transporters pump bile salt (sulfates) back from liver to blood, thereby protecting the liver and bile ducts from bile salt toxicity.

Chronic cholestasis leads to steatorrhea and weight loss because of fat malabsorption. In some forms of chronic cholestasis, pruritus may be severe. Ultrasonography is the best technique to detect gallstones in the gallbladder. With magnetic resonance imaging (MRI), endoscopic ultrasound, or endoscopic retrograde cholangiograpy (ERCP) one can detect bile duct stones, and these techniques and CT-scan (CAT scan) can be used to detect a cholangiocarcinoma, a pancreatic tumor or tumor of the papil of Vater.

## Therapeutic Principles

Extrahepatic bile duct stones can be removed endoscopically or bypassed by an endoscopically placed stent. Ductal stone removal is usually followed by a (laparoscopic) cholecystectomy. Extrahepatic obstructing tumors can be bypassed by a stent or removed surgically.

## JBS

►Jacobsen Syndrome

# Jejunal Atresia

Alexander K. C. Leung[1], Andrew L. Wong[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Department of Surgery, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Jejunal atresia usually presents with bilious vomiting within the first 24 h after birth [1]. The affected infant often fails to pass meconium in the first day of life. On the other hand, passage of meconium does not exclude jejunal atresia as one third of affected infants will pass some meconium and gray plugs of mucus. Approximately 60% of jejunal atresias are located in the proximal jejunum and 40% in the distal jejunum (Fig. 1) [1].

In general, the more distal the obstruction, the greater is the likelihood of abdominal distention. Neonatal jaundice is not an uncommon finding, due to an elevation of indirect bilirubin. A history of maternal polyhydramnios may be elicited in 25–35% of cases [1]. In contrast to duodenal atresia, jejunal atresia is infrequently associated with extraintestinal anomalies. Extraintestinal anomalies include intrauterine volvulus, gastroschisis, biliary atresia, and Hirschsprung's disease. However, 5–10% of patients with jejunal atresia have multiple atresias in the remaining intestine [1].

## Prevalence

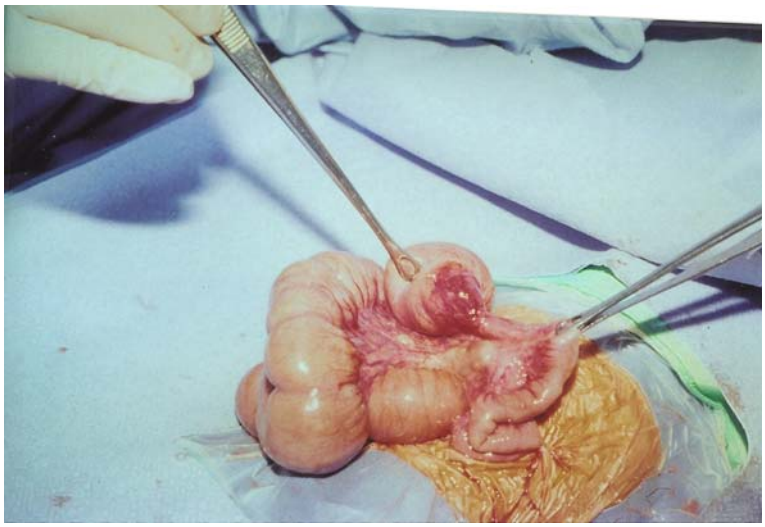
Jejunal atresia occurs in approximately 1 in 40,000 live births [1].

## Genes

Jejunal atresia is usually not genetically determined but hereditary forms have rarely been described.

## Molecular and Systemic Pathophysiology

Jejunal atresia is thought to eventuate from an ischemic injury to the developing bowel. The presence of meconium, squamous epithelial cells, lanugo hair or bile droplets distal to the atretic segment and the rarity of extraintestinal anomalies are evidence that the insult occurs after major organogenesis [2,3]. This ischemia may be the result of a primary intrauterine mesenteric vascular catastrophe such as venous thrombosis, embolization, and placental vascular compromises or secondary to a mechanical obstruction such as herniation, volvulus, and intussusception [2]. The condition may also result from maternal use of cocaine or the use of toluidine blue in genetic amniocentesis in twins [4]. Both cocaine and toluidine blue have vasoconstricting action. The affected segment is infarcted and reabsorbed, resulting in an atresia. The bowel proximal to the atretic segment is dilated and hypertrophied. A deficiency of mucosal enzymes and muscular adenosine triphosphatase is also found [5]. In



**Jejunal Atresia. Figure 1** Intraoperative finding of a neonate with jejunal atresia. Note the atretic jejunal segment.

the atretic segment, ganglion cells are atrophic with minimal acetylcholinesterase activity [5].

### Diagnostic Principles

Erect and recumbent abdominal radiographs show air fluid levels and a few distended loops of bowel proximal to the lesion and absence of air in the distal bowel [1]. Peritoneal calcification signifies prenatal intestinal perforation. The condition may be detected prenatally by ultrasonography which shows dilated foetal bowel proximal to the atresia.

### Therapeutic Principles

Preoperative measures include nasogastric decompression, intravenous hydration, and correction of electrolyte disturbance. During surgery, the bowel proximal to the obstruction is often found to be distended while the distal bowel is collapsed. Bowel reconstruction is usually achieved by end-to-end anastomosis. The remaining bowel should be evaluated for additional atresias. The prognosis is excellent in the absence of associated anomalies.

## Jejunal Stenosis

Alexander K. C. Leung[1], Andrew L. Wong[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Department of Surgery, The University of Calgary, Alberta Children's Hospital, Calgary, AB, Canada

### Definition and Characteristics

Jejunal stenosis is characterized by a localized narrowing of the jejunum without a disruption of continuity or defect in the mesentery [1]. At the stenotic site, there is often a short, narrow segment with a minute lumen where the muscularis is irregular and the submucosa is thickened. The resultant intestinal obstruction is incomplete. Infants with jejunal stenosis present with bilious vomiting, abdominal distention, and failure to pass meconium on the first day of life [1]. A history of maternal polyhydramnios is not uncommon. About 30% of affected infants have unconjugated hyperbilirubinemia [1]. Dehydration and aspiration pneumonia may result from delayed diagnosis and treatment [1].

### Prevalence

The exact incidence is not known, but the condition is rare. Jejunal stenosis accounts for 5% of jejunoileal obstructions in children [2].

### Molecular and Systemic Pathophysiology

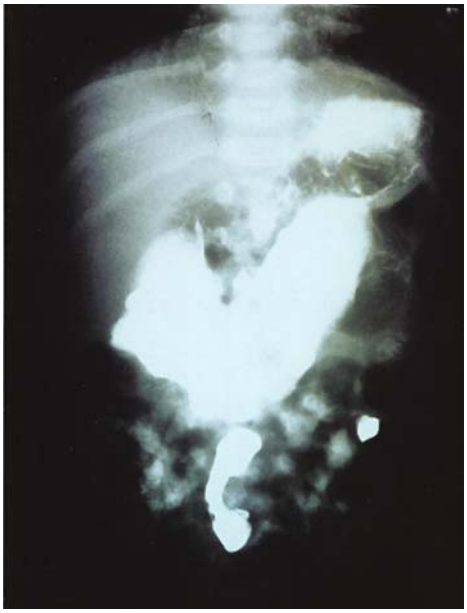
Jejunal stenosis is thought to be caused by a late intrauterine mesenteric vascular catastrophe, which produces aseptic necrosis [1]. Healing of the necrotic bowel results in a narrow segment. The bowel proximal to the stenotic segment is dilated and hypertrophied. The discrepancy between the lumen of the bowel proximal and distal to the stenotic segment may vary from 2 to 20 times depending on the completeness of the obstruction [2]. Because of the obstruction, reabsorption of fluid and electrolytes is compromised. Also, sepsis may result secondary to overgrowth of enteric microorganisms and passage of these microorganisms to the bloodstream [2]. As a result of the distension of the bowel wall, blood shunts away from the capillary bed and this may lead to ischemia and infarction [2]. Jejunal stenosis may also be acquired postnatally, as a result of mesenteric vein thrombosis [3]. Mesenteric venous thrombosis may lead to venous stasis, edema of the bowel wall, intramural hemorrhage, and sometimes, jejunal stenosis [4].

### Diagnostic Principles

The abdominal radiograph usually shows a few dilated loops of bowel with air-fluid levels. The more distal the stenosis, the greater are the number of dilated loops of bowel and air-fluid levels. The differential diagnosis includes midgut volvulus, meconium ileus, and internal hernia. An upper GI tract series may reveal the exact site of stenosis (Fig. 1).

### Therapeutic Principles

Preoperative measures include nasogastric suction and intravenous correction of fluid and electrolyte imbalance. Surgery involves laparotomy, resection of the stenotic segment, and an end-to-end anastomosis between the dilated proximal bowel and the collapsed distal bowel.



**Jejunal Stenosis. Figure 1** An upper GI series showing stenosis of the jejunum.

# Jervell-Lange-Nielsen Syndrome

Birgit Haack, Nikolaus Blin
Department of Molecular Pathology, University Hospital of Tuebingen, Tuebingen, Germany

## Synonyms

Recessive form of long QT syndrome; LQTS; JLNS

## Definition and Characteristics

Autosomal recessive ion channel defect leading to cardiac arrhythmias and severe hearing impairment. The disorder of cardiac repolarization leads to relative bradycardia, T wave abnormalities and episodic ventricular tachyarrhythmias, particularly torsade de pointes [1]. Patients show episodes of syncope, seizures and sudden death, usually in young individuals. Compared to the mostly dominantly inherited form of long QT syndromes, the Romano-Ward syndrome, JLNS patients show more severe symptoms. Hearing impairment of patients suffering from Romano-Ward syndrome ranges from mild to moderate. Individuals with JLNS show profound defects in hearing or deafness. Due to the fact that autosomal recessive Romano-Ward cases have also been reported and both syndromes show variable phenotypes, an exact clinical classification of these syndromes becomes more delicate.

## Prevalence

The incidence of the congenital long QT syndromes has been estimated as 1:10,000–1:15,000 of live births [2].

## Genes

KCNQ1 encoding the alpha subunit of a voltage gated potassium channel is localized on 11p15.5. KCNE1 encoding the beta subunit of the KCNQ1 potassium channel is localized on 21q22.1 [3].

## Molecular and Systemic Pathophysiology

Mutations in either of the two genes encoding potassium channel subunits lead to delayed channel aperture, a prolonged action potential of myocytes and therefore to a prolonged QT interval [1]. In the inner ear KCNQ1/KCNE1 potassium channels are responsible for maintenance of the endolymphatic homeostasis [4].

## Diagnostic Principles

In the majority of patients the QT interval is >440 ms, but in 5–12% of patients it is within normal limits [5]. Molecular diagnosis can be performed by direct sequencing of KCNE1 and in the case of KCNQ1 by segregation analysis and/or sequencing.

## Therapeutic Principles

To prevent the recurrence of malignant ventricular arrhythmias, antiarrhythmic drugs are essential. All LQTS patients should reduce physical activity, particularly competitive sporting activities and swimming [5]. Individuals affected by hearing impairment are in general equipped with hearing aids.

### Synonyms

Juvenile Polyposis Coli

### Definition and Characteristics

The predisposition for the development of hamartomatous ("juvenile") polyps in the gastrointestinal tract characterizes the juvenile polyposis syndrome (JPS) [1–4]. The term "juvenile" refers to the histological type of polyp and not to the age of manifestation. Hamartomatous polyps have a smooth surface with normal epithelium and mucus-filled cystic glands in the edematous and inflamed lamina propria [1].

Apart from JPS, hamartomatous polyps are part of other syndromes such as the Cowden syndrom (CS), or the Bannayan riley ruvalcaba syndrom (BRRS) [4]. CS is characterised by additional mucocutaneous lesions and associated tumours of the thyroid, breast and endometrium, whereas in BRRS mental retardation, lipomas and hemangiomas occur. In the absence of extraintestinal features consistent with CS and BRRS, Juvenile polyposis syndrome can be diagnosed according to following criteria:

1. more than five juvenile polyps of the colorectum;
2. juvenile polyps throughout the gastrointestinal tract; and/or
3. any number of juvenile polyps with a family history of juvenile polyposis.

Patients with JPS usually develop 50–200 polyps distributed throughout the colorectum; the stomach and small intestine are infrequently affected. Symptoms of JPS include acute or chronic gastrointestinal bleeding, anaemia, prolapsed rectal polyps, abdominal pain, and diarrhoea. In the paediatric population bowel infarction due to intussusception is one of the major complications. JPS has significant malignant potential. The risk of gastrointestinal cancer commences from the age of 20 years and increases with aging [3]. The cumulative risk is 68% at the age of 60 [2,3].

### Prevalence

Juvenile polyposis syndrome was first described in 1964. It affects 1 in 16,000 to 1 in 100,000 children compared to 2% of children and adolescents with solitary juvenile polyps of no malignant potential.

### Genes

JPS is an autosomal dominant condition with incomplete penetrance. Approximately 20–50% of affected individuals have a familial polyposis history. Two germ line mutations have been identified causing disruption of the transforming growth factor β (TGFβ) signal transduction pathway: SMAD4 and BMPR1A with a prevalence of approximately 20%, each, in JPS patients [5]. Mutations in PTEN (phosphatase and tensin homolog (mutated in multiple advanced cancers 1)) are associated to CS and BRRS.

## Molecular and Systemic Pathophysiology

SMAD4 is located on chromosome 18q21.1 and encodes a cytoplasmic mediator of the TGFβ signal transduction pathway: TGFβ activates members of the TGFβ receptor family are activated by phosphorylation. These serine/threonine kinase receptors phosphorylate SMAD2 and SMAD3, which then form heteromeric complexes with SMAD4. The complex translocates into the nucleus, interacts with cellular DNA and mediates apoptotic and growth inhibitory responses.

BMPR1A (bone morphogenic protein receptor 1A; chromosome 10q22.3) is located upstream from SMAD4 in the TGFβ pathway and encodes for a type I serine/threonine kinase receptor that belongs to the TGFβ receptor superfamily. When BMPR1A is activated through phosphorylation, it phosphorylates several SMAD family members with the above mentioned consecutive reactions. Mutations of BMPR1A within the intracellular serine/threonine kinase domain result in loss of intracellular signal transduction.

Thus, SMAD4 is a tumor suppressor gene and the loss of growth inhibition due to SMAD4 or BMPR1A mutations results in neoplastic progression [5].

## Diagnostic Principles

The histopathological classification of polyps is essential for the diagnosis of JPS. Typically, large, mucus-filled cysts are seen within the lamina propria of juvenile polyps. The surface is smooth and it is covered by intact epithelium. Signs of proliferation (as in adenomas) are not characteristic for juvenile polyps.

Genetic testing of the SMAD4 and BMPR1A genes may be used to verify diagnosis of JPS, in order to perform family surveillance (predisposition testing) or for prenatal diagnosis. In families with an identified mutation, genetic testing should induce surveillance strategies in gene carriers, allowing for early detection and management of polyps and malignancies. Regular full blood counts and endoscopy are indispensable parts of surveillance [2,3].

## Therapeutic Principles

There are no dietary or drug prevention strategies. Endoscopic polypectomy can be applied in patients with few uncomplicated polyps. The indications for total colectomy are dysplasia, numerous polyps that are too difficult to remove endoscopically, and severe hemorrhage. A sphincter preserving surgery with mucosal proctectomy and ileoanal anastomosis is preferable.

## Kabuki Make-up Syndrome

►Kabuki Syndrome

## Kabuki Syndrome

Mario Vaccaro, Claudio Guarneri
Institute of Dermatology, Policlinico Universitario, Messina, Italy

### Synonyms

Kabuki make-up syndrome; Niikawa-Kuroki syndrome

### Definition and Characteristics

Kabuki syndrome (KS, MIM#147920), first described in 1981 by two independent groups, Niikawa et al. and Kuroki et al., is a multiple congenital anomalies/mental retardation syndrome of unknown cause. The term "Kabuki make-up syndrome," now often dropped as it is upsetting to some families, was given because of the most striking feature of the face of patients, the eversion of lower lateral eyelid, which resembles the make-up of the actors of Kabuki, a traditional form of Japanese theatre [1,2].

Cardinal manifestations of the syndrome can be divided into five categories: craniofacial, skeletal abnormalities, dermatoglyphic abnormalities, mental retardation, and short stature. Only craniofacial abnormalities are always present. Other features can be helpful for diagnosis, but are not contributory to it. In addition to the aforementioned cardinal manifestations, other clinical signs reported in patients with KS are visceral abnormalities (ventricular or atrial septal defect, coarctation of aorta, patent ductus arteriosus, transposition of great vessels, renal/urinary tract malformations, biliary atresia, diaphragmatic hernia, anorectal anomalies) and a higher susceptibility to infections like otitis media, upper respiratory tract infections, and pneumonia; in single cases, severe immunodeficiency or autoimmune diseases (autoimmune hemolytic anemia and polycytemia, chronic idiopathic trombocytopenia, acquired hypogammaglobulinemia with anti-$I_gA$ antibodies) were demonstrated. Some authors also observed the presence of abnormal hair (trichorrhexis nodosa, caliber irregularities, twisting of the hairshaft, "scanty scalp hair") and nails (short and fragile nails) [3,4].

### Prevalence

This rare syndrome has been reported in about 350 infants from Asia, the near East, Europe, Australia, North and South America. The prevalence of KS in the Japanese population has been estimated to be 1/32,000. The minimal birth prevalence of KS in Australia and New Zealand population has been estimated to be 1/86,000. On the basis of many reports from other populations, it is likely that the prevalence could be approximately that seen in the Japanese population [1,2].

### Genes

The genetic defect responsible for KS is still unknown. Until recently, although numerous cytogenetic anomalies were identified, no single abnormality was found repeatedly. Literature also reports some cases of documented autosomal dominant inheritance, and hypotheses were made about insertional balanced translocation and small ring X-chromosome [3,4].

Milunsky et al. recently reported chromosome 8p22–8p23.1 duplication in six patients, but a number of other groups have not found a similar association in patients with classical KS (Miyake et al., 2004; Engelen et al., 2005, Hoffman et al., 2005; Sanlaville et al., 2005; Schoumans et al., 2005; Turner et al., 2005).

However, since the vast majority of patients are sporadic cases, due to fresh mutations, and the disease has a wide spectrum of clinical manifestations, it is likely that KS is caused by microdeletions involving many contiguous genes ("contiguous gene syndrome").

### Molecular and Systemic Pathophysiology

The molecular pathogenetic mechanism of KS is unknown. To date, candidate gene approach has been

undertaken only once to this aim. Bottani et al. have speculated that the transforming growth factor beta receptor 1 and 2 (TGFBR1 and TGFBR2) pathway could explain, at least in part, the phenotypic complexity observed [5]. This hypothesis was based on the similarity between some features of KS and Loeys–Dietz aneurysm syndrome, a disorder caused by mutations of TGFBR1 and TGFBR2. In the proposed model, impaired TGFBR-mediated signaling could also result in reduced function of the interferon regulatory factor (IRF-6) pathway. However, the researches performed by the same authors showed that, although a role for TGFBR-mediated pathway in KS can not be completely excluded, it is very unlikely that this could be a major effect.

### Diagnostic Principles

Diagnosis is exclusively based on clinical features, since no decisive laboratory, histopathological or instrumental exams are still known. The complex phenotype of KS combines characteristic facial features (sparse arched eyebrows, long palpebral fissures and lower palpebral eversion, broad and flat nasal bridge, short nose with anteverted tip, prominent or cupped ears) with dermatoglyphic, skeletal, and visceral anomalies, postnatal growth retardation and mental retardation. The single most striking feature that prompts clinical diagnosis is the particular facial appearance [3].

### Therapeutic Principles

No treatment is, until now, available; preventive and therapeutic interventions should be aimed at avoiding and, if possible, curing the aforementioned frequent complications [1–4].

## Kahlbaum's Syndrome

►Periodic Catatonia

## Kaposi's Sarcoma

Richard F. Ambinder, S. Diane Hayward
Viral Oncology Program, Sidney Kimmel Cancer Center, Johns Hopkins University, Baltimore, MD, USA

### Definition and Characteristics

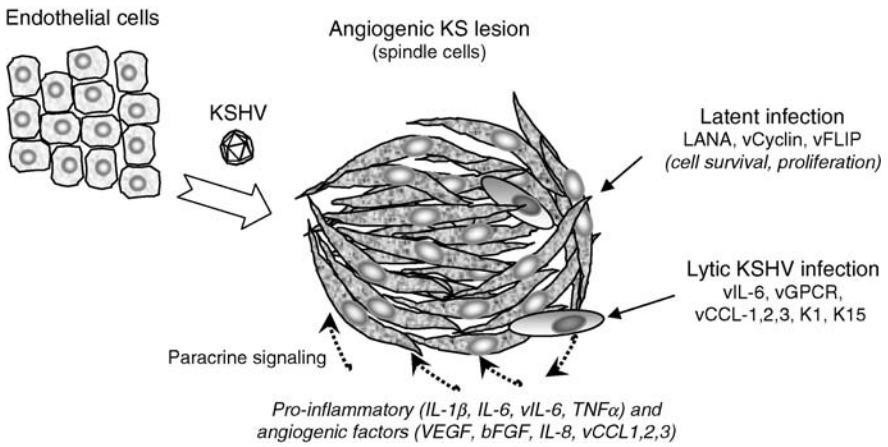
The gammaherpesvirus KSHV (Kaposi's sarcoma associated herpesvirus; also known as human herpesvirus 8 or HHV-8) is invariably present in KS lesions [1]. KSHV is also associated with the B cell malignancies primary effusion lymphoma and plasma cell variant multicentric Castleman's disease. KSHV infects B cells and endothelial cells. The B cell serves as the reservoir for long-term KSHV latency. KSHV is transmitted in saliva and in endemic regions mother to child transmission is a significant source of infection. Once infected an individual carries the virus for life.

### Prevalence

KSHV, unlike most herpesviruses, is not ubiquitous in the population. Seroprevalence rates are low in Northern Europe and the US (0–5%), intermediate in Mediterranean countries (5–35%) and highest in regions of sub-Saharan Africa (30–60%) [2]. Since KS development requires KSHV infection, the incidence of KS is influenced by the prevalence of KSHV. The incidence of KS in the HIV infected has decreased substantially in Western countries with the use of highly active anti-retroviral therapy (HAART) but KS remains the most frequent cancer in patients with AIDS. KS incidence is steadily increasing in Africa where in some regions it is the most common cancer in men. KS is more common in men than in women. In classical KS the ratio is as high as 15:1 while in the setting of immune suppression, either in the context of transplantation or HIV infection in Africa, the ratio is between 2:1 and 4:1.

### Genes

KSHV has a 165-kb double stranded DNA genome and establishes either a latent infection in which only 3–4 viral genes (LANA, vCyclin, vFLIP, IRF-3) are expressed or a lytic infection in which the full genetic complement is expressed and viral replication produces progeny virions. KSHV encodes a cytokine (vIL-6), a chemokine receptor (vGPCR) and chemokines (vCCL-1,2,3) that are expressed as part of the viral lytic program and contribute to tumorigenesis through paracrine signaling.



**Kaposi's Sarcoma. Figure 1** Model for KS development. KSHV infects endothelial cells which undergo morphological changes and become spindle shaped. The spindle cells are predominantly latently KSHV infected and express LANA (latency associated nuclear antigen), vCyclin and vFLIP (viral FLICE inhibitory protein). LANA replicates the latent KSHV genomes and alters cell gene expression through manipulation of the Wnt/β-catenin pathway to promote S-phase entry, cell proliferation and cell survival [3]. vFLIP upregulates NF-κB activity, induces pro-inflammatory cytokines, is anti-apoptotic and drives the morphological changes. vCyclin is a D-type cyclin that promotes cell cycle progression. A small number of infected cells progress to express KSHV lytic cycle proteins among which are vIL-6 (viral interleukin 6), vGPCR (viral G protein coupled receptor), vCCL1,2,3 (viral C-C chemokines), K1 and K15. Signaling downstream of these proteins promotes angiogenesis in part through the induction of VEGF (vascular endothelial growth factor), bFGF(basic fibroblast growth factor) and IL-8 and the VEGF receptor FLT-2. vGPCR also induces an array of cytokines including IL-1β (interleukin 1β), TNFα (tumor necrosis factor α) and cellular IL-6 that together with vIL-6 produce inflammatory, mitogenic and cell survival responses [4].

## Molecular and Systemic Pathophysiology

KS lesions are composed of spindle-shaped cells, neovascular slit-like spaces and extravasated red blood cells. Spindle cells express endothelial and macrophage markers and are thought to originate from circulating peripheral blood hematopoietic precursor cells. In organ transplant recipients, tumor cells may be of donor origin. The median time to KS development in transplant patients is 2½ years. In many instances KS lesions are clonal. Immunohistochemistry and in situ hybridization detect KSHV proteins or nucleic acid in the spindle cells and in some of the cells of the inflammatory infiltrate (Fig. 1).

## Diagnostic Principles

Before AIDS, Kaposi's sarcoma (KS) was a rare disease seen in older men of Eastern European or Mediterranean descent, in parts of Africa where it often occurred in children and in organ transplant recipients. With the advent of HIV, the vast majority of cases of KS in North America and Europe were HIV associated. KS is more common in men who have sex with men than in other HIV risk groups [5]. KS typically arises on the skin as flat deep purple lesions. These may progress to form nodules. The legs and face (especially nose and ears) are frequently involved. Oral lesions are common and the gut and lungs may also be involved.

## Therapeutic Principles

Local therapies are used for patients with a few lesions and slowly progressive disease. These include injections of chemotherapeutic agents into lesions and radiation of lesions. In organ transplant recipients, withdrawal or reduction of immunosuppression may lead to tumor responses. Similarly, in HIV infected patients, anti-retroviral therapy will often induce partial or even complete remissions. In the HIV setting, in addition to restoration of immune function, the reduced exposure to HIV proteins such as TAT and inflammatory cytokines may also be important. Traditional anti-cancer chemotherapy agents, notably liposomal anthracyclines or paclitaxel, are active in all of these settings. Response rates are better in HIV positive patients with higher CD4 T cell counts. Ganciclovir treatment in patients with HIV and CMV (cytomegalovirus) retinitis appears to lower the incidence of KS. However, treatment of established KS with herpes antivirals is not effective.

# Kartagener Syndrome

Marcia Spinelli Casanova
Department of Oral Diagnosis, UNICAMP, Piracicaba Dental School, São Paulo, Brazil

## Synonyms

Kartagener triad; Immotile cilia syndrome; Primary ciliary dyskinesia

## Definition and Characteristics

Kartagener syndrome (KS) is a triad of symptoms, an autosomal recessively inherited disease. An unusual pathology, it is described as a triad of situs inversus (mirror image organ placement), bronchiectasis and sinusitis. Patients present a high incidence of respiratory infections. This disorder affects the activity of proteins important for the movement of cilia, especially in the respiratory tract and the spermatozoa.

In 1933, Manes Kartagener described this unusual triad in four patients, and the disorder became known as Kartagener syndrome (KS). Actually, it was first mentioned in the literature in 1904 by Sieverst who reported the case of a 21-year-old man in whom the three elements of the syndrome were present. Nowadays the most used designation is primary ciliary dyskinesia (PCD), which implies cilia with decrease or total absence of motility.

## Prevalence

The incidence of Kartagener syndrome in the population is 1 in 15,000–20,000 births. The disorder is inherited as an autosomal recessive trait. Males and females are affected equally. The complete syndrome has high familial evidence, appearing only in one generation, and multiple siblings may have various combinations of its components, which do not appear in their children.

## Genes

The high incidence of consanguinity among the apparently normal parents of affected children supports the contention that the genetic abnormality is carried as an autosomal recessive gene.

Genetic linkage analyses have shown that this disease is genetically heterogeneous even within specific ultrastructural phenotypes. The outer dynein arm defect is the only ultrastructural phenotype for which mutations have been identified. The genes in which mutations have been characterized are DNAI1, DNAH5 and DNAH11 located on human chromosomes 9p, 5p and 7p, respectively.

## Molecular and Systemic Pathophysiology

The syndrome's etiology had been unknown up to 1975. At that time some ultrastructural defects of the respiratory cilia were found with an electronic microscope in patients with KS. These defects could affect the ciliary movement of the respiratory epithelium, restricting movement or even leading to total immotility. Because ciliary motility is a prerequisite for mucociliary transport, when the patient's ciliary beat frequency does not fall within the normal range, the effective mucociliary transport cannot be visualized. These abnormal ciliary movements result in impaired mucociliary clearance and manifest as recurrent and/or persistent sinopulmonary infections, among other problems.

In KS, the majority of the ciliary cells are involved in presenting this abnormal ultrastructure of cilia. Ciliated cells are also found in the ependymal lining of the brain and fallopian tubes. This last condition can explain subfertility, including the incidence of ectopic pregnancy, in female patients. In addition, the spermatozoa flagellum, which has a core structure that is identical to cilia, also exhibited cilia that appeared abnormal, with poor mobility, and missing dynein arms, thus accounting for the high rate of infertility among male patients with KS.

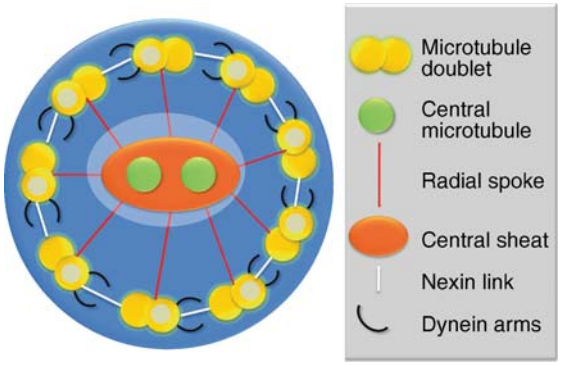
Cilia are highly complex organelles, which are composed of over 200 different polypeptides. All cilia contain nine outer pairs of microtubules, and two central single tubules. From each outer pair of microtubules, a pair of dynein arms reaches towards the next pair of microtubules. The dynein arms actually grab the adjacent pair of microtubules in a specific order, which causes the cilia to bend. Radial spokes extend from each outer pair of microtubules towards the inner central tubules. Nexin links also join each outer pair of microtubules with the adjacent outer pair. Radial spokes and nexin links help stabilize the cilia structure (Fig. 1).

## Diagnostic Principles

Symptoms result from defective cilia motility which is due to an ultrastructural defect in the cilia structure. Cilia abnormalities may be primary, inherited, or secondary, caused by environmental factors. Absent or reduced inner and/or outer dynein arms, absent radial spokes,

alterations of central microtubule, and translocation of microtubular doublets are the primary ciliary defects. The first ultrastructural defect to be reported was absent dynein arms and defects of the outer and/or inner dynein arms remain the most common ultrastructural defects identified. The ultrastructural abnormalities are summarized in Fig. 2.

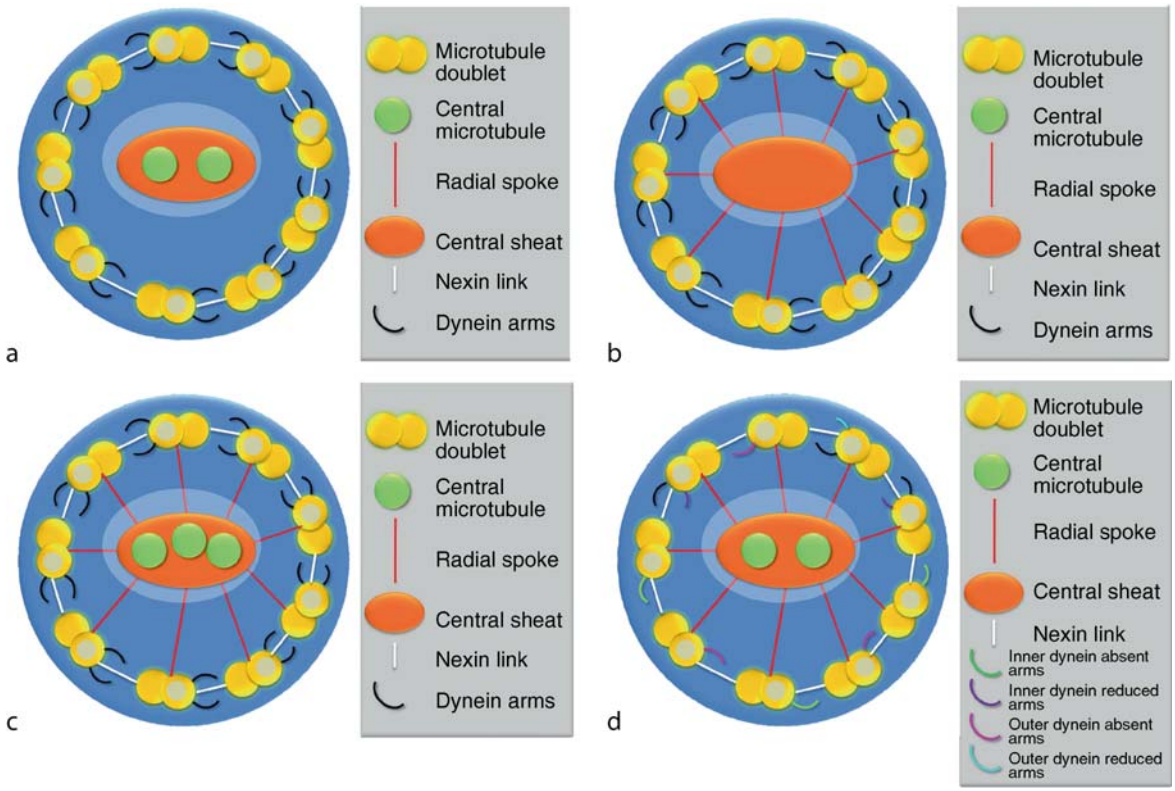
Other abnormalities, such as compound cilia, addition or deletion of peripheral microtubules, disorganized axonemes, ciliary disorientation, blebs or discontinuity of axoneme membrane, and "swollen cilia" with excess cytoplasm are nonspecific or secondarily acquired structural abnormalities.



**Kartagener Syndrome. Figure 1** Schematic drawing of the Cilia structure (Courtesy of Sergio Lopes, DDS – Dentomaxillofacial Radiology; Oral Diagnosis – Belo Horizonte, Brazil).

## Therapeutic Principles

Treatment of Kartagener syndrome is much the same as that for bronchiectasis from other etiologies. The goal of therapy is to reduce symptoms and slow disease progression. Prophylactic measures such as appropriate immunizations, particularly influenza vaccine and pneumococcal vaccine, and vigorous pulmonary toilet are the mainstays of therapy. Acute bouts of bronchitis must be treated with antibiotics. The choice of drug should be based, when possible, on findings from gram-stained sputum samples. Patients who develop recurrent pneumonia or hemoptysis and do not respond to antibiotics may benefit from segmental lung resection or lobectomy.



**Kartagener Syndrome. Figure 2** Schematic drawing of some of the possible ultrastructural cilia defects: (a) Absent radial spokes; (b) Absent central microtubule; (c) Added central microtubule; (d) Alterations of inner and/or outer dynein arms (Courtesy of Sergio Lopes, DDS – Dentomaxillofacial Radiology; Oral Diagnosis – Belo Horizonte, Brazil).

The long-term prognosis of patients with Kartagener syndrome is good, with many patients living to an advanced age. Decreased quality of life is caused by chronic respiratory symptoms.

## Kawasaki Syndrome

Oladapo Adewuya, Ferid Murad
Department of Integrative Biology and Pharmacology, The Medical School, University of Texas Health Sciences Center, Houston, TX, USA

### Synonyms

Kawasaki disease; Mucocutaneous lymph node disease; MCLD

### Definition and Characteristics

An acute febrile mucocutaneous illness accompanied by swelling of the cervical lymph nodes with major complications of coronary artery abnormalities such as aneurysm formation. A family history of Kawasaki syndrome may be a major risk factor for increased severity of the disease [1].

### Prevalence

Occurs worldwide in all racial and ethnic groups. Higher incidence in people of Asian descent. Affects mostly children under 5 years with peak incidence at 18–24 months of age. Also affects adults, though much less commonly. The incidence is slightly higher in males. Peaks in winter and spring. KS is one of the commonest causes of acquired heart disease in children.

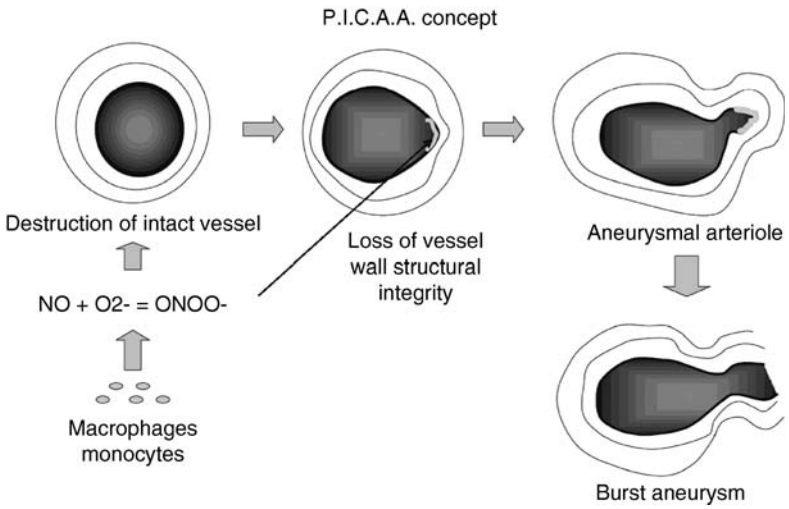
### Genes

Increased expressions of genes (in the acute phase of the disease) such as the inflammatory response gene (S-100 A9 protein), anti-inflammatory genes (TSG-6), and the adrenomedullin (ADM) gene known to be associated with coronary artery dilatation in Kawasaki disease has been recently identified by microarray analysis in monocytes/macrophages in the blood of humans [2].

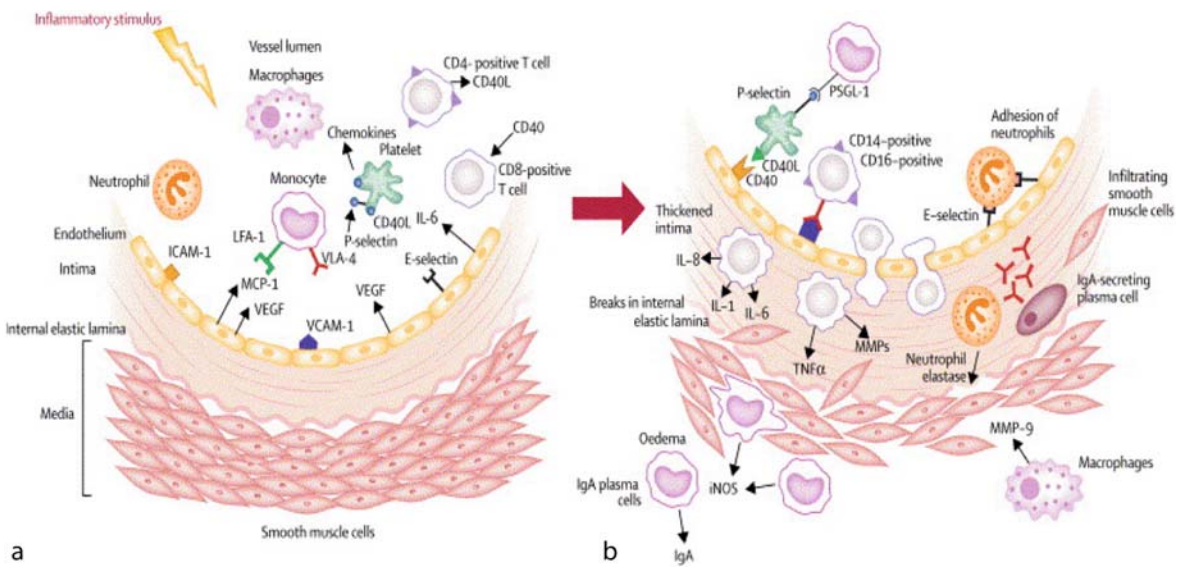
### Molecular and Systemic Pathophysiology

Kawasaki disease is initiated by a yet to be determined stimulus. Mouse experiments have replicated Kawasaki-like vasculitis after injection with Lactobacillus Casei by inducing pericoronary arteritis involving production of nitric oxide (NO) and peroxynitrite initiated arterial wall damage, and subsequent coronary abnormalities as seen in Fig. 1 [3]. This provides a mechanism between the inflammatory stimulus, response, vascular changes and aneurysm formation.

Studies have shown that in humans, an unknown inflammatory stimulus starts a series of events. These events in genetically predisposed individuals involves an inflammatory-cell infiltration, myointimal propagation, destruction and thinning of the media, and



**Kawasaki Syndrome. Figure 1** Peroxynitrite-induced coronary artery aneyrysm (PICAA Concept). This illustrates the stepwise destruction of coronary arterioles leading to a burst aneurysm (by the cytotoxic peroxynitrite-α byproduct of nitric oxide) in severe pericoronary arteritic mice induced by injection with lactobacillus casei.



**Kawasaki Syndrome. Figure 2** Proposed events in the evolution of vasculitis in Kawasaki syndrome.

subsequent aneurismal dilation of the vessel. In Fig. 2, firstly, activated circulating mononuclear cells and platelets interact with endothelial cells that express surface adhesion molecules (SAM), intercellular adhesion molecule 1(ICAM-1), vascular-cell adhesion molecule 1(VCAM-1), P-selectin, E-selectin. These then starts a margination of activated monocytes, platelets and neutrophils. Activated endothelial cells also secrete monocyte chemoattractant protein 1(MCP-1), which further attracts monocyte/macrophages, and vascular endothelial growth factor (VEGF), which increases vessel permeability.

Secondly, platelets stick onto the vascular wall elements. Inflammatory cells traverse the endothelium, build up in the intima, and liberate proinflammatory molecules including interleukins (IL) 1, 6, and 8, tumor necrosis factor alpha (TNF-α), and matrix metalloproteinases (MMPs). Neutrophils release neutrophil

elastase, which damages the internal elastic lamina and contributes to the destruction of the extracellular matrix. Activated macrophages secrete the inducible form of nitric oxide synthase (iNOS). Oligoclonal IgA-secreting plasma cells infiltrate into the media. Thickening of the intima results from penetration and propagation of smooth-muscle cells [4]. A study found an increase in IL-18 involved in the Th-1 cytokine pathways in the subacute phase of the disease, which correlated with presence of coronary artery abnormalities and the severity of the disease [5]. IL-18 was purified from the liver of mice treated with propionobacterium acnes.

### Diagnostic Principles

This is based on specific clinical criteria. They include: a high spiking and remittent fever (up to 40°C/104°F or higher) for at least five days, with four of five other major criteria in the absence of other explanations for the clinical picture. The five major criteria are: bilateral conjuctival injection; oral mucosa changes (erythematous dry fissured lips, strawberry tongue, erythema of the pharynx); changes of the hands and feet (redness and swelling in the acute phase, periungal desquamation in the subacute phase); skin rash, principally on the trunk (maculopapular, erythema multiforme, or scarlatiniform, not vesicular); cervical lymphadenopathy (node diameter, >1.5 cm). However, in the presence of coronary artery abnormalities and presence of the characteristic fever, a diagnosis of Kawasaki syndrome can be made with less than four of the five major criteria.

### Therapeutic Principles

High dose aspirin and intravenous gamma globulin (IVGG) is the mainstay of management. Administration of IVGG in the first ten days of the illness significantly reduces the risk of the development of coronary artery aneurysms [4].

A trial of pulsed steroid therapy may be of benefit in IVGG non-responders. However some information speculates worsening of coronary artery disease in patients with Kawasaki syndrome. Dipyridamole, an antiplatelet agent, can be used in place of aspirin where there is a high risk of thrombosis.

## Keratoacanthoma

Zoran Gatalica
Department of Pathology, Creighton University School of Medicine, Omaha, NE, USA

### Definition and Characteristics

Keratoacanthoma (KA) is a clinico-pathologically defined neoplasm of keratinocytes usually presenting

as solitary dome-shaped nodule on sun-exposed skin that grows rapidly over a period of 1–2 months [1]. Spontaneous involution occurs within 3–6 months, but some tumors may not regress and persist for over a year.

Histologically, the tumor shows cup-shaped invagination of epidermis with keratin-filled central crater (Fig. 1). A lip-like partial overlying of the crater by a normal epidermis is usually seen. Neoplastic keratinocytes are large with pale "glassy" eosinophilic cytoplasm and they mature toward the center of the crater. Peripheral cells at advancing edge show mild atypia and infiltrate dermis in irregular tongues. There is a mixed inflammatory cell infiltrate at the advancing edge and intraepithelial neutrophilic abscesses are characteristic. Desmoplasia is absent.

The main differential diagnosis is well-differentiated squamous cell carcinoma (SCC), and some authors regard keratoacanthoma as a variant of SCC. There is no single absolutely reliable characteristic distinguishing KA from SCC. Additionally, keratoacanthomas recur in approximately 8% of cases, and extensive destruction of the nose and eyelids may be seen. Unusual variants include enlarging type (KA centrifugum), subungual KA, and mucous membranes KA.

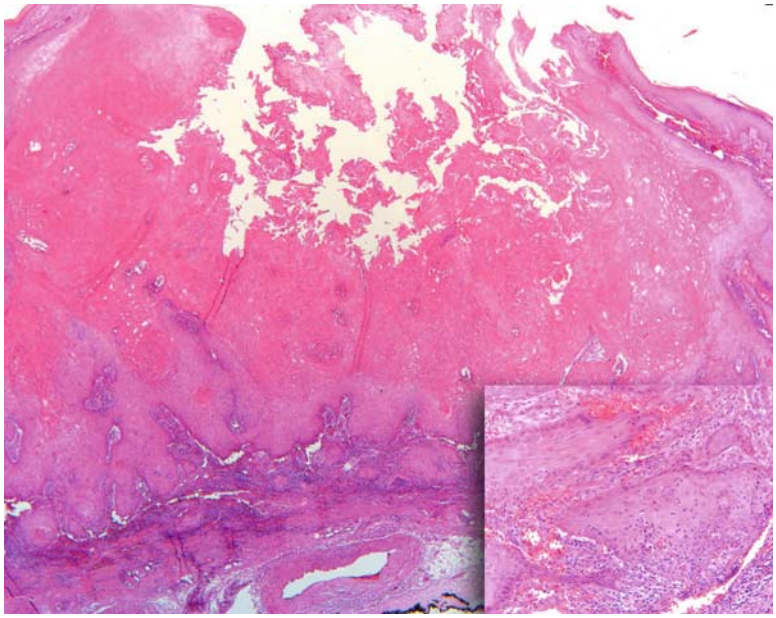
## Prevalence

It is reported that one keratoacanthoma is diagnosed for every four SCC of the skin. Solitary KAs are most often diagnosed in sixth and seventh decade of life with a male predominance. In Australian non-Aborigines this is a common tumor with incidence of 150 per 100,000.

## Molecular and Systemic Pathophysiology

Keratoacanthomas occur as solitary or multiple tumors; they occur sporadically or as a part of a syndrome. Different and overlapping pathophysiologic mechanisms may underlie development of KA in these different clinical situations.

The most common form is solitary, sporadic tumor. Using comparative genomic hybridization, 33% of keratoacanthomas arising in nonimmunosuppressed patients (and 36.4% in arising in immunosuppressed patients) showed genetic aberrations [2]. The most frequent aberrations were gains on 8q, 1p, and 9q; and losses on 3p, 9p, 19p, and 19q. In the absence of proven genetic susceptibility these sporadic cases were presumed to be the consequence of solar ultraviolet radiation exposure. In a small fraction of KAs, point mutations in the p53 gene were found. Occupational exposure to tar (chemical carcinogenesis) has been implicated in a small number of cases. In contrast to keratoacanthomas associated with Muir–Torre syndrome (below), microsatellite instability does not appear to be of significance in the induction of sporadic keratoacanthomas.



**Keratoacanthoma. Figure 1** Microscopic appearance of a keratoacanthoma. The cup-shaped proliferation of large, pale, eosinophilic keratinocytes is associated with irregular infiltration of the dermis at the bottom of the lesion. Strong inflammatory cell response (inset) with intraepithelial neutrophils is common.

Using polymerase chain reaction (PCR), human papilloma virus (HPV) DNA sequences were detected in up to 70% of KA arising in immunosuppressed and 40% of immunocompetent patients. No predominant HPV type was identified [3].

Immunosuppression (such as in organ transplant patients) strongly increases skin cancer incidence, approximately 65–250 times more than in the general population. The contribution and mechanism of immune surveillance in nonmelanocytic skin cancer (including KA) varies. Presence of CD8 lymphocytes in KA varies dependent on the stage of progression. These cytotoxic T-lymphocytes may induce apoptosis in their target cells by the FasL (Fas ligand) pathway or the perforin/granzyme B pathway. Abrogation of Fas-FasL extrinsic apoptotic pathway may be one of the mechanisms for increased incidence of KAs in immunosuppressed patients and possibly responsible for the progression to SCC.

Multiple KAs arising in nonimmunosuppressed patients are seen in several distinct syndromes, where their development has different underlying pathophysiologic mechanisms [1]. In multiple self-healing squamous epithelioma (MSSE, Ferguson-Smith type KAs), a presumed tumor suppressor gene responsible for the occurrence KAs was mapped to chromosome 9q22.3, but has not yet been characterized [4]. Patients present with intermittent development of multiple (some with >100) KAs that undergo spontaneous resolution over a period of months, leaving pitted scars and sometimes severe disfigurement.

In Muir–Torre syndrome (MTS, autosomal dominant hereditary cancer syndrome characterized by cutaneous sebaceous neoplasms associated with visceral malignancy) multiple keratoacanthomas are variably present. The MTS is a variant of hereditary nonpolyposis colorectal cancer (HNPCC, Lynch syndrome) caused by germline mutation in one of the major mismatch repair genes (MLH1, MSH2, MSH6, and PMS2). Most MTS families carry a germline mutation in MSH2 gene and microsatellite instability was detected in approximately 30% of KAs in MTS [5].

The etiology of generalized eruptive KAs (Grzybowski type) and multiple familial keratoacanthoma of Witten and Zak are not known.

### Therapeutic Principles

Given the current controversy over the diagnosis of KA (vs. well-differentiated SCC) the preferred treatment of the suspected (solitary) lesion is surgical, with conservative complete excision. Successful uses of topical immune response modifier Imiquimod (5%), interferon alpha-2b, and intralesional methotrexate were reported in a small number of patients with clinically typical KAs. Multiple lesions in MSSE and Grzybowski type may require systemic chemotherapy.

# Keratosis Pilaris

Alexander K. C. Leung[1],
William Lane M. Robson[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]The Childrens' Clinic, Calgary, AB, Canada

## Definition and Characteristics

Keratosis pilaris is characterized by the presence of minute, discrete, keratotic, follicular papules with variable perifollicular erythema (Fig. 1) [1]. The lesions are not grouped and show no tendency to coalesce and form plaques. The affected skin looks like goose-flesh and feels like sandpaper. The lesions are not pruritic. Keratin plugs cannot be expressed with pressure and are usually painless [2]. The lesions can be isolated or widespread, and have a predilection for the lateral aspects of the upper arms and thighs. The neck, torso, and buttocks are less commonly involved. The hands and feet are usually spared, but the palmar and plantar markings are more accentuated. A generalized eruption is rare.

## Prevalence

Keratosis pilaris is a very common disorder. Approximately 40% of the population is affected [3]. The condition develops during childhood and reaches a peak during adolescence. The prevalence in adolescents of both genders is estimated to be at least 50%, and up to 80% of adolescent girls can be affected [3]. The disorder resolves spontaneously and is less common during adult life [3]. There is no racial predominance.

**Keratosis Pilaris. Figure 1** Keratosis pilaris on the arms.

## Molecular and Systemic Pathophysiology

The exact etiology is not known. An autosomal dominant mode of inheritance with incomplete penetrance has been postulated. The high prevalence and intensity seen at puberty suggests a hormonal influence. Hyperandrogenism in the presence of obesity is associated with an increased incidence and severity of keratosis pilaris. Pathologically, the follicular orifice is distended by a keratotic plug. Mild perivascular infiltration with mononuclear cells is often present.

Keratosis pilaris is more common in patients with ichthyosis vulgaris and atopic dermatitis [4]. Other conditions reported to be associated with keratosis pilaris include Cushing disease, hypothyroidism, diabetes mellitus, vitamin A intoxication, vitamin C deficiency, monilethrix, Hodgkin disease, monosomy 18p, Noonan syndrome, Down syndrome, and cardio-facio-cutaneous syndrome. Given the high prevalence of keratosis pilaris, some of these associations might be coincidental.

## Diagnostic Principles

The differential diagnosis includes folliculitis, miliaria, acne, Darier's disease, phrynoderma, pityriasis rubra pilaris, and lichen spinulosus. The hallmark of keratosis pilaris is the presence of rough bumps. The clinical features of keratosis pilaris are sufficiently distinct that the diagnosis is usually straightforward.

## Therapeutic Principles

Prevention of excessive skin dryness is helpful. This can be accomplished by reduction in the frequency of skin cleansing, brief, tepid showers rather than long, hot baths, use of mild soaps, and humidification of the air in the home. In mild cases, a moisturizing cream or an emollient such as hydrophilic petrolatum or a 10–20% urea cream usually alleviates the rough surface. More pronounced or widespread lesions require treatment with a keratolytic agent such as lactic acid, salicylic acid, or urea in combination with a topical corticosteroid or retinoic acid.

# Ketotic Hyperglycinemia

►Propionic Acidaemia

# Ketotic Hypoglycaemia of Infancy

Khalid Hussain
Great Ormond Street Children's Hospital NHS Trust and the Institute of Child Health, Unit of BEM, University College, London, UK

## Synonyms

Idiopathic ketotic hypoglycaemia; Idiopathic hypoinsulinaemic ketotic hypoglycaemia; Ketotic hypoglycaemia of infancy

## Definition and Characteristics

Ketotic hypoglycaemia is the most common form of hypoglycaemia beyond infancy [1]. The usual presentation is between the ages of 18 months and 5 years and then remits spontaneously by the age of about 10 years. The typical history is of a child who may miss a meal due to an intercurrent illness (such as an upper respiratory tract infection or diarrhoea and vomiting) and then develops hypoglycaemia. The hypoglycaemic episodes seem to be unpredictable, only occurring sometimes. Seizures may occur at the time of the hypoglycaemia, but neurological sequelae are rare and prognosis seems to be good. The hypoglycemia responds promptly to glucose administration. Ketotic hypoglycaemia is more common in Caucasian males with low body weight.

## Prevalence

The true prevalence of ketotic hypoglycaemia is not known.

## Genes

Currently it is not known if idiopathic ketotic hypoglycaemia has a genetic basis. So far no genetic defects have been described in patients presenting with idiopathic ketotic hypoglycaemia. It is possible that some patients with ketotic hypoglycaemia may represent one end of the normal spectrum of metabolic responses to fasting.

## Molecular and Systemic Pathophysiology

The pathophysiology and possible molecular mechanisms of ketotic hypoglycaemia remains unclear. Some earlier studies suggested a functional defect of gluconeogenesis or a lack of gluconeogenic substrates, including alanine [2] but not all studies have been able to replicate these biochemical findings. More recent studies show that ketotic hypoglycaemia is caused by a failure to sustain sufficient hepatic glucose production rather than by increased glucose oxidation [3]. Leucine oxidation rates are reduced while energy expenditure is significantly increased during episodes of ketotic hypoglycaemia [3].

## Diagnostic Principles

Ketotic hypoglycaemia is a diagnosis of exclusion. Biochemically the hypoglycaemia is associated with appropriately raised ketone bodies (ketonuria) and free fatty acids with suppressed insulin levels and an appropriate counter regulatory hormonal response. There are also no abnormalities in the carnitine and acylcarnitine profiles, the urine organic acids are normal but some patients may show low serum alanine levels [2]. Rare conditions such as hepatic glycogen synthase deficiency and acetoacetyl CoA thiolase deficiency have been reported as presenting with ketotic hypoglycaemia and these need to be excluded.

## Therapeutic Principles

Treatment involves providing ample glucose either enterally or intravenously. Patients should be admitted, if the parent is sufficiently concerned to bring the child to hospital. Each patient should have an emergency management plan for the hypoglycaemia at times of an illness. Treatment consists of giving high glucose polymer drinks if the child is not vomiting and is able to tolerate enteral feeds. However if the child is unable to tolerate enteral feeds they should be admitted to hospital. In hospital most children will require an intravenous infusion of glucose.

# Kidney Cancer

►Renal Cell Carcinoma

# Kindler Syndrome

Dieter Metze
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Congenital bullous poikiloderma

## Definition and Characteristics

Kindler syndrome is an inherited disease that clinically combines features of dystrophic epidermolysis bullosa and congenital poikilodermas such as Rothmund–Thomson syndrome. Autosomal recessive or dominant inheritance is suggested. Hereditary acrokeratotic poikiloderma of Weary is discussed to be a variant of Kindler syndrome [1].

Kindler syndrome presents with congenital acral blisters, blistering after trauma or sun exposure, erythema and itching after sun exposure, and generalized progressive hyper- and hypopigmentation with atrophy and telangiectases (poikiloderma). Other features include palmoplantar hyperkeratosis, diffuse cutaneous atrophy and wrinkling, nail dystrophy, and fusion of fingers and toes. Mucocutaneous complications are periodontal disease, dental caries, and synechia of mucosal membranes. Blistering and photosensitivity improves in adulthood, while poikiloderma persists.

## Prevalence

Kindler syndrome is a rare disorder.

## Genes

Independently, Jobard et al. and Siegel et al. identified mutations in a gene on chromosome 20p12.3 that encodes for a protein termed Kindlerin or Kindlin-1 [2,3].

## Molecular and Systemic Pathophysiology

Kindlin-1 is a human homolog of the C. elegans protein Unc112, a membrane-associated structural/signaling protein that had been implicated in linking the actin cytoskeleton to the extracellular matrix. Accordingly, Kindler syndrome might be regarded as the first skin fragility disorder to be caused by a defect in the actin–extracellular matrix linkage.

## Diagnostic Principles

Electron microscopy demonstrates duplication of the lamina densa, focal absence of the basement membrane, and cleft formation at different levels at the epidermal–dermal junction [4].

## Therapeutic Principles

Treatment is supportive.

# Kissing Disease

►Mononucleosis, Infectious

# Klinefelter Syndrome

Stefan R. Bornstein
Medical Clinic III, University Hospital Dresden, Dresden, Germany

## Synonyms

X Polysomy, in males

## Definition and Characteristics

In Klinefelter syndrome, numeral chromosome aberrations with one or more extra X chromosomes cause various symptoms and endocrinologic dysfunction. The syndrome is characterized by hypogonadism (small testes, azoospermia/oligospermia), gynecomastia at late puberty, psychosocial problems, hyalinization and fibrosis of the seminiferous tubules, and elevated gonadotropins.

## Prevalence

Klinefelter syndrome is the most frequent cause of primary hypergonadotropic hypogonadism (incidence 1:1,000 men). The recurrence risk is not increased above that of the general population.

## Molecular and Systemic Pathophysiology

Nondisjunction in the meiosis I, II, or mitosis leads to numeral chromosome aberrations with one or more extra X chromosomes. In 80%, the karyotype is 47, XXY. In some cases, there are aneuploidien (48, XXXY; 49, XXXXY), a extra Y chromosome (e.g., 48, XXYY), or a mosaik (e.g., 46, XY/47, XXY).

The addition of more than 1 extra X or Y chromosome to a male karyotype results in variable physical and cognitive abnormalities. In general, the extent of phenotypic abnormalities, including mental retardation, is related directly to the number of supernumerary X chromosomes. As the number of X chromosomes increases, somatic and cognitive development are more likely to be affected. Skeletal and cardiovascular abnormalities can become increasingly severe. Gonadal development is particularly susceptible to each additional X chromosome, resulting in seminiferous tubule dysgenesis and infertility as well as hypoplastic and malformed genitalia in polysomy X males. Moreover, mental capacity diminishes with additional X chromosomes. The intelligence quotient (IQ) is reduced by approximately 15 points for each supernumerary X chromosome, but conclusions about reduced mental capacity must be drawn cautiously. All major areas of development, including expressive and receptive language and coordination, are affected by extra X-chromosome material.

*Risk Factors*: There are different factors with high risk leading to numeral chromosome aberrations. One of them is the high age of the mother and another point is the long time of meiosis.

*Clinic*: Many XXY males are not diagnosed due to the absence of specific symptoms. However, if they are to be diagnosed, chances are greatest at one of the following phases in life: before or shortly after birth, early childhood, adolescence, and in adulthood (as a result of testing for infertility).

The major consequences of the extra X chromosome are hypogonadism, gynecomastia, and psychosocial problems. Klinefelter syndrome is a form of primary testicular failure, with elevated gonadotropin levels arising from lack of feedback inhibition of the pituitary gland. Testosteron deficiency causes eunuchoid body proportions; sparse or absent facial, axillary, pubic, or body hair; decreased muscle mass and strength; feminine distribution of adipose tissue; gynecomastia; small testes and penis; diminished libido; decreased physical endurance; and osteoporosis.

Increased incidence of autoimmune disorders, such as systemic lupus erythematosus, rheumatoid arthritis, and Sjögren syndrome, has been reported. This may be due to lower testosterone and higher estrogen levels, since androgen may protect against (and estrogen promote) autoimmunity.

## Diagnostic Principles

Most males born with Klinefelter syndrome go through life without being diagnosed. Diagnosis, when made, usually occurs in adulthood. The most common indications for karyotyping are hypogonadism and infertility.
Growth:

- Infants and children have normal heights, weights, and head circumferences. About 25% have clinodactyly. Height velocity is increased by age 5 years, and adult height usually is taller than average. Affected individuals also have disproportionately long arms and legs.
- Some individuals with Klinefelter variant 49, XXXXY have short stature.

Central nervous system:

- Most 47, XXY males have normal intelligence. Family background influences IQ. Subnormal

intelligence or mental retardation may be associated with the presence of a higher number of X chromosomes.
- About 70% of patients have minor developmental and learning disabilities. These may include academic difficulties, delayed speech and language acquisition, diminished short-term memory, decreased data-retrieval skills, reading difficulties, dyslexia, and attention-deficit disorder.
- Patients may exhibit behavioral problems and psychological distress. This may be due to poor self-esteem and psychosocial development or a decreased ability to deal with stress.
- Psychiatric disorders involving anxiety, depression, neurosis, and psychosis are seen more commonly in this group than in the general population.

Dental:

- Taurodontism (enlargement of the molar teeth by an extension of the pulp) is present in about 40% of patients.
- Incidence is about 1% in normal XY individuals.

Sexual characteristics:

- Patients may lack secondary sexual characteristics because of a decrease in androgen production. This results in sparse facial/body/sexual hair, a high-pitched voice, and a female type of fat distribution.
- By late puberty, 30–50% of boys with Klinefelter syndrome manifest gynecomastia, which is secondary to elevated estradiol levels and increased estradiol/testosterone ratio. The risk of developing breast carcinoma is at least 20 times higher than normal.
- Testicular dysgenesis (small firm testis, testis size <10 mL) may be present in postpubertal patients.
- Infertility/azoospermia may result from atrophy of the seminiferous tubules. Infertility is seen in almost all individuals with a 47, XXY karyotype. Patients with Klinefelter syndrome mosaicism (46, XY/47, XXY) can be fertile.
- Patients may have an increased frequency of extragonadal germ cell tumors such as embryonal carcinoma, teratoma, and primary mediastinal germ cell tumor.

Cardiac and circulatory problems:

- Mitral valve prolapse occurs in 55% of patients.
- Varicose veins occur in 20–40% of patients.
- The prevalence of venous ulcers is 10–20 times higher than normal, and the risk of deep vein thrombosis and pulmonary embolism is increased.

Klinefelter variants:

- 48, XXYY variant: Patients typically have mild mental retardation, tall stature, eunuchoid body habitus, sparse body hair, gynecomastia, long thin legs, hypergonadotropic hypogonadism, and small testes.
- 48, XXXY variant: Patients typically have mild-to-moderate mental retardation, speech delay, slow motor development, poor coordination, immature behavior, normal or tall stature, abnormal face (epicanthal folds, hypertelorism, protruding lips), hypogonadism, gynecomastia (33–50%), hypoplastic penis, infertility, clinodactyly, and radioulnar synostosis and benefit from testosterone therapy.
- 49, XXXYY: Patients typically have moderate-to-severe mental retardation, passive but occasionally aggressive behavior and temper tantrums, tall stature, dysmorphic facial features, gynecomastia, and hypogonadism.
- 49, XXXXY variant: The classic triad is mild-to-moderate mental retardation, radioulnar synostosis, and hypergonadotropic hypogonadism. Other clinical features include severely impaired language, behavioral problems, low birth weight, short stature in some individuals, abnormal face (round face in infancy, coarse features in older age, hypertelorism, epicanthal folds, prognathism), short or broad neck, gynecomastia (rare), congenital heart defects (patent ductus arteriosus is most common), skeletal anomalies (genu valgus, pes cavus, fifth finger clinodactyly), muscular hypotonia, hyperextensible joints, hypoplastic genitalia, and cryptorchidism. Pea-size testes, micropenis, and infantile secondary sex characteristics are characteristic in patients with 49, XXXXY, whereas patients with 48, XXXY exhibit milder hypogonadism similar to that of patients with 47, XXY.

## Therapeutic Principles

Early identification and anticipatory guidance are extremely helpful (although the syndrome rarely is diagnosed in prepubertal males).

Treatment should address three major facets of the disease: hypogonadism, gynecomastia, and psychosocial problems.

Considerable gynecomastia places psychological strain on the patient and increases risk of breast cancer; therefore, mastectomy may be indicated for gynecomastia.

Androgen replacement therapy is the most important aspect of the treatment. Testosterone replacement should begin at puberty to correct androgen deficiency, provide appropriate virilization, and improve psychosocial status. Regular testosterone injections can promote strength and facial hair growth; build a more muscular body type; increase sexual desire; enlarge size of testes; improve mood, self-image, and behavior; and protect against precocious osteoporosis.

A multidisciplinary team approach will help speech impairments, academic difficulties, and other psychosocial and behavioral problems.

# Klippel-Feil Syndrome

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

The clinical manifestations of Klippel-Feil syndrome (sequence) are a short neck, a low posterior hairline, and limitation of head and neck movements [1]. Rotational loss is usually more pronounced than the loss of flexion and extension. The head seems to sit in the thorax. Torticollis or a webbed neck may be present. The scapula is frequently high. Affected patients might have synkinesia, in which movements in one hand are mirrored in the other. The condition is characterized by fusion of two or more cervical vertebrae (Fig. 1).

Four subtypes of Klippel-Feil syndrome are recognized: type 1 presents with massive fusion of the cervical vertebrae and sometimes the upper thoracic vertebrae; type 2 involves fusion at only one or two cervical intervertebral spaces; type 3 occurs when lower thoracic or lumbar spine anomalies are associated with type 1 or type 2 anomaly; and type 4 is associated with sacral agenesis. Fusion of the cervical vertebrae might result in hypermobility and instability of the cervical spine at unfused levels, subluxation of the vertebrae, spinal cord compression from disk protrusion, and osteoarthritic changes at a later age. Traumatic tetraplegia has been reported following minor trauma. Klippel-Feil syndrome is associated with a spectrum of anomalies. Scoliosis occurs in approximately 60% of affected patients; hearing loss in over 50%; genitourinary anomalies in 25–35%; rib abnormalities in 33%; Sprengel deformity in 20–30%; congenital heart disease in 14–29%; and cleft palate in 15% [2].

## Prevalence

The incidence is estimated at 1:43,000 live births [3]. The female-to-male ratio is approximately 1.3:1.

**Klippel-Feil Syndrome. Figure 1** Klippel-Feil syndrome. Note fusion of the cervical vertebrae in the cervical radiograph.

## Genes

Most cases are sporadic. Both autosomal recessive inheritance and autosomal dominant inheritance with variable expression have been described [4].

## Molecular and Systemic Pathophysiology

Klippel-Feil syndrome results from abnormal embryonic formation of the vertebral mesenchymal anlagen and failure of the mesodermal somites to divide during the third to eighth week of gestation. The anomaly is most likely caused by disturbed expression or mutation in the PAX 1 gene, which regulates segmentation and resegmentation of the spine [5]. The gene has been mapped to chromosome 20p11.2 [5].

## Diagnostic Principles

Lateral flexion-extension radiographs of the cervical spine confirm the diagnosis and establish the range of motion of each open interspace. A lateral radiograph of the skull will demonstrate occipitocervical abnormalities. MRI of the cervical cord and craniocervical junction is indicated before any orthopedic procedure and whenever neurologic symptoms or signs are present in the upper extremities. Audiology testing is indicated for all affected patients. Kidney and bladder ultrasonography should be performed to screen for urinary anomalies. Echocardiography is indicated when congenital heart disease is suspected. The differential diagnosis includes MURCS (müllerian duct aplasia, renal hypoplasia/dysgenesis/ectopia, and cervical-thoracic somite dysplasia) and VATERLS (vertebral anomalies, anal anomalies, tracheoesophageal fistula and atresia, renal defects, radial upper limb hypoplasia, and single umbilical artery) association.

## Therapeutic Principles

Treatment is mainly symptomatic. Affected patients should avoid contact sports and any exercise that might exacerbate instability of the cervical spine.

# Krabbe Disease

KUNIHIKO SUZUKI
Neuroscience Center, University of North Carolina School of Medicine, Chapel Hill, NC, USA

## Synonyms

Globoid cell leukodystrophy; GLD

## Definition and Characteristics

Deficiency of galactosylceramidase activity. Autosomal recessive. Clinical phenotype is exclusively neurological, involving particularly white matter of the brain and the peripheral nervous system. Neuropathology is unique with nearly total demyelination and infiltration of characteristic "globoid cells." Typically an infantile and rapidly progressive disease. One of the classical genetic leukodystrophies [1].

## Prevalence

1–2/100,000 births with higher incidence in the Scandinavian countries. A small pocket of Druse population in Israel has incidence of 6/1,000 births. No cases known among Jews.

## Genes

Defective galactosylceramidase gene located on human chromosome at 14q31 causes Krabbe disease in all mammalian species. Saposin A, encoded by prosaposin gene located on human chromosome 10q22.1, is an essential in vivo activator of galactosylceramidase and thus its deficiency causes a late-onset, chronic form of globoid cell leukodystrophy in the mouse. The corresponding human disease may be anticipated [2,3].

## Molecular and Systemic Pathophysiology

The main substrate of galactosylceramidase is galactsylceramide. Since it is nearly exclusively a constituent of myelin, clinical and pathological phenotype is limited to the nervous system. Another substrate of galactosylceramidase that has important pathophysiological implications is galactosylsphingosine (psychosine). Galactosylceramide synthase not only synthesizes galactosylceramide, it also synthesizes psychosine. In normal brain, psychosine is degraded rapidly. In Krabbe disease, however, it accumulates abnormally due to the genetic defect in galactosylceramidase. Psychosine is highly cytotoxic with potent apoptosis-inducing capacity. Because of the unique localization of its synthesis, abnormal accumulation occurs only in the myelin-generating cells reaching the locally toxic level. This is postulated to be the pathogenetic mechanism operating in Krabbe disease (psychosine hypothesis) [4]. Other substrates are of negligible consequences. Over 70 disease-causing mutations have been identified in the human galactosylceramidase gene. A major deletion of 30 kb that always occurs on a 502T polymorphic background (502T/del) is common among patients from Northern Europe. The 502T/del mutation makes up about 50% of the total mutant alleles among European patients and 75% of the mutant alleles in Swedish infantile patients. It has not been found among Japanese patients. Two other mutations (C1538T and A1652C) constitute additional 10–15% of the mutant alleles in infantile patients with European ancestry.

## Diagnostic Principles

Early onset, rapidly progressive severe white matter disease with high spinal fluid protein points to the diagnosis of classical cases. Late-onset cases are difficult to diagnose on the clinical ground alone. Galactosylceramidase assay followed by identification of mutations establishes the diagnosis. Saposin A deficiency is likely to require peripheral nerve biopsy followed by direct identification of mutation in the saposin A domain of the prosaposin gene.

## Therapeutic Principles

There is no treatment that can "cure" Krabbe disease. Gene therapy is still in a highly experimental phase, primarily with *in vitro* systems and animal models. Significantly beneficial outcome has been reported with bone marrow transplantation in late-onset forms. When given at very early stages, the beneficial results of bone marrow transplantation may extend to infantile patients [5]. Limiting substrate synthesis is being tried in animal models with varying results. Dramatic improvements in the clinical and pathological phenotype occurred in the saposin A-deficient mice during pregnancy, and the beneficial effects were largely duplicated by administration of high dosage of estrogen [3]. Two unrelated GLD patients due to saposin A deficiency are now known, one published from Israel [6] and the other in France yet to be published (Vanier, personal communication). Both have the same one – codon deletion in the saposin domain of the prosaposin gene. Galactoxylceramidase activity was low in leukocytes but normal in cultured fibroblasts in both patients.

## Synonyms

Kussmaul breathing

## Definition and Characteristics

In a case report from 1874 in the Dtsch Arch Klin Med., Adolph Kussmaul described the hyperventilation associated with diabetic ketoacidosis (DKA) now known as Kussmaul respirations:

"There is nothing here, as in ordinary dyspneas, to indicate that the air has to overcome the slightest obstacle on its way into or out of the lungs; on the contrary, it comes in and out with the greatest ease; the thorax widens itself splendidly in all directions, without any evidence of pulling in of the lower end of the sternum or the intercostals spaces, and a complete inspiration followed each complete respiration; down to the deepest part of the lungs, one hears a pure, loud and sharp vesicular breathing (so-called puerile breathing); and that all points to the highest degree of air hunger (Lufthunger), as does the oppressive pain of which the patient complains, as well as the tremendous activity of the respiratory muscles, which are so readily seen, the loud noise which the mighty respiratory and even stronger expiratory air stream produces in the larynx … The breathing furthermore proceeded *with great regularity*, was not interrupted and showed no sudden changes in rate… In spite of the great distress, the dyspnea did not become orthopnea, because the patients were too weak to hold themselves up. The contrast of the general weakness with the strength of the respiratory movements is one of the most remarkable characteristics in this picture." [1]

He also describes the frequency of respirations being for the most part 20–24 times per minute preceding the coma, although sometimes higher. In summary, Kussmaul respirations have a very deep character suggestive of "air hunger," proceed with great regularity, and are not associated with stridor or pulmonary congestion. Furthermore, these respirations are a sign of serious acidosis and may precede coma and death if the underlying condition goes untreated. Kussmaul respirations may also be present due to other causes of metabolic acidosis, such as lactic acidosis and the acidosis of renal failure.

## Prevalence

Hyperventilation is often seen in patients with impaired consciousness, as described below. The incidence

of DKA is between 4.6 and 8.0 per 1,000 person-years among patients with diabetes [2], and Kussmaul respirations may occur in some proportion of these, as well as patients with the other conditions discussed below.

## Molecular and Systemic Pathophysiology

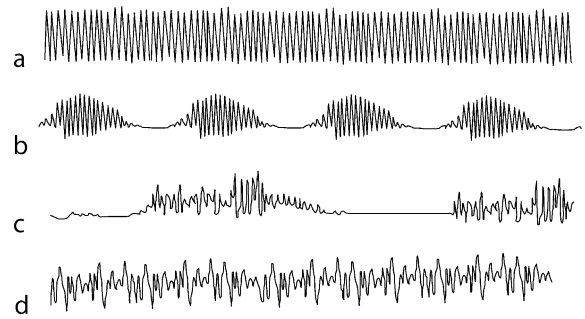
DKA results from inadequate levels of insulin relative glucagon leading to hyperglycemia. In the DKA state, triglycerides are broken down, resulting in the mobilization of free fatty acids and fatty acid oxidation as lipogenesis is inhibited. The free fatty acids cannot enter the citric acid cycle but rather are oxidized by mitochondria to the ketone bodies acetoacetate and β–hydroxybutyrate. It is the accumulation of these weak acids that results in the metabolic acidosis (low pH with low $HCO_3^-$). The body may then compensate for this metabolic acidosis by trying to decrease the $CO_2$ in the blood by expelling it through the lungs. The result may be hyperventilation (or Kussmaul respirations). Indeed, Kussmaul was correct when he postulated that this breathing was due to "chemical disturbances of the body in diabetes," although "the nature of this toxic agent" was unknown [1]. We now know that these "toxic agents" are the ketone bodies as described above.

In patients with DKA with alterations in consciousness, the pH is usually less than 7.0 [3]. Metabolic causes of hyperventilation and impaired consciousness include metabolic acidosis due to uremia, alcoholic ketoacidosis, lactic acidosis, and poisoning with toxins such as ethylene glycol, methyl alcohol, salicylates, as well as primary respiratory alkalosis due to hepatic failure or sepsis.

The respiratory rhythm in the setting of this metabolic disturbance is regulated to a large extent by a network of neurons in the ventrolateral medulla, with inputs from central ventral medullary chemoreceptors, as well as peripheral chemoreceptors such as the carotid body via the carotid sinus branch of the glossopharyngeal nerve terminating in the solitary tract. The carotid body is a polymodal arterial chemoreceptor located at the bifurcation of the common carotid artery into the internal and external carotid arteries. The carotid body usually responds first to the acidosis, with central chemoreceptors playing a more important role after the pH drops below 7.32. The medullary respiratory center also has a peripheral input from pulmonary stretch receptors via the vagus nerve and central inputs from the pons and forebrain, which may also cause hyperventilation.

## Diagnostic Principles

Kussmaul respirations, as noted above, may have a very deep character suggestive of "air hunger," proceed with great regularity, and occur in the absence of stridor or pulmonary congestion. Kussmaul respirations may be distinguished from other types of hyperventilation sometimes present in patients with impaired consciousness. In addition to the metabolic causes listed above, other causes of hyperventilation which must be distinguished from Kussmaul breathing include Cheyne-Stokes respiration, ataxic breathing, central neurogenic hyperventilation, and cluster breathing [4] (Fig. 1).



**Kussmaul Respirations. Figure 1** Different respiratory patterns associated with hyperventilation and alter mental status: (a) Kussmaul respirations; (b) Cheyne-Stokes respirations; (c) Cluster breathing; (d) Ataxic breathing.

Cheyne-Stokes respiration, with tidal volumes gradually increasing and decreasing in magnitude, may be seen with heart failure due to increased transit time for blood from the lungs to reach the carotid and cerebral chemoreceptors. Central neurogenic hyperventilation has a respiratory pattern similar to Kussmaul respirations, has an association with metabolic encephalopathies and results in sustained hyperventilation with relatively constant tidal volumes. Cluster breathing (Biot's respirations) is characterized by irregular clusters of breathing, while ataxic breathing, in which respirations are completely irregular, is associated with lesions in the pontomedullary junction.

## Therapeutic Principles

Treatment of Kussmaul respirations should be focused on correcting the underlying metabolic acidosis. In the case of diabetic ketoacidosis, treatment should include fluid hydration, insulin administration and electrolyte replacement. In other situations, treatment should be directed to the specific cause of the acidosis.

# Labial Fusion

Alexander K. C. Leung[1],
William Lane M. Robson[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]The Childrens' Clinic, Calgary, AB, Canada

## Synonyms

Vulvar fusion; Synechia of the vulva; Adhesion of the labia minora; Agglutination of the labia minora

## Definition and Characteristics

Labial fusion is defined as partial or incomplete adhesion of the labia minora [1]. On inspection, the vulva is flat and the edges of the labia are sealed in the midline by a thin translucent membrane (Fig. 1).

The fusion typically begins posteriorly and extends anteriorly [2]. In 70% of cases, the fusion extends from the posterior fourchette to just below the clitoris, such that the vaginal introitus is obscured and the hymen is not visible [1]. There is usually a small opening anteriorly through which urine passes. The condition is usually asymptomatic. Post-void dribbling of urine or dampness with change in posture might occur because of retention of urine behind the fused labia [3].

## Prevalence

Labial fusion is most common between the ages of 3 months and 4 years [2]. The peak incidence occurs between 13 and 23 months, during which approximately 3.3% of girls have the condition [2]. The disorder occasionally persists to puberty and has been reported in postmenopausal women [4]. Congenital labial fusion is rare [2].

## Molecular and Systemic Pathophysiology

Labial fusion is an acquired condition that develops after denudation of the superficial squamous epithelial layer of the labia minora. Denudation occurs with inflammatory conditions such as chemical or infectious vulvitis or vulvovaginitis. Less than optimal genital hygiene is a common predisposition. Trauma due to masturbation, sexual abuse, or straddle injury can predispose to labial fusion. Fibrous tissue forms during the healing process, and agglutination develops in the opposed areas.

Hypoestrogenism is associated with a reduction in the thickness of the labial epithelial cells. The reduced incidence of labial fusion in the first few months of life is likely related to the presence of maternal estrogen [1]. Thereafter, the physiologically low estrogen level might predispose infants and preschool children to labial fusion. The higher levels of circulating estrogen after puberty likely prevent labial fusion [4]. The low estrogen levels that follow menopause might predispose older women to labial fusion.

## Diagnostic Principles

Labial fusion can be mistaken for vaginal agenesis and imperforate hymen. The translucent line of fusion in the midvulvar area is pathognomonic of labial fusion. In vaginal agenesis and imperforate hymen, the labia minora are clearly visible.

## Therapeutic Principles

Urinary tract infection is more common in children with labial fusion [1]. Labial fusion can be complete enough to cause urinary outflow obstruction with resultant bladder distension and hydronephrosis [5].

Precise twice a day application of a small amount of topical estrogen cream to the fused area usually results in resolution within a few months [5]. Side effects of estrogen cream consist mainly of breast enlargement and pigmentation of the labia and areolae [5]. The effects are reversible when treatment is discontinued [5]. As the labia minora separate, petroleum jelly should be applied to the edges to prevent re-adhesion [5].

## Lack of ADH or ADH Action

►Diabetes Insipidus

## Lactase Nonpersistence

►Lactose Intolerance

## Lactose Intolerance

Carsten Büning[1], Johann Ockenga[1], Janine Büttner[1], Hartmut Schmidt[2]
[1]Department of Gastroenterology, Hepatology and Endocrinology, Charité, University Hospital, Berlin, Germany
[2]University Hospital of Muenster, Muenster, Germany

### Synonyms

Adult-type hypolactasia; Lactase nonpersistence

### Definition and Characteristics

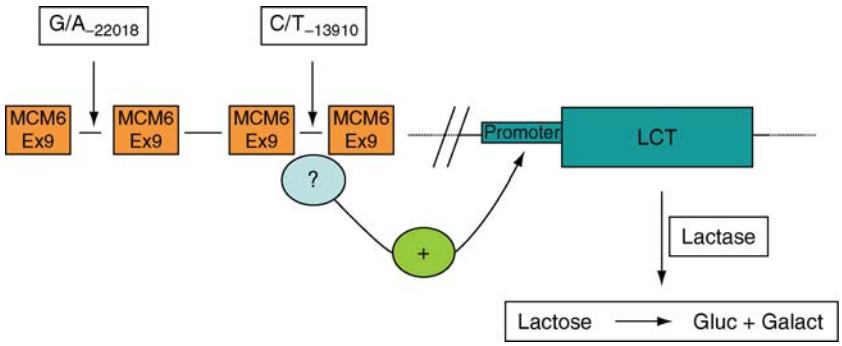
The common use of lactose intolerance refers to the term of adult-type hypolactasia, where the enzymatic lactase activity declines after weaning. This decline is genetically determined and occurs after birth within 1–2 years among the Thai population and after 10–12 years among Finns [1]. Adult-type hypolactasia is a common autosomal recessive inherited condition that can cause abdominal pain, diarrhea, bloating, and flatulence after consumption of lactose. Second, lactose intolerance can also be secondary due to various diseases that affect the intestinal mucosa, such as ►Crohn's disease or coeliac disease. Third, lactase deficiency can result from a complete congenital loss (congenital alactasia), but this is a very rare incident with presentation immediately after birth.

### Prevalence

Adult-type hypolactasia nowadays affects 75% of the population worldwide with high regional differences in prevalence ranging from 100% in some Asian countries, 25% in the United States, 15% in Germany, and 2% in Northern Europe. Therefore, most of the world's population is hypolactatic.

### Genes

It is suggested that more than 10,000 years ago, all human beings were considered to have the lactase nonpersistence phenotype. Around that time, a mutation is suggested to have occurred resulting in the genetic trait of lactase persistence. This resulted in a strong survival benefit because these individuals were able to tolerate milk-containing products. It has been shown that the longer the tradition of dairy farming and thus ingestion of milk-containing products in the



**Lactose Intolerance. Figure 1** Hypothesis for the pathogenesis of adult-type hypolactasia: The region at C/T$_{-13910}$ located within introns of the MCM6 gene is suggested to act as an upstream gene regulator with enhancer activity. A currently unknown transcription factor (?) binds to this site and enhances the LCT promoter actvity. The regulatory function of the G/A$_{-22018}$ variant is currently unknown.

population, the lower the presence of the lactase nonpersistent phenotype. Indeed, the selection pressure for lactase persistence is the strongest that has been identified for any human gene. Two particular DNA variants (C/T$_{-13910}$ and G/A$_{-22018}$) are highly associated with adult-type hypolactasia [2]. These two SNPs are located within introns of the MCM6 gene, which is located 3 kb upstream of the initiation site of the LCT gene encoding for the lactase-phlorizin hydrolase (LPH). The C$_{-13910}$ and the G$_{-22018}$ variants are associated with lactase nonpersistence whereas the T$_{-13910}$ and the A$_{-22018}$ variants are associated with lactase persistence.

## Molecular and Systemic Pathophysiology

The enzyme LPH hydrolyses lactose in small intestinal cells; the resulting products are glucose and galactose. Adult-type hypolactasia is based on a decreased activity of LPH. Herein, lactose is not efficiently hydrolyzed in the small intestine and reaches the distal ileum and colon where it is fermented by bacteria. Some of the clinical symptoms are suggested to result from these fermentative products. LPH activity is regulated through the DNA variants C/T$_{-13910}$ and G/A$_{-22018}$. Expression of LPH mRNA in the intestinal mucosa in individuals with T$_{-13910}$ A$_{-22018}$ alleles is several times higher than that found in individuals with C$_{-13910}$, G$_{-22018}$ alleles. The C/T$_{-13910}$ variant seems to be directly involved in the regulation of the LCT gene, probably through transcriptional enhancing of the lactase promoter activity (Fig. 1). It is currently unknown which transcription factors mediate this regulated activity.

## Diagnostic Principles

Numerous methods are available to diagnose lactose intolerance. Measurement of lactase activity within duodenal biopsies is the gold standard but is invasive and is usually not used for screening. The hydrogen ($H_2$) breath test and the blood glucose test are most widely applied in clinical practice. Genotyping for the C/T$_{-13910}$ variant has shown to have high sensitivity and specificity and also allows in combination with the hydrogen breath test the differentiation between primary and secondary lactose intolerance [3]. Once secondary lactose intolerance is assumed, further efforts are required to identify the underlying cause.

## Therapeutic Principles

Therapy of lactose intolerance is based on the avoidance of lactose-containing products such as milk, ice cream, and cottage cheese. In addition, lactose is added to a large number of foods and drinks without being on the label (“hidden lactose”). Because of its excellent tablet-forming properties, lactose is also included in a variety of medications. Overnight incubation of milk with lactase preparation results in milk with reduced lactose concentration and might be tolerable by many patients. Furthermore, lactase tablets are available that can be added to the ingestion of lactose-containing products.

Comprehensive Epilepsy Program, Epilepsy Genetics/Genomics Laboratories and Epilepsy Center of Excellence, UCLA School of Medicine and VA GLAHS, Los Angeles, CA, USA

### Synonyms

Lafora's disease; Progressive myoclonus epilepsy type 2; EPM2

### Definition and Characteristics

Lafora's disease (LD), an autosomal recessive fatal epileptic encephalopathy syndrome like other progressive myoclonic epilepsies (PME), is characterized by the triad of stimulus-sensitive myoclonus, epilepsy, and progressive intellectual, cerebellar, and neurological deterioration [1]. A greater frequency of visual auras, the rapid course of the illness with death occurring 10 years after onset of epilepsy, and the presence of Lafora polyglucosan inclusion bodies in the brain, muscles, liver, heart, retina, peripheral nerves, and skin separate LD from other PMEs [1].

Two subsyndromes have been identified: classic or adolescent LD and atypical or childhood LD [2]. Classic LD begins during early adolescence (10–14 years) with grand mal, absence seizures, and stimulus-sensitive myoclonic epilepsy in an otherwise normal individual. Visual auras are present in 25%. Progressive deterioration in memory, cognition, intelligence, and coordination from 11 to 17 years results in dementia, apraxia, visual loss, mutism, and a vegetative state including respiratory and swallowing difficulties by 17–20 years [2].

In contrast, initial manifestations of atypical LD are childhood learning problems at 4–8 years, with rare absence or grand mal seizures occurring in 50%. Frequent stimulus-sensitive myoclonus, grand mal, and absence seizures usually begin at 8–13 years, with visual auras occurring in 60%. Ataxia and spasticity develop between 13 and 17 years. Subsequent dementia, apraxia, visual loss, and mutism result in a vegetative state at 16–18 years, with respiratory and swallowing difficulties [2].

### Prevalence

Lafora's disease is found in the Mediterranean countries of Southern Europe (Spain, Portugal, Italy, Herzegovina, Croatia, Slovenia, Bosnia, Albania, Greece), Northern Africa (Morocco, Algeria, Tunisia, Libya), and the Middle East (Syria, Israel, Lebanon, Turkey, Cyprus, Egypt) [1–3]. It is also found in Ukraine, Uzbekistan, Kazakstan, Turkmenistan, Azebajian, Armenia, Malaysia, Indonesia, India, Pakistan, and other countries where consanguinity occurs [1–3].

### Genes

The EPM2A gene on chromosome 6q24 encodes laforin, a dual specificity phosphatase (dsP) with a carbohydrate-binding domain (CBD) [1–3]. It is composed of four exons. Mutations in exon 1, which encodes the amino-terminal CBD, is mainly associated with childhood LD, while mutations in exon 4, which encodes the carboxyl-terminal dsP, is mainly associated with classic adolescent LD [2]. Mutations of EPM2A may be responsible for up to 80% of Lafora's disease [1]. The second gene, EPM2B or NHLRC1 encodes malin E3 ubiquitin ligase and was identified within a 2.2-Mb critical region on chromosome 6p22 [4].

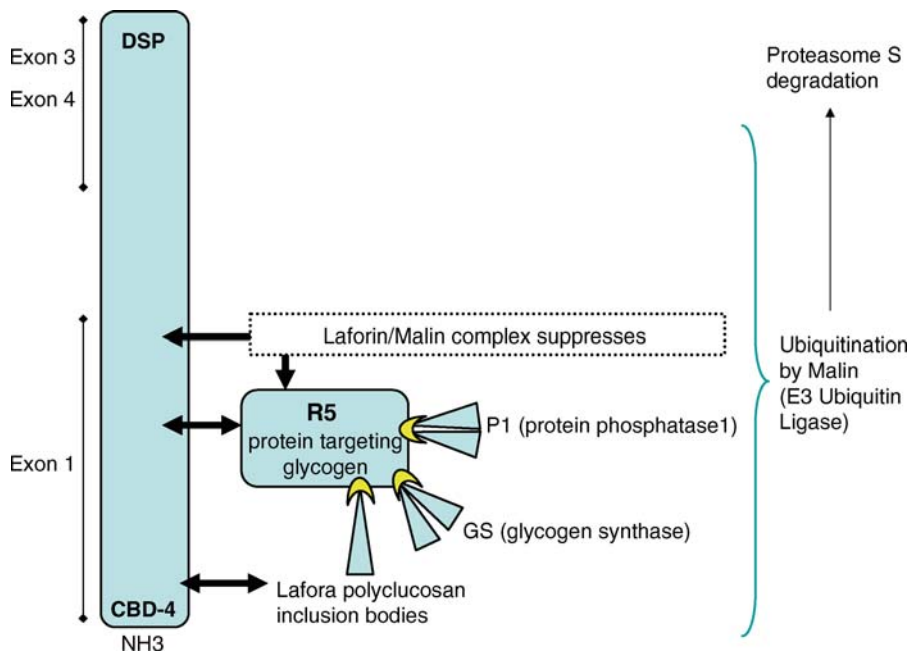
### Molecular and Systemic Pathophysiology

On autopsy of human brains, mild diffuse cerebral atrophy with neuronal loss in the globus pallidus and dorsal medial nucleus of the thalamus is seen [5]. Modest loss of Purkinje and granule cells with glial reaction is present in cerebellar cortex while cell loss is

the most severe in the dentate nucleus [5]. The hallmark of Lafora's disease is the Lafora body, a 1–30-μm concentric lamellar target-like intracytoplasmic neuronal inclusion particle composed of polyglucosan, found freely in the neurophil and nerve cell processes [5]. Most numerous in the central and prefrontal motor cortex and cerebellum, it is also found in the globus pallidus, thalamus, and substantia nigra, and less in the caudate, putamen, brainstem, and spinal cord [5]. Glial and capillary endothelial cells of the brain, retina, peripheral nerves, muscles, liver, and sweat glands also harbor these inclusions [5].

How Lafora bodies form is slowly being unraveled (Fig. 1). Figure 1 diagrams the functional and interacting sites of EPM2A/Laforin with its dual specificity phosphatase (DSP) domain in exons 3 and 4 and R5, the protein targeting glycogen (PTG) scaffold in the carbohydrate binding domain (CBD-4) of exon 1. R5 and PTG (protein targeting glycogen) is a scaffold adaptor protein that binds and brings the enzymes involved in glycogen synthesis to Laforin which is normally located in the vicinity of the endoplasmic reticulum inside neurons. This function includes bringing protein phosphatase 1 to glycogen synthase, thus activating this enzyme which synthesizes glycogen. PTG also normally brings glycogen synthase to laforin. The laforin-malin complex degrades R5/PTG and blocks glycogen binding, protein phosphatase 1 activation of glycogen synthase and glycogen synthesis. Overexpression of R5/PTG leads to glycogen deposition in cultured neurons and apoptosis. Thus, the laforin-malin complex ensures a blockade of neuronal glycogen synthesis under normal conditions. In the presence of a mutation in either the Laforin or the Malin gene, excessive glycogen is deposited in neurons and apoptotic cell death results [6,7]. Lafora bodies are stained metachromatically with methyl violet and toluidine blue [5]. Their basophilic cores are stained intensely with periodic acid-Schiff and Alcian blue, resist predigestion with diastase and hyaluronidase, and often contain a ninhydrin-Schiff- or alloxan-Schiff-positive protein granule [5]. PAS and alcian blue stain the pale amphophilic outer zone less intensely [5]. On electron microscopy, the Lafora body is composed of glycogen-like granules, interspersed with fine filaments and fine granular material that are not membrane bound [5].

Transgenic mice with homozygous deletions of the dsP-coding exon show non-apoptotic cell death at



**Lafora's Progressive Myoclonus Epilepsy. Figure 1** Laforin/Malin complex purge neurons of glycogen and lafora bodies. Functional and interacting sites of EPM2A/Laforin with its dual specificity phosphatase (DSP) domain and R5, the protein targeting glycogen scaffold in carbohydrate binding domain (CBD-4). Laforin and malin in concert suppress binding/targeting of protein phosphatase glycogen synthase to R5, thus keeping glycogen synthase in an inactive phosphorylated state. Glycogen in turn inhibits laforin suggesting a feedback system. Malin polyubiquitinates laforin and Lafora bodies and eliminates the "polyubiquinated laforin-Lafora polyglucosan inclusion and glycogen complex" through proteasome S degradation [6,7].

2 months, develop deficits in retention with enhanced excitability at 4 months, and muscle weakness, ataxia, and myoclonias at 9 months [3]. Neuronal degeneration precedes formation of Lafora bodies [3]. Similar to the human condition, Lafora bodies are found in the hippocampus, cerebellum, cerebral cortex, thalamus, and brainstem, and consist of small fragmented fibrillar material surrounded by fine punctiform particles resembling ribosomes, with no limiting membrane. In the brain, Lafora bodies stain positive for ubiquitin suggesting misfolded proteins set for degradation, and for advanced glycation end-products (AGEP) suggesting generation of reactive oxygen species and free radicals [3]. Because one of the enzymes modulated by dsP is glycogen synthase kinase-3B, it is hypothesized that glycogen synthase kinase-3B is in overdrive as a result of EPM2A mutations, resulting in the formation and accumulation of excessive polyglucosans [1]. Alternatively, laforin may mediate disposition of normally produced polyglucosans by binding to these and participating in inter- and intracellular migration [3].

The CBD of laforin determines its intracellular localization and site of action by targeting it to and associating directly with intracellular glycogen particles (Fig. 1). Mutations in this CBD alter the ability of laforin to bind to glycogen with only a limited effect on its protein phosphatase activity. Hence, such mutations may result in Lafora's disease by mistargeting the action of laforin's carboxyl-terminal dsP.

Ultrastructural analysis of cerebral, cerebellar, and hippocampal cortex cells in transgenic mice show unequivocal somatic degeneration as early as 2 months of age with distorted and shrunken cytoplasm, displacement and loss of morphology of organelles, and atrophy and distortion of dendrites and axons. The absence of nuclear or cytoplasmic "blebbing" and DNA fragmentation in these degenerating neurons suggests a non-apoptotic mechanism of cell death [3]. Neuronal cell death may not necessarily follow Lafora body formation because Lafora bodies are absent in most degenerating cells, and not all neurons with Lafora bodies degenerate [3].

The in vivo substrate of laforin functioning as a dual specificity phosphotase is probably glycogen synthase which it dephosphorylates. Mutations in Laforin lead to excessive phosphorylation of glycogen, aberrant branching and formation of lafora bodies.

## Diagnostic Principles

Electroencephalography typically shows a disorganized slow background interrupted by trains of photosensitive, high-voltage, frequent bilaterally synchronous, spike wave, and polyspike–wave complexes. Axillary skin biopsy demonstrates PAS-positive Lafora inclusion bodies in sweat glands and apocrine myoepithelial cells and is the diagnostic procedure of choice [1,3].

## Therapeutic Principles

Affected individuals are treated symptomatically with antiepileptic drugs and supportive care. Advances in nursing and supportive care have extended life expectancies to 28 years [2]. Current therapeutic research involves pegylated immunoliposome delivery of EPM2A to reverse pathology in transgenic mice deficient in laforin. If nonsense mutations are present in human LD, intravenous gentamicin, a premature stopcodon readthrough drug, is clinically justified for "compassionate use" in this fatal disorder.

Angela Vincent, John Newsom-Davis*
Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Department of Clinical Neurology, University of Oxford, Oxford, UK

### Synonyms

*Subtypes*: Paraneoplastic; P-LEMS; Principal associated neoplasm small cell lung cancer; SCLC; Non-paraneoplastic; NP-LEMS; Idiopathic disorder often associated with other autoimmune disorders [1]

### Definition and Characteristics

Both subtypes are antibody-mediated presynaptic disorders of neuromuscular transmission. NP-LEMS onset is from early childhood to old age; P-LEMS onset typically 4th decade or later; it may precede the appearance of the tumor by 2 years or more. Muscle weakness is caused by a defect in neuromuscular transmission. Difficulty in walking is the usual presenting symptom. Weakness predominantly affects proximal limb muscles and trunk muscles. Ocular symptoms are much less common than in myasthenia gravis. Tendon reflexes are absent or depressed but can show post-tetanic potentiation. Autonomic symptoms (dry mouth, constipation, erectile failure in males) are usually present [1].

### Prevalence

The prevalence of the two subtypes is similar, but the incidence of P-LEMS is much higher (reduced survival), estimated at around 1 per million. It affects 2–3% of SCLC patients and may improve survival.

### Molecular and Systemic Pathophysiology

Presynaptic P/Q type VGCCs mediate the calcium-induced acetylcholine release both at the neuromuscular junction, and to a varying extent at autonomic synapses. VGCCs, are reduced in number and disorganized at the neuromuscular junctions of LEMS patients. Loss of VGCCs leads to reduced acetylcholine release, and reduced amplitude of the endplate potentials, as recorded from intercostal muscle biopsies. During repetitive motor nerve stimulation the endplate potential increases, probably due to build up of calcium in the motor nerve terminal. Similar changes are found in mice that have been injected with IgG purified from patients with LEMS, indicating that the electrophysiological and morphological changes are likely to be due to the VGCC IgG antibodies [2]. The mice also show defects in neuromuscular transmission in the bladder and vas deferens, reflecting the autonomic dysfunction found in the patients.

*Autoantibodies:* Autoantibodies that bind to a subtype of voltage-gated calcium channel (VGCC) called the P/Q-type are found in 90% of P- and non-P-LEMS patients. The antibodies are detected by radioimmunoprecipitation of VGCCs extracted from rabbit or human cerebellum, and prelabeled with $^{125}$1-ω CmTx MVII, a cone-snail toxin that binds specifically to P/Q-type VGCCs. These autoantibodies act in vivo by cross-linking the VGCCs on the surface of the presynaptic motor nerve membrane. This leads to clustering, internalization and loss of VGCCs [3]. The antibodies seldom directly inhibit VGCC function, and complement deposition has not been demonstrated.

*Immunopathology:* The anti-P/Q-type VGCC antibodies in P-LEMS appear to be provoked by SCLC VGCCs. NP-LEMS associates with HLA A1 DR3, like myasthenia gravis, and is probably a spontaneous autoimmune disorder.

### Diagnostic Principles

The dominant symptom complex is the association of proximal muscle weakness with autonomic dysfunction,

*deceased

and the dominant clinical sign is improvement in strength following voluntary contraction. Electromyography (EMG) shows a reduced compound muscle action potential (CMAP) amplitude at rest, further decrease during low-frequency nerve stimulation but striking increase (100–1,000%) following a ~10 s maximum voluntary contraction. Detection of VGCC antibodies confirms the diagnosis but the test may be negative in up to 10% of patients.

## Therapeutic Principles

Symptomatic treatment includes 3,4 diaminopyridine to increase acetylcholine release. In those at risk from P-LEMS (cigarette smokers), a tumor search should be initiated and repeated until the tumor is identified. Specific tumor therapy can improve the neurological disorder; prednisone may also be beneficial. In NP-LEMS, immunosuppression (prednisone, azathioprine, cyclosporine) can be effective. Plasma exchange leads to a few weeks of clinical improvement, although the response tends to be slower than in myasthenia gravis. Intravenous immunoglobulin therapy resulted in the improvement of several parameters of strength, and an associated decline in specific antibody, in a double blind crossover trial in eight LEMS patients [4].

# Lamellar Ichthyosis

Vinzenz Oji
Clinic for Dermatology, University of Muenster, Muenster, Germany

## Synonyms

Ichthyosis congenital; Autosomal recessive congenital ichthyosis; Non-bullous congenital ichthyosiform erythroderma

## Definition and Characteristics

Lamellar ichthyosis (LI), also referred to as non-bullous congenital ichthyosiform erythroderma (NCIE), comprises different types of non-syndromic autosomal recessive congenital ichthyoses (ARCI). This cornification disorder is characterized by generalized hyperkeratosis and scaling ranging from a mild to very severe phenotype. Most patients (~90%) are born encased in a tight shiny covering, called collodion membrane, and often show a certain skin inflammation/erythroderma. The membranes are gradually replaced during the first weeks of life, and patients develop large, dark or plate-like scales. In contrast, individuals with the NCIE phenotype show a pronounced erythroderma with fine, white scaling. Approximately 10% of all collodion babies heal completely, a condition called Self-healing collodion baby (SHCB). Non-erythrodermic, non-lamellar ARCI is regarded as a very mild intermediate phenotype within the spectrum of LI situated at one end of the pole and NCIE at the other [1,2].

## Prevalence

1:200,000–300,000.

## Genes

Six chromosomal loci and five genes have been identified so far (Table 1).

## Molecular and Systemic Pathophysiology

In about 35–40% LI/NCIE is caused by homozygous or compound heterozygous mutations in TGM1 (LI/NCIE type 1) leading to a deficiency of keratinocyte transglutaminase. Transglutaminases are $Ca^{2+}$-dependent enzymes involved in the assembly of the cornified cell envelope. This resilient sheath of ε-(γ-glutamyl) lysine cross-linked proteins is deposited subjacent to the plasma membrane in terminally differentiating keratinocytes. The covalent γ-amide bonds between various proteins or peptides are formed by transglutaminase-1, -3 and -5. An important specific function of transglutaminase-1 is the cross-linking of ω-hydroxyceramides to the cornified cell envelope [3]. The LI/NCIE locus on chromosome 17p13, which is more often associated with the NCIE phenotype, revealed missense mutations or deletions in ALOXE3 or ALOX12B. These genes encode epidermal lipoxygenase-3 (eLOX3) and 12R-lipoxygenase (12R-LOX). Lipoxygenases are iron-containing dioxygenases, which metabolize essential fatty acids, phospholipids or triglycerids. In the epidermis, eLOX3 and 12R-LOX participate in the same metabolic pathway, which converts arachidonic acid into specific epoxyalcohol products [4]. Loss of function in one of these enzymes probably impairs the epidermal lipid formation. Lefèvre et al. (2004) reported

**Lamellar Ichthyosis. Table 1** Overview of different molecular causes of lamellar ichthyosis/non-bullous congenital ichthyosiform erythroderma

| | | | 606545 | |
| 6 | 5q33 | Ichthyin | 609383 | Disruption of ichthyin, which is a transmembrane protein of (so far) unknown function |

about a new LI/NCIE locus and gene, mutations of which cause a NCIE-like phenotype with palmoplantar keratoderma. The so called ichthyin gene encodes a putative transmembrane protein, which might be a receptor for products of the epoxyalcohol/lipoxygenase pathway. Patients with IL/NCIE type 2 (2q34) were all born with collodion membrane and presented a generalized pure lamellar ichthyosis with palmoplantar keratoderma [5]. This phenotype is associated with missense mutations in the ABCA12 gene, the same gene, in which large intragenic deletions and frameshift deletions cause Harlequin ichthyosis. The ATP-binding cassette (ABC) transporter family encompasses a variety of membrane proteins involved in the energy-dependent transport across membranes. In the epidermis, ABCA12 has an important function for the lamellar granules, which traffic lipids, proteases and various functional proteins across the apical keratinocyte membrane into the interstitial space. The exact molecular cause of LI/NCIE type 3 and 4 remains to be established. Attempts to refine the classification of LI and NCIE phenotypes by the use of clinical, biochemical and ultrastructural observations have so far failed to yield a consistent scheme. This difficulty is illustrated by the fact that the same TGM1 mutation can give rise to either LI or NCIE. The distinct SHCB phenotype can be due to a particular mutation in TGM1 leading to an impaired transglutaminase-1 function under intrauterine water pressure.

## Diagnostic Principles

The patient's history includes a detailed family history. Clinical main criteria are the presence of ichthyosis since birth (excluding ichthyosis vulgaris or X-linked recessive ichthyosis) and the isolated phenotype of non-bullous, generalized hyperkeratosis. A very severe collodion baby with maximal ectropion/eclabium and extreme hyperkeratosis constricting the thorax and/or extremities is suggestive of Harlequin ichthyosis. Symptoms of other organ systems such as severe failure to thrive, frequent superinfections, neurological symptoms, limb defects, hair/nail anomalies etc. indicate a syndrome with associated congenital ichthyosis (Table 2). First of all, the laboratory procedure includes a skin biopsy for histological analysis (e.g. to screen for epidermolytic hyperkeratosis), for electron microscopy (ultrastructural subclassification of LI/NCIE), and for immunhistochemical analysis (e.g. for the transglutaminase activity test). The DNA sequencing analysis (from EDTA blood) is based on the clinical and morphological findings and often establishes the specific molecular diagnosis important for genetic counseling.

## Therapeutic Principles

To date, there is no causative therapy available. Taking into account the daily effort of the patients, which is especially necessary for the removal of the hyperkeratosis and scaling, the symptomatic topical treatment can improve the phenotype to a very large extent. This therapy includes a regular bath (e.g. with sodium bicarbonate or oil) and the daily use of ointments with a scaling effect (urea, propylene glycol, lactic acid, etc.). Special attention must be given to the potentially life threatening increased transepidermal water loss and temperature dysregulation of the neonates. Therefore, they must often be kept in an incubator during the first week(s) of life (80–90% humidity, 33–35°C). The contact with a self support group may be very helpful for affected individuals and

# Langerhans' Cell Histiocytosis

Jochen Utikal, Alexei Gratchev, Sergij Goerdt
Department of Dermatalogy, Venereology and Allergology, University Medical Center Mannheim, Ruprecht-Karls University of Heidelberg, Mannheim, Germany

## Synonyms

Cutaneous indeterminate cell histiocytosis (progenitor LCH); Eosinophilic granuloma (single-organ involvement); Hand-Schüller-Christian disease (triad of exophthalmos, diabetes insipidus, bone and skin lesions); Hashimoto-Pritzker disease (progenitor LCH); Histiocytosis X; LCH; Letterer-Siwe disease (aggressive multisystemic variant rarely seen in adults); Langerhans cell (eosinophilic) granulomatosis; Nonlipid reticuloendotheliosis (obsolete); Pure cutaneous histiocytosis

## Definition and Characteristics

Langerhans' cell histiocytosis (LCH) is regarded as a clonal accumulation and proliferation of abnormal bone-marrow-derived Langerhans' cells. These dendritic cells or, respectively, their progenitor cells form infiltrates typical for the disease that may be found in various organs (skin, bone, lung, liver, spleen, and pituitary) to a different extent resulting in variable clinical behavior [1].

## Prevalence

Annual incidence of 4–5.4 per million. Affecting mainly children but with a possible onset at any age. Peak incidence from 1 to 3 years. Male to female ratio above 2:1. Higher rate of concordance for LCH in monozygotic twins (86%) than in dizygotic twins (12%) [2].

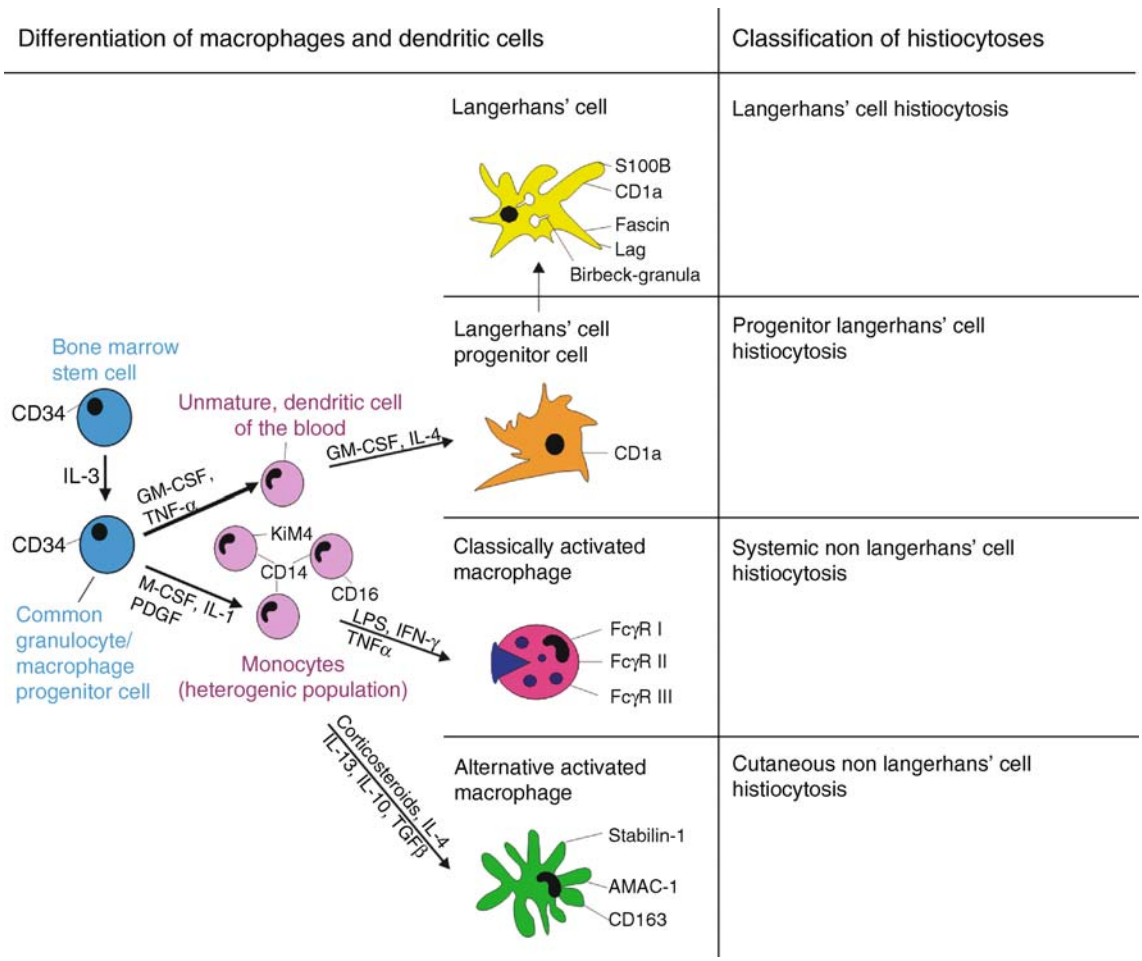
## Molecular and Systemic Pathophysiology

The term histiocytes refers to three groups of immune cells: classically and alternative activated macrophages and dendritic Langerhans' cells. Monoclonal Langerhans' cells (LC) form infiltrates in LCH (Fig. 1).

Lesional Langerhans' cells show an immature phenotype and function and have been shown to be clonal by X-inactivation studies. They coexpress LC antigens CD1a and langerin that induces formation of the LC Birbeck granules together with monocyte antigens CD68 and CD14. Class II antigens are intracellular, and LC almost never express CD83 or CD86 or dendritic cell (DC)-Lamp, despite their CD40 expression. In addition, LCH lesions express the immature dendritic cell (DC) marker CCR6 on the lesional Langerhans' cells without expressing the mature DC marker CCR7. Regardless of the tissue site, LCH lesions overexpress CCL20/MIP-3alpha, the ligand for CCR6 as well as other inflammatory chemokines such as CCL5/RANTES and CXCL11/I-TAC. This might explain the recruitment of eosinophils and $CD4^+$ $CD45RO^+$ T cells commonly found in LCH lesions. Despite abundant TNF-alpha, lesional Langerhans' cells remain in an immature state and are induced to produce chemokines, which via autocrine and paracrine mechanisms cause not only the retention of the lesional Langerhans' cells but also the recruitment and retention of other lesional cells. In addition they may be involved in the expansion of T-regs in vivo, resulting in the failure of the host immune system to eliminate LCH cells [3]. The lesional cells in progenitor LCH are even more immature as the cells of LCH since they lack LC Birbeck granules.

## Diagnostic Principles

Definitive diagnosis requires the finding of Birbeck granules (subdomains of endosomal recycling compartment) in cells of the lesion by electron microscopy and/or positive staining for CD1a, S100B, Lag or Fascin on



**Langerhans' Cell Histiocytosis. Figure 1** Differentiation of monocytes/macrophages and dendritic cells as well as histogenesis and classification of histiocytic disorders.

the lesional cell. The progenitor LCH do not show Birbeck granules [4].

### Therapeutic Principles

Depending on the extent of the disease, the age at diagnosis, and the presence of organ dysfunction. Spontaneous remission of the disease was also described [4].

*Single system disease:* Curettage and excision of solitary nodes, intralesional steroid or interferon-γ injection, PUVA therapy, and topical nitrogen mustard (Mechlorethamine) have been used. Radiotherapy is recommended only in inoperable lesions compromising vital structures (optic nerve, spinal cord). It has also has been shown that imatinib mesylate is effective.

*Multisystem disease:* Chemotherapy (DAL HX, LCH I-III studies) [5]. Study reference center of the "Histiocyte Society".

►Granuloma, Eosinophilic

## Laron Syndrome

Zvi Laron
Schneider Children's Medical Center, Petah Tikva/Tel Aviv, Israel

### Synonyms

Congenital IGF-I deficiency; Primary growth hormone (GH) resistance or insensitivity

### Definition and Characteristics

Laron syndrome is an autosomal recessive form of dwarfism resembling and indistinguishable from congenital growth hormone (GH) deficiency, however, with abnormally high serum GH and low or undetectable insulin-like growth factor (IGF-I) levels. The clinical characteristics are:

*At birth*: Short birth length (42–48 cm); sparse hair, hypogenitalism, hypoglycemia;

*In infancy*: Protruding forehead, acromicria; small head circumference, sparse hair, obesity, hypogenitalism and hypogonadism, high pitched voice, delayed skeletal maturation, and motor development;

*Childhood and adolescence*: Crowded and defective dentition, delayed puberty, underdeveloped lean body mass, thin bones; variable intellectual deficits; [1]

*In adults*: Short stature (males:110–142 cm, females:108–136 cm) hypogonadism with reproductive ability, progressive and severe obesity, insulin resistance, hypercholesterolemia, occasional glucose intolerance, muscular weakness, cervical spinal canal stenosis; variable CNS damage, and its complications; [2,3] protection from cancer [4] diabetes mellitus and intellectual capacity.

### Prevalence

First described among Jews of Oriental origin in Israel in 1966 and 1968. It was subsequently diagnosed in many Mediterranean and South Asian populations or their descendants. In most instances the probands come from consanguineous families by recessive transmission; however, spontaneous mutations have been reported from many parts of the world. Heterozygotes for the defects seem little affected. At present several hundreds of patients are known.

### Genes

The affected genes causing this syndrome are the GH receptor gene, Stat 5b mutations in the post-receptor cascade, and the IGF-I gene.

### Molecular and Systemic Pathophysiology

The disease is caused by mutations or partial deletions of the GH-receptor (GH-R) gene, (chromosome 5p13.1) or in the post receptor pathways, resulting in an inability to generate IGF-I, the anabolic effector of GH. Most of the 60 molecular defects described so far reside in the extracellular domain of the GH-R [5]. The IGF-I gene resides on chromosome 12q23.

### Diagnostic Principles

Marked growth retardation (<-4SDS), high serum GH and low to undetectable serum IGF-I levels which do not rise upon 1 week administration of exogenous hGH (IGF-I stimulation test). Patients with molecular defects in the extracellular domain (the great majority of LS patients) have very low or undetectable serum GH binding protein (GHBP) levels, the rare patients with transmembrane intracellular domain or post receptor defects have normal or high levels. Patients with post- GH receptor and IGF-I gene defects (and normal GH-R) do not always present the typical phenotypical features of classical LS [6].

### Therapeutic Principles

The pharmacological IGF-I replacement treatment available is daily injections of IGF-I – to children 150–200 μg/kg/day s.c. in one or two doses and to adults 50–100 μg/kg/day. Gene therapy is not available [6].

[1]Department of Ophthalmology, Klinikum Hanau, Hanau, Germany
[2]Division of Clinical Genetics, Innsbruck Medical University, Innsbruck, Austria
[3]Department of Ophthalmology, University of Saarland, Homburg/Saar, Germany

### Synonyms

Lattice corneal dystrophy type I (Biber-Haab-Dimmer); LCDI; *Variants*: Lattice corneal dystrophy III and IIIa

## Definition and Characteristics

LCDI, the most common form of LCD, is an autosomal dominantly inherited disorder characterized by a network of delicate, branching lattice-like lines that occur in the anterior stroma paracentrally and spread posteriorly and centrifugally with time, leaving the peripheral 1 mm or so clear. The lattice lines are refractile with a double contour by retroillumination. The disease usually begins in the first decade of life with the occurrence of fleck opacities on the superficial center of the cornea. Recurrent painful epithelial erosion is an almost constant symptom, presenting prior to the development of typical lattice lines. Diffuse opacification of the central stroma develops slowly as a sequel to diffuse amyloid accumulation. These diffuse opacities become denser in later life and extend to the corneal periphery masking the lattice lines. Misdiagnosis of this condition as herpetic or bacterial keratitis combined with recurrent erosion in the early or mid stages, and corneal leukoma in the late stage has been noted. The progression of LCDI usually leads to substantial discomfort and visual loss by the third to fourth decade. Lattice corneal dystrophy type IIIa (LCDIIIa) is distinguished from LCDI by much more pronounced lattice lines, and the onset of visual failure between the fourth and sixth decade.

Autosomal recessive inheritance was originally assumed in Lattice corneal dystrophy III (LCDIII), however LCDIII appears to be the homozygous form of LCDIIIa [1]. LCDIII patients show pronounced lattice lines. However, central diffuse opacities are less pronounced than in LCDI, and epithelial erosions have not been reported. A number of LCD patients were described in the literature with an atypical presentation based on the age of onset and the nature of the opacities and lattice lines, or based in one instance on asymmetry of the findings. Given the known intra- and interfamilial variability of LCDI, we consider the delineation of further LCD subtypes or "atypical" cases as inappropriate.

## Prevalence

LCDI was first described by Biber in 1890 [2]. LCDI and the variants are rare corneal disorders. LCD was identified as an inherited amyloidosis restricted to the cornea in 1967 [3]. Many further family reports of LCD (not including LCDII or Meretoja syndrome) are from (alphabetically): Argentina, Australia, Austria, Bangladesh, Brazil, Bulgaria, Canada, China, Finland, France, Germany, Hungary, India, Israel, Italy, Japan, Korea, Sweden, Switzerland, Spain, Thailand, Ucraine, United Kingdom, USA, and Vietnam.

## Genes

A locus for LCDI, and distinct corneal dystrophies was mapped to chromosome 5q31 by linkage analysis (see also the chapters of RBCD, TBCD, GCDI, and GCDII). LCDI and its variants listed above are due to mutations in the transforming growth factor beta-induced gene (TGFBI). The most frequent mutation in LCDI represents the Arg124Cys mutation. To date, many other independent mutations have been reported with regard to LCDI, IIIa, and other variants: Pro501Thr; Val505Asp; Leu518Pro; Leu527Arg; Thr538Arg; Val539Asp; The540del; The540Ser; Asn544Ser; Ala546Thr; Ala546Asp; Pro551Gln; Leu569Arg; His572del; His572Arg; Gly594Val; Asn622His; Asn622Lys; Gly623Asp; Val624_Val625del; His626Arg; His626Pro; Val627SerfsX44; Thr629_Asn630ins; AsnValPro; Val631Asp; and Leu509Pro (own unpublished data). Yamada and associates found a homozygous Leu527Arg mutation in LCDIII [1].

## Molecular and Systemic Pathophysiology

Clout and Hohenester propose two routes for corneal dystrophy formation resulting from point mutations in the TGFBI protein based on the prediction of structural consequences of the missense mutations described so far [4]. The common mutations at positions 124 and 555 may directly affect protein–protein interactions (either homo-or heterophilic), whereas the rare mutations are likely to cause misfolding within the cell. TGFBI contains four FAS1 domains, and it is possible to predict the organization of domains three and four by comparison with the structure of fascilin I [4]. TGFBI has been shown to bind in vitro to a number of extracellular matrix components including fibronectin, laminin, integrin, and several collagen types. The precise functions of TGFBI in vivo are unknown, but it has been proposed that it may act as a cell adhesion molecule and as a bifunctional linker protein interconnecting different matrix molecules to each other and to cells. Different mutations in the TGFBI gene influencing intra- or extracellular abundance of TGFBI protein, its structural integrity, or its binding properties may specifically affect interactions with individual matrix proteins, and as a consequence the organization and modulation of different matrix protein architectures.

## Diagnostic Principles

The clinical diagnosis of LCD is based on the slitlamp examination in direct and indirect illumination, and fluorescein staining, best seen with dilated pupil. Especially in LCD it is very important to disclose the axial and dichotomic extending lines by dilated pupil. These double contoured lines together with the central subepithelial diffuse opacity are the landmarks of the full stage of LCDI. The dominance of thicker lattice lines with less of diffuse opacity presents the landmark of LCDIII and LCDIIIa. Further LCD variants such as LCDIV, LCDV, LCDVI and LCDVII are described

in the literature due to different TGFBI mutations and to subtle different phenotypical features with regard to LCDI. The authors do not consider this classification justified. We were able to examine seven LCDI families with an Arg124Cys mutation in the past. Here, we were able to observe marked intra- and interfamilial phenotypical differences in spite of the same TGFBI mutation causing the disease in each family. Lattice corneal dystrophy type II (LCDII), a misnomer for the Meretoja syndrome, represents an autosomal dominantly inherited systemic amyloidosis with similar corneal lattice lines as in LCDI and with other extraocular symptoms. Histologically, the lesions of all LCD types consist of multiple, fusiform stromal amyloid deposits, which are positive for Congo red staining with apple-green birefringence under polarized light [3].

### Therapeutic Principles

The frequent LCDI epithelial erosions may be treated at first with topical antibiotics and artificial tears. The use of contact lenses can be helpful. Significant visual impairment due to diffuse stromal opacification needs surgical interventions such as lamellar or penetrating keratoplasty. Limbo-keratoplasty tends to be associated with fewer recurrences but the difference is not yet statistically significant. LCDI recurrences usually occur 3–4 years after penetrating keratoplasty. Eyes with LCDI suffer from delayed epithelial healing after PTK and might need additional treatment such as hyaluronic acid drops, autologous serum drops, simultaneous amnion membrane patching, or even temporary lateral tarsorrhaphy [5]. Successful retreatment with PTK is possible.

## Leber Congenital Amaurosis

Birgit Lorenz, Markus N. Preising
Department of Pediatric Ophthalmology, Strabismology and Ophthalmogenetics, University of Regensburg Medical Centre, Regensburg, Germany

### Synonyms

Early onset retinitis pigmentosa; Early onset rod cone dystrophy; Early onset cone rod dystrophy; EOSRD; LCA

### Definition and Characteristics

Early-onset severe retinal dystrophies (EOSRD) are a heterogeneous group of disorders usually summarized as Leber's congenital amaurosis (LCA) and juvenile retinitis pigmentosa. Common to all types of the disease is a severe visual impairment from birth or early childhood. The visual impairment varies considerably ranging from complete congenital blindness to impaired but useful vision up to the second decade of life. The phenotypes summarized as EOSRD/LCA show allelic and non-allelic heterogeneity including characteristic gene specific features. Both photoreceptor systems i.e., rods and cones, are involved and the resulting dystrophies follow either a rod-cone or a cone-rod pattern of degeneration.

### Prevalence

5% of patients with hereditary retinal degenerations, 2 – 3:100,000 newborn.

### Genes

See Table 1.

### Molecular and Systemic Pathophysiology

By May 2007, 12 genes and loci have been reported for EOSRD/LCA and are listed in Table 1. All but two are associated with autosomal recessive disease. These have a diverse impact on the function of the photoreceptors, the retinal pigment epithelium (RPE) and the Müller glia cells. The mutation detection rate in the recently published literature points toward 50% [1] but does not yet include the recently identified genes CEP290 and its homologue C6ORF152/lebercilin which have been reported with an exceptionally high incidence. Also the detection rate may vary depending on the cohort of patients screened [1].

EOSRD/LCA is a disorder of the retina, though CEP290 mutations have been reported with olfactory dysfunction [2] and mutations in AIPL1 have been shown to be accompanied with keratoconus. Mental retardation has been associated with LCA but to date only CEP290 has been shown to cause phenotypes combining retinal and brain features.

CRX is a transcription factor controlling the expression of retinal genes. It causes the only autosomal dominant degeneration in this set of disorders and affects both photoreceptor systems though the only phenotype in well documented cases is a cone-rod dystrophy (CRD) [3]. A CRD is also the resulting phenotype of mutations in GUCY2D which cause a severe connatal reduction of vision with preserved normal fundus appearance for many years. GUCY2D mutations are a major cause of EOSRD/LCA. GUCY2D patients are the classical patients of congenital amaurosis. GUCY2D restores the excitability of bleached photoreceptors by recovering the cGMP level.

Also functionally included in the process of vision are LRAT and RPE65, two genes coding for important steps of the retinoid cycle, activating bleached retinol by covalently binding an acyl group to form an all-trans retinol ester (LRAT ) and isomerisation into 11-cis-retinol by isomerohydrolase (RPE65) [1]. Both genes cause EOSRD manifesting as rod-cone dystrophy (RCD) with night blindness and preserved vision in the first decade of life [4]. RPE65 mutations underlie EOSRD in about 10% of patients. LRAT is a rare cause and has been reported in single cases only.

**Leber Congenital Amaurosis. Table 1** Genes involved in EOSRD/LCA

| Disease | Locus | CRD genes | RCD genes | OMIM | Gene OMIM | Assignment |

| Leber Congenital Amaurosis, type 9 | LCA9 | | | 608553 | | 1p36 |
| Leber Congenital Amaurosis, type 10 | LCA10 | | CEP290 | 204000 | 610142 | 12q21.3 |
| Leber Congenital Amaurosis, type 11 | LCA11 | | IMPDH1 | 204000 | 146690 | 7q31.3-q32 |

RDH12 belongs to the family of retinol dehydrogenases and is localized in the inner segment of photoreceptors. Recent literature argues against a function in retinoid processing and support detoxifying activity in the photoreceptor. RDH12 also causes EOSRD.

A third site of activity is covered by RPGRIP, CEP290 and C6ORF152/lebercilin. These genes code for proteins of intracellular transport and are closely associated with the transport of proteins along the microtubules. A homologue of CEP290 NPHP4 functionally associates with RPGRIP. While RPGRIP causes a CRD in about 7% of cases, CEP290 patients have been described with LCA and additional features like keratoconus and neurological disorders in up to 20% of LCA cases carrying rest-of-function mutations. Null mutations were associated with Joubert syndrome. C6ORF152/lebercilin is a very recently identified gene involved in microtubule function of cilia in photoreceptors and cells from other tissues [5].

Mutations in AIPL1 also cause LCA in a minor set of patients but with a severe and early onset of RCD and characteristic fundus appearance. AIPL1 is widely accepted as a chaperon supporting the distribution of photoreceptor proteins especially phosphodiesterase subunits.

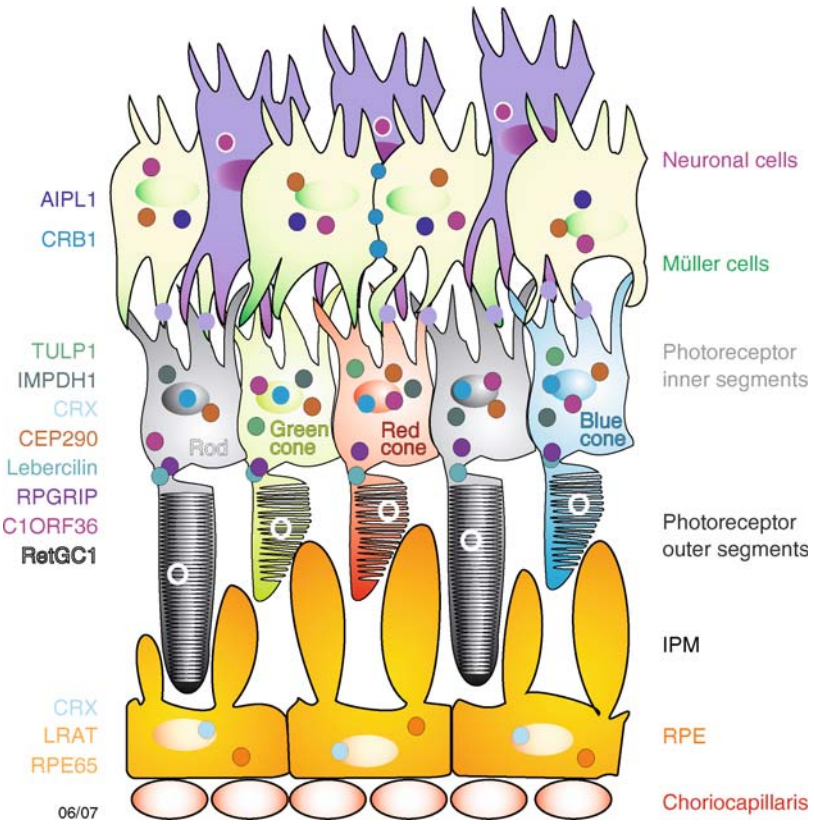
Another major set of patients has mutations in the human homologue of the Drosophila crumbs gene (CRB1). CRB1 is a component of adherrens junctions connecting photoreceptors and Müller glia cells in the outer limiting membrane region. Up to 15% of all EOSRD/LCA cases have been shown to be caused by mutations in CRB1. Mutations in CRB1 cause an early onset RCD. A Coats-like appearance may occur and para-arteriolar preservation of the RPE (RP12) has been reported. As a specific feature mutations in CRB1 are associated with a thickened retina.

Finally, three genes have to be mentioned which have been implicated in the pathology of EOSRD/LCA. Heterozygous inosine monophosphate dehydrogenase type I (IMPDH1) mutations have been identified in two LCA cases but could not be substantiated as a cause of LCA. Mutations in RD3 have also been reported but regarded as a very rare cause of LCA. Finally, mutations in TULP1 have been implicated in EOSRD/LCA in a single study which was not replicated by other authors.

The phenotype is usually severe from birth onwards but can vary and present with less severe expression.

## Diagnostic Principles

The diversity of functions and localizations of the involved genes argues for a sophisticated diagnostic approach to EOSRD/LCA. In addition to the basic examinations such as funduscopy, electroretinography, Goldmann perimetry, acuity testing, and colour vision testing, Optical Coherence Tomography (OCT) and fundus autofluorescence (FAF) recordings are useful for further refining the phenotype and help to discern cases with mutations in CRB1 (thickening of retinal layers) and RPE65 (lack of FAF) (Fig. 1) [1,2].



**Leber Congenital Amaurosis. Figure 1** Localisation of the 12 LCA gene products in the retinal layers. Proteins are colour coded corresponding to the dots in the schematic.

## Therapeutic Principles

Currently no therapeutic access is possible for most of the subspecialties of EOSRD/LCA. A recently started gene therapy approach in a canine model of RPE65 mutations has been successful. Human clinical trials in RPE65 patients have been started in the beginning of 2007. (http://www.moorfields.nhs.uk/Aboutus/Mediaoffice/Mediareleases/Firstclinicaltrialofgenetherapyforchildhoodblindness) First results are expected by the end of 2007.

# LECD

►Corneal Dystrophy, Lisch Epithelial

# Lecithin Cholesterol Acyltransferase Deficiency

Nosratola D. Vaziri
Division of Nephrology and Hypertension,
UCI Medical Center, Irvine, CA, USA

## Synonyms

LCAT deficiency

## Definition and Characteristics

Rare inherited disorder, caused by more than 40 different autosomal recessive mutations of the LCAT gene leading to reductions of plasma LCAT, HDL cholesterol, ApoA-I, and ApoA-II. Clinical presentations are variable and include corneal opacification, anemia, proteinuria, and nephropathy known as familial LCAT deficiency (FLD), isolated corneal opacification know as fish eye disease (FED), and occasionally atherosclerotic cardiovascular disease [1,2]. In addition, compound heterozygosity in the LCAT gene can lead to an intermediate phenotype [3]. Finally, acquired LCAT deficiency can occur in genetically normal humans and animals [4,5].

## Prevalence

While the hereditary forms of LCAT deficiency are quite rare, acquired LCAT deficiency associated with chronic kidney disease, nephrotic syndrome, and inflammatory states is relatively common.

## Genes

The LCAT gene is located in the q21–q22 region of chromosome 16 and consists of 4.2 kb and six exons.

## Molecular and Systemic Pathophysiology

LCAT (EC2.3.1.43) is a 63 kDa glycoprotein enzyme that is produced by the liver for release in the plasma. Following activation by ApoA-I, LCAT catalyzes hydrolysis of lecithin (phospholipase activity) and esterification of cholesterol (esterase activity) in the plasma using HDL as the preferred substrate. Different mutations can variably affect activation, substrate binding/recognition, phospholipase or esterase activities, or production of LCAT leading to different biochemical/clinical phenotypes. For instance, some mutations lead to lack of enzyme's activity against HDL but not ApoB-containing lipoproteins. LCAT deficiency frequently results in significant reductions of plasma ApoA-I and ApoA-II due to catabolism of nascent HDL. Based on their biochemical and clinical features, hereditary LCAT deficiencies are classified as: Class I or null mutation, marked by lack of LCAT activity and protein mass; Class II, missense mutations marked by loss of activity with normal, reduced or absent mass; class III, missense mutations resulting in reduced activity against LDL alone or together with HDL and reduced enzyme mass; Class IV, missense mutations leading to the loss of activity against HDL (but not LDL), normal or reduced LCAT mass and clinical presentation of FED [1,2]. Acquired forms of LCAT deficiency represent quantitative abnormalities caused by either loss in the urine (nephrotic syndrome) or downregulation (e.g., chronic renal failure, inflammation) of the structurally intact LCAT, presenting as impaired HDL maturation, reduced HDL cholesterol and elevated unesterified cholesterol [4,5].

## Diagnostic Principles

Presence of reduced HDL cholesterol, elevated unesterified/esterified cholesterol ratio, reduced plasma LCAT, family history, detection of mutations in the LCAT gene and diagnosis of underlying diseases capable of causing acquired deficiency.

## Therapeutic Principles

Presently no definitive treatment is available for hereditary LCAT deficiency; however, low-fat diet, cholestyramine and enzyme replacement may improve the lipid profile. When possible, treatment of the underlying disease reverses acquired LCAT deficiency.

# Left Bundle Branch Block

John F. MacGregor, Roger A. Freedman
Division of Cardiology, University of Utah, Salt Lake City, UT, USA

## Synonyms

LBBB

## Definition and Characteristics

Electrocardiographic disorder characterized by intracardiac conduction block in the left bundle branch, below the level of the His bundle, which arises in the setting of a variety of inherited and acquired conditions.

## Prevalence

The prevalence of bundle branch block in a northern European male population is 1% at age 50 and 17% at age 80 (of which roughly one third is isolated left bundle branch block).

## Genes

Genes associated with LBBB include the SCN5A gene, the primary gene encoding the cardiac $Na^+$ channel, the desmin and lamin A/C genes (coding for nuclear envelope proteins), localized to chromosome 1p1 21q, the Cypher/ZASP gene (encoding myocardial z band proteins), localized on chromosome 10q21–q23, and the Myotonin gene coding for myotonin (a protein kinase involved in numerous cellular metabolic processes), localized on chromosome 19q 13.3. Dystrophin gene mutations (X-linked) produce Duchenne & Becker muscular dystrophy. Mutations in the emerin gene (X-linked) produce Emery-Dreifuss muscular dystrophy.

## Molecular and Systemic Pathophysiology

LBBB can be caused by a variety of molecular mechanisms. In Lenegre's disease (a progressive, fibrotic, sclerodegenerative disease of the cardiac conduction system), cardiac $Na^+$ channel mutations have been implicated. Age-related myocardial fibrosis and progressive conduction system disease have been described in this disorder.

In myotonic dystrophy, an autosomal dominant inherited disorder, an unstable DNA sequence characterized by CTG repeat sequences predisposes patients to cardiac conduction system disease in addition to musculoskeletal manifestations. A recent series from Italy evaluated clinical and electrocardiographic characteristics of myotonic dystrophy patients who had been divided into quartiles on the basis of absolute number of CTG repeat sequences identified; incidence of complete LBBB was highly correlated with CTG repeats, increasing from 5% in the lowest quartile to 42% in the highest two quartiles combined ($p = 0.01$) [1].

Duchenne and Becker muscular dystrophy are characterized by absence of or inactivity of the dystrophin protein in the sarcolemmal membrane of skeletal and cardiac muscle, respectively. Both conditions predispose to cardiac conduction abnormalities, though the latter is more likely to produce bundle branch block which can progress to complete heart block. In Emery-Dreifuss muscular dystrophy (progressive skeletal muscle dysfunction, contractures, and cardiomyopathy), infranodal disease and AV block place patients at high risk for sudden death.

Kearns-Sayre syndrome (KSS) is caused by deletions of mitochondrial DNA, affecting genes coding for components of the respiratory chain (thus tissues with relatively high energy demand are most greatly affected). Conduction abnormalities in KSS range from LBBB to complete AV block.

More than ten mutations in cytoskeletal/sarcomeric protein-encoding genes have been implicated in familial dilated cardiomyopathy (FDC) to date; in particular, mutations in desmin and lamin A/C have been implicated in FDC associated with LBBB. A recent study of 49 families with dilated cardiomyopathy isolated lamin A/C mutations in four families, three of which manifested a FDC and one a sporadic dilated cardiomyopathy; of 12 affected individuals with lamin A/C mutations, five manifested cardiac conduction abnormalities, two of which were complete LBBB [2].

Less common causes of LBBB arise from a variety of molecular mechanisms. Isolated noncompaction of the left ventricular myocardium (INLVM) is a rare disorder characterized by a dilated, hypertrophic left ventricle with deep trabeculations. In one series from England, 13 of 45 consecutive patients (29%) referred to a specialty clinic for INLVM over a 10 year period manifested LBBB [3]. The HLA-B27 associated seronegative spondyloarthropathies (notably Ankylosing Spondylitis and Reiter's Syndrome) have a strong association with AV block; however, intracardiac electrophysiologic testing of affected patients has revealed that as many as 95% of cases involve block above the bundle of His; therefore, isolated LBBB in these conditions is relatively rare. Sera from patients with Chagas disease, a parasitic infection caused by Trypanosoma cruzi, can induce high-grade AV block in isolated rabbit hearts; this effect is likely mediated by antibody interaction with muscarinic receptors, as it is blocked by atropine. Studies of specialized cardiac gap junctions, of which connexin proteins are integral components, show that both AV block and bundle branch block can be induced in connexin40 knockout mice [4]; this finding suggests a target for future studies in humans with congenital LBBB.

### Diagnostic Principles

LBBB is an electrocardiographic diagnosis, characterized by QRS duration of greater than 0.12 s, deep and wide S wave in leads V1 and V2, and wide R wave in the lateral leads. Inherited disorders described above have specific diagnostic criteria described elsewhere.

### Therapeutic Principles

Acquired LBBB has an established predictive value for future development of clinically relevant cardiovascular (CV) disease; therefore, appropriate screening for CV disease should be undertaken when LBBB is identified. LBBB in the setting of inherited disorders can pose a significant risk for progression to complete heart block; this is particularly true for myotonic dystrophy, KSS, and the muscular dystrophies, in which prophylactic cardiac pacemaker implant should be considered.

# Leigh Syndrome

Thomas Klopstock
Department of Neurology, Friedrich-Baur-Institute and Ludwig-Maximilians-University, Munich, Munich, Germany

## Synonyms

Leigh disease; Subacute necrotizing encephalopathy; Infantile subacute necrotizing encephalomyelopathy

## Definition and Characteristics

Devastating mitochondrial encephalopathy of infancy or early childhood characterized pathologically by symmetrical lesions in basal ganglia and brainstem, and clinically by psychomotor regression and brainstem dysfunction. The molecular causes are manifold, including maternally and autosomally inherited defects in enzymes of the energy metabolism.

## Prevalence

The preschool incidence of Leigh syndrome was 1/32,000 in a population-based study from western Sweden. The point prevalence of all mitochondrial encephalomyopathies in children under age 16 was 1/21,000 [1].

## Genes

Mutations in several genes can lead to Leigh syndrome. The most frequent causes are mutations in the (i) mitochondrial DNA (mtDNA), in particular, at nucleotide positions 8993 (►Neuropathy, ataxia and retinitis pigmentosa) and 8344 (►Myoclonus epilepsy with ragged red fibres), leading to maternally inherited Leigh syndrome; (ii) nuclear subunits of complex I, II, and III, leading to autosomal recessive Leigh syndrome; (iii) SURF1 gene encoding an assembly factor for cytochrome c oxidase (COX), leading to autosomal recessive Leigh syndrome; (iv) E1-α subunit of the pyruvate dehydrogenase (PDH) complex, leading to an X-linked form of Leigh syndrome.

## Molecular and Systemic Pathophysiology

One of the principal goals of all metabolisms is to convert food into energy. A key enzyme for this process is the PDH complex, catalyzing the oxidative decarboxylation of pyruvate to acetyl-CoA. The latter enters the Krebs cycle, which serves to produce reduction equivalents in the form of NADH and $FADH_2$. These are oxidized in the respiratory chain, and coupled via oxidative phosphorylation to energy production.

All forms of Leigh syndrome are due to defects in genes (see above) that contribute to energy metabolism. More precise molecular mechanisms for the mtDNA mutations at positions 8993 and 8344 are provided in the chapters on ►NARP and ►MERRF. Here, the molecular mechanisms of SURF1 mutations will be emphasized.

SURF1 encodes a protein homologous to yeast Shy1p, which is required for efficient assembly of COX. The domain structure of this 30 kDa inner mitochondrial membrane protein is well conserved. Loss-of-function mutations have been associated with Leigh syndrome with COX deficiency [2]. Steady-state levels of COX are markedly reduced in patient cells, consistent with a failure to assemble or maintain a normal amount of the enzyme complex. The COX defect causes a depressed electrochemical proton gradient on the inner mitochondrial membrane, and consecutively decreased calcium inflow and ATP synthesis [3]. Despite the complete lack of Surf1 protein, there is some residual COX activity in patients. This may be the reason why the onset of clinical symptoms is delayed.

## Diagnostic Principles

The occurrence of psychomotor regression and brainstem or basal ganglia symptoms in childhood points to the disease. Brain imaging shows symmetrical lesions in basal ganglia and brainstem. In most cases, there is marked lactic acidosis. The diagnosis is confirmed by detection of the biochemical deficiencies or the mutations described above.

## Therapeutic Principles

There is no specific therapy. Some patients benefit from the administration of coenzyme Q 10 or thiamine. Dichloroacetate improves lactic acidosis not only in PDH deficiency but also in other disorders of energy metabolism. The only double-blind trial performed so far reported significant decreases of blood lactate, pyruvate, and alanine as well as significant improvement of MR-spectroscopic parameters in 11 patients with various mitochondrial disorders [4]. Gene therapy is not yet available. With regard to maternally inherited Leigh syndrome due to the 8993 mutation, nuclear expression of a wild-type ATPase 6 protein coupled to a mitochondrial targeting signal led to import of the construct into mitochondria, incorporation into complex V, and a significant increase in ATP synthesis [5].

# Leiomyomatosis and Renal Cell Cancer, Hereditary

Arndt Hartmann[1], Wolfgang Dietmaier[2]
[1]Institute of Pathology, University of Erlangen, Erlangen, Germany
[2]Institute of Pathology, University of Regensburg, Regensburg, Germany

## Synonyms

HLRCC

## Definition and Characteristics

Hereditary leiomyomatosis and renal cell cancer (HLRCC) is an autosomal dominant tumor syndrome characterized by predisposition to benign leiomyomas of the skin and uterus. Predisposition to renal cell carcinoma and uterine leiomyosarcoma is present in a subset of families [1]. The diagnostic criteria for HLRCC are not well defined yet. The presence of multiple leiomyomas of the skin and uterus and of papillary type II renal cell carcinomas or uterine leiomyosarcomas in young patients are suggestive for the disease. Definitive diagnosis of HLRCC relies on the detection of fumarate hydratase (FH) germline mutations [2].

Multiple leiomyomas of the skin and uterus occur with a penetrance of approximately 85% with a mean age of onset of 30 years. Cutaneous leimyomas have a size of 0.5–2 cm, uterine leiomyomas are frequently very large. Histomorphologically, both lesions cannot be distinguished from their sporadic counterparts. Progression to leiomyosarcomas in the uterus is rare and occurs in less than 3% of the families [1].

The occurrence of kidney cancer seems to be less penetrant than leiomyomatous manifestation. Renal tumors have been identified in approximately one third of HLRCC families [3]. The average age at onset is much earlier than in sporadic kidney cancer (median age 36–44 years). The tumors are usually unilateral and solitary and show a very specific histopathology which lead to the identification of this syndrome [1]. Typically, HLRCC renal cell carcinoma display papillary type II histology, high nuclear grade, and are biologically very aggressive with metastatic disease and death within 5 years in the vast majority of patients [4].

## Prevalence

Not determined.

## Genes

In 2002, germline mutations in the fumarate dehydratase (FH) gene at chromosome 1q42.3-q43 were detected in patients with HLRCC [2]. FH consists of 10 exons and encodes a 511 amino acid peptide. The first exon encodes a mitochondrial signal peptide, but processed FH without this signal peptide is also detected in the cytosol. FH acts as a tumor suppressor gene with biallelic inactivation in almost all kidney cancers and uterine leiomyomas in HLRCC patients. FH germline mutations have been found in 85% of the HLRCC families with more than 50 different mutations described. Several founder mutations were detected in Finnish (H153R and del2bp181) and North American (R190H) families.

Fumarate deficiency is a recessive disease caused by biallelic germline mutations in the FH gene. The syndrome is characterized by neurological impairment, growth retardation, developmental delay, and fumaric aciduria. FH enzyme activity is reduced or absent in all tissues in these patients. Tumor predisposition similar to HLRCC is likely. Genotype–phenotype correlations are not clearly described yet. Papillary renal cell carcinomas and uterine leiomyosarcoma occur only in a minority of families, but the same mutations (e.g. del2bp281 or R190H) were detected in families with or without malignancies. Some families have a very high risk of cancer at an early age, thus modifying genes seems to play an important role in the development of malignancies in families with HLRCC.

## Molecular and Systemic Pathophysiology

Mitochondrial fumarate hydratase is an enzyme of the Krebs cycle that catalyses the conversion of fumarate to malate. Postulated mechanisms for the connection of defective tricarboxylic cycle and tumor development in HLRCC are aberrant apoptosis or oxidative stress. However, the most convincing experimental findings support an important role of pseudohypoxic drive with activation of hypoxia response signaling pathways under normal oxygen conditions. There is a nuclear accumulation of HIF-1α in kidney tumors and uterine leiomyomas of HLRCC patients. In addition, downstream HIF-1α targets were detected in renal cell

carcinomas of HLRCC patients with increased microvessel density, VEGF upregulation, and thrombospondin 1 downregulation. Although there is convincing evidence of activation of pseudohypoxic pathways in HLRCC tumors, the molecular mechanisms underlying this phenomenon remains unclear. The absence of FH could presumably result in increased levels of fumarate and molecules indirectly linked to the tricarboxylic cycle. The increased fumarate levels can lead directly to diminished levels of hydroxylated HIF-1α with longer half-life and decreased degradation, linking FH deficiency to HIF1-α-related pseudohypoxic drive [5]. In addition, there is clear evidence that FH depletion results in upregulation of the GLUT1 protein, glucose uptake, and lactate production in normoxic cells. These findings provide a molecular basis of the Warburg effect in tumors of HLRCC patients leading to preferential energy production of cancer cells via glycolysis despite adequate oxygen levels.

### Diagnostic Principles

There are no guidelines yet about screening and surveillance measurements in HLRCC patients. All patients with multiple leiomyomas or multifocal leiomyomas or leiomyosarcomas of the uterus occurring at early age should be screened for renal cell carcinomas by computer tomography and abdominal ultrasound. However, as renal cell carcinomas occur only in a subset of families with FH germline mutations, it is not clear, if surveillance should be recommended for all HLRCC families.

Markus Böhm, Thomas A. Luger
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Multiple lentigines syndrome; Generalized lentiginosis; Lentiginosis profusa syndrome; Cardiocutaneous syndrome; Progressive cardiomyopathic lentiginosis

## Definition and Characteristics

Autosomal dominant disorder with variable expression characterized by **l**entigines (present on skin and lips but absent from other mucosal sites), **e**lectrocardiographic abnormality, **o**cular hypertelorism (with other dysmorphic features), **p**ulmonary stenosis, **a**bnormalities of genitalia, **r**etardation of growth, and sensorineuronal **d**eafness (and other neurological defects). Additional abnormalities may occur. The related syndrome Noonan syndrome shares many features of LEOPARD syndrome.

## Prevalence

Extremely rare. The exact prevalence is unknown. Approximately 100 cases have been reported.

## Genes

There is accumulating evidence that LEOPARD and Noonan syndrome are allelic disorders caused by different mutations of PTPNII, a gene encoding a non-receptor tyrosine phosphatase located at chromosome 12q22-qter [1]. In nearly half of the cases gain of function mutations of PTPNII may occur [2].

## Molecular and Systemic Pathophysiology

The mutated PTPNII gene in LEOPARD syndrome leads to abnormal signal of the RAS-mitogen-activated protein kinase pathway which is activated by multiple growth factors.

## Diagnostic Principles

Diagnostic criteria are multiple lentigines plus at least two other abnormalities (electrocardiographic, cardiovascular, genitourinary, hypertelorism and other dysmorphic features, growth retardation, deafness and other neurological abnormalities). In absence of lentigines at least three abnormalities as listed above plus a positive family history are required. Differential diagnosis includes Peutz-Jeghers syndrome, Noonan syndrome, Carney complex, Mulvihill-Smith syndrome, neurofibromatosis type 1, Watson syndrome (probably a variant of LEOPARD syndrome).

## Therapeutic Principles

Early diagnosis of cardiovascular abnormalities is crucial to prevent cardiac failure. Neoplasms have also been reported in patients with LEOPARD syndrome. For cosmetic reasons dermabrasion and electrodessication may be offered to treat facial lentigines. Frequent follow-up examinations and genetic counseling are essential.

# Léri-Weill Dyschondrosteosis

Gudrun Rappold
Institute of Human Genetics, Heidelberg, Germany

## Synonyms

Léri-Weill syndrome

## Definition and Characteristics

Pseudoautosomal dominant SHOX gene defect leading to disproportionate short stature and Madelung deformity.

## Prevalence

Unknown. Probably lower than 1:10.000.

## Genes

Defects in the short stature homeobox containing gene SHOX on the X and Y chromosome are causative in the majority of cases [1,2]. A SHOX mutation database is available and lists all currently known mutations (http://www.shox.uni-hd.de).

## Molecular and Systemic Pathophysiology

Deletions, missense, frameshift and nonsense mutations of the short stature homeobox gene SHOX are causative for the disorder [3]. SHOX is a transcription factor that binds to the DNA of its target genes. SHOX plays a role in bone metabolism and is highly expressed in hypertrophic chondrocytes of the fetal and prepubertal growth plates [4]. Langer mesomelic dysplasia represents the homozygous form of Léri-Weill dyschondrosteosis.

## Diagnostic Principles

Léri-Weill dyschondrosteosis is characterized by mesomelic short stature with shortening of the middle segments of the long bones of arm and leg. A characteristic anomaly of the syndrome is Madelung deformity, a deformity of the forearm consisting of shortening and bowing of the radius and distal dislocation of the ulna leading to limited mobility of the wrist [5]. The Madelung

wrist deformity probably originates from disorganized growth of part of the radial epiphysis, leading to radial bowing, premature fusion of the epiphysis, dorsal dislocation of the ulna and wedged carpal bones.

### Therapeutic Principles

Management of short stature is possible by growth hormone treatment as demonstrated in clinical trials. Occasionally surgery of the Madelung deformity is warranted.

## Leucine Sensitivity

Andrea Kelly, Changhong Li
Division of Endocrinology, Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, PA, USA

### Synonyms

Leucine-sensitive hypoglycemia; Glutamate dehydrogenase hyperinsulinism; GDH-HI; Hyperinsulinism/hyperammonemia syndrome (HI/HA)

### Definition and Characteristics

GDH-HI is characterized by hyperinsulinemic hypoglycemia and hyperammonemia. Unlike infants with congenital hyperinsulinism (HI) due to defects in the ATP-sensitive potassium channel ($K\text{-}_{ATP}$ HI), infants with GDH-HI do not typically present in the newborn period with large for gestational age birthweight and hypoglycemia but later in infancy. Traditionally, leucine-sensitive hypoglycemia was used synonymously with congenital hyperinsulinism. However, recognition of the genetic defects responsible for HI has determined that leucine-sensitivity is rather specific for GDH-HI [1]. This sensitivity to the amino acid leucine manifests as protein-induced hypoglycemia [2]. Affected individuals also have fasting hypoglycemia. A spectrum of disease severity has been appreciated: while some affected individuals present in infancy with hypoglycemic seizures, other affected family members have milder symptoms and are not diagnosed until adulthood, when their child/grandchild is diagnosed. An asymptomatic hyperammonemia, 3–5 times normal, distinguishes GDH-HI from other forms of HI, and hence, this disorder has also been referred to as the hyperinsulinism/hyperammonemia

syndrome (HI/HA). Unlike other metabolic disorders, the hyperammonemia is not influenced by protein ingestion [3].

## Prevalence

Unknown.

## Genes

GDH-HI: gain of function mutations in GLUD1 (10q23.3) which encodes the enzyme glutamate dehydrogenase (GDH).

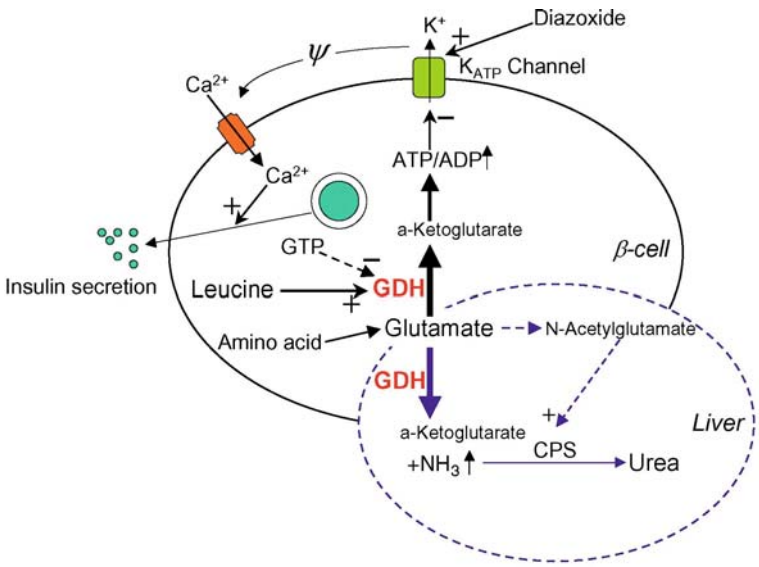
## Molecular and Systemic Pathophysiology

GDH catalyzes the oxidative deamination of glutamate to α-ketoglutarate. It is allosterically activated by leucine and inhibited by GTP. GDH activity within the β-cell leads to ATP generation which causes closure of the β-cell $K_{ATP}$ channel and ultimately to insulin secretion (Fig. 1). With glutamate as its substrate and leucine as its allosteric activator, GDH is positioned to be the mediator of amino acid-stimulated insulin secretion. In GDH-HI, gain of function mutations lead to impaired inhibition of GDH by GTP [4]. This loss of negative regulation leads to excessive leucine-stimulated insulin secretion, which manifests as protein-induced hypoglycemia, and to excessive insulin secretion with fasting. Patients with $K_{ATP}$-HI may also display protein-induced hypoglycemia but in the absence of leucine-sensitivity [5]. In $K_{ATP}$–HI, amino acid stimulated insulin secretion occurs through a GDH- and $K_{ATP}$ channel-independent pathway and, hence, excessive leucine-stimulated insulin secretion in lacking.

The hyperammonemia is thought to arise from (i) depletion of N-acetylglutamate, which plays a key role in ureagenesis and (ii) excessive ammonia production from upregulated GDH-mediated oxidative deamination of glutamate (Fig. 1) [3].

## Diagnostic Principles

The diagnosis of hyperinsulinism must first be established. At the time of hypoglycemia (blood glucose ≤50 mg/dL) free fatty acids and ketones are suppressed and a glycemic response (increase in blood glucose by at least 30 mg/dL) to glucagon occurs. The finding of hyperammonemia in the setting of hyperinsulinism makes the diagnosis of GDH-HI likely; care must be taken to assure that the specimen is properly obtained and the assay completed in a timely fashion to avoid falsely elevated plasma ammonium levels. Additional studies include an oral protein tolerance test (1 g/kg of protein) with close monitoring of blood glucose. While protein-induced hypoglycemia occurs



**Leucine Sensitivity. Figure 1** Physiologic Basis for GDH-HI. Normally, leucine allosterically activates GDH thereby increasing glutamate oxidation which leads to an increase in ATP/ADP resulting in $K_{ATP}$ channel closure, β-cell membrane depolarization, voltage-gated calcium channel opening, and, ultimately, insulin release. HI-causing gain of function mutations in GDH cause loss of sensitivity of GDH to GTP inhibition leading to an unregulated GDH-mediated insulin secretion pathway and excessive β-cell insulin secretion. Hyperammonemia arises from loss of inhibitory control of hepatic GDH: GDH gain of function mutations cause enhanced oxidative deamination of glutamate leading to (i) increased ammonia production and (ii) depletion of N-acetylglutamate, an essential co-factor for carbamoyl phosphate synthetase (CPS), which catalyzes a critical step in ureagenesis.

in the setting of other forms of HI, the finding of excessive leucine-stimulated insulin secretion is rather specific for GDH-HI. The acute insulin response test to leucine has been developed to identify leucine-sensitivity because it relies on the insulin response and avoids development of hypoglycemia, upon which traditional tests depend. Leucine (15 mg/kg) is administered as an intravenous bolus and insulin measured at baseline 1 and 3 min. An increase in insulin ≥15 IU/dL is found in GDH-HI [1]. Mutational analysis of GLUD1 can confirm the diagnosis.

### Therapeutic Principles

Diazoxide (5–15 mg/kg/day) is usually an effective treatment for GDH-HI. In addition, patients should avoid pure protein meals; eating carbohydrates before protein consumption is encouraged. To determine whether a dose adjustment is required, children should be admitted yearly to monitor blood glucose on their home regimen and during a safety fast. An oral protein tolerance test while on diazoxide may also guide further management; the occurrence of protein-induced hypoglycemia may indicate the need for an increase in diazoxide dose. Families should also learn glucagon administration in the case of severe hypoglycemia.

## Leukemia, Chronic Lymphocytic

Françoise Vuillier
Unité d'Immuno-Hématologie et d'Immunopathologie, Institut Pasteur, Paris, France

### Synonyms

B-cell chronic lymphocytic leukemia; CLL; B-cell chronic lymphoproliferative disorder

### Definition and Characteristics

Progressive monoclonal absolute lymphocytosis of small, mature-looking CD5+/CD19+ B-cells which continue to accumulate in the peripheral blood, bone marrow and lymphoid organs [1,2]. B-CLL cells display features consistent with a defect in programmed cell death (apoptosis) and also have a prolonged in vivo survival. However when circulating CLL cells are isolated from the blood or tissues and cultured in vitro they do undergo spontaneous apoptosis.

### Prevalence

CLL accounts for about 40% of all adult leukemias over the age of 65 years and is the commonest leukemia encountered in the western world [1]. CLL increases in incidence with age and only rare cases occur <30 years of age. It is most frequently encountered in Europe, North America and Australasia and is far less common in Asian countries like India, Japan and China.

### Genes

So far, no particular gene has been identified as playing a major role in CLL pathogenesis.

### Molecular and Systemic Pathophysiology

CLL includes two subtypes in terms of clinical course and mutational status of immunoglobulin variable region genes expressed by the B-cells [1,3]. A profile of unmutated IgVH genes is mostly associated with an aggressive clinical course and a poorer survival. This is in contrast to those cases with mutated VH genes who have a relatively benign course and a longer median survival. The definite pathogenesis and origin of these CLL subtypes is still unclear. There is a biased expression of IgVH genes. The VH1–69 clearly predominates among patients displaying unmutated VH genes, whereas the VH3–23 and VH4–34 predominate among mutated forms. Interestingly, the VH3–21 gene is overexpressed in patients from northern European countries and its expression is associated with poor prognosis whether unmutated or not.

## Diagnostic Principles

The current definitive criteria requires an absolute peripheral blood lymphocytosis of more than $5{\cdot}10^9$/l consistent with the appearance of small mature looking lymphocytes, with an immunophenotype based on the combination of $CD19^+$ B cells which also are $CD5^+$ and $CD23^+$ and weakly express CD22, CD79b and surface IgM [2,4].

## Therapeutic Principles

A combination of the clinical stage and prognostic factors provide quite an accurate guide for decision making and choice of therapy. Classical clinical staging systems (Rai or Binet) are initially used to categorize the patients into prognostic groups on the basis of the presence of hepato-spenomegaly, anemia or thrombocytopenia associated with lymphocytosis. However, additional parameters like lymphocyte doubling time, serum levels of β2-microglobulin and thymidine kinase and soluble CD23, as well as CD38 expression on malignant cells can help predict disease activity [2,3]. However, the presence in the leukemic B cells of cytogenetic abnormalities like 11q or 17p deletions or somatic mutations in the immunoglobulin heavy chain genes and expression of ZAP-70 in malignant B cells are better predictors of rapid progression and survival. The advent of these novel biological variables has had a major impact in our understanding of CLL. Some of them appear to be of considerable prognostic importance but as yet there is not available evidence indicating that changing therapeutic approaches on the basis of these results will lead to an improvement in outcome. There is a pressing need for prospective clinical trials to address the stratification of patients according to these factors.

CLL is usually recognized first by the patient's primary care physician. Therapeutical decisions are often difficult, since the physician should be able to answer two major questions: when to treat and how to treat [1,5]. Patients with Stage A or Stage 0 and indolent Stage I from Rai, which include about 2/3 of newly diagnosed patients need only observation until progression of the disease is observed. For young patients (<65 years) presenting initially or following an indolent course with aggressive form of the disease and for whom a cure is possible intensifications strategies associating purine analogs and monoclonal antibodies like anti-CD20 or anti-CD52 and/or autologous bone marrow transplantation can be considered in the frame of randomized trials. For an older patient, or one with considerable co-morbidity, the aim should be palliation. Chlorambucil or oral fludarabine can be used in these cases. For patients who do not fit either category, therapeutic decisions vary. Some physicians, prefer to start with chlorambucil and switch to mini-CHOP or purine analogues if there is no response, whereas other physicians initiate treatment with fludarabine. Fludarabine is the best option for patients refractory to alkylating agents and anti-CD52 for patients who are refractory to fludarabine.

In older patients (superior to 65 years) who have truly indolent disease, no treatment is required until clear evidence of progression is identified by the classic clinical criteria or by surrogate markers predicting who in this group is likely to have a more aggressive course. When a therapy is required in this elderly age group, it consisted of a single oral agent (such a chlorambucil or fludarabine). An alternative issue of combination chemotherapy in this age group could be left for further consideration depending on their initial response or if they have progressive disease on therapy.

# Leukocyte Adhesion Deficiency Syndromes

Amos Etzioni
Department of Immunology, Meyer Children's Hospital, Haifa, Israel

## Synonyms

LAD

## Definition and Characteristics

LAD syndromes are a group of rare conditions in which there is a defect in the ability of leukocytes to adhere to endothelial cells in the blood vessel. In LAD I

syndrome there is a delayed separation of the umbilical cord, severe recurrent infection with no pus formation and a defect in wound healing. LAD II is characterized by milder episodes of infection, severe growth and psychomotor retardation and the rare Bombay (H) blood group. Patients with LAD III suffer from a severe bleeding tendency as well as the features of LAD I.

### Prevalence

LAD I has been described in several hundreds of patients, LAD II and LAD III in less than ten cases each.

### Genes

LAD I-INTG2-coding for β2 integrin localized on chromosome 21q22.3. LAD II-GDP-FucTP coding for the GDP specific fucose transporter localized on chromosome 11p 11.2. LADIII-CaLDAG-GEF I localized on chromosome 11q13.1.

### Molecular and Systemic Pathophysiology

In LAD I a structural defect in the β2 subunit of the integrin leads to an inability of leukocytes to stick to the vessel endothelium, thus preventing the cells from leaving the vessels to arrive at the sites of infections. This causes severe infection and poor wound healing. In most cases there is no expression of the β2 integrin (CD18) on leukocyte surfaces [1].

In LAD II there is no expression of glycoproteins containing fucose on the leukocyte surface. Thus, the ligand for the selectin sialyl Lewis X(CD15a), is absent, leading to a defect in the first step of the adhesion cascade, the rolling phase. The primary defect is in a specific fucose transporter from the cytoplasm to the Golgi apparatus where fucose is incorporated into glycoproteins. The cause for the growth and mental retardation is not yet clear [2].

LAD III includes several patients in whom a general defect in integrin activation exists. All integrins are structurally intact. The primary molecular genetic defect was found to be located in the gene encoding for a Rap1 activator, which is an essential element in integrin activation [3,4].

### Diagnostic Principles

The clinical picture is very suggestive in these syndromes. The diagnosis can be confirmed by flow cytometry studies of the adhesion molecules, functional assays and genetic analysis.

### Therapeutic Principles

Antibiotic prophylaxis is very crucial. Bone marrow transplantation should be considered in patients with LAD I and III. Gene therapy may be an option in the future. In LAD II fucose supplementation can be beneficial in selected cases.

## Leukocytoclastic Vasculitis

Cord Sunderkötter
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Hypersensitivity vasculitis; Allergic angiitis; Schönlein-Henoch purpura

### Definition and Characteristics

The term “vasculitis” denotes an inflammatory condition in which destruction of the wall of blood vessels by leukocytes is the primary event. Leukocytoclastic vasculitis is the inflammation of small vessels, e.g., of postcapillary venules, featuring apoptosis of infiltrating granulocytes with fragmentation of the nuclei (karyorrhexis or leukocytoclasia), necrosis of the vascular wall with subsequent extravasation of erythrocytes (hemorrhage). Damage of the surrounding tissue is usually not very marked.

### Prevalence

Varies widely due to different etiology and age-related differences.

### Molecular and Systemic Pathophysiology

Leukocytoclastic vasculitis generally arises when there is a certain constellation consisting of altered adhesion processes coupled with activation of neutrophils at the vessel wall [1]. Deposition of circulating immune complexes at the wall of small vessels is the most common cause. Only few vasculitides are caused by a Shwartzman reaction-like pathology (septic vasculitis) or by direct microbial invasion of endothelial cells (e.g., some forms of tick-bite fever caused by *Rickettsiae*). The usual sequence of events encompasses formation and vascular deposition of large lattices of immune complexes, subsequent activation of the complement system, and the cytotoxic reaction of granulocytes [2–4]. Lodging of immune complexes along the vessel basement membrane is facilitated, e.g., by locally

increased dilation and permeability of blood vessels, and possibly the exclusive expression of human FcyRIIa (CD32) on endothelial cells of the superficial vascular plexus [5]. Activation of local mast cells by immune complexes via FcγRIII with release of TNF results in recruitment of granulocytes that are mandatory for the damaging effects [1]. Neutrophil-mediated injury of endothelial cells requires complex molecular interaction of products from both neutrophils and endothelial cells. It includes conversion of xanthine dehydrogenase into xanthine oxidase in endothelial cells by neutrophil elastase, subsequent generation of superoxide anion ($O^{2-}$) and $Fe^{2-}$ that both participate in reduction of neutrophil $H_2O_2$ into the highly reactive oxygen radical $HO^-$ that is likely to execute the decisive cytotoxic blow to endothelial cells.

## Diagnostic Principles

Palpable purpura due to inflammatory infiltrate and hemorrhage from necrotic vessels is pathognomonic. Histology confirms the diagnosis; indirect immunofluorescence may help in detecting vascular immunoglobulines. Basic blood tests should include CRP, repeated urine analysis as well as hemoccult and blood pressure in order not to overlook severe systemic involvement. In severe or remittent forms of vasculitis, a complete work-up may become necessary in an attempt to determine the cause of the inflammation.

## Therapeutic Principles

For cutaneous leukocytoclastic vasculitis, there are few controlled randomized therapeutic trials. Steroids and/or cytotoxic agents are only advised for patients with significant systemic involvement or with significant cutaneous ulcerations. Otherwise, cutaneous vasculitis is recommended to be treated with compression stocking to prevent further deposition of immune complexes along dilated vessels. In chronic or remittent forms, anti-inflammatory and immunomodulatory agents can be tried that are generally less toxic than immunosuppressive strategies.

## Definition and Characteristics

Primary leukodystrophy refers to a heterogeneous group of inherited cerebral white matter diseases characterized by dysmyelination (defective myelination), demyelination (destruction of myelin sheath) or both. Eight known diseases are identified by clinical, radiological, biochemical and molecular features (Table 1). In a given disease, the clinical phenotypes are distinguished by age of onset, rate of progression and associated findings. In the frequently encountered childhood forms, the common presentation includes psychomotor regression with progressive pyramidal and cerebellar dysfunction with or without optic pathway involvement and the adult form usually manifests with psychosis or dementia. Subacute neurological deterioration may follow trauma or febrile episode in LVWM, ALD and MLC. Macrocephaly is observed in AD, CD and MLC and peripheral neuropathy may be encountered in MLD and KD. Adrenal insufficiency and testicular atrophy may be associated with ALD while ovarian failure may be noted in LVWM. Rarely acute cholecystitis may the presenting symptom of MLD. The absence of these extra-neural manifestations, however, cannot be used to rule out the disease. In general, brain magnetic resonance imaging (MRI) reveals abnormal signal alterations in the cerebral white matter. MRI and MR spectroscopic findings are shown in Table 1. The clinical profile, mode of inheritance and pattern recognition on brain MRI may aid

**Leukodystrophy. Table 1** Overview of well-characterized primary leukodystrophies

| Diseases | Clinical phenotypes | MRI/MRS findings | Histopathology | Mode of inheritance | Chromosomal locus | Gene symbol and mutation | Biochemical defect and molecular pathogenesis [1,2,3] | Diagnosis |
|---|---|---|---|---|---|---|---|---|
| MLD | Clinical phenotypes: Late infantile, juvenile and adult forms | Diffuse white matter signal alteration and radial stripes | Characterized by demyelination, gliosis, and lysosomal storage of metachromatic granules in the central and perhipheral system (a lysosomal storage disorder) | AR | 22q13.3-qter | *ARSA;* mutations display striking degree of allelic heterogeneity and missense mutation is the most predominant type | Primary deficiency of the lysosomal enzyme arylsulfatase A, encoded by *ARSA,* impairs the hydrolysis of sulfatides. Defective resorption of sulfatides within myelin sheath and progressive accumulation of metachromatic material within the oligodendroglia and Schwann cells (myelin producing cells in peripheral nervous system) might result in abnormal myelin composition, restructuring and breakdown. MLD like phenotype is also observed in related disorders such as multiple sulfatase deficiency and saposin B (sulfatide activator protein) deficiency | Suggested by low activity of arylsulfatase A in peripheral leukocytes and skin fibroblasts and confirmed by molecular genetic testing or demonstration of increased concentration of sulfatides in the urine or demonstration of metachromatic lipid deposit in nerve biopsy |
| ALD | Clinical phenotypes: Childhood cerebral form, spinocerebellar form, adult adrenomyeloneuropathy; and Addison disease only | Frontal/occipital predominance with contrast enhancement | Characterized by inflammatory demyelination (with secondary axonal loss) in the cerebral form and distal axonopathy in the long tracts of spinal cord in adrenomyeloneuropathy and presence of striated adrenocortical cells (a peroxisomal storage) | XR | Xq28 | *ABCD1;* mutations show similar allelic heterogeneity and predominance of missense mutation as in MLD | The precise molecular mechanism is not fully understood. *ABCD1* encodes peroxisomal membrane transporter, ALD protein/ ATP-binding cassette sub-family D member 1. However, the biochemical defect involves β oxidation of very long chain fatty acids (VLCFA), possibly due to altered interaction of the ALD protein with the peroxisomal enzyme involved in VLCFA metabolism. Abnormal lipids containing excessive VLCFA might activate microglia, perivascular cells and astrocytes leading to inflammatory demyelination | Suggested by the presence of adrenal dysfunction and confirmed by molecular genetic testing or high plasma levels of VLCFA. |

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| KD | Clinical phenotypes: Infantile, late infantile, juvenile, and adult forms | Occipital predominance | Presence of multinucleated globoid cells in the white matter (hence this lysosomal storage disease is also called globoid cell leukodystrophy). | AR | 14q31 | *GALC;* 30-kilobase deletion accounts for the vast majority of the characterized mutations in the Caucasians | Primary deficiency of lysosomal enzyme galactocerebrosidase, encoded by *GALC,* leads to impaired degradation of galactosylceramide and psychosine. The undegraded substrates induce globoid cell infiltration, premature death of oligodendroglia and myelin loss | Confirmed by molecular genetic testing or reduced activity of galactocerebrosidase in peripheral leukocytes or cultured skin fibroblasts |
| CD | Clinical phenotypes: neonatal and infantile forms | Involvement of subcortical U fibers and markedly elevated N acetyl aspartate (NAA) peak | Characterized by spongy degeneration or vacuolation in cerebral white matter, swelling of protoplasmic astrocytes and distortion of mitochondria | AR | 17pter-p13 | *ASPA;* of the characterized mutations, missense mutations predominate over deletion | Primary deficiency of enzyme aspartoacylase encoded by *ASPA,* leads to increased concentration of NAA in the brain and body fluids. The pathogenesis is not fully understood. Proposed mechanisms include neurotoxic effects of NAA or related metabolites and interference with the function of N-methyl-D-aspartate receptors by N-acetyl-aspartyl-glutamate | Confirmed by molecular genetic testing or demonstration of high concentration of NAA in the urine or amniotic fluid or reduced aspartoacylase activity in skin fibroblasts, leucocytes or amniocytes |
| AD | Clinical phenotypes: neonatal, infantile, juvenile and adult forms | Frontal predominance with contrast enhancement | Characterized by hypomyelination and abundant Rosenthal fibers that are homogeneous eosinophilic inclusions within astrocytes | AD | 17q21 | *GFAP;* mutations exert toxic gain of function and missense mutation is the most predominant type | Mutations in *GFAP* encoding glial fibrillary acidic protein (intermediate filament protein in the astrocytes) lead to accumulation of the altered protein in the Rosenthal fibers. The mutant protein presumably interferes with the interaction between astrocytes and oligodendroglia | Confirmed by molecular genetic testing |

**Leukodystrophy. Table 1** Overview of well-characterized primary leukodystrophies (Continued)

| Diseases | Clinical phenotypes | MRI/MRS findings | Histopathology | Mode of inheritance | Chromosomal locus | Gene symbol and mutation | Biochemical defect and molecular pathogenesis [1,2,3] | Diagnosis |
|---|---|---|---|---|---|---|---|---|
| PMD | Clinical phenotypes: Connatal (neonatal) and Classic forms; Genetically related (allelic) disorder includes spastic paraplegia 2 (complicated and pure forms) | Involvement of the subcortical U fibers and radial stripes | Characterized by diffuse cerebral hypomyelination, tigroid appearance due to preservation of islands of myelin (in the classic form) and fibrillary gliosis | XR | Xq22 | *PLP1;* duplication leading to overexpression of gene product, accounts for the vast majority of the characterized mutations | *PLP1* encodes proteolipid protein and its isoform DM 20 (PLP/DM20), a major myelin protein. Mutant gene products accumulate in rough endoplasmic reticulum affecting their intracellular trafficking and activate apoptosis of oligodendroglia. In general, point mutations affecting transcription of both PLP and DM20 result in severe connatal form | Confirmed by molecular genetic testing. |
| LVWM | Clinical phenotypes: Congenital, infantile, early childhood, juvenile and adult forms | Progressive vanishing of white matter and cystic changes | Characterized by spongiform degeneration with diffuse vacuolation and cavitation of the white matter and presence of oligodendroglia with “foamy” cytoplasm and hypotrophic astrocytes | AR | 12, 14q24, 1p34.1, 2p23.3, 3q27 | *EIF2B1–5;* the known mutations are observed in 90% of cases with typical clinico-radiological phenotype and missense mutation is the most predominant type | *EIF2B1–5* encodes eukaryotic translation initiation factor 2B, subunits 1–5 respectively. This protein complex plays a crucial role in regulating protein synthesis during cellular stress. Altered regulatory function might account for rapid clinical deterioration following trauma and fever. Further, the mutations have been associated with decreased nucleotide exchange activity in vitro. However, the exact molecular pathogenesis is yet to be understood | Confirmed by molecular genetic testing |

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| MLC | Clinical phenotypes: Neonatal and infantile forms | Subcortical cysts in anterior-temporal and fronto-parietal regions and mildly swollen cerebral white matter | Characterized by vacuolating myelinopathy with splitting of outer lamellae of myelin sheath | AR | 22q13.3 | *MLC1;* missense mutation is the most frequent type | *MLC1* encodes megalencephalic leukoencephalopathy with subcortical cysts 1 protein that might be an integral membrane transporter. However, the precise molecular pathogenesis is yet to be determined | Confirmed by molecular genetic testing |

Abbreviations used in the table include: MLD = Metachromatic leukodystrophy; ALD = Adrenoleukodystrophy; KD = Krabbe disease; CD = Canavan disease; AD = Alexander disease; PMD = Pelizaeus- Merzbacher disease; LVWM = Leukoencephalopathy with vanishing white matter; MLC = Megalencephalic leukoencephalopathy with subcortical cysts; AD = autosomal dominant; AR = autosomal recessive; XR = X linked recessive.

in the differential diagnosis and choice of appropriate biochemical and genetic tests.

## Prevalence

1:40,000 to 1:160,000 in MLD, 1:20,000 to 1:50,000 in ALD, 1:100,000 to 1:200,000 in KD, 1:6,400 to 1:13,500 (in Ashkenazi Jews) in CD, 1:200,000 to 1:500,000 in PMD. Exact prevalence is not known in AD, LVWM and MLC.

## Genes

The causative gene for each disease is listed in Table 1. The gene products can be broadly classified as enzymes involved in lipid metabolism (e.g., arylsulfatase A, galactocerebrosidase) or organic acid metabolism (e.g., aspartoacylase), membrane transporters (e.g., ALD protein/ATP-binding cassette sub-family D member 1, megalencephalic leukoencephalopathy with subcortical cysts 1 protein), intermediate filament proteins (glial fibrillary acidic protein (GFAP), myelin protein (e.g., proteolipid protein), and regulatory protein complexes (e.g., eukaryotic translation initiation factor 2B, subunits 1–5). The most frequent type of mutation in the various diseases is a point mutation with some exceptions: in KD, the most common type is deletion and in PMD, the predominant type being increased gene dosage (e.g., duplication).

## Molecular and Systemic Pathophysiology

The myelin sheath insulates neuronal axons, thereby facilitating impulse transmission. Myelin is produced and maintained by oligodendroglia, under the influence of astrocytes, in the central nervous system. The important constituents of myelin include galactosylceramide, sulfatides (sulfated glycolipids), myelin basic protein, proteolipid protein (PLP) and its isoform, DM 20. In the developing brain, there is rapid turnover of myelin constituents during the peak time of myelin formation. Though the precise mechanisms underlying primary leukodystrophy are not completely understood, there are several possible ways in which genetic mutations can affect myelin formation or its integrity: (i) Misfolding or deficiency of myelin proteolipid protein (e.g., PMD); (ii) inappropriate activation of unfolded protein response that might play a crucial role in inducing apoptosis of oligodendroglia (e.g., PMD, LVWM); (iii) premature death of oligodendroglia due to toxic substance (e.g., KD); (iv) alteration in myelin composition or turnover due to enzyme defect in the metabolism of sulfatides (e.g., MLD) or galactosylceramide (e.g., KD); (v), peroxisomal membrane transporter defect that possibly alters the metabolism of very long chain fatty acid (e.g., ALD); (vi) enzyme defect in the metabolism of organic acid that possibly results in neurotoxic metabolites (e.g., CD); (vii) astrocytic dysfunction due to altered glial intermediate filament protein that presumably affects myelination (e.g., AD); (viii) loss of astrocytic membrane transporter protein that presumably results in white matter swelling (e.g., MLC); (ix) loss of regulatory complex in protein synthesis during cellular stress (e.g., LVWM). The myelin defect may be associated with axonal loss and gliosis. In general, the genetic abnormalities correspond to loss-of-function defect except in AD and many cases of PMD, where mutations exert toxic gain-of-function. Gain of function mutations usually leads to overexpression, abnormal conformation, and aggregation of the mutant proteins. The type of mutation, modifier genes and environmental factors may determine the phenotypic variations to some extent. For instance, homozygosity for null alleles results in severe phenotype in MLD [1]; missense mutations that alter the expression of both PLP and DM 20 produce the devastating form in PMD [1,2,3]; and the influence of modifier genes may account for intrafamilial variability in AD [2]. Apart from nervous system, extraneural sites such as gallbladder (in MLD and congenital LVWM), kidney, pancreas (in MLD, LVWM), adrenal gland (in ALD), gonads (in ALD and LVWM) may reveal biochemical or structural alterations.

## Diagnostic Principles

In the setting of typical clinical and radiological manifestations, the diagnosis is confirmed by molecular genetic testing or appropriate biochemical tests or enzyme assays (Table 1). Genetic testing also aids in carrier detection, prenatal diagnosis and genetic counseling.

## Therapeutic Principles

In the absence of specific treatment, symptomatic and supportive care involves multidisciplinary team approach. Corticosteroid replacement therapy is required for ALD with adrenal insufficiency. Bone marrow or hemacoietic stem cell transplantation may be useful as preventive therapy for presymptomatic or mildly symptomatic individuals in KD, ALD and MLD. The exact mechanism of how such therapy works for metabolic brain diseases is not clear but possibly results from partial replenishment of missing gene products expressed by normal microglia derived from transplanted hematopoietic cells. Using animal models, gene therapy, cell based therapy, and enzyme replacement are under investigation for some of these diseases.

## Lichen Planus

Jan Ehrchen, Stefan Beissert
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Lichen ruber; Lichen ruber planus; Lichen planopilaris

### Definition and Characteristics

Lichen planus (LP) is a chronic, inflammatory mucocutaneous disease of unknown etiology.

### Prevalence

LP is one of the most common inflammatory dermatoses with a prevalence in the general population of approximately 0.5–1%.

### Molecular and Systemic Pathophysiology

There is a growing acceptance that LP presents a cellular autoimmune response directed against epidermal antigens [1–2]. The inflammatory infiltrate consists primarily of T cells both of the CD8+ and the CD4+ phenotype and macrophages. A current hypothesis for the immunopathogenisis of oral LP includes the following molecular and cellular mechanisms [2]: Activation of basal keratinocytes and epidermal antigen presenting cells by viral infections (e.g., hepatitis C [3]) or other stressors triggers antigen presentation and secretion of chemokines (e.g., CCL5) that attract lymphocytes into the developing LP lesion. Mast cells and their degranulation products seem to be involved in amplification of this process. Antigen presentation via MHC-II results in activation and expansion of CD4+ Th1 cells which secrete IFNγ and IL2. Both cytokines further stimulate CD8+ cytotoxic T-cells, which have been activated by MHC-I dependent antigen presentation. Cytotoxic T-cells induce keratinocyte apoptosis (e.g., by secretion of TNF-alpha). The nature of the antigens involved in LP is presently unknown, however, many aspects of LP-like association with other autoimmune diseases and the presence of autocytotoxic T-cell clones in LP lesions [4] point to a true autoimmune etiology of LP.

### Diagnostic Principles

LP is characterized clinically by violaceous, polygonal, flat topped pruritic papules displaying a lace-like pattern of white lines on their surfaces (Wickham sign [5]). It can involve skin and mucous membranes. Characteristic histological findings are a dense band-like dermal monocyte and T-cell rich infiltrate, epidermal alterations (acanthosis, hypergranulosis, hyperkeratosis) and the presence of apoptotic basal keratinocytes (interface dermatitis).

### Therapeutic Principles

Numerous antiinflammatory therapies are used in the treatment of LP. They range from topical application of e.g., glucocorticoids, calcineurin inhibitors or retinoids to systemic medication including the use of systemic glucocorticoids, retinoids, hydroxychloroquine, dapsone and immunosuppressive agents like azathioprine or cyclosporin A.

## Lichen Sclerosus

Fenella Wojnarowska[1], Gudula Kirtschig[2]
[1]Department of Dermatology, Churchill Hospital, Oxford, UK
[2]Department of Dermatology, VU Medical Centre, Amsterdam, The Netherlands

### Synonyms

Lichen sclerosus (LS); Lichen sclerosus et atrophicus; LSA/LSEA; Balanitis xerotica obliterans; BXO

### Definition and Characteristics

LS is a common inflammatory skin disease of both adults and children. It is characterized by plaques of ivory white atrophic or thickened skin, purpura, erosions, occasional blistering, and mutilating architectural changes due to fusion and sclerosis [1]. LS chiefly affects the genitals causing major physical and psychological morbidity. The morbidity is due to severe pruritus and pain, destructive changes in end stage disease and the possible confusion with sexual abuse in childhood cases. The architectural changes are caused by the severe inflammation and result in labial resorption, burying of the clitoris and narrowing of the introitus interfering with micturition, sexual function, conception and childbirth, requiring surgery in some women. In men the scarring may cause phimois, interfering with micturiton and sexual function and requiring circumcision (BXO). There is an association with genital cancer (2–5% of cases).

### Prevalence

1:30 to 1:1,000 of all females; occurring more in females than in males; clustering in prepuberty and postmenopause.

### Genes

Familial cases suggest a genetic component.

HLA studies in vulval LS show that HLA DRB1*12 and its associated DRB1*12/DQB1*0301/04/09/010 haplotype confers susceptibility and that HLA DRB1*0301/04 and its associated DRB1*0301/04/DQB1*0201/02/03 haplotype is protective. There is no HLA association with clinical features or course of the disease.

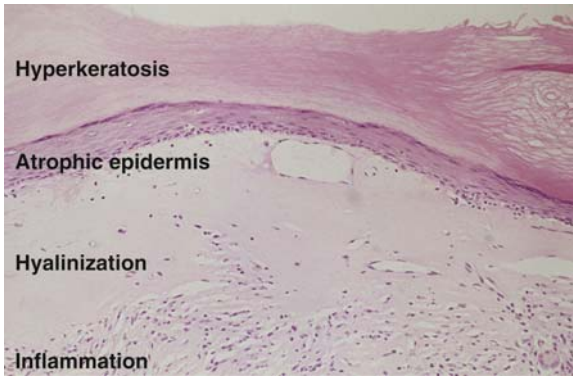
### Molecular and Systemic Pathophysiology

The cause of LS is unknown. Infective agents have been postulated to induce LS but data to support that theory is poor. LS is considered to be an autoimmune disease in genetically predisposed individuals because of the association with autoimmune diseases, circulating autoantibodies, and family history of autoimmune disease [2]. Recently a humoral immune response to structural proteins of the skin has been demonstrated, to the glycoprotein extracellular matrix protein 1 (ECM1) and to the basement membrane component collagen XVII (BP180) in particular [3]. An animal model has shown that ECM1 antibodies can induce inflammation. A pilot study has shown a T cell response to collagen XVII.

Oxidative stress, which is involved in the pathogenesis of several autoimmune and malignant disorders, may contribute to these processes in LS. Increase of lipid peroxidation products was found within the basal cell layers of the epidermis of LS, thus co-localizing with ECM1. Oxidative DNA damage was detected throughout LS biopsies indicating that oxidative damage to lipids, DNA and proteins may contribute to sclerosis, autoimmunity and carcinogenesis in LS. The possible role of TP53 mutations in the development of vulval cancer in LS is postulated.

In early LS the inflammatory infiltrate is adjacent to the BMZ. In established LS there is a zone of hyalinization/sclerosis in the upper dermis and below it a region of inflammation with infiltration of lymphocytes (Fig. 1). The epidermis may be thickened or thinned. A vacuolar degeneration of basal keratinocytes and a disruption of the basement membrane zone (BMZ) may be observed leading to a loss of dermal epidermal adhesion.

CD4+ and CD8+ lymphocytes are detected in the dermal infiltrate in approximately equal proportions. Less numerous CD4+ and CD8+ lymphocytes were seen adjacent to the dermo-epidermal junction and also occasionally seen in the lower epidermis. There was an increased number of CD68+ cells (a macrophage



**Lichen Sclerosus. Figure 1** Typical histology of LS showing the zone of sclerosis/hyalinization (resembling the genetic disease Lipoid Proteinosis) and the deeper zone of inflammation.

marker) and increased expression of HLA-DR within the inflammatory infiltrate and around keratinocytes, suggesting that these keratinocytes might be involved in antigen presentation.

It is not certain whether LS is a Th1 or Th2 related disease. Tchorzewski et al. demonstrated an increase in CD4+CD25+ suppressor T cells, decreased numbers of CD3+CD26+ activated lymphocytes, and diminished reactive oxygen intermediate (ROI) production by peripheral blood granulocytes of LS patients [4]. They also showed increased basal secretion of IL12 and stimulated secretion of IL2, IL5, IL10, and TNFα by lymphocytes from patients with LS. They conclude that a disturbance in the production of these regulatory cytokines by activated T cells of LS patients directly proves the presence of an autoimmune reaction in LS pathogenesis. However, in a recent study Farrell et al. detected an increased staining of CD25, CD11a, and ICAM1 and also the cytokines IFNγ, TNFα, IL1α, INFγ-receptor in skin specimens of genital LS. This cytokine profile in LS is similar to that of lichen planus and chronic wounds and is more suggestive of a Th1 profile [5].

## Diagnostic Principles

The diagnosis is made clinically and confirmed by histopathology. Histology demonstrates an interface dermatitis in early LS and a band of hyalinization in the upper dermis and a deeper zone of lymphocytic inflammation in established LS.

## Therapeutic Principles

Treatment consists of very potent topical steroids (e.g., clobetasol propionate 0.05% ointment) or topical immunosuppressants (e.g., tacrolimus).

# Lichen Sclerosus et Atrophicus

►Lichen Sclerosus

# Lichen Striatus

Alexander K. C. Leung[1],
William Lane M. Robson[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]The Childrens' Clinic, Calgary, AB, Canada

## Synonyms

Lichenoid trophoneurosis; Nevus linearis; Zonal dermatosis; Linear neurodermatitis; Neurodermite zoniforme

## Definition and Characteristics

Lichen striatus is a benign, self-limited T-cell mediated dermatosis. The condition is more common in children and presents with an inflamed, linear, papular eruption [1]. The onset is usually abrupt. The initial eruption consists of discrete, flesh-colored or pink, flat-topped papules, 1–3 mm in diameter (Fig. 1).

The papules often coalesce to form either a continuous or an interrupted linear band [1]. The lesions are usually hyperpigmented, but in dark-skinned individuals the lesions might be hypopigmented. The lesion is usually

**Lichen Striatus. Figure 1** A 15-year-old boy with lichen striatus on the right arm.

solitary, unilateral, and follows the lines of Blaschko [2]. Although lichen striatus can involve any part of the body, the arms and legs are the most commonly affected [2]. Penile lesions are rare [1]. Lesions can extend over the entire length of an extremity, but this is rare. The lesion is usually asymptomatic and non-pruritic [3]. When the eruption involves the posterior nail fold and matrix, onychodystrophy can occur, and can precede the development of the skin lesion, but nail lesions are uncommon [2].

## Prevalence

Lichen striatus is most common in children between 5 and 15 years of age [1]. The condition has been described in infants and adults. The female-to-male ratio is approximately 2 to 3:1 [2]. There is no known racial predilection. The condition is more common in the spring and summer. Approximately 85% of patients have a personal or family history of atopy [1]. Lichen striatus usually occurs sporadically, but simultaneous familial occurrences have been reported [3].

## Molecular and Systemic Pathophysiology

The etiology has not been clarified but the condition might be due to a form of cutaneous mosaicism in which an abnormal clone of keratinocytes arises due to post-zygotic somatic mutation [4]. In this situation, the body tolerates the aberrant clone until the abnormal cells are unmasked by an acquired event such as a viral infection or trauma, which results in a T-cell mediated inflammatory reaction [4]. A perivascular histiocytic and $CD8^{+}$T lymphocytic infiltrate in the superficial and deep dermis is characteristic. Spongiosis, exocytosis, hyperkeratosis, and parakeratosis are also observed.

## Diagnostic Principles

The differential diagnosis includes lichen planus, linear psoriasis, linear epidermal nevus, linear verrucous nevus, and allergic and atopic dermatitis. Lichen planus and linear psoriasis are usually associated with multiple lesions and are intensely pruritic. The lesion of lichen planus is usually violaceous, tends to be larger, and is often hypertrophic. The lesion of linear epidermal nevus usually appears in early infancy and does not regress. With time, the lesion becomes more keratotic and hyperpigmented than that of lichen striatus. The lesion of inflammatory linear verrucous nevus tends to be extensive and is markedly pruritic. The lesions of allergic dermatitis and atopic dermatitis are pruritic.

## Therapeutic Principles

Lichen striatus is a self-limited condition that commonly resolves within 1 year [2]. When associated with onychodystrophy, the lesion tends to persist longer. When therapy is desired for cosmetic reasons, a topical corticosteroid or an immunomodulator such as tacrolimus or pimecrolimus hastens resolution.

# Lichenoid Trophoneurosis

►Lichen Striatus

# Liddle's Syndrome

Laurent Schild, Bernard C. Rossier
Department of Pharmacology and Toxicology, Lausanne University, Lausanne, Switzerland

## Synonyms

Pseudoaldosteronism

## Definition and Characteristics

Liddle's syndrome is an autosomal dominant form of moderate to severe hypertension with early onset during teenage years [1]. High blood pressure is associated with hypo- or normo-kalemia, high urinary potassium excretion, low plasma aldosterone in relation to chronic suppression of aldosterone secretion, low plasma renin activity likely due to chronic plasma volume expansion. Moderate metabolic alkalosis may occur.

The clinical features of this syndrome are consistent with an abnormally high sodium reabsorption in the distal part of the nephron leading to expanded plasma volume, and hypertension.

## Prevalence

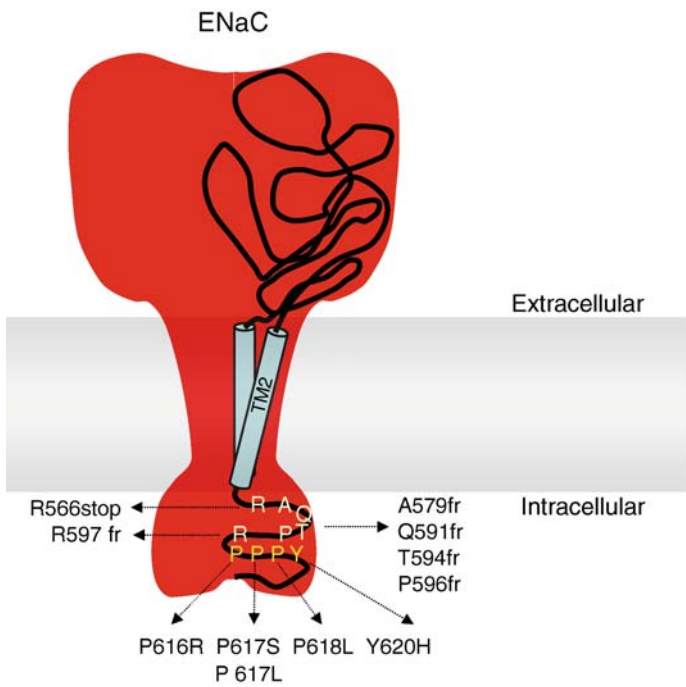
Liddle's syndrome is a rare mendelian form of hypertension with less than 50 families identified worldwide.

## Genes

Liddle's syndrome is caused by missense, deletion or frameshift mutations in the SCNN1B or the SCNN1G genes (locus 16p13-p12, OMIM 177200) coding for the β and γ subunits of the epithelial sodium channel (ENaC) (Fig. 1) [2]. ENaC mediates $Na^+$ absorption in the distal nephron (connecting tubule and collecting duct) under the control of aldosterone. Mutations in Liddle's syndrome delete or alter a proline-rich sequence (PPPxY, x being any amino-acid) located in the cytosolic carboxy-terminus of the β and γ ENaC subunits. This proline-rich sequence (PY motif) is conserved among all α β γ ENaC homologs, but only mutations in the β and γ subunits are associated with Liddle's syndrome.

## Molecular and Systemic Pathophysiology

Replication of these Liddle mutations in cDNAs encoding the β and γ ENaC subunits, and functional expression of the ENaC channel mutants in Xenopus



**Liddle's Syndrome. Figure 1** Schematic representation of the epithelial sodium channel (ENaC). ENaC is made of three homologous α β γ subunits, only the β subunit is shown on the figure. Each subunit contains 2 transmembrane helices, and a large extracellular domain; the amino and carboxy termini are facing the intracellular side of the membrane. Mutations causing Liddle's syndrome are found in the cytosolic carboxy terminus of the β (shown on the figure) or γ ENaC subunits, and delete or modify the sequence of a conserved PY motif (PPPxY sequence): "fr" denotes frameshift mutations, "stop" denotes premature stop codon mutations.

oocytes reveals an increase in ENaC-mediated $Na^+$ transport relative to wild type ENaC, i.e., an elevated ENaC-mediated $Na^+$ current measured by electrophysiological techniques [3]; these gain of function mutations are consistent with the clinical features of the syndrome, and result from a retention of highly active ENaC channels at the cell surface.

The link between mutations in the conserved PY motif of the cytosolic carboxy-terminus of β or γ ENaC subunits, and surface retention of active ENaC channels has been investigated in details. Proline-rich sequence such as the PY motif of β or γ ENaC subunits are often involved in protein-protein interactions. In the case of β and γ ENaC, the PY motif of the C-terminus serves as a binding site for a cytosolic ubiquitin ligase named Nedd4–2. Nedd4–2 is a negative regulator of ENaC, which upon ubiquitylation of the channel, leads to the endocytosis of ENaC and its degradation by the proteasome [4]. The Nedd4–2 dependent ubiquitylation of ENaC occurs on specific lysine residues in the cytosolic N-terminus of α and γ ENaC subunits.

Deletion or missense mutations found in Liddle's syndrome abrogate the binding interaction between the Nedd4–2 and ENaC, and subsequent ubiquitylation of the channel. Internalization of active ENaC from the cell surface is impaired, and abnomal retention of active ENaC promotes increased $Na^+$ entry into the cell. The pathophysiological consequences of such prolonged half-life of the ENaC at the cell surface have been studied in transgenic mouse models bearing the PY motif deletion in the β ENaC subunit: these mice show an exacerbated stimulatory response of ENaC to aldosterone, expanded plasma volume and salt-sensitive hypertension [5].

## Diagnostic Principles

Among the affected individuals high blood pressure and hypokalemia show a variable penetrance. Thus, high blood pressure and hypokalemia associated with low plasma renin activity is not diagnostic of Liddle's syndrome. A low 24 h urinary aldosterone and/or a blunted response of aldosterone to ACTH represent useful tests for the diagnosis. Diagnosis is made on the basis of a genetic screen demonstrating missense or deletion mutations of the PY motif of β or γ ENaC subunits.

## Therapeutic Principles

In adolescents, administration of amiloride 10–20 mg/day for 1 month together with a low sodium diet tends to normalize blood pressure and correct hypokalemia. Spironolactone is ineffective. Amiloride treatment has almost no effect on plasma aldosterone which remains very low. Ultimately renal failure may develop and kidney transplant normalizes all the biological parameters.

L

# Li-Fraumeni Syndrome

Wolfgang Dietmaier[1], Arndt Hartmann[2]
[1]Institute of Pathology, University of Regensburg, Regensburg, Germany
[2]Institute of Pathology, University of Erlangen, Erlangen, Germany

## Synonyms

LFS1; Sarcoma family syndrome of Li and Fraumeni; SBLA syndrome

## Definition and Characteristics

Li-Fraumeni syndrome (LFS) is an autosomal dominant inherited familiar cancer syndrome. A characteristic feature of LFS is the occurrence of multiple primary neoplasms in children and young adults, with a predominance of breast cancer and sarcomas of soft tissues and bone. Other LFS-associated neoplasms include brain tumors (gliomas), adrenocortical carcinomas affecting the outer layer of the adrenal glands, cancer of the colon and pancreas as well as leukemias. LFS is diagnosed in patients fulfilling established clinical criteria [1]. Similar to LFS, a condition called Li-Fraumeni-like syndrome (LFL) shares some, but not all of the features of the classic LFS. In more than 50% of clinically defined

LFS individuals, disease-causing germline mutations in the tumor suppressor gene TP53 were reported. Most of these mutations can be detected by sequence analysis, confirming the diagnosis and enabling a predictive molecular testing in asymptomatic relatives.

## Prevalence

LFS is a rare hereditary cancer syndrome, with fewer than 400 families reported worldwide.

## Genes

In 1990, germline mutations of TP53 were reported as the underlying cause of LFS [2]. The TP53 gene encompasses 20 kilobases (kb) in genomic length and is located on chromosome 17 (17p13.1). The TP53 gene consists of one noncoding and ten coding exons and shows five highly conserved regions. Region I provides a transactivation domain of TP53, the regions II–IV make up the core DNA-binding domain (Fig. 1).

Over 75% of TP53 mutations are single base substitutions (missense or nonsense) and are predominantly located in the DNA binding domain encoding exons 5–8. Codons 175, 245, 248, 273, and 282 are mutation hotspots that can be found not only as germline mutations in LFS but also as somatic mutations in numerous types of cancers. Beside these mutations, about 20% of mutations may be located outside exon 5–8, and mutations may also affect splice site junctions.

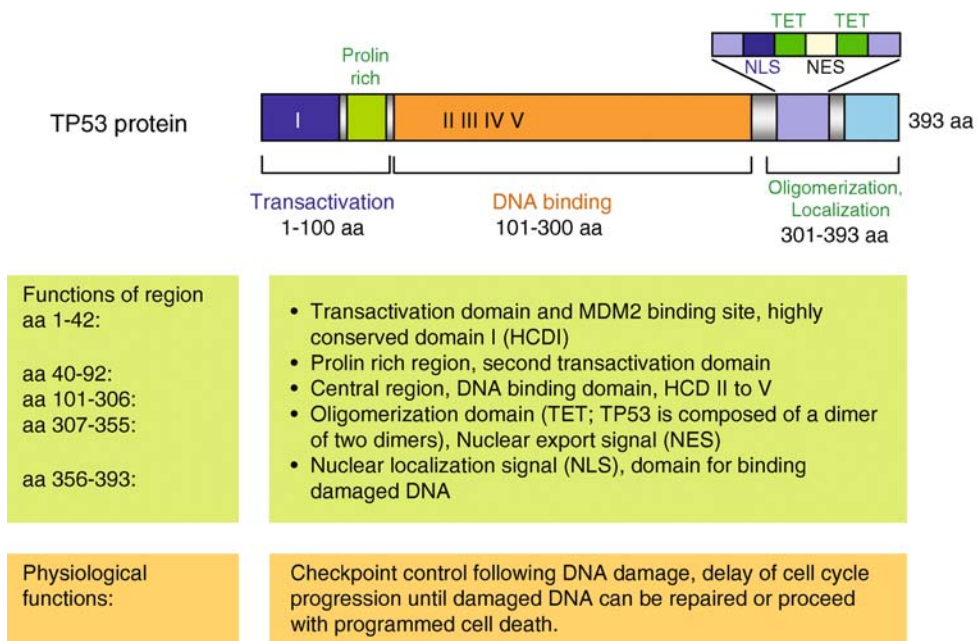
Brain tumors are often associated with missense TP53 mutations in the DNA-binding loop that interact with the minor DNA groove. Early onset brain tumors seem to correlate with mutations leading to absence or loss of function of TP53 [3]. Adrenocortical carcinomas, which are pathognonomic for LFS if they develop before the age of 18, were reported to be associated with missense mutations in the loops opposite the protein-DNA content surface [3].

In rare cases, germline mutations in the CHEK2 gene have been identified in LFS and several LFL families [4]. CHEK2 is a putative tumor suppressor gene and encodes a protein kinase required for DNA damage and replication checkpoints. CHEK2 protein is capable of binding to and regulating BRCA1 in processes to repair double-stranded DNA breaks.

## Molecular and Systemic Pathophysiology

The TP53 gene was first identified in 1979 and encodes a protein that complexes to the large T antigen of SV40. Since its cooperation with HRAS to transform cells, TP53 was believed to act as an oncogene. However, the capability to abrogate the tumorigenic phenotype if transfected into tumor cell lines, the frequent finding of inactivation of both alleles in tumor cells, and the association with hereditary cancers led to the final classification as a tumor suppressor gene.

The cellular TP53 protein forms a tetramer, which is actually a dimer of dimers. Termed as the "guardian of the genome," the major function of p53 protein is to determine whether cells undergo arrest for purposes of DNA repair or programmed cell death (apoptosis).



**Li-Fraumeni Syndrome. Figure 1** Scheme of BRCA1 gene showing the functional domains.

Cellular TP53 protein thus acts as a checkpoint control following DNA damage, leading to delay of cell cycle progression until the damaged DNA can be repaired or proceed with programmed cell death.

Normally, TP53 is constitutively expressed in most cell types, but is subjected to a rapid degradation by the proteasome machinery. This process is mediated by the TP53 binding protein MDM2 whose expression is also induced by the TP53 protein. In situations of cellular stress, TP53 undergoes posttranslational modifications that release TP53 from MDM2 leading to an intranuclear accumulation of TP53 and its activation as a transcription factor. As a consequence, downstream targets like cell cycle regulatory genes (p21/WAF1, GADD45, 14–3–3S, CYCLIN-G), proapoptotic genes (FAS/APO1/CD95, KILLER/DR5, AIF1, PUMA, BAX), DNA repair genes ($O^6$MGMT, MLH2), and the MDM2 gene are transactivated and cause cell cycle arrest, DNA repair, and/or programmed cell death.

## Diagnostic Principles

The classic LFS is defined by the following criteria: (i) occurrence of a sarcoma diagnosed before 45 years of age, (ii) a first-degree relative with any cancer under 45 years of age, and (iii) a first- or second-degree relative with any cancer under 45 years of age or a sarcoma at any age [1].

A similar syndrome, called LFL shares some, but not all of the features of the classic LFS. Beside these clinical criteria, the molecular detection of a disease causing TP53 germline mutation in an individual confirms LFS and enables a predictive molecular testing in asymptomatic relatives.

## Therapeutic Principles

A prophylactic mastectomy to reduce the risk of breast cancer is an option for females with a germline TP53 mutation. Albeit surveillance measures have not been proven to reduce morbidity or mortality among individuals with LFS or LFL, routine mammograms and clinical breast exams are effective in women over 40 years.

The following surveillance strategies for individuals at risk for LFS or LFL have been suggested: (i) at-risk children (yearly): complete physical examination, urinalysis, complete blood count, abdominal ultrasound examination, and additional organ-specific surveillance based on family history. (ii) adult at-risk individuals should be surveyed by complete physical examination every 12 months, dermatologic examination every 12 months, urinalysis, complete blood count every 12 months, clinical breast examination every 6 months (women), annual mammograms, and annual breast MRI examination starting at age 20–25 years (women). However, routine mammograms in women with LFS is controversially discussed due to its possible radiation sensitivity associated with TP53 mutations [5]. Organ-targeted surveillance based on family history as well as full-body MRI examination or PET scan has been suggested, but real evidence demonstrating a benefit of full-body MRI examination or PET is missing.

# Ligand-defective Apolipoprotein B-100, Familial

Hubert Scharnagl[1], Winfried März[2]
[1]Clinical Institute of Medical and Chemical Laboratory Diagnostics, Medical University, Graz, Austria
[2]Synlab Center of Laboratory Diagnostics, Heidelberg, Germany

## Synonyms

Familial defective ApoB-100; FDB

## Definition and Characteristics

Autosomal codominant disorder associated with hypercholesterolemia and premature coronary artery disease [1]. Clinical characteristics of FDB are tendon xanthomas and/or arcus lipoides. The disorder is caused by mutations in the LDL receptor-binding domain of apolipoprotein (apo) B-100.

## Prevalence

The frequency of the most common mutation, R3500Q, is 1:300–1:500 in Caucasians. Recently, a new mutation (H3542Y) was identified with higher prevalence in patients who underwent coronary angiography compared to the R3500Q mutations (0.47% vs. 0.12%) [2].

## Genes

APOB gene coding for apolipoprotein B localized on chromosome 2p24. To date, five missense mutations have been reported: R3500Q, R3500W, R3531C, R3480W, and H3543Y.

## Molecular and Systemic Pathophysiology

ApoB-100 is a ligand for the low density lipoprotein (LDL) receptor and is essential for the receptor-mediated endocytosis of LDL particles. Site B (amino acid residues 3,359–3,369) of the apo B protein was identified as the receptor binding domain. However, the region in the vicinity of residue 3,500 is critical for the interaction of apo B with the LDL receptor [3]. Single-site mutations in this region diminish receptor binding of apo B and decrease the receptor-mediated uptake of LDL. As a result, the flux of LDL particles in the liver decreases and the plasma concentration of LDL cholesterol increase. Enhanced plasma concentrations of apoB-containing lipoproteins have been demonstrated to be major risk factors for atherosclerosis and coronary artery disease.

Hypercholesterolemia is less severe and the incidence of CAD appears to be lower in FDB compared to familial hypercholesteremia (FH), in which the LDL receptor is defective. This could be due to an enhanced removal of apo E-containing LDL precursors and a reduced production of LDL particles [4]. In addition, a study in a patient homozygous for FDB suggested, that the buoyant and medium sized LDL retained some receptor binding, whereas dense LDL particles were unable to interact with LDL receptors [5]. Thus, the accumulation of dense LDL could contribute to the cardiovascular risk in FDB patients.

## Diagnostic Principles

FDB is characterized by increased plasma concentrations of LDL cholesterol and apoB, triglyceride concentration usually is within the reference range. The frequent mutations can be determined by analysis of the restriction fragment length polymorphism (RFLP) in specialised laboratories.

## Therapeutic Principles

The therapeutic goal in FDB is the reduction of LDL cholesterol below 130 mg/dL or, in the case of a history of CAD, below 100 mg/dL. The most effective drugs in lowering LDL cholesterol are HMG-CoA reductase inhibitors (statins). Other therapeutic options include bile-acid binding resins, niacin, and the cholesterol absorption inhibitor ezetimibe. Combination drug therapy may be appropriate.

# Lignac-De Toni-Debré-Fanconi Syndrome

►Fanconi Syndrome

# Limb Girdle Muscular Dystrophy, Autosomal Dominant Type 1A (Myotilin)

James M. Gilchrist
Department Clinical Neurosciences, Brown Medical School, Providence, RI, USA

## Synonyms

LGMD 1A; Myotilinopathy

## Definition and Characteristics

LGMD1A is an autosomal dominant progressive myopathy with onset in the third decade, affecting proximal hip and shoulder girdle muscles and later

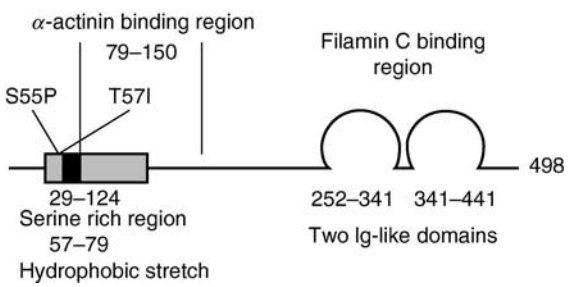
involving distal limb muscles. Progression is slow, leading to loss of ambulation only after 20 years and not in all patients. A nasal dysarthria is common, as are decreased or absent ankle deep tendon reflexes, usually accompanied by Achilles tendon contractures. Creatine kinase levels are increased to 5–15× normal early in the disease. Electromyography is consistent with a destructive myopathy as nerve conduction studies are normal and needle electromyography shows small, polyphasic motor unit potentials and abnormal spontaneous activity. Muscle biopsy reveals fiber size variation and splitting, central nuclei, myofiber necrosis, endomysial fibrosis and fatty replacement, all indicative of a dystrophic myopathy. Rimmed vacuoles are frequent. Immunohistological staining for components of the dystrophin-glycoprotein complex is normal.

## Prevalence

Autosomal dominantly inherited LGMD accounts for only 5% of all LGMD patients. As of 2003, only two families have been described with LGMD 1A, one from the USA of German origin and the other from Argentina.

## Genes

The locus for LGMD1A was mapped to chromosome 5q31 in a 2 Mb region flanked by markers D5S479 and D5S594. Independently, the protein myotilin was discovered and found to be encoded by the myotilin gene in the same region of 5q31. Subsequently, two families with LGMD1A and separate mutations of the myotilin gene have been reported, both mutations co-segregating with the disease, thus establishing that mutations in the myotilin gene cause LGMD1A. The myotilin gene has ten exons, though the first is not transcribed, and encodes a protein of 498 amino acids. The two Ig-like domains (Fig. 1) are coded in exons VI through IX.



**Limb Girdle Muscular Dystrophy, Autosomal Dominant Type 1A (Myotilin). Figure 1** A schematic diagram of myotilin protein structure. The serine rich region is in the box, with the hydrophobic region darkened. The two known mutations causing LGMD1A are indicated in bold.

## Molecular and Systemic Pathophysiology

Myotilin is a 57 kD protein with a unique N-terminal sequence containing a serine rich region, within which is a smaller hydrophobic region. (Fig. 1) The most distinct feature is two C2-type Ig-like domains near the C-terminal, which bear considerable homology to Ig-like domains of titin. Myotilin forms homodimers at the C-terminal portion and in adult muscle, is expressed only in skeletal and cardiac muscle. It localizes to the I-band of the sarcomere and to a lesser extent, to the sarcolemmal membrane. It co-localizes with α-actinin and filamin C (γ-filamin) at the Z-disk of the sarcomere, and all three molecules, plus others including titin, telethonin and nebulin, are involved in anchoring actin filaments to the Z-disk. Myotilin has been shown to bind actin filaments directly and serves an essential role in the stabilization and anchoring of actin filaments at the Z-disk. Filamin C is unique amongst its isoforms in having a single Ig-like domain, which interacts with the two Ig-like domains of myotilin. The region of myotilin that interacts with α-actinin is closer to the N-terminal, between residues 79 and 150 (Fig. 1).

Two families with LGMD1A have been found with separate missense mutations of myotilin. The first mutation described converts a threonine at residue 57 to isoleucine at the onset of the hydrophobic region. The second described mutation is only two amino acids away at residue 55 and converts a serine to phenylalanine. Neither mutation disrupts transcription and myotilin in both families localizes at normal levels to the Z-disk, with intact binding to α-actinin and filamin C. The mechanism by which the abnormal myotilin protein causes disease is unknown, but a disrupted interaction with an undefined protein, possibly the actin thin filaments, is likely. Z-line streaming is seen on electron microscopy of muscles from LGMD1A patients, which is non-specific but suggests breakdown of the Z-disk.

## Diagnostic Principles

LGMD1A should be suspected in any autosomal dominant progressive proximal myopathy, especially when muscle biopsy reveals dystrophic changes and prominent rimmed vacuoles. The presence of dysarthria and tight heel-cords is also highly suggestive. Cardiac abnormalities are not a feature of the disease. Another autosomal dominant disorder localized to 5q31 but not associated with myotilin mutations is distal myopathy with vocal cord and pharyngeal weakness (VCPMD).

## Therapeutic Principles

There is no specific therapy available for LGMD1A. For now, supportive therapy aimed at alleviating symptoms and disabilities is the best that can be offered. Ambulation should be assessed for safety and devices such as canes, forearm crutches, walkers and wheelchairs used

as needed. Surgery to alleviate Achilles heel contractures may be helpful if the contractures significantly impair gait.

# Limb Girdle Muscular Dystrophy, Autosomal Dominant Type 1B

Rabah Ben Yaou[1,2,3], Gisèle Bonne[1,2,4]
[1]Inserm, Paris, France
[2]Institut de Myologie, UPMC, Paris, France
[3]Association Institute de Myologie, Groupe Hospitalier Pitié-Salpêtrière, Paris, France
[4]AP-HP, Groupe Hospitalier Pitié-Salpêtrière, Paris, France

## Synonyms

LGMD1B

## Definition and Characteristics

Among the limb girdle muscular dystrophies (LGMD), the rare autosomal dominant forms comprise a recently identified subtype 1B [1]. This disease is characterized by the coexistence of a slowly progressive muscular atrophy and weakness involving the proximal parts of the limbs (scapular and pelvic) and cardiac disease with conduction defects, arrhythmias and dilated cardiomyopathy. The age of onset is mainly in the 2nd decade (4–39 years old) by involvement of the lower limbs extending to the upper limbs in the 4th decade, while cardiac disease often occurs after the age of 25 years. Other neuromuscular features have been also reported including late and non extending joint contractures (Achilles' tendons and elbows), hypertrophied calves, moderately elevated CPK and dystrophic features on muscle biopsy.

## Prevalence

The exact prevalence of LGMD1B is still unknown. But LGMD1B is extremely rare, as for example in France since 2000, 22 cases were genetically identified so far.

## Genes

Heterozygous mutations in the LMNA gene encoding lamins A/C are responsible for LGMD1B [2]. Lamins A/C are type V intermediate filament and component of the nuclear lamina underlying the inner nuclear envelope. LGMD1B belongs therefore to the group of laminopathies. All types of mutations have been observed all along the LMNA gene (for details see http://www.umd.be:2000/). However, mutations involving the arginine residue 377 and the splice donor site of intron 9 account for more than 60% of the families affected by LGMD1B.

## Molecular and Systemic Pathophysiology

On the basis of the different roles assigned to lamins A/C, two main models are proposed to explain the pathogenesis of lamins A/C related diseases involving striated muscles [3]. The structural model is based on the fact that mutated lamins A/C lead to defects in maintaining the structural integrity of the nucleus of the skeletal and cardiac muscles fibers, as they are particularly subjected to mechanical load leading to structural damage and cell death. The cell proliferation model postulates that satellite muscle cell differentiation is disturbed for mutated lamins A/C thus leading to perturbation of muscle regeneration in patients showing striated muscle disease such as LGMD1B. Those two hypotheses are not mutually exclusive and may both participate to the pathomechanisms of the LMNA mutations.

## Diagnostic Principles

See chapter on ►Muscular dystrophy Emery-Dreifuss, autosomal dominant.

As for other muscular dystrophies, LGMD1B diagnosis is mainly based on:

- The presence of the classical proximal pattern of muscular involvement without early and extending joint contractures associated to dilated cardiomyopathy with conduction defects and arrhythmias in the older patients.
- The exclusion of other LGMDs with cardiac involvement such as dystrophinopathies, desmin related myopathies, FKRP related myopathies and proximal myotonic myopathy.
- The autosomal dominant pattern of inheritance may be obvious from the familial history. However, the possible de novo occurrence of the LMNA mutation and the high intrafamilial phenotypic variability rate

may lead to the absence of this typical pattern of inheritance and the presence of other laminopathic traits within the same family.

The formal genetic LGMD1B diagnosis is based on the identification of LMNA gene mutations, as protein analysis of lamins A/C on several tissues (muscle, fibroblasts) shows normal protein amounts.

## Therapeutic Principles

See chapter on ►Muscular dystrophy Emery-Dreifuss, autosomal dominant.

Neurological and cardiological evaluations at initial diagnosis and follow up procedures are based on the routine investigations (clinical examination, functional muscular evaluation, ECG, Holter-ECG monitoring, echocardiography). Electrophysiological testing may be required in a selected set of patients. Cardiologic assessment once a year is highly recommended patients. Free of cardiac symptoms. Respiratory function evaluation and follow up may be required is some patients showing vital capacity impairment. Prevention of orthopaedic complications (promoting mobility and preventing joints contractures by physiotherapy and stretching exercises) and systemic thromboembolisms (antithromboembolic drugs such as vitamin K antagonists, warfarin, heparin) may be required. Treatment of Manifestations may include orthopaedic surgeries (for releasing of Achilles tendons and other contractures, scoliosis if indicated), use of mechanical aids (canes, walkers, orthoses, wheel chairs) as needed to help ambulation, treatment of cardiac manifestations may require specific treatments including antiarrhythmic drugs, cardiac devices (pacemaker, implantable cardioverter defibrillator) for primary or secondary prevention of sudden death [4], and both pharmacological and non-pharmacological therapy for heart failure. Heart transplantation is often required in the end stages of heart failure. Use of respiratory aids (respiratory muscle training and assisted coughing techniques, mechanical ventilation) may be required if indicated in late stages.

# Limb Girdle Muscular Dystrophy, Autosomal Dominant Type 1C

Benedikt G. H. Schoser
Department of Neurology, Friedrich-Baur-Institute, Ludwig-Maximilians University Munich, Munich, Germany

## Synonyms

LGMD 1C

## Definition and Characteristics

Dominant, recessive and sporadic patients are reported with four distinct, sometimes overlapping muscle disease phenotypes, limb girdle muscular dystrophy (LGMD 1C), rippling muscle disease (RMD), distal myopathy and hyperCKemia [1]. Besides the classic limb girdle muscular dystrophy or distal myopathy phenotype, rippling muscle disease is characterized by signs of increased muscle irritability such as percussion/pressure-induced rapid muscle contractions, electrically silent wave-like contractions (rippling muscle) and muscle mounding on percussion. This rather benign myopathy is usually not progressive and not accompanied by dystrophic changes. According to the clinical presentation, rippling muscle disease is the major phenotype of caveolinopathies [1–3].

## Prevalence

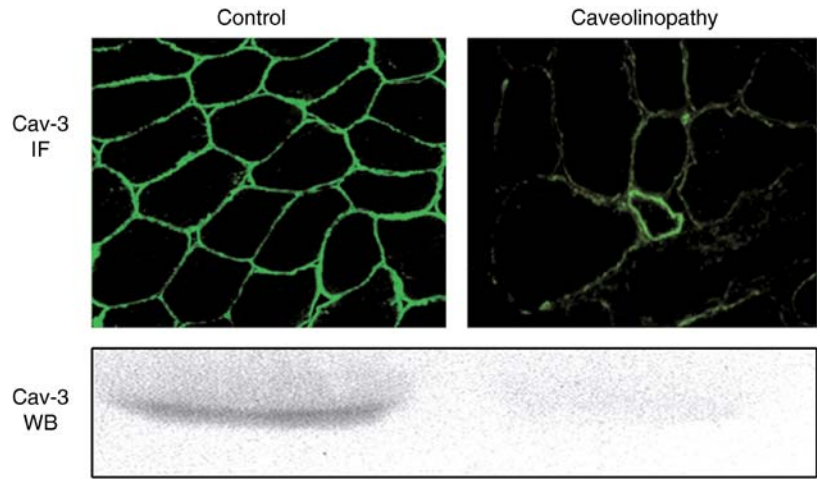
Rare, ~1:1,000,000.

## Genes

Caveolin-3 mutations located on chromosome 3p25 can result in all four described phenotypes. Disease causing Caveolin-3 gene mutations are mainly substitutions and rarely deletions [1–5].

## Molecular and Systemic Pathophysiology

Caveolin-3 is the muscle-specific member of the caveolin protein family. Caveolins constitute the main component of caveolae, 50–100 nm invaginations of the plasma membrane, which play a role in endocytosis, lipid transport and homeostasis and signal transduction.



**Limb Girdle Muscular Dystrophy, Autosomal Dominant Type 1C. Figure 1** Caveolin-3 immunofluorescence and Western blotting. Immunofluorescence analysis of caveolin-3 (Cav-3) in a muscle biopsy of a patient with heterozygous RMD (left) compared to a control biopsy (right). In the patient there are a very few fibers, with abnormal patchy plasma membrane staining for Cav-3, while the control shows normal sarcolemmal Cav-3 staining. Immunoblot analysis of the muscle biopsy from the same RMD patient. Samples containing identical amounts of protein were subjected to immunoblotting with anti-Cav-3 antibodies. Lane 1, normal control; lane 2 heterozygous RMD patient. In the RMD patient Cav-3 is completely absent.

Caveolin-3 is known to interact with beta-dystroglycan, a key protein of the dystrophin-glycoprotein complex (DGC), nNOS, associated with the DGC and dysferlin. Absence of caveolin-3 leads to loss of sarcolemmal caveolae, structural abnormalities in the T-tubule system and changes in the distribution of DGC members and associated proteins. Nevertheless, present data suggest that mutations involving the scaffolding domain lead to the most severe phenotype (LGMD1C). In LGMD1C, inhibited signaling has been documented with regard to nNOS and caveolar lipid raft domains. In contrast to decreased nNOS expression in LGMD1C, increased inducibility of nNOS has been documented in heterozygous and homozygous RMD, which may explain, at least in part, the mechanical hyperirritability of the rippling muscle [1–5].

## Diagnostic Principles

Clinical picture (RMD; LGMD); muscle biopsy with caveolin-3 immunohistochemisty and Western blotting (Fig. 1) or direct gene analysis available [1–3].

## Therapeutic Principles

Up to now no gene therapy or pharmacological therapy is available. Physiotherapy is recommended for LGMD1C. Carbamazepine or gabapentin should be tried for painful rippling [2,3].

Calpainopathy; LGMD2A

## Definition and Characteristics

LGMD2A is one of the several subtypes of autosomal recessive limb-girdle muscular dystrophy (AR-LGMD), a heterogeneous group of progressive disorders characterized by pelvic and shoulder muscle weakness with great clinical variability, a myopathic electromyography (EMG) and a dystrophic pattern on muscle biopsy [1]. The clinical features of the 2A form, include muscular atrophy with early pelvic girdle involvement, inability to walk on heels before the inability to walk on toes, scapular winging, lordosis and primary contractures [2,3]. Calf hypertrophy is not a common feature. Wheelchair confinement usually occurs 4–20 years after onset. Cardiac involvement is rare. Serum CK ranges from normal levels, even in ambulant patients, to more than a 20-fold increase. Atypical features such as fasciculation as well as a neurogenic EMG have been described in some calpainopathy patients [4].

## Prevalence

The estimated prevalence of the LGMD group ranges from 1 in 14,000 to 1 in 20,000. Twenty genes, 13 autosomal recessive (LGMD2A to LGMD2M) and 7 autosomal dominant (LGMD1A to LGMD1G), have been mapped to date. The recessive forms represent more than 95% of the cases. Calpainopathy is the most frequent form of LGMD2 in many countries such as Italy, Spain and Brazil, representing more than 30% of the AR-LGMD forms [4].

## Genes

Calpain-3 (CANP3), mapped at 15q15.1–15.3. More than 100 pathogenic independent mutations, distributed along the whole coding sequence, have been identified. Most are private mutations but some common changes have been found in Basque Brazilian and Italian patients, as a result of a founder effect. Patients that carry null mutations in the calpain-3 gene have on average a more severe phenotype (age of onset around 10 years old) than those with missense changes (age at onset around 18 years old) [2].

Muscle calpain-3 in LGMD2A patients may show a total, a partial or no deficiency at all. No direct correlation has been observed between the amount of calpain-3 and the severity of the phenotype [2].

## Molecular and Systemic Pathophysiology

Calpain-3, a calcium-activated neutral protease, is the muscle specific 94 kD enzyme that binds to titin. As a cysteine protease, it seems to play a role in the disassembly of sarcomeric protein, but it may also have a regulatory role in modulation of transcription factors.

## Diagnostic Principles

The deficiency of calpain-3 in muscle biopsies suggests the possibility of LGMD2A. However, secondary calpain-3 reductions may occur in other forms of LGMD, such as dysferlinopathy or titinopathy. In addition, the presence of an apparently normal amount of calpain-3 does not allow the exclusion of a diagnosis of calpainopathy. A definite diagnosis should be confirmed through the detection of pathogenic mutations on both alleles of the calpain-3 gene.

## Therapeutic Principles

Physiotherapy to prevent contractures and assisted ventilation in older patients.

# Limb Girdle Muscular Dystrophy Type 2B and Miyoshi Myopathy

Tracey Weiler[1], Patrick Frosk[2], Kiaus Wrogemann[2], Cheryl R. Greenberg[2]
[1]Division of Rheumatology, Cincinnati Children's Hospital Medical Centre, Cincinnati, OH, USA
[2]Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, MB, Canada

## Synonyms

LGMD2B; Miyoshi distal myopathy

## Definition and Characteristics

Progressive, early onset autosomal recessive limb girdle muscular dystrophy (LGMD2B) or distal myopathy (MM), resulting in wasting and weakness of the muscles of the pelvic and shoulder girdles and/or gastrocnemius muscles (Table 1 [1]).

**Limb Girdle Muscular Dystrophy Type 2B and Miyoshi Myopathy. Table 1** Diagnostic principles of limb girdle muscular dystrophy, type 2B and Miyoshi myopathy

| | MM | LGMD2B |
|---|---|---|
| Age at onset | Second or third decade | |
| Presentation | Difficulty running and climbing stairs, calf pseudohypertrophy, weakness and signs may be asymmetric | |
| | Fall when walking, difficulty standing and walking on tiptoes | Progressive proximal muscle weakness with a positive Gower sign |
| Presymptomatic Patients | Grossly elevated serum CK that may be associated with asymmetric calf pseudohypertrophy ultimately progressing to atrophy | |
| Initial muscle atrophy | Gastrocnemius and soleus | Pelvic girdle muscles, early involvement of gastrocnemius |
| Progression | Lower leg to thigh, hips and arms, grip strength reduced, forearms mildly affected | Pelvic girdle to shoulder girdle Pulmonary function impaired, contractures evident |
| Unaffected | No fasciculations, myotonia, initial contractures, cardiomyopathy, neurogenic involvement, intellectual deficit | |
| | Anterior tibial and peroneal muscles, small hand muscles unaffected | Scapular muscles unaffected |
| Serum CK levels | 25–100× normal, declines with age | |
| EMG | Myopathic | |
| Muscle Biopsy | Dystrophic changes with evidence of inflammatory process Abnormal immunohistochemical staining with anti-dysferlin antibodies; normal staining with dystrophin and sarcoglycans | |
| Mutations | Diverse | Diverse |
| Other | Individuals with either MM or LGMD2B presentation can coexist in the same family | |

## Prevalence

The prevalence of LGMD in the general population is 1/15,000. The proportion of LGMDs that can be attributed to dysferlinopathy varies between populations:

- Denmark – 2% (2/118)
- Turkey – 5% (1/20)
- Brazil – 37% (52/140)
- Italy – 20% (31/155)
- Japan – 28% (31/107)

## Genes

DYSF encodes the ubiquitously expressed, 230 kD membrane protein dysferlin [2,3]. The gene has been localized to chromosome 2p13.

## Molecular and Systemic Pathophysiology

Work in a mouse model of dysferlinopathy indicates that dysferlin is involved in calcium-dependent sarcolemmal repair [4]. Dysferlin contains C2 domains (calcium-dependent domains involved in membrane trafficking and signal transduction) and has homology to other proteins involved in vesicle fusion. Dysferlin is mainly localized to the sarcolemma [5] but faint cytoplasmic staining is also observed, stemming from dysferlin associated with small vesicular membranes. Dysferlin appears to facilitate vesicle docking and fusion with the sarcolemmal membrane. When dysferlin is mutated, tears in the sarcolemmal membrane caused by mechanical stress are not repaired, resulting in muscle cell necrosis [4]. Ultrastructural studies of patient biopsies showing vesicular aggregation below the sarcolemmal membrane and a significant inflammatory process further support this hypothesis [5].

## Diagnostic Principles

See Table 1 [1].

## Therapeutic Principles

Treatment is supportive and of a symptomatic nature.

# Limb Girdle Muscular Dystrophy Type 2G

Eloisa De Sá Moreira, Mariz Vainzof, Mayana Zatz, Maria Rita Passos-Bueno
Human Genome Research Center, Department of Genetics and Evolutionary Biology, Institute of Biosciences, University of São Paulo, São Paulo, Brazil

## Synonyms

Telethoninopathy

## Definition and Characteristics

Autosomal recessive, relatively mild form of progressive neuromuscular disorder with a wide spectrum of inter- and intra-familial clinical variability. The age at onset ranges from 9 to 15 years old and loss of ambulation occurs during the third or fourth decade in about 30% of the patients. Clinical features include proximal involvement and marked weakness and/or atrophy in the distal muscles of the legs. Asymmetric calf hypertrophy is a common sign. Heart involvement is not rare. Serum CK is 3-fold to 30-fold increased. Muscle biopsy shows a dystrophic pattern, including rimmed vacuoles.

## Prevalence

Described first in five unrelated Brazilian families [1] and confirmed in three additional Brazilian families in 2005 [2]. Represents about 1–2% of the AR-LGMD forms. The prevalence of LGMDs ranges from 1 in 14,000 to 1 in 20,000.

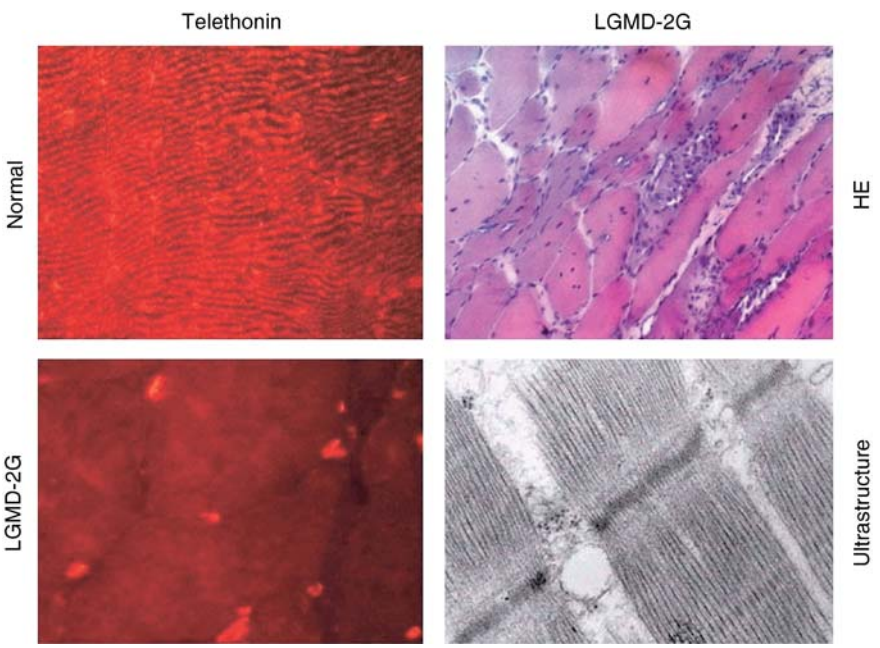
## Genes

T-CAP, mapped at 17q11–12. One prevalent pathogenic change was identified in seven families in a homozygous state (c.157C > T (Q53X) and a second mutation in a compound heterozygote (c.639-640delGG/c.157C > T). Both changes lead to premature stop codons [1].

## Molecular and Systemic Pathophysiology

Telethonin, encoded by T-CAP, is a sarcomeric protein of 19 kD present in the Z disk of the sarcomere of the striated and cardiac muscle and one of the substrates of the serine kinase domain of titin. Telethonin also interacts with the muscle-specific LIM protein (MLP), another Z disc protein and with myostatin, a key negative regulator of skeletal muscle growth [3–5]. Muscle protein analysis in Brazilian LGMD2G patients with null mutations showed deficiency of telethonin, but the ultrastructure of the muscle was preserved [1,4] (Fig. 1).

How this molecular defect could cause muscle dystrophy is still unknown.



**Limb Girdle Muscular Dystrophy Type 2G. Figure 1** Histological, immunohistochemical and ultrastructural analysis of a muscle biopsy from a patient with LGMD2G who was homozygous for a frameshift mutation.

Furthermore, normal expression of dystrophin, sarcoglycans, dysferlin, calpain 3 and titin was observed in these LGMD2G patients, suggesting that telethonin is not functionally related to these proteins [3].

### Diagnostic Principles

Clinical diagnosis of neuromuscular disease, with proximal/distal weakness, 3-fold to 20-fold serum CK increase, dystrophic features on muscle biopsy, deficiency of the telethonin protein on immunofluorescence and/or Western blot analysis of muscle biopsies. Molecular diagnosis: screening for mutations in the two exons.

### Therapeutic Principles

Physiotherapy, management of cardiac and respiratory problems and assisted ventilation in older patients.

## Limb Girdle Muscular Dystrophy Type 2H

Patrick Frosk[1], Tracey Weiler[2], Klaus Wrogemann[1], Cheryl R. Greenberg[1]
[1]Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, MB, Canada
[2]Division of Rheumatology, Cincinnati Children's Hospital Medical Centre, Cincinnati, OH, USA

### Synonyms

LGMD2H; Sarcotubular myopathy; STM

### Definition and Characteristics

Autosomal recessive limb girdle muscular dystrophy with onset in the second or third decade, resulting in wasting and weakness of the pelvic and shoulder girdle muscles.

### Prevalence

Only one mutation is present in the North American Hutterite population (p.D487N). Currently the most conservative estimate of carrier frequency in the Hutterites is 1/12, prevalence of the disorder is >1/500 [1]. To date, only one non-Hutterite family has been identified with mutations in TRIM32. This family is from a small village in Germany and both patients were found to be homozygous for the same p.D487N allele found in the Hutterites. The disease allele from this family and the Hutterite allele share an ancestral relationship and therefore p.D487N remains the only known myopathy-causing mutation at this locus [2].

### Genes

TRIM32 (HT2A) encodes an E3-ubiquitin ligase [3]. The gene has been localized to chromosome 9q32 and consists of two exons, the larger of which includes the entire coding region of 653 aa [1].

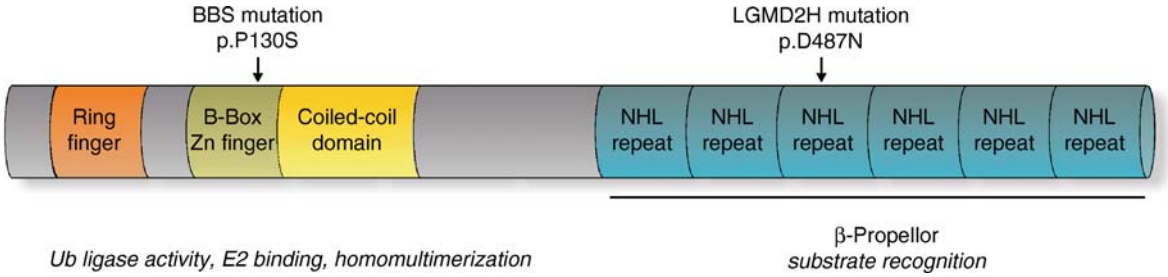
### Molecular and Systemic Pathophysiology

The TRIM32 protein has, from the N to C terminus, a RING finger domain, a B1 box, a coiled-coil domain and six NHL repeats (Fig. 1).

The three N-terminal domains form a tripartite motif making TRIM32 part of a growing family of TRIM proteins. Current knowledge of TRIM proteins suggests that TRIM32 is an E3-ubiquitin ligase that functions in the ubiquitin-proteasome pathway [1]. The common Hutterite mutation (p.D487N) is present within the third NHL repeat and possibly abrogates substrate binding, thereby preventing the substrate from being sent for degradation by the proteasome. The native substrate(s) of TRIM32 are unknown, however possible candidates are Piasy [3] and muscle actin [4]. In LGMD2H, the loss of TRIM32 function may increase the levels of these or other factors leading to abnormally high muscle cell death. In addition to myopathy, TRIM32 has been linked to skin cancer (increased levels rather than loss of function) [3] and to Bardet-Biedl syndrome (BBS p.P130S) [5].

### Diagnostic Principles

LGMD2H patients present with difficulty running and climbing stairs and with back pain. Pelvic and shoulder girdle weakness appears in the second or third decade of life and may slowly progress to wheelchair confinement. No cardiac or facial involvement is observed. LGMD2H can be differentiated from the other form of LGMD present in the Hutterite population (LGMD2I) by the absence of cardiac involvement, respiratory involvement, calf hypertrophy and macroglossia. In addition, Hutterite LGMD2H patients follow a milder course and generally present later in life than LGMD2I patients. Serum CK levels can be up to 30× normal and



**Limb Girdle Muscular Dystrophy Type 2H. Figure 1** Domain architecture of TRIM32.

fall to normal levels with disease progression. EMG shows myopathic features. Muscle biopsies show dystrophic changes with normal staining for dystrophin and sarcoglycans but characteristic vacuoles of sarcoplasmic origin may be present [2].

## Therapeutic Principles

Treatment is supportive and of a symptomatic nature.

# Limb Girdle Muscular Dystrophy Autosomal Recessive Type 2I

Adel Driss
Winship Cancer Institute, Emory University, Atlanta, GA, USA

## Synonyms

LGMD 2I; FKRP-pathy; Dystroglycanopathy

## Definition and Characteristics

Limb-girdle muscular dystrophies (LGMDs) constitute a clinically and genetically heterogeneous group of disorders. The LGMD type 2I has an autosomal recessive mode of inheritance and is characterized by a primary and progressive skeletal muscle degeneration of the pelvic and shoulder girdle muscles [1]. Age of onset varies from birth to over 40 years old. The progression and severity are also variable, ranging from severe forms with rapid onset and loss of ambulation by teenage, to very mild forms with late onset and loss of ambulation by the sixth decade.

## Prevalence

First reported in a large consanguineous Tunisian family, and mapped to chromosome 19q13.3 [1], LGMD2I appears to be a relatively large subgroup of LGMDs with cases reported in families originally from Tunisia, Brazil, Canada, England, Germany, Denmark, Italy, the Netherlands and Taiwan and amongst Bedouins and Hutterites [2].

## Genes

Mutations in the fukutin-related protein gene (FKRP) cause LGMD2I as well as a form of congenital muscular dystrophy (MDC1C) [3]. The FKRP gene consists of four exons containing a 1,488 base pair open reading frame that encodes a 495 amino acid protein [4]. Over 90% of the mutations causing LGMD 2I are associated with a missense allelic mutation Leu276Ile (C826A).

## Molecular and Systemic Pathophysiology

FKRP is ubiquitously expressed in human tissues with highest levels in skeletal muscle and heart. FKRP contains conserved sequence elements suggesting that it is a glycosyltransferase [4]. FKRP has been suggested to be associated with the glycosylation processing of α-dystroglycan (α-DG).

α-DG is a member of a transmembrane glycoprotein complex that binds to laminin-α2 (merosin), neurexin, agrin and perlecans in the extracellular matrix. Abnormal expression of α-DG and of laminin-α2 is observed by immunohistochemical and Western blot studies [3,5]. Patients with MDC1C also show abnormalities in α-DG and laminin-α2 expression.

### Diagnostic Principles

The upper extremities are preferentially involved, with upper arm weakness and atrophy. The prevalence of cardiac and respiratory involvement is high. The clinical course can vary from very fast (rarely) to slow (generally). Muscle hypertrophy is common. Serum creatine kinase is elevated. No structural brain involvement has been observed in LGMD2I patients.

Laboratory tests, immunohistochemical and genetic studies are essential to distinguish this LGMD from others. General characteristics include high serum creatine kinase, a typical dystrophic muscle biopsy (variation in fiber size, necrotic and regenerating muscle fibers with predominant type 1 fibers and an increase in connective tissue), a reduction of α-DG and laminin-α2 staining and a genetic localization on chromosome 19q13.3.

### Therapeutic Principles

Gene, pharmacological and dietary therapies are unavailable. Other possible treatments are under investigation.

Department of Dermatology, University Medical Center, Freiburg, Germany

### Synonyms

Linear IgA bullous dermatosis; Linear IgA disease; IgA bullous pemphigoid. *In children*: Chronic bullous disease of childhood; CBDC; Linear IgA disease of childhood; LAD

### Definition and Characteristics

Linear IgA dermatosis (LAD) and chronic bullous disease of childhood (CBDC) are rare autoimmune blistering diseases, defined by a linear deposition of IgA at the dermoepidermal junction. The typical clinical manifestation consists of annular or grouped vesiculobullous lesions, often associated with pruritus and involvement of mucous membranes [1].

### Prevalence

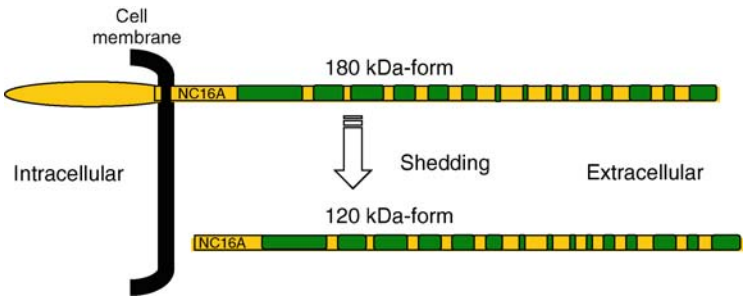
Not known. The estimated annual incidence is $5 \times 10^{-6}$.

### Genes

HLA association of LAD is discussed controversially. Some investigators reported a predominance of HLA-B8.

### Molecular and Systemic Pathophysiology

IgA-antibodies in LAD patients react with a 120 kDa/97 kDa protein present in normal human skin. The 120 kDa protein corresponds to the shed ectodomain



**Linear IgA Dermatosis. Figure 1** Schematic structure of the forms of collagen XVII/BP180. Collagen XVII is a type II transmembrane protein containing an intracellular domain, a short transmembrane domain and a collagenous C-terminal extracellular domain. Cleavage of full-lenght collagen XVII occurs within the juxtamembranous NC16a-domain resulting in a 120 kDa soluble ectodomain.

of BP180 (collagen XVII) (Fig. 1), a transmembrane protein of hemidesmosomes. Additional proteolytic cleavage at the C-terminus results in a 97 kDa polypeptide [2].

Since antibodies in LAD target more efficiently the shed 120 kDa-ectodomain of BP180 than the full-length protein it is conceivable that shedding generates new conformational epitopes that are antigenic in LAD [3]. Using a passive transfer mouse model Zone et al. showed that IgA-antibodies against the 97 kDa protein induced neutrophil infiltration and vesiculation [4].

Since LAD has frequently been reported in association with drugs (most frequently vancomycin), gastrointestinal disease, malignancies and infections, one can speculate that these disorders and drugs may trigger the production of IgA antibodies.

### Diagnostic Principles

The diagnosis relies on subepidermal blistering with neutrophilic infiltrates in histology and linear IgA deposits at the basement membrane zone in direct and indirect immunofluorescence. IgA-autoantibodies directed against the shed ectodomain of collagen XVII can be detected in the majority of patients by immunoblotting with keratinocyte medium as antigen.

### Therapeutic Principles

The disease is well controlled with oral dapsone (diaminodimethyl sulfone) or sulfapyridine. A gluten-free diet is not efficient.

## Synonyms

Hyalinosis cutis et mucosa; Urbach-Wiethe disease; Lipoproteinosis; LiP

## Definition and Characteristics

Lipoid proteinosis (LiP; OMIM 247100) is a rare, autosomal recessive disorder that usually presents in infancy with a hoarse voice, followed by pox-like or acneiform scars, along with infiltration and thickening of the skin and certain mucous membranes. Neurological and psychiatric abnormalities such as epilepsy, sometimes in association with calcification in the temporal lobes or hippocampi, may also occur. Histological and ultrastructural examination reveals widespread deposition of hyaline-like material and disruption/reduplication of basement membrane around blood vessels and at the dermal-epidermal junction. In 2002, LiP was mapped to chromosome 1q21.2 and pathogenetic loss-of-function mutations were identified in the extracellular matrix protein 1 gene (ECM1) [1].

## Prevalence

Although the precise prevalence of LiP is unknown, over 300 cases have been described throughout the world. LiP is particularly common in parts of South Africa, including Namaqualand, where propagation of a mutated common ancestral allele dating back to a mid-seventeenth century settler from Germany, has been demonstrated [2].

## Genes

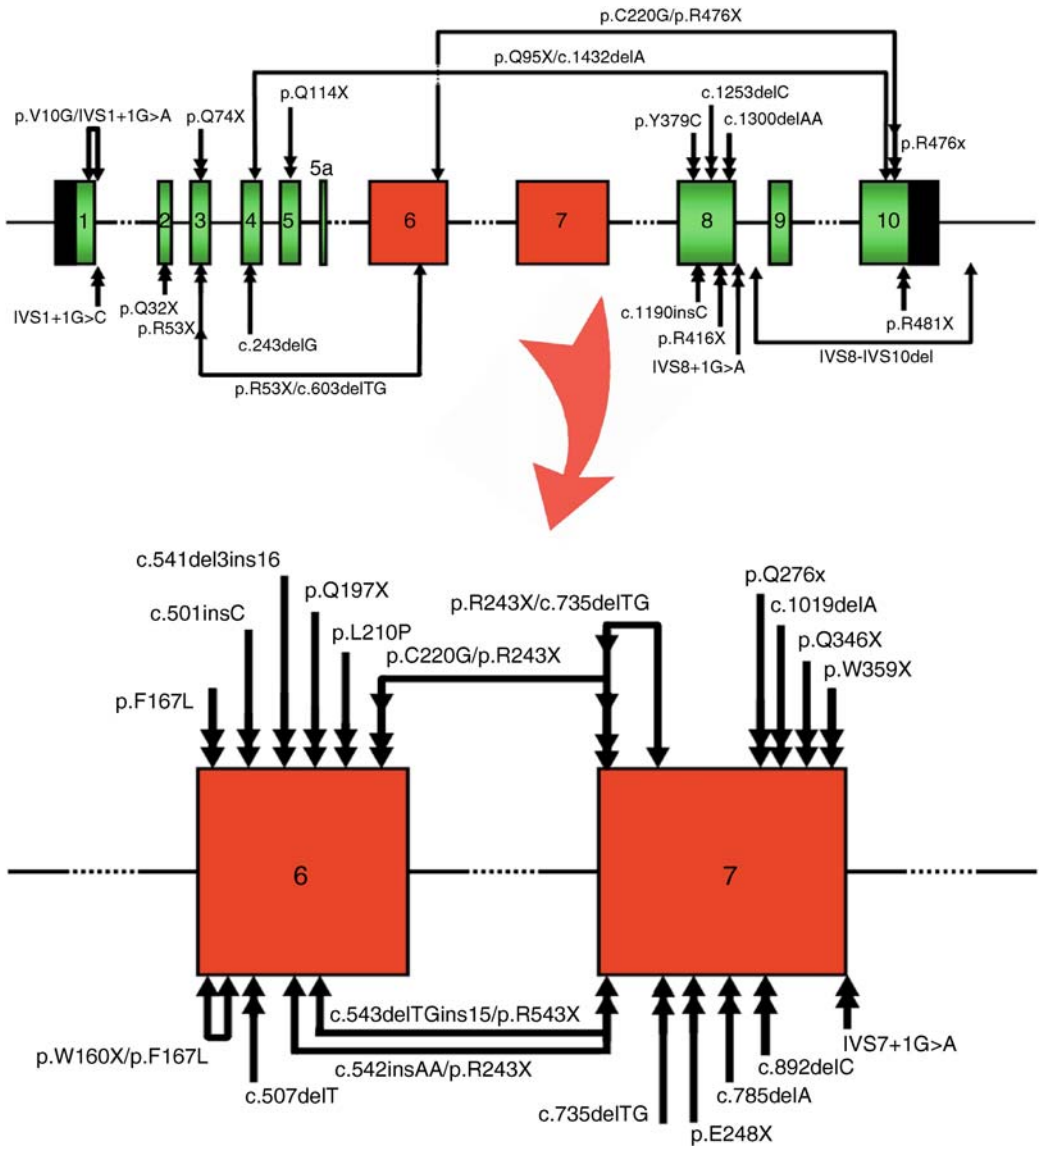
Mutations in ECM1 (1q21.2) encoding ECM1 [1]; no evidence of genetic heterogeneity.

## Molecular and Systemic Pathophysiology

Forty-one different mutations in ECM1 have been published in patients with LiP (Fig. 1). These comprise 15 nonsense, 15 small insertions/deletions, 6 missense, 4 splice site mutations and one large internal deletion mutation. Just over half of all mutations (22 of 41) are located within exons 6 or 7 (including adjacent splice sites). Globally, the most common mutation is c.507delT in exon 6 which has been reported in individuals from several different ethnic backgrounds but, since most mutations are family specific, this mutation only accounts for less than 5% of the total molecular pathology. With respect to the type and position of all pathogenic mutations reported thus far, there does not appear to be any clear paradigm for genotype-phenotype correlation. Human ECM1 encodes a glycoprotein which is the counterpart to an 85-kDa secreted protein first identified in a murine osteogenic stromal cell line, MN7 [3]. Early functional studies showed that ECM1 has key roles in bone mineralization, epidermal differentiation and in aspects of angiogenesis. Furthermore, in vitro protein-protein interactions have been demonstrated between ECM1 and perlecan, fibulin-1 and matrix metalloproteinase 9 (MMP-9). Loss of these interactions in vivo may help explain the clinico-pathological manifestations of LiP. It is also plausible that one of the main functions of ECM1 in the skin is to act as a form of "biological glue" maintaining dermal homeostasis, including regulation of basement membrane and interstitial collagen fibril macro-assembly as well as growth factor binding. Other clinical clues to the function of ECM1 in vivo have emerged from recent studies that identified circulating autoantibodies against ECM1 in ~75% of patients with lichen sclerosus, a common acquired inflammatory skin disorder, that has several histopathological features in common with LiP [4].

## Diagnostic Principles

Once established, the mucocutaneous features of LiP usually make the clinical diagnosis relatively straightforward: the two most reliable physical signs are (i) a hoarse voice and (ii) an inability to protrude the tongue due to a thickened sub-lingual frenulum. However, LiP can be difficult to diagnose in early life and in some cases the onset of the disorder may be delayed until later childhood [2]. One helpful test is skin biopsy labeling with an antibody to ECM1, although this is not widely available [5]. In cases of LiP, there is reduced skin immunostaining



**Lipoid Proteinosis. Figure 1** The spectrum of mutations in the *ECM1* gene in LiP. To date, 41 different pathogenic mutations have been published. Over half of all mutations (22 of 41) are located within exons 6 or 7. Double arrowheads represent homozygous mutations; joined arrows indicate compound heterozygous combinations of mutations.

which is typically attenuated or absent. Alternatively, since the ECM1 gene only contains ten relatively small exons, molecular screening for mutations by direct sequencing of genomic DNA is another feasible option if LiP is clinically suspected. The optimal mutation detection strategy is to first sequence exons 6 and 7 before analyzing the rest of the gene [6].

## Therapeutic Principles

Currently, there is no satisfactory treatment for LiP. There have been a number of mostly anecdotal reports of treatment with oral steroids, oral dimethyl sulfoxide, oral D-penicillamine or intra-lesional heparin, but none can be recommended on the basis of the published evidence. Practical measures, however, can be important. For example, the thickened vocal cords may respond well (at least temporarily) to carbon dioxide laser surgery, epilepsy should be treated with conventional anti-convulsant drugs and formal neuro-psychiatric evaluation may be useful in exploring subtle cognitive dysfunction. Now that mutations in the ECM1 gene have been established as the molecular basis of LiP, new research can now be planned to develop the pre-clinical work necessary for future gene, protein, cell and other drug therapies.

**Lipoprotein Lipase Deficiency, Familial.**
**Figure 1** Eruptive xanthomas.

# Lipoprotein Lipase Deficiency, Familial

August H. M. Smelt
Department General Internal Medicine, Leiden University Medical Center, Leiden, The Netherlands

## Synonyms

Type I hyperlipoproteinemia; HLP; Hyperchylomicronemia

## Definition and Characteristics

Autosomal recessive lipid disorder caused by mutations in the lipoprotein lipase (LPL) gene. LPL deficiency becomes manifest in early childhood with clinical symptoms of severe abdominal pain, acute pancreatitis, eruptive xanthomas (Fig. 1), lipaemia retinalis and hepatosplenomegaly.

## Prevalence

Extremely rare; 1:1,000,000 or less [1].

## Genes

LPL gene coding for lipoprotein lipase, localized on chromosome 8p22.

## Molecular and Systemic Pathophysiology

Lipoprotein lipase (LPL) is essential for the hydrolysis of triglycerides. In humans, LPL contains four disulfide bridges of which three are essential for the stabilization of the N-terminal part of the enzyme. The N-terminal domain contains the active site of the enzyme. The carboxy-terminal domain may interact with lipoproteins and their receptors. Lipoprotein lipase is produced in muscle cells and adipocytes and after stimulation by insulin transported to the endothelial cells where most of it binds to heparin sulfate-containing proteoglycans (HSPG). In the presence of apolipoprotein C-II LPL hydrolyses triglycerides from triglyceride containing lipoproteins (chylomicrons and very-low density lipoprotein (VLDL)) for the release of free fatty acids that can be taken up by muscle cells for energy production or by adipocytes for storage (Fig. 2).

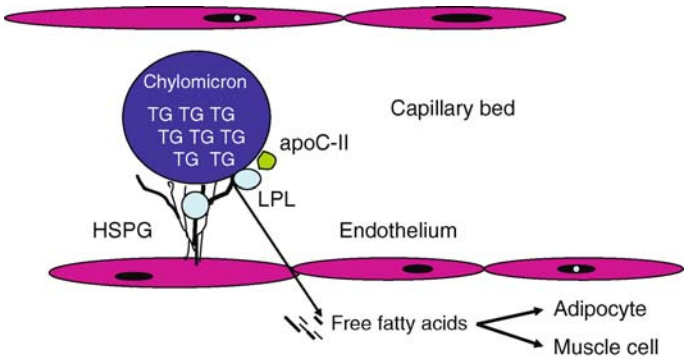
LPL is active as a dimer and disintegrates in monomers with loss function. Also LPL mediates hepatic up-take of triglyceride-rich lipoproteins.

Several LPL gene mutations could result in loss of hydrolytic function of LPL, causing hyperchylomicronemia. Chylomicrons are very large TG-rich lipoproteins produced by intestinal cells and secreted into the intestinal lymph vessels. Due to lack of LPL function chylomicrons remain in the vascular system, which results in very high plasma TG levels.

Moreover also triglycerides of very low-density lipoproteins (VLDL) produced by the liver will not be hydrolyzed and accumulate in the blood as well.

More than 100 LPL gene mutations are known, some with only moderate effects on LPL function. Partial LPL deficiency may occur in heterozygous LPL mutants and may, often in combination with other TG raising factors, also lead to hypertriglyceridemia.

The high plasma TG levels may cause eruptive xanthomas especially of buttocks, elbows and knees and recurring pancreatitis which may be lethal.



**Lipoprotein Lipase Deficiency, Familial. Figure 2** Schematic presentation of triglyceride hydrolysis in the capillary bed. *TG* triglyceride; *LPL* lipoprotein lipase; *HSPG* heparan sulphate-containing proteoglycans; *Apo C-II* apolipoprotein C-II.

## Diagnostic Principles

The diagnosis is usually made in early childhood when clinical symptoms, as described in the characteristics, appear. The milky plasma contains chylomicrons causing very high (10–100 times elevated) plasma triglyceride levels. Finally the diagnosis is confirmed when LPL mass and activity in peripheral blood is very low or absent.

Homozygosity or compound heterozygosity for mutations in the LPL gene may cause LPL deficiency. DNA analysis of this gene showing LPL mutation(s) may complete the diagnosis of familial LPL deficiency.

ApoC-II deficiency may also present with chylomicronemia and clinical manifestations similar to LPL deficiency.

## Therapeutic Principles

The first therapeutical objective in LPL deficiency is to prevent pancreatitis. For the patient without any residual LPL no effective therapy is available. A low fat diet (less than 25% of total calories), preferably medium-chain triglycerides may have some effect but is not sufficient to normalize plasma TG levels. Lipid lowering drugs are usually not effective. LPL gene therapy is in development and may be a promising option [2].

## Definition and Characteristics

Lissencephaly is a malformation of the cerebral cortex characterized by absent (agyria) or decreased (pachygyria) convolutions, producing a smooth cerebral surface with a thickened cortex.

About 85% of all cases are associated with LIS1 or DCX genes. LIS1 lissencephaly is more severe in the posterior brain regions (the p > a gradient), whereas DCX mutations result in more severe abnormality in the anterior brain (the a > p gradient) [1].

Among all the patients with isolated lissencephaly (ILS), 40% exhibit a deletion involving the entire LIS1 gene and 25% an intragenic mutation (4% gross rearrangement, 17% deletion/truncating mutations, 4% missense mutations) [2]. Missense mutations generally cause less severe malformations and milder clinical impairment. Truncating mutations cause severe lissencephaly, while missense mutations cause pachygyria and rare cases of subcortical band heterotopia (SBH). DCX mutations usually cause anteriorly predominant lissencephaly in males and SBH in females. Mutations resulting in protein truncation cause a more severe brain abnormality and reproductive disadvantages and are usually found in sporadic females, while familial cases usually have missense mutations. Missense mutations of DCX have also been found in males with anterior SBH and in their female relatives with normal brain appearance on magnetic resonance imaging.

Lissencephaly is associated with severe mental retardation, epilepsy, and motor disability. Seizures occur in over 90% of children, with onset before age 6 months in about 75%. About 80% have infantile spasms, although the EEG may not show typical hypsarrhythmia.

*Miller-Dieker Syndrome:* Miller-Dieker syndrome (MDS) is caused by a contiguous gene deletion. Classical lissencephaly is accompanied by distinct dysmorphic facial features including prominent forehead, bitemporal hollowing, flattened ear helices, mild hypertelorism, epicanthic folds, short nose and anteverted nares, prominent lateral nasal folds and round philtrum. Additional malformations can be observed. Affected children have severe developmental delay, epilepsy and feeding problems. Deletions of 17p13.3, including the LIS1 gene, are found in almost 100% of patients. Deletion of two additional genes, CRK and 14-3-3ε, telomeric to LIS1, may contribute to the most severe lissencephaly grade and dysmorphic features observed in MDS [3].

*Autosomal Recessive Lissencephaly with Cerebellar Hypoplasia (Norman-Roberts Syndrome):* An autosomal recessive form of lissencephaly associated with severe abnormalities of the cerebellum, hippocampus, and brainstem was mapped to 7q22, and mutations were identified in the RELN gene [4]. Patients presented dysmorphic facial features including bitemporal hollowing, sloping forehead, widely set eyes and prominent nasal bridge. A similar phenotype had previously been described as the Norman-Roberts syndrome.

*X-Linked Lissencephaly with Corpus Callosum Agenesis and Ambiguous Genitalia (XLAG):* The anatomoclinical spectrum includes lissencephaly with a posterior-to-anterior gradient and only moderate increase in the cortical thickness (6–7 mm), absent corpus callosum, microcephaly, neonatal-onset epilepsy, hypothalamic dysfunction including deficient temperature regulation, chronic diarrhea, and ambiguous genitalia with micropenis and cryptorchidism. Early death is not uncommon [5]. Mutations of the X-linked *aristaless*-related homeobox gene (ARX) were identified in individuals with XLAG and in some female relatives. The mutations of the ARX gene in XLAG are predominantly premature terminations. Patients carrying nonconservative missense mutations within the homeodomain show less severe XLAG, while conservative substitution in the homeodomain causes Proud syndrome (agenesis of the corpus callosum with abnormal genitalia).

Nine additional phenotypes have been also associated with the agyria-pachygyria-subcortical band heterotopia spectrum. Clinical features and associated genes or loci, when identified, are reported in Table 1.

## Prevalence

Classic lissencephaly has a prevalence of 11.7 per million births but the prevalence of the other phenotypes is unknown.

## Genes

## Molecular and Systemic Pathophysiology

*LIS1:* see chapter on ►Cortical malformations and migration disorders.

*Reelin* acts on migrating cortical neurons by binding to the very low-density lipoprotein receptor (VLDLR), the apolipoprotein E receptor 2 and protocadherins. Reelin is thought to control cell-cell interactions critical for cell positioning in the brain.

*ARX:* see chapter on ►Cortical malformations and migration disorders.

*POMT1*, *POMT2* and *POMGNT1* have a possible role in the onset of muscular dystrophy and neuronal migration disorders.

*FKRP* is required for the post-translational modification of dystroglycan. Aberrant processing of dystroglycan caused by a mislocalized FKRP mutant may cause congenital muscular dystrophy.

*FCMD* Fukutin deficiency affects the modification of glycosylation of alpha-dystroglycan, which then cannot localize or function properly. This disruption underlies the developmental, structural and functional damage to muscles in patients with FCMD.

## Diagnostic Principles

Magnetic resonance imaging identifies cortical malformation phenotypes. Genetic analysis and family ascertainment are also required.

## Therapeutic Principles

Pharmacological therapy for epilepsy and rehabilitation for motor impairment are required.

## Synonyms

Livedo reticularis with summer and winter ulcerations; Atrophia blanche; Livedo vasculitis (misnomer, as it is no true vasculitis (see chapter on ►Leukocytoclastic vasculitis)

## Definition and Characteristics

A syndrome characterized by livedo reticularis, recurrent painful ulceration with predilection for the malleolar site, leaving residual white atrophic scars

(atrophie blanche). It is an occlusive vasculopathy due to a hypercoagulable state. Though it has been divided into symptpomatic livedo vasculopathy associated with a defined coagulopathy and into an idiopathic vasculopathy without underlying disease, it is likely that in the latter case the molecular defects leading to a hypercoagulable state have not been defined yet.

## Prevalence

Estimated annual incidence is 1 per 100,000 persons and the estimated female: male ratio is 3:1.

## Molecular and Systemic Pathophysiology

The characteristic irregular livedo pattern in the skin with open bluish patterns reflects the color of blood with a higher percentage of deoxygenated hemoglobin at sites of impaired blood flow due to partial or complete occlusion at single sites of the cutaneous vasculature. On histology there is thrombotic microangiopathy or occlusion by fibrin thrombi in the acute stage, often associated with hyaline thickening of the vascular wall. There is no marked infiltration with neutrophils consistent with vasculitis. Later stages encompass reorganization of thrombi, subintimal proliferation and segmental hyalinization of vessels.

The characteristic irregular pattern in the skin with the appearance of a partially torn fishnet is not to be confused with a regular fishnet-like livedo pattern (cutis marmorata) which occurs when there is evenly distributed vasodilation of intact vessels, leading to slow blood flow and increased deoxygenation of blood, but not to single thrombotic events. As the vessels with bluish, deoxygenated hemoglobin are evenly spread, the whole superficial vascular plexus shines bluishly through the skin. Since deoxygenation stays within normal range, this state is never associated with ulcers. In contrast, the recurrent thrombotic events in livedo vasculopathy result in recurrent small punctuate ulcers which heal by leaving small stellate or atrophic scars.

There are several molecular defects leading to recurrent thrombotic events. They often encompass the presence of anti-phospholipid antibodies (see corresponding chapter), but also deficiency in protein C or protein S, reduced plasma levels of activator of plasminogen, increased plasma levels of plasminogen activator inhibitor, homocysteinemia, or increased levels of cryoproteins (cryglobulinemia, cryofibrinogenemia) [1–3].

In addition there must be factors which facilitate increased livedo pattern and ulcer formation at the malleolar region. They include venous stasis, trauma, heat, and cold, or generally all those factors which lead to slowing of blood flow and thereby add to a thrombophil constellation.

Livedo vasculopathy is a part of Sneddon syndrome. The irregular livedo pattern can also be a sign of polyarteritis nodosa.

## Diagnostic Principles

The characteristic combination consists of livedo reticularis, painful, recurrent ulcera with predilection at the area of malleoli, atrophie blanche and scar formation, without vasculitis. It needs to be clarified whether there is systemic disease (Sneddon syndrome, anti phospholipid antibody syndrome) due to severe coagulopathy, and if the molecular defect leading to coagulopathy can be defined or treated.

## Therapeutic Principles

They depend also on the underlying disease. If, e.g. there is deficiency in protein C or protein S administration of warfin can only be done under precautions such as parallel injection of low molecular weight heparin (LMWH), because the antithrombotic proteins C and S are reduced earlier than the procoagulatory proteins II, VII, IX and X which leads to a transient shift towards increased coagulatory activity.

The common treatment consists of low molecular weight heparin (LMWH). When there is no improvement or when there is e.g. a history of recurrent deep vein thrombosis or pulmonary embolism (e.g. due to anti-phospholipid antibodies) a long-term anticoagulant therapy with warfin is recommended [4].

# Liver Cancer

►Hepatocellular Carcinoma

# Liver Cell Carcinoma

►Hepatocellular Carcinoma

# Liver Cirrhosis

Olav A. Gressner
Institute of Clinical Chemistry and Pathobiochemistry, RWTH University Hospital, Aachen, Germany

## Synonyms

Laënnec's cirrhosis

## Definition and Characteristics

Cirrhosis is defined by hepatic nodule formation, fibrosis, liver dysfunction, and altered hemodynamics as consequence of a sustained wound healing response to chronic liver injury from a variety of causes including viral, parasitic, toxic (ethanol), autoimmune, drug-induced, cholestatic, and metabolic diseases. Pathobiochemically, cirrhosis is characterized by hepatocellular necrosis and apoptosis, regeneration, inflammation, and extracellular matrix synthesis.

## Prevalence

Cirrhosis affects hundreds of millions of patients worldwide. In the USA, cirrhosis is the most common non-neoplastic cause of death among hepatobiliary and digestive diseases accounting for approximately 30,000 deaths per year. In addition, 10,000 deaths occur because of liver cancer, the majority of which arise in cirrhotic livers. The number of cirrhotic patients in Germany is estimated to be 700–800,000, and some 25,000 patients die of cirrhosis per year. The mortality is twice as high in men as in women.

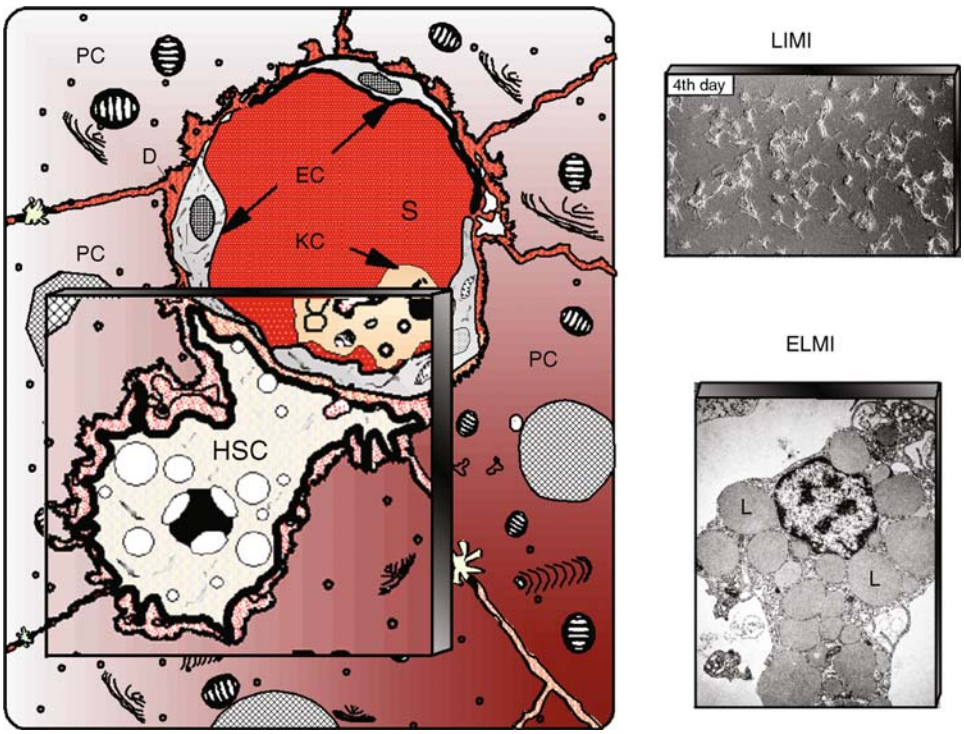
## Molecular and Systemic Pathophysiology

Immunologic, toxic, metabolic, and other forms of sustained hepatocellular damage result in inflammatory tissue reaction with recruitment of leucocytes (e.g., macrophages, Th1 and Th2 lymphocytes, granulocytes), activation of Kupffer cells, and binding and disintegration of thrombocytes, which all release a wide array of peptide (cytokines, chemokines, growth factors) and non-peptide (e.g., reactive oxygen metabolites, lipid peroxides, prostacyclins) mediators [1]. These signal molecules activate in a paracrine manner perisinusoidal hepatic stellate cells (HSC, ITO cells, vitamin A-, retinoid-storing cells), which are a special type of liver pericytes, located in the perisinusoidal space of Disse in close proximity to hepatocytes and sinusoidal endothelial cells [2] (Fig. 1).

They store more than 80% of the retinoid content of the liver. Activation of HSC leads to their proliferation, transdifferentiation to smooth-muscle α-actin positive, retinoid-depleted myofibroblasts (MFB), expression and secretion of the broad spectrum of collageneous (e.g., type I, III, and IV collagens) and non-collageneous extracellular matrix proteins (e.g., laminin, fibronectin, tenascin, undulin, thrombospondin, SPARC, proteoglycans), and glycosaminoglycans (hyaluronan). A certain fraction of HSC/MFB might derive from bone marrow reaching the site of liver injury via the systemic circulation. Thus, HSC are the major contributor to fibrosis, which comprises all the complexity of changes of the liver extracellular matrix including the following:

1. three- to ten-fold increase of most of the extracellular matrix molecules,
2. a disproportioned elevation of certain subspecies of individual extracellular matrix molecules (types of collagens, proteoglycans, hyaluronan, and structural glycoproteins),
3. subtle changes in the microcomposition of specific types of extracellular matrix molecules, e.g., degree of hydroxylation of collagen α-chains, of the number, length, and degree of sulfation (charge density) of glycosaminoglycans occupying the core protein of proteoglycans,
4. topographic redistribution of the extracellular matrix leading to an early and preponderant subendothelial deposition in the space of Disse (perisinusoidal fibrosis) and to other forms of periportal, bridging, diffuse, or focal fibrosis. Together with parenchymal cell destruction and consecutive hepatocellular regeneration, fibrosis leads to the disorganization of the lobular architecture with pseudolobules throughout the whole of the liver.

In addition, MFB acquire contractility in response to specific agonists (e.g., endothelin-1) and regulate sinusoidal blood flow. Most important fibrogenic cytokines, chemokines, and growth factors are transforming growth factor β (TGF-β1) [3], platelet-derived growth factor (PDGF-BB), connective tissue growth factor (CTGF), vascular endothelial growth factor (VEGF), insulin-like growth factor (IGF-1), leptin, endothelin (ET-1), interleukins (IL-6, -8, -10), monocyte chemoattractant protein (MCP-1), and others. MFB produce in addition to extracellular matrix also cytokines and chemokines, which are involved in autocrine MFB stimulation (leptin, PDGF, ET-1,



**Liver Cirrhosis. Figure 1** Schematic presentation of hepatic stellate cells (HSC) in liver tissue. They are located in the space of Disse (D), the body embedded in rezessus of adjacent hepatocytes (PC) with cellular extensions surrounding sinusoidal endothelial cells (EC). S, sinusoid; KC, Kupffer cells; LIMI, light microscopic (Nomarsky) appearance of isolated and cultured hepatic stellate cells at the fourth day of culture; ELMI, electron micrograph of a hepatic stellate cell showing multiple lipid-containing vacuoles, in which retinoids are solved.

MCP-1) and paracrine activation of HSC and induction of hepatocellular apoptosis (by TGF-β1). They contribute to a perpetuation of the fibrogenic process. Accordingly, fibrogenesis has been subdivided to a pre-inflammatory phase due to hepatocellular damage, in an inflammatory step due to activation of Kupffer cells and platelets, and a post-inflammatory phase based on autocrine stimulation of MFB (Fig. 2).

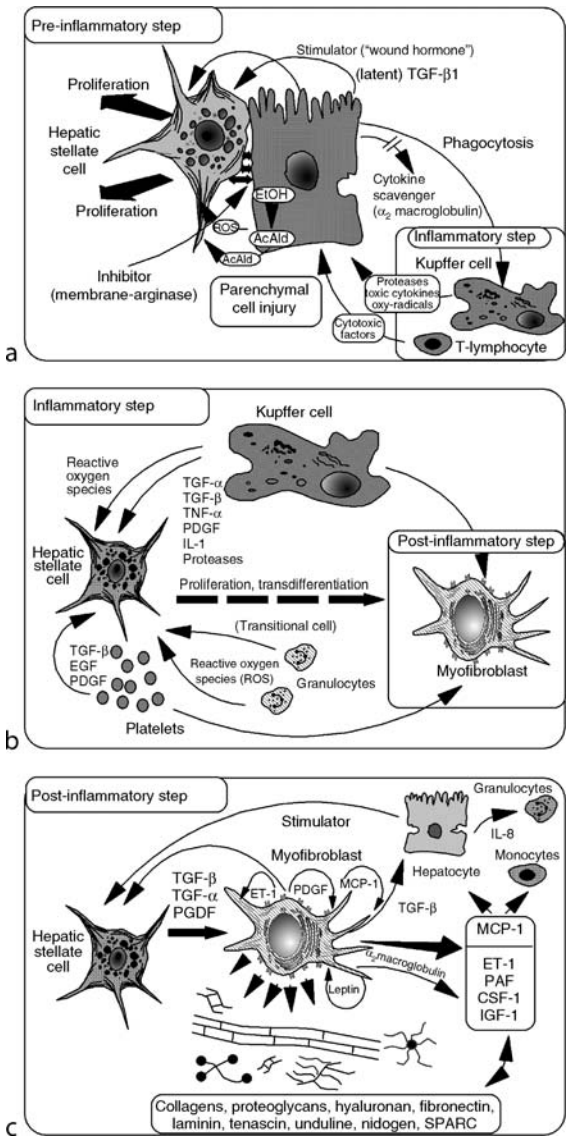
MFB secrete specific types of matrix metalloproteinases (MMPs) and their respective tissue inhibitors (TIMP-1, -2). TGF-β1 not only activates HSC to MFB and stimulates matrix synthesis, but also inhibits matrix degradation by raising the expression of TIMPs and downmodulation of MMPs. MFB can undergo CD 95-dependent apoptosis, which might be an important clearance mechanism for activated HSC/MFB during resolution of fibrosis.

## Diagnostic Principles

Diagnosis and monitoring of cirrhosis uses histological examination of biopsy specimens (grading of fibrogenic activity, staging of the extent of fibrosis), imaging procedures (sonography, computer tomography, magnetic resonance imaging, positron emission tomography (PET) scanning), laparoscopy, transient elastography measuring liver stiffness due to scarring, and clinical–chemical function tests of liver cell damage and inflammation (e.g., AST, ALT, GLDH, immunoglobulins), of liver cell insufficiency (e.g., global clotting tests and clotting factors, albumin, transthyretin), cholestasis (e.g., bilirubin, γ-GT, alkaline phosphatase), and fibrogenesis (e.g., circulating breakdown products of extracellular matrix and enzymes such as procollagen peptides, tenascin, laminin, MMPs, TIMP-1, hyaluronan). A laboratory index consisting of serum concentrations of $\alpha_2$-macroglobulin, haptoglobin, γ-glutamyltransferase, γ-globulin, total bilirubin, and apolipoprotein A (fibrotest) has been suggested as a marker for the stage of (HCV-induced) liver fibrosis [4,5].

## Therapeutic Principles

The most effective way to treat cirrhosis and fibrosis is to clear the primary cause of liver disease, be it from viral (e.g., hepatitis B, C), metabolic (e.g., hemochromatosis, Wilson's disease), drug-induced (e.g., methotrexate, hypervitaminosis A), ethanol-induced (>50 g



**Liver Cirrhosis. Figure 2** The three-step cascade model of hepatic stellate cell activation (Gressner (1994) Gut 35:1331). (a) The pre-inflammatory step is initiated by damage of the hepatocytes, which releases the stimulators of hepatic stellate cell proliferation and decreases membrane-associated inhibitors such as membrane arginase. In addition, the metabolism of ethanol (EtOH) to acetaldehyde (AcAld) and the generation of lipid peroxides initiate matrix gene expression in the stellate cells before the inflammatory stimuli (second step) become effective. (b) In the inflammatory step, mitogens from activated Kupffer cells, invaded macrophages, and disintegrated platelets are the most potent stimulators of hepatic stellate cell proliferation and transdifferentiation into myofibroblasts. Activated macrophages in turn can damage via the release of proteases, toxic cytokines (e.g., TNF-a), and oxygen radicals membrane damage of the hepatocytes. (c) In the post-inflammatory step, fully transformed hepatic stellate cells (myofibroblasts) release various cytokines, chemokines, and growth factors (TGF-α, TGF-β, ET-1, PDGF, and FGF-2), which stimulate non-transformed stellate cells in a paracrine way and, in an autocrine loop, the myofibroblast itself. The cytokines interact with and are sequestrated by the extracellular matrix components and $\alpha_2$-macroglobulin ($\alpha_2$M) secreted by the myofibroblast. Abbreviations: CSF-1, colony-stimulating factor; PMN, polymorphonuclear leucocytes;$\alpha_2$M,$\alpha_2$-macroglobulin.

ethanol per day), or autoimmune causes (autoimmune hepatitis, primary biliary cirrhosis). Antiviral medication for HCV and HBV with pegylated interferon α and ribavirin may reach reversibility of advanced fibrosis and even cirrhosis. Experimental therapies are focused on inactivation of the most important profibrogenic cytokine TGF-β 1 either by applying soluble type II or type III TGF-β receptor proteins, siRNAs, or by gene therapy with cDNAs encoding the soluble, extracellular domain of type II or type III TGF-β receptor. Overexpression of Smad7, an intracellular inhibitory mediator of TGF-β1 signal transduction, in HSC and in the liver in vivo was shown to be an effective means to suppress fibrosis. Hepatocyte growth factor gene therapy inhibits fibrogenesis and hepatocyte apoptosis and produces complete resolution of fibrosis in the cirrhotic liver. Antisense RNA complementary to TGF-β1 inhibits fibrogenic activities of HSC in culture.

Also a number of chemicals, which inhibit HSC activation (e.g., trichostatin A, phosphatidyl-choline, halofuginone, pentoxifylline, glycyrrhizin, pirfenidone, *N*-acetyl-L-cysteine), are in experimental use [6].

# Liver Cirrhosis, Alcoholic

Sören Siegmund, Stephan Haas, Manfred V. Singer
Department of Medicine II (Gastroenterology, Hepatology and Infectious Diseases), University Hospital of Heidelberg, Mannheim, Germany

## Synonyms

Ethanol-induced liver cirrhosis; End-stage alcoholic liver disease

## Definition and Characteristics

Alcoholic liver cirrhosis is the end stage of alcoholic liver disease and is defined as an irreversible remodeling of the normal liver architecture with diffuse and bridging fibrosis, loss of vascular cross-sectional area, and irregular nodular regeneration of hepatocellular parenchyma as a result of chronic alcoholic injury. Nowadays, chronic alcoholic injury of the liver is the most frequent cause of all etiologies of end-stage liver disease in western countries and accounts for more than 50% of all cases [1].

## Prevalence

The prevalence of alcoholic liver cirrhosis in alcoholics ranges between 17 and 30.8%, and the rate in the regular population is unclear [2].

## Genes

Genetic polymorphisms in alcohol dehydrogenase (ADH) 2 and 3, acetaldehyde dehydrogenase (ALDH) 2 and in the 5′-flanking region of cytochrome P4502E1 (CYP2E1) are involved in individual susceptibility to alcoholism, but their role in the progression of alcoholic liver disease remains controversial. Genetic variations of the "A" allele of the interleukin (IL)-10 gene, the superoxide dismutase gene, and in the promoter region of the tumor necrosis factor (TNF)-α gene are risk factors for developing alcoholic liver cirrhosis [3].

## Molecular and Systemic Pathophysiology

Alcoholic liver cirrhosis features several specialities in comparison with other origins of liver cirrhosis. In alcoholic liver disease, the inflammatory response of Kupffer cells and other types of leucocytes is augmented due to elevated gut-derived endotoxin plasma levels. This leads to amplified formation of reactive oxygen species (ROS), pro-apoptotic or pro-fibrogenic cytokines (e.g., tumor necrosis factor (TNF)-α or tissue growth factor (TGF)-$\beta_1$, resp.), which are together responsible for increased hepatocellular cell death and activation of hepatic stellate cells (HSCs), the key cell type of liver fibrogenesis. Ethanol metabolism induces hypoxia in the pericentral region of the liver lobule causing first hepatocellular damage at this site. This is contrary to other origins of liver injury, which start mostly periportally. Furthermore, ethanol metabolites, such as acetaldehyde, aldehyde–protein adducts, or lipid oxidation products directly enhance HSC activation and production of collagen, leading to liver fibrosis. The irregular, distorted, and destroyed hepatic architecture determines the pathophysiology of alcoholic liver cirrhosis and accounts for its irreversibility. It occurs because of (i) the continuing hepatocellular cell death due to persistent alcohol consumption and ongoing inflammation, (ii) the excessive accumulation of ECM scar mass by activated hepatic stellate cells, (iii) the increased hepatocellular regeneration due to the hepatocytes' distinctive ability to proliferate, and (iv) the rearrangement of the hepatic microvasculature [1]. However, alcoholic liver cirrhosis features mostly micronodular regeneration of hepatocellular tissue due to the inhibitory effect of ethanol on hepatocyte proliferation [4]. Ethanol blocks the signaling cascades of growth factors, such as epidermal growth factor (EGF) and insulin or by upregulating the expression of anti-proliferative and pro-fibrogenic cytokines such as TGF-$\beta_1$ [4]. Generally, the clinical consequences of liver cirrhosis do not differ depending on the origin of the disease.

## Diagnostic Principles

There are no pathognomonic physical signs or symptoms for alcoholic liver cirrhosis. Results of the physical examination are similar to those of liver cirrhosis of other origins (i.e., hepatomegaly, splenomegaly, signs of portal hypertension (esophagus and gastric varices, hypertensive gastropathy), ascites, jaundice, spider angioma, Dupuytren's contracture, palmary erythema, etc.). Further diagnostic tools comprise endoscopy or imaging methods (e.g., ultrasound, CT scan). Definitive proof for the presence of liver cirrhosis will be provided by laparoscopy or liver biopsy. Laboratory test result abnormalities are mostly similar to those of other chronic liver diseases. However, almost all patients will have elevation of AST > ALT with both below 300 IU/ml. An AST/ALT ratio > 2 is highly suggestive of alcoholic liver disease. Chronic alcohol consumption is also often associated with hypertriglyceridemia, hyperurecemia, hypokalemia, and hypomagnesemia, as well as elevated mean corpuscular erythrocyte volume (MCV) [5].

## Therapeutic Principles

Therapy for alcoholic liver cirrhosis has still to be rather symptomatic than causative. The first therapeutic step is a change in lifestyle. Patients with cirrhosis benefit from alcohol abstinence as well as from quitting smoking

and nutrition high in calories [5]. Furthermore, antioxidants, such as vitamin E, S-Adenosylmethionine, *N*-Actetylcysteine, or Silymarin, seem to be beneficial for patients with alcoholic liver cirrhosis. The phosphodiesterase inhibitor Pentoxifylline has been shown to decrease proinflammatory cytokines including TNF-α. Glucocorticosteroids should be reserved for cases of severe acute alcoholic hepatitis. The ultima ratio is liver transplantation [5].

# Liver Cirrhosis, Cryptogenic

Matthias Wettstein
Internal Medicine I, Passau Hospital, Passau, Germany

## Definition and Characteristics

Cryptogenic liver cirrhosis reflects a poorly defined group of patients in which no definite cause of the liver disease can be identified. Thus, classification of liver diseases as "cryptogenic" is dependent on the current scientific knowledge and e.g. on the sensitivity of the virological tests used. Recently, it has become clear that nonalcoholic steatohepatitis (NASH) is the most common cause of cryptogenic liver cirrhosis.

## Prevalence

7–14% of patients undergoing liver transplantation have cryptogenic liver disease and approximately 70% of the patients are women [1].

## Molecular and Systemic Pathophysiology

As cryptogenic cirrhosis is a heterogenous group of liver diseases, different pathogenetic mechanisms are involved. Nonalcoholic steatohepatitis (NASH) is the underlying disease in 30–50% of the patients [2,3]. Obesity, diabetes mellitus type 2 and hyperlipidemia are major risk factors for NASH. Another 20–30% of the patients with cryptogenic cirrhosis show clinical, histological and biochemical characteristics of autoimmune hepatitis, although respective antibody testing (antinuclear antibodies, smooth muscle antibodies, antibody to liver–kidney microsome type 1) is negative.

In the remaining third of patients with cryptogenic cirrhosis a variety of other etiologies may play a role.

Underlying diseases identified in patients with cryptogenic liver cirrhosis:

- Nonalcoholic steatohepatitis
- Seronegative autoimmune hepatitis
- Toxic liver injury of unidentified origin
- Occult viral infection
- Mutations of keratin 8 and 18 genes
- Non-classified cholestatic liver disease

Some of these patients have a history of blood transfusion and yet unidentified viral infections may be present. Sensitive HBV-DNA testing revealed that in regions where hepatitis B is endemic occult hepatitis B infection with negative HBs-antigen testing may contribute to cryptogenic liver cirrhosis in a significant amount.

Keratin 8 and 18 filaments are the major keratin types in liver parenchymal cells. Out of 55 patients with cryptogenic liver disease, five had mutations of the keratin 8 gene, whereas this mutation was not found in patients with liver disease of different origin and normal subjects [4]. Mutation of keratin 18 was also demonstrated in a patient with cryptogenic cirrhosis.

Hepatitis G virus infection and heterocygocity in the C282Y mutation of the HFE gene (most common mutation in hereditary hemochromatosis) were not found to be associated with cryptogenic liver disease.

## Diagnostic Principles

The classification as cryptogenic liver disease is made by exclusion of known causes of liver disease such as alcohol- and drug-induced liver injury, viral hepatitis, cholestatic liver disease, autoimmune hepatitis, metabolic or hereditary disorders. Extensive laboratory evaluation including testing for HBV-DNA and HCV-RNA and autoimmune antibodies as well as liver biopsy are mandatory.

## Therapeutic Principles

Patients with NASH should reduce weight and diabetes must be treated if present. Medical therapy is still

experimental. Patients with characteristics of autoimmune hepatitis may respond to steroids and immunosuppressive therapy. Recurrent disease is more frequent in transplanted livers of patients with cryptogenic cirrhosis than in patients transplanted for other reasons.

# Liver Cirrhosis, Posthepatitic

Olav A. Gressner
Institute of Clinical Chemistry and Pathobiochemistry, RWTH Universtity Hospital, Aachen, Germany

## Definition and Characteristics

Development of cirrhosis typically over a period of many years and decades as consequence of chronic infection with hepatitis C virus (HCV) or hepatitis B virus (HBV) with or without concomitant hepatitis Delta (D) virus (HDV) infection.

## Prevalence

The frequency of chronic hepatitis following acute HBV infection is 5–10%. In childhood HBV infection has a much higher rate of chronicity. Additional HDV infection leads to a much more severe course with cirrhosis developing in 60–70% of cases. The total number of patients with chronic HBV infection is estimated to be 300 million world-wide.

The frequency of chronic hepatitis following acute HCV infection is 50–80% [1]. World-wide about 170 million patients are suffering from chronic hepatitis C, the prevalence is estimated to average 3% (ranging from 0.1 to 5% in different countries). The incidence of new symptomatic infections is estimated to be 1–3 cases/100,000 persons annually.

Chronic hepatitis E-virus (HEV) infection is not observed.

## Molecular and Systemic Pathophysiology

Only few studies have assessed the progression rate of cirrhosis and fibrosis in chronic HBV infection. The progression rate has been correlated with HBV genotype and several SNPs and polymorphisms in a number of candidate genes (e.g. TGF- β, angiotensinogen, TNF α, TIMP-1, CYP2E1) [2]. Co-infection or super-infection with HDV (anti-HDV-IgM and/or HDV-RNA in serum) enhances the frequency of developing cirrhosis and the rate of progression (in about 15% already within 1–2 years). Underlying hemochromatosis gene mutations and/or chronic ethanol consumption might increase the risk and the progression rate of cirrhotic development.

Chronic HCV infection normally progresses slowly over 30 years to cirrhosis, which develops in 20% of patients [1]. However, the time course is remarkably variable, which is not due to viral factors because there is no relationship between viral load or genotype and cirrhosis/fibrosis but genetic markers of the patient such as promoter polymorphisms of TGF-β 1 and angiotensin and the host immune phenotype might be critical. Additional risk factors for rapid progression of HCV are older age at time of infection, concurrent liver disease due to HBV or alcohol (>50 g/day), male gender, increased body mass index with hepatic steatosis, HIV infection or immunosuppression and iron overload [3,4]. Once cirrhosis is established, the risk of hepatocellular carcinoma is 1–4%/year [1].

## Diagnostic Principles

Viral infection and the immune response of the patient are recorded by quantitative specific RNA/DNA determinations and immunochemical measurement of specific viral antigens and antibodies, respectively. Viral genotyping helps to predict the outcome of therapy and is performed with adequate PCR assays. Pathobiochemical partial reactions of the liver (liver cell damage, liver insufficiency, cholestasis, fibrogenesis) are monitored by biopsy, imaging procedures and clinical-chemical liver function tests, respectively. A combined clinical and laboratory index has been suggested, which has a good correlation with fibrosis stage in patients with chronic HCV. The index (fibrotest) includes serum α 2-macroglobulin, haptoglobin, γ-glutamyl transferase, γ-globulin, total bilirubin, and apolipoprotein A [5]. Several additional scores have been elevated in recent years [5].

Transient elastography (fibroscan) is a non-invasive, clinical method to detect advanced fibrosis by measuring the increased stiffness of the fibrotic liver.

## Therapeutic Principles

Drug therapy includes four groups of substances: antiviral agents (e.g. pegylated interferon α, nucleoside analogues), immunostimulants (e.g. interferon α, thymosin α, interleukins), molecular biological drugs (e.g. antisense oligonucleotides), adjuvant substances (e.g. ursodesoxycholic acid, flavonoids). Monotherapy

and combination therapy, respectively, are in use. Liver transplantation is indicated in patients with life-threatening cirrhosis and those with hepatocellular carcinoma on cirrhosis.

# Liver Cirrhosis, Postnecrotic

Olav A. Gressner
Institute of Clinical Chemistry and Pathobiochemistry, RWTH Universtity Hospital, Aachen, Germany

## Synonyms

Postdystrophic cirrhosis

## Definition and Characteristics

Cirrhosis developing after massive subacute necrosis (hepatic dystrophy) induced by exposure to facultative or obligatory hepatotoxins or by strong (auto-)immune reactions.

## Prevalence

It is a rare form of cirrhosis.

## Molecular and Systemic Pathophysiology

Exposure of individuals to chemical agents or pharmaceuticals, which belong to facultative or obligatory hepatotoxins and excessive (auto-)immune reactions can cause massive subacute liver necrosis (dystrophy) with more or less extensive destruction of parenchyma (hepatocytes) within a short time period. As a consequence, regenerative nodules are formed from the remaining parenchyma, and extracellular matrix (collagens, structural glycoproteins, proteoglycans) is synthesized in activated hepatic stellate cells and deposited as scar tissue [1]. The activation of hepatic stellate cells and their transdifferentiation to myofibroblasts results in part from mediators released by damaged hepatocytes, which affect both the mitogenic activity of the stellate cells [2,3] and their ability to synthesize extracellular matrix [4]. Transforming growth factor-β1 (TGF-β1) is one of the important cytokines released from injured hepatocytes. Further profibrogenic signals are generated by oxidative stress, which activates stellate cells and stimulates collagen gene expression [5]. Together with bile duct proliferation these severe alterations lead to irregular histological structure (pseudolobuli formation) and impaired intrahepatic microcirculation (with the consequence of portal hypertension), which determines the clinical outcome.

## Diagnostic Principles

Diagnoses and disease monitoring use the same principles as applied for other forms of cirrhosis: liver biopsies, imaging techniques, clinical–chemical function tests (in particular of liver cell necrosis, liver cell insufficiency, cholestasis, and fibrogenesis).

## Therapeutic Principles

Basic rules of therapy include elimination of the noxious agent and liver support (e.g., anti-oxidative drugs, liver assist devices, transplantation).

# Liver Enlargement

►Hepatomegaly

# Liver Failure, Acute

Dieter Häussinger
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

Acute liver dystrophy; Fulminant hepatic failure; ALF

## Definition and Characteristics

Acute liver failure (ALF) is a life threatening disorder due to acute liver injury with severe impairment of liver function and development of hepatic encephalopathy in a patient with a previously healthy liver. Depending on the time interval between jaundice and presentation of encephalopathy symptoms, the liver failure is termed hyperacute (latency <7 days), acute (latency 8–28 days) or subacute (latency 29–72 days). The terms fulminant and subfulminant hepatic failure refer to latencies of less or more than 2 weeks, respectively [1]. These distinctions are clinically important, because these forms differ with regard to prognosis and clinical features. Prognosis without liver transplantation is better in hyperacute and fulminant hepatic failure than in subacute or subfulminant hepatic failure. Cerebral edema is more common in fulminant hepatic failure, whereas renal failure and portal hypertension are more frequently observed in subfulminant liver failure.

The most frequent causes of ALF are viral hepatitis, drugs and intoxications (Table 1).

**Liver Failure, Acute. Table 1** Causes of acute liver failure

| | |
|---|---|
| Infections | Viral hepatitis A–E, yellow fever, cytomegaly, Epstein-Barr virus infection, Q-fever, tuberculosis, sepsis |
| Drugs and toxins | *Amanita phalloides*, ethanol, designer drugs, carbon tetrachloride, halothane, paracetamol, isoniazid, tetracyclines, valproate, non-steroidal antirheumatics |
| Cardiovascular | Budd-Chiari syndrome, portal vein thrombosis, right heart failure, circulatory shock |
| Metabolic | Morbus Wilson, acute fatty liver of pregnancy, Reye syndrome, hereditary fructose intolerance, galactosemia |
| Others | Excessive liver metastasis, autoimmune hepatitis, liver resection |

## Prevalence

The exact prevalence of acute liver failure is unknown and may depend upon the region examined. Rough estimates suggest about 3.5 deaths per million people. ALF occurs in less than 1% of patients with acute viral hepatitis, out of these 30–70% are due to hepatitis B virus and 20–50% due to hepatitis C virus infection. Up to 60% of the cases with ALF are due to intoxications or drugs, such as paracetamol (dose usually >8 g) and Amanita phalloides poisoning (lethal dose 10–50 g). There are regional differences with regard to the underlying causes of ALF; whereas viral hepatitis predominates in Germany, in the United Kingdom and the US paracetamol poisoning is the most frequent cause of ALF.

## Genes

No genetic predispositions have been identified so far for acute liver failure in general, however, a genetic basis is evident in cases with ALF due to inborn errors of metabolism. Not yet identified immunological differences may account for the development of ALF in viral hepatitis B, which is characterized by an overshooting attack of the immune system on hepatocytes in some patients. In other patients the immune system tolerates hepatitis B virus infection without apparent liver damage.

## Molecular and Systemic Pathophysiology

Liver pathology reveals large confluent necroses in the liver. The mechanisms underlying the massive necroapoptotic loss of hepatocytes depend upon the causative agent. Oxidative stress and radical formation, redox cycling, attacks of the immune system, disturbances of protein synthesis and protein modifications and hypoxia due to massive reductions of liver blood flow may be involved. In any case, the loss of viable liver tissue results in a critical decrease in metabolic liver function with consequences for the function of other organ systems. Consequences of acute liver failure include large increases in serum transaminase activities, development of jaundice, a tendency towards hypoglycemia, blood coagulation defects due to impaired synthesis of clotting factors, respiratory and metabolic alkalosis, a tendency towards infections and circulatory and renal failure. Hepatic encephalopathy is present and can progress from mild forms to deep coma, brain edema with convulsions and eventually death due to brain stem herniation. Patients usually die from infections, cerebral complications or multiorgan failure.

ALF has a high mortality, but recovery is possible even with conservative management. Apparently, the severity and dynamics of liver injury on the one hand and the efficacy of simultaneously initiated liver

regenerative processes on the other are determinants of the probability of spontaneous hepatic recovery [2,5]. The prognosis is also determined by the cause underlying the ALF. Without liver transplantation, the mortality of viral hepatitis induced ALF is 80–90%, of paracetamol induced ALF about 50%, whereas ALF due to Budd-Chiari syndrome or Wilson disease has an almost 100% mortality. With liver transplantation 1-year survival rates of about 80% are achieved.

## Diagnostic Principles

The occurrence of hepatic encephalopathy and severe signs of liver damage (highly elevated serum transaminases and bilirubin) and dysfunction (blood coagulation defect) in a patient with a previously healthy liver is strongly suggestive of ALF. Overt hepatic encephalopathy is diagnosed by the clinical picture. In mild forms with preserved consciousness in the patients, determination of critical flicker frequency is suitable for following the evolution of hepatic encephalopathy.

## Therapeutic Principles

The basic treatment includes intensive care, prophylaxis and management of all potential complications of acute liver failure. In any case a decision has to be made whether a given patient should receive a liver transplant. Because only those patients who will not recover spontaneously from ALF will benefit from liver transplantation, several criteria catalogs [1,2], such as the Kings' College or Clichy criteria have been developed in order to identify those patients requiring liver transplantation. This decision cannot be made on the basis of a single criterion and includes parameters such as pH, prothrombin time, serum creatinine age, underlying cause, bilirubin levels and the extent of encephalopathy. Hypothermia and liver dialysis systems may help to bridge the period until an organ for liver transplantation is available in these emergency conditions [3,4].

# Liver Fibrosis

Massimo Pinzani
Dipartimento di Medicina Interna, Università degli Studi di Firenze, Florence, Italy

## Synonyms

Hepatic fibrosis

## Definition and Characteristics

Progressive accumulation of fibrillar extracellular matrix (ECM) in the liver with major angioarchitectural changes, generally as a consequence of reiterated liver tissue damage due to infective (mostly hepatitis B –HBV- and C –HCV- viruses), toxic/drug-induced, metabolic and autoimmune causes, and the relative chronic activation of the wound healing reaction. The process may result in clinically evident liver cirrhosis and hepatic failure. Cirrhosis is defined as an advanced stage of fibrosis, characterized by the formation of regenerative nodules of liver parenchyma that are separated by and encapsulated in fibrotic septa. Although cirrhosis is the common result of progressive fibrogenesis, there are distinct patterns of fibrotic development, related to the underlying disorders causing the fibrosis. Biliary fibrosis, due to the co-proliferation of reactive bile ductules and periductular (myo)fibroblast-like cells at the portal-parenchymal interface, tends to follow a portal-to-portal direction. In contrast, the chronic viral hepatitis pattern of fibrosis is considered the results of portal–central (vein) bridging necrosis, thus originating portal–the central septa. Finally, a peculiar type of fibrosis development is observed in alcoholic and metabolic liver diseases (e.g., nonalcoholic steatohepatitis), in which the deposition of fibrillar matrix is concentrated around the sinusoids (capillarization) and around groups of hepatocytes (chicken-wire pattern) [1].

## Prevalence

While millions of patients worldwide are affected by chronic liver diseases potentially leading to cirrhosis, only a minority (~25–30%) are likely to develop significant fibrosis and cirrhosis. This is particularly true for chronic hepatitis due to HCV infection, whose prevalence is predicted to peak between the years 2010 and 2015. Regardless, both in the USA and Europe, liver cirrhosis is the most common non-neoplastic cause of death among hepatobiliary and digestive diseases. In addition, this condition is largely associated with primary liver cancer, with a further increase in the relative mortality rate [2]. In general terms, the following clinical features have been shown to be predictors of the development of significant fibrosis, or at least, of a

faster progression to cirrhosis: (i) male gender (for groups of age <50 years), (ii) age at infection (hepatitis virus, particularly HCV), (iii) obesity and diabetes mellitus, (iv) daily alcohol intake, independently from the major cause of hepatocellular damage, and (v) hepatic iron content. In addition, individual factors are likely to affect several aspects of the fibrogenic process (i.e., differences in handling a metabolic/toxic load, in the immune system reactions toward infectious agents and autoantigens, and in the management of the chronic wound healing reaction), with markedly different rates of fibrosis progression for apparently similar clinical features.

## Molecular and Systemic Pathophysiology

The normal liver parenchyma is organized as a "model epithelium" with an epithelial component (hepatocytes), an endothelial lining distinguished by fenestrations or pores (sinusoidal), tissue macrophages (Kupffer cells), and liver-specific pericytes known as hepatic stellate cells (HSC). The sinusoid is the liver microvascular unit, with the subendothelial space of Disse separating the hepatocytes from the sinusoidal endothelium. This space contains a basal membrane-like matrix essential for maintaining the differentiated function of all resident liver cells and for ensuring optimal metabolic exchange between the bloodstream and the hepatocytes. Hepatic sinusoids originate from vascular structures (branches of the portal vein and of the hepatic artery) included in portal tracts. Portal tracts are key structures in the architecture of liver tissue and also include bile ducts, lymphatic ducts, and a stromal mesenchymal cells (portal myofibroblast and fibroblasts). As the liver becomes fibrotic, there are both quantitative and qualitative changes in the composition of the hepatic ECM. The total content of collagenous and noncollagenous components increases threefold to fivefold, accompanied by the shift in the type of ECM in the subendothelial space from the normal low-density basement membrane-like matrix to interstitial type matrix containing fibril-forming collagens. These quantitative and qualitative changes in the composition of ECM, in addition to their mechanical and physical implications, contribute to the formation of a new biochemical environment. Indeed, each ECM component has the ability to modulate cell growth, migration, gene expression, and other important cellular functions directly by interaction with cell adhesion molecules and, indirectly, by functioning as a biologic reservoir for pro-inflammatory and pro-fibrogenic mediators in their active or inactive forms [3].

The cellular source of connective tissue components in fibrotic liver has been controversial for many years. Among other cell types potentially involved in the abnormal progressive deposition of fibrillar ECM, HSC have received much attention, mostly in reason of the possibility of isolating them from liver tissue with a relatively high purity. Consequently, most of the present knowledge on the cell and molecular biology of hepatic fibrosis derives from in vitro studies employing culture activated HSC isolated from rat, mouse, or human liver. Regardless, it is now evident that distinct ECM-producing cells, each with a distinct localization and a characteristic immunohistochemical and/or electron microscopic phenotype, are likely to contribute to liver fibrosis. These include fibroblasts and myofibroblasts of the portal tract, smooth muscle cells localized in vessel walls, and myofibroblasts localized around the centrolobular vein. It is also evident that the relative participation of these different cell types is dependent on the development of distinct patterns of fibrosis. It is likely that all these different ECM-producing cell types undergo a process of activation in conditions of chronic liver damage or, anyhow, in conditions in which the physiological homeostasis of the tissue is chronically perturbed. For the reasons previously mentioned, the process of HSC activation has been the object of several studies, and consistent information is at present available. Following prolonged culture on plastic, HSC undergo a process of activation from the quiescent "storing" phenotype to the highly proliferative "myofibroblast-like" phenotype. This process is still regarded as similar to that occurring in liver tissue following chronic damage, although this assumption likely represents an oversimplification. The activated phenotype is characterized by a dramatically increased synthesis of collagen types I and III, which appears predominant over the synthesis of collagen type IV (I>III>>IV) and other ECM components. Studies performed in recent years have emphasized some important aspects potentially related to the initiation of HSC activation. The first important element concerns the disruption of the normal ECM pattern that follows liver tissue injury and acute inflammation. A perturbation in the composition of the normal hepatic ECM and/or of the cell–cell relationship between epithelial and mesenchymal cells present in liver tissue, typical of some cholestatic disorders (i.e., those characterized by bile duct proliferation and lobular invasion) could also be considered a potent stimulus for the activation and proliferation of HSC, as well as other ECM-producing cells. Indeed, loss of adhesion with the various elements constituting the basal membrane-like ECM of the space of Disse is likely to determine a marked increase of the proliferative and synthetic properties of HSC. This issue is becoming more and more important with the demonstration that the movement, shape, and proliferation of cells are greatly influenced by the cooperation of ECM components and cell adhesion molecules.

Another important aspect related to the initiation of activation concerns the exposure of HSC to soluble

mediators that may potentially affect their proliferative attitude and/or synthetic ability. It is again important to stress that exposure to these mediators, generically defined as "inflammatory," may be time limited or chronically present according to the nature, extent, and reiteration of parenchymal damage. Following liver injury, several cell types, resident or infiltrating, could be involved in the synthesis and release of soluble factors playing a biological role in HSC. In this regard, it should be stressed that the term "inflammation" indicates a rather complex association of different cell types (i.e., lymphocytes, neutrophils, mononuclear cells, platelets) playing different roles. This distinction implies that clusters of soluble factors, specifically directed at different cell targets, are contemporaneously present in the tissue. It is likely that none of these factors work alone and that a complex network of interactions occurs between these mediators and their targets. In vitro studies have indicated that all these factors, taken singularly or in combination, have some effect on FSC proliferation, chemotaxis, and/or ECM deposition. However, consolidated experimental evidence suggests that two polypeptide growth factors, namely platelet-derived growth factor (PDGF) and transforming growth factor-β1 (TGF-ß1), greatly contribute to the profibrogenic role of HSC [4]. When chronic liver injury is not clearly associated with an abundant inflammatory infiltrate, other soluble agents may sustain the activation of HSC through pathways that are specific for a particular type of damage. In alcoholic liver injury, for example, acetaldehyde, the main metabolite of ethanol, is able to increase gene transcription and synthesis of different ECM components in activated HSC. In addition to acetaldehyde, products of lipid peroxidation generated by exposure to ethanol or the production of iron overload may also perpetuate HSC activation. Along these lines, stimulation of lipid peroxidation or exposure to 4-hydroxynonenal, a highly reactive aldehydic end-product of lipid peroxidation, increases procollagen I gene expression in activated human HSC.

## Diagnostic Principles

Liver biopsy is still considered the "gold standard" for assessing liver histology, disease activity and liver fibrosis. Several scoring systems are available and are used for this purpose. However, liver biopsy is associated with potential morbidity and mortality and has several limitations, including sampling error and high inter-observer variability. Moreover, the information provided by liver biopsy is static and does not reflect either the ongoing balance between ECM production and degradation or the rate of progression toward cirrhosis. Accordingly, there is a compelling need for non-invasive/dynamic methods for the evaluation of liver fibrosis, and current research efforts are focused on the development of a panel of non-invasive serum markers for the evaluation of liver fibrosis [5].

## Therapeutic Principles

Since fibrosis is in general the consequence of the chronic activation of wound healing response to reiterated hepatocellular damage, the best treatment for reducing hepatic fibrosis is the effective treatment of the causes of such damage, when available. However, the improved understanding of the mechanisms underlying hepatic fibrosis makes effective anti-fibrotic therapy an imminent reality, although thus far no drugs have been approved as anti-fibrotic agents in humans. Putative anti-fibrotic drugs include (i) agents able to reduce inflammation and immune response, (ii) agents able to reduce the activation of ECM-producing cells and their pro-fibrogenic properties (proliferation, motility, ECM deposition, contraction), (iii) agents with pro-apoptotic potential for ECM-producing cells, and (iv) agents able to increase fibrillar ECM degradation [5].

## Synonyms

Romano-Ward syndrome; Jervell & Lange-Nielsen syndrome; Andersen-Tawil syndrome; Timothy syndrome

## Definition and Characteristics

Autosomal dominant or autosomal recessive defects of genes of ion channels or membrane adapter located on chromosomes 3, 4, 7, 11, 12, 17 and 21.

## Prevalence

The prevalence of heterozygotes is reported to be 0.02%.

## Genes

See Table 1.

## Molecular and Systemic Pathophysiology

*Congenital long QT syndrome:* The common phenotype of the congenital form of long QT syndrome (LQTS) is a prolonged QT interval in the electrocardiogram (ECG) and a polymorphic ventricular tachycardia known as Torsade de Pointes (TdP) [1], leading to severe cardiac events such as syncope and/or sudden cardiac death, most often during physical exercise or mental stress (Table 1). Ten forms (LQT1–LQT10) of the Romano-Ward syndrome have been reported to be caused by mutations in genes encoding for potassium, sodium and calcium channels [2]. Two autosomal recessive forms (JLN1–JLN2) of the Jervell & Lange-Nielsen syndrome, which are characterized by a more severe cardiac phenotype and neurosensorial deafness, have been identified [2].

*Romano-Ward syndrome (LQT1, LQT5):* Heterozygous mutations in KCNQ1 and KCNE1, which encode for the α and β subunits of the slowly activating delayed rectifier potassium channel ($I_{Ks}$), cause a reduction of $I_{Ks}$, resulting in LQT1 and LQT5 forms of LQTS, respectively. Defective KCNQ1/KCNE1 channel proteins co-assemble with wild-type protein, and can alter the channel function in a dominant negative fashion, leading to a greater than 50% decrease in $I_{Ks}$. Other mechanisms responsible for a reduction of $I_{Ks}$ current include failure of intracellular protein trafficking, failure of KCNQ1/KCNE1 co-assembly, and defects in channel phosphorylation by altered interaction of KCNQ1/KCNE1 with the yotiao targeting protein which binds to KCNQ1 by a leucine zipper motif. Over 100 mutations in the KCNQ1 gene have been reported. LQT1 constitutes 30–50% of the genotyped LQTS patients, and is most sensitive to sympathetic β-adrenergic stimulation. Cardiac events most frequently occur during exercise (62%) but only rarely during sleep and rest (3%) [3]. Swimming is a common trigger in LQT1 and the characteristic T wave pattern in the ECG is a broad-based prolonged T wave. The clinical phenotype is less well defined in LQT5, which accounts for less than 5% of cases.

*LQT2, LQT6:* KCNH2 and KCNE2 encode for the α and β subunits of the rapidly activating delayed rectifier potassium channel ($I_{Kr}$). Heterozygous mutations in KCNH2 and KCNE2 gene reduce $I_{Kr}$ current, causing LQT2 and LQT6, respectively. More than 100 mutations in the KCNH2 gene have been reported, accounting for 30 – 40% of genotyped patients. Loss of function is due to multiple mechanisms, including a decrease of current density, failure of intracellular protein trafficking, and abnormal gating kinetics. A distinguishing ECG feature in LQT2 is a low-amplitude T waves with a notched or bifurcated appearance. Cardiac events occur during exercise (13%) or sleep/rest (15%) [3]. A sudden startle in the form of an auditory stimulus (a telephone, alarm clock, ambulance siren, etc.) is a specific trigger for TdP. Although female gender is a risk factor in LQTS, women with LQT2 are most susceptible during the postpartum periods. LQT6 is rare and the clinical phenotype is not well defined.

*LQT3:* SCN5A encodes for the α subunit of the voltage-dependent cardiac sodium channel. In contrast KCNQ1 and KCNH2 channels, which are formed by co-assembly of four homologous proteins, the sodium channel forms a functional channel by folding onto itself. Mutations in *SCN5A* increase (gain of function) late sodium current (Late $I_{Na}$), thus causing LQT3, which accounts for approximately 10% of genotyped patients. The ECG of LQT3 patients often displays a late-appearing T waves with a prolonged isoelectric ST-segment. Cardiac events usually occur during sleep and rest (39%); exercise-related cardiac events are rare (13%) [3].

*LQT4:* A mutation in Ankyrin-B, a member of a family of versatile membrane adapters, leads to intracellular calcium overload which is thought to contribute to the LQT4 syndrome. Only a single four-generation French family has been reported to be linked to the LQT4. In addition to QT prolongation, this syndrome is associated with sinus bradycardia and paroxysmal atrial fibrillation. Prominent U waves and T wave abnormalities are observed in the ECG following long pauses.

**Long QT Syndrome. Table 1** Defect of Ion channels or membrane adaptor protein responsible for the long QT syndrome

| Loci | Chromosome | Gene | Ion channel |
|---|---|---|---|
| *Congenital long QT syndrome* | | | |
| Romano-Ward syndrome | | | |
| LQT1 | 11 (11p15.5) | KCNQ1 | $I_{Ks}$ |
| LQT2 | 7 (7q35–36) | KCNH2 | $I_{Kr}$ |
| LQT3 | 3 (3p21–23) | SCN5A | $I_{Na}$ |
| LQT4 | 4 (4q25–27) | Ankyrin-B | Na-K ATPase, $I_{Na\text{-}Ca?}$ |
| LQT5 | 21 (21q22.1–q22.2) | KCNE1 | $I_{Ks}$ |
| LQT6 | 21 (21q22.1–q22.2) | KCNE2 | $I_{Kr}$ |
| LQT7 | 17 (17q23.–24.2) | KCNj2 | $I_{K1}$ |
| LQT8 | 12 (12p13.3) | CACNA1C | $I_{Ca\text{-}L}$ |
| LQT9 | 3 (3p25) | CAV3 | $I_{Na}$ |
| LQT10 | 11 (11q23.3) | SCN4B | $I_{Na}$ |
| Jervell & Lange-Nielsen syndrome | | | |
| JLN1 | 11 (11p15.5) | KCNQ1(homozygous) | $I_{Ks}$ |
| JLN2 | 21 (21q22.1–q22.2) | KCNE1(homozygous) | $I_{Ks}$ |
| *Acquired long QT syndrome* | | | |
| | 11 (11p15.5) | KCNQ1 | $I_{Ks}$ |
| | 7 (7q35–36) | HERG | $I_{Kr}$ |
| | 3 (3p21–24) | SCN5A | $I_{Na}$ |
| | 21 (21q22.1–q22.2) | KCNE1 | $I_{Ks}$ |
| | 21 (21q22.1–q22.2) | KCNE2 | $I_{Kr}$ |

*LQT7:* Mutations in KCNJ2, which encodes for the inward rectifier potassium channel ($I_{K1}$), give rise to a rare periodic paralysis disorder associated with prolongation of the QT interval and ventricular arrhythmias, known as Andersen-Tawil syndrome or LQT7. The ECG displays enlarged U waves separated from the T wave and frequent extrasystoles.

*LQT8:* A mutation in CACNA1C was reported to be responsible for a gain of function of the L-type calcium channel ($I_{Ca\text{-}L}$), which underlies Timothy syndrome also known as LQT8. The syndrome is characterized by a prolonged QT interval and ventricular arrhythmias and is associated with dysfunction of multiple organ systems, including congenital heart disease, syndactyly, immune deficiency, and autism.

*LQT9, LQT10:* The most recent genes associated with LQTS are CAV3, which encodes caveolin-3, and SCN4B, which encodes $Na_VB4$, an auxiliary subunit of the cardiac sodium channel. Mutations in both genes produce a gain of function in late $I_{Na}$, causing an LQT3-like phenotype [4,5].

*Others:* A recent study identified a common genetic variant in the NOS1 regulator (NOS1AP; CAPON) that modified cardiac repolarization. It is not known to what extent this variant may contribute to congenital or acquired LQTS.

*Jervell & Lange-Nielsen syndrome JLN1, JLN2:* Homozygous or compound heterozygous mutations in KCNQ1 and/or KCNE1 genes cause the autosomal recessive forms (JLN1 – JLN2) of the Jervell & Lange-Nielsen syndrome, which is usually associated with neurosensorial deafness. QT prolongation is generally more prominent and ventricular arrhythmias more severe than those in the Romano-Ward syndrome.

*Sudden infant death syndrome (SIDS):* Sudden cardiac death is attributable to QT prolongation and ventricular arrhythmias at least in some cases of sudden infant death syndrome (SIDS) similar to that in the congenital LQTS. SCN5A and KCNH2 mutations have been reported in some cases of SIDS.

*Acquired long QT syndrome:* Agents with Class III actions (action potential prolongation), electrolyte abnormalities (hypokalemia or hypomagnesemia), bradycardia, and dilated and hypertrophic cardiomyopathies can cause marked QT prolongation associated with abnormal T wave morphology and an episode of TdP (Table 1). The QT interval after withdrawal of drugs or correction of electrolyte disturbances is often at the upper normal limit of normal (420 – 460 ms). Mutations in KCNQ1, KCNH2, SCN5A, KCNE1 and KCNE2 genes have been associated with cases of acquired LQTS.

*Cellular mechanism:* QT prolongation is commonly associated with life-threatening TdP arrhythmias that develop as a consequence of the amplification of electrical heterogeneities intrinsic to the ventricular myocardium. These heterogeneities exist because of differences in the time course of repolarization of the three predominant cell types that make up the ventricular myocardium, giving rise to transmural voltage gradients and a dispersion of repolarization responsible for the inscription of the electrocardiographic T wave. Some congenital mutations, drugs and conditions that reduce net repolarizing current can amplify the intrinsic spatial dispersion of repolarization, thus creating the substrate for the development of reentry. The result is a prolongation of the QT interval, abnormal T waves and the development of TdP. These conditions also predispose M cells and Purkinje fibers to develop early after depolarization-induced extrasystoles, which are thought to trigger episodes of TdP. Agents that prolong the QT interval but do not increase transmural dispersion of repolarization, generally do not induce TdP. The available data suggest that that the principal problem with the long QT syndrome is not long a QT interval, but rather the dispersion of repolarization that often accompanies prolongation of the QT interval.

## Diagnostic Principles

A prolonged QT interval in the ECG, syncope, aborted cardiac arrest due to TdP or ventricular fibrillation point to congenital LQTS. LQTS diagnostic criteria were proposed by Schwartz and co-workers in 1993 (Table 2). Definite LQTS is defined by an LQTS score ≥4. The ECG diagnostic criteria of Keating et al. includes a corrected QT (QTc) ≥ 470 ms in asymptomatic individuals and a QTc ≥440 ms for males and ≥460 ms for females associated with ≥1 of the following: (i) stress-related syncope, (ii) documented TdP, or (iii) family history of early sudden cardiac death.

**Long QT Syndrome. Table 2** 1993 LQTS diagnostic criteria

| Point | |
|---|---|
| *ECG findings* | |
| QTc | |
| ≥480 $ms^{1/2}$ | 3 |
| 460–470 $ms^{1/2}$ | 2 |
| 450 $ms^{1/2}$ (in males) | 1 |
| Torsade de Pointes[a] | 2 |
| T wave alternans | 1 |
| Notched T wave in three leads | 1 |
| Low heart rate for age | 0.5 |
| *Clinical history* | |
| Syncope[a] | |
| With stress | 2 |
| Without stress | 1 |
| Congenital deafness | 0.5 |
| *Family history* | |
| Family members with definite LQTS | 1 |
| Unexplained sudden cardiac death below age 30 among immediate family members | 0.5 |

*LQTS* long QT syndrome; *QTc* corrected QT interval by Bazett's formula.
[a]Mutually exclusive.
Scoring: ≤1 point, low probability of LQTS; 2–3 points, intermediate probability of LQTS; ≥4 points, high probability of LQTS.

## Therapeutic Principles

*Congenital long QT syndrome LQT1, JLN1, (LQT5), (JLN2):* Limitation of exercise is required in genotypes with an $I_{Ks}$ defect. β-Blockers more frequently suppress episodes of syncope and sudden cardiac death in LQT1 patients (81%) than in the other forms (LQT2, 59% or LQT3, 50%) [3]. Mexiletine, a class IB sodium channel blocker, which blocks late $I_{Na}$, or verapamil, an L-type calcium current ($I_{Ca\text{-}L}$) blocker, may warrant consideration as adjunctive therapy to β-blockers in LQT1 patients. Left cardiac sympathetic denervation (LCSD) has been reported to be effective in LQTS patients refractory to β-blockers. LCSD may be most effective in the LQT1 syndrome. An implantable cardioverter-defibrillator (ICD) is indicated for LQTS patients who have suffered an aborted cardiac arrest and/or who have repetitive episodes of syncope in the presence of pharmacological or non-pharmacological therapy, regardless of genotype.

*LQT2, (LQT6):* A β-Blocker is the first choice for pharmacological therapy of LQT2 patients, however the recurrence rate is higher than that in LQT1 patients. Increase in the extracellular potassium concentration by exogenously administered potassium or long-term oral potassium administration was reported to shorten QT interval in LQT2 patients. The indication of the ICD is similar as that in the LQT1 syndrome.

*LQT3:* β-Blockade is less effective in LQT3 patients than in LQT1 or LQT2 patients [3]. A class IB sodium channel blocker, mexiletine is more effective in abbreviating the QT interval in the LQT3 than in the LQT1 or LQT2 syndrome, making mexiletine a first line therapy in LQT3. Pacemaker therapy may be beneficial in LQT3 patients, especially in patients with bradycardia.

*LQT4, LQT7, LQT8 and Genotype-unknown LQTS:* Genotype-specific therapy is unknown in the other forms, LQT4, LQT7 and LQT8. β-Blockade is first line therapy in patients with these genotypes and unknown LQTS genotypes.

*LQT9, LQT10:* Genotype-specific therapy is unknown in LQT9 and LQT10. A class IB sodium channel blocker, mexiletine may be effective, as in LQT3,

because these forms of LQTS have all been associated with an increase in late $I_{Na}$.

*Acquired long QT syndrome:* Discontinuation of the causes or triggers responsible for acquired LQTS is indicated. Following normalization of the QT interval, the patients must be counseled on avoidance of QT prolonging drugs. A list of such drugs can be found at www.qtdrugs.org.

## Synonyms

Lowe oculo cerebro renal syndrome

## Definition and Characteristics

X-linked disorder with the hallmark features of bilateral cataract, mental retardation, and renal Fanconi syndrome. While dense congenital cataracts are considered a cardinal finding required for Lowe syndrome diagnosis, renal and neurological phenotypes are more variable.

## Prevalence

1–10 boys per million people in European countries, USA, and Japan.

## Genes

OCRL1 is localized at X q25-26, is ubiquitously expressed and encodes a 105 kDa protein designated OCRL1 [1]. Tissue-specific alternative splicing gives rise to two isoforms (a and b) differing by an insertion of eight amino acids (exon 18a) in isoform a; b isoform is most abundant in all tissues but isoform a is highly predominant in brain.

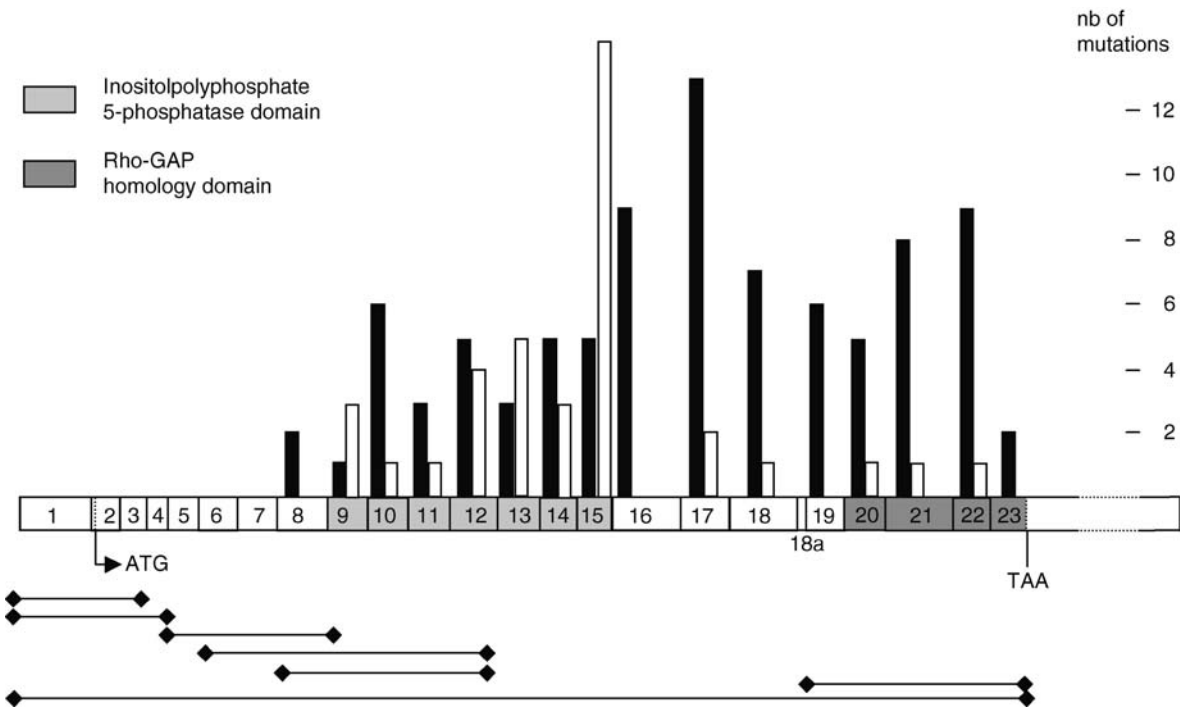
## Molecular and Systemic Pathophysiology

OCRL1 contains two conserved domains: a central inositolpolyphosphate 5-phosphatase domain and a C-terminal RhoGAP-like domain. OCRL1 is a type II 5-phosphatase, i.e., it can hydrolyze phosphoinositides PI(4,5)P2 and PI(3,4,5)P3 as well as soluble inositolphosphates; however, its preferred substrate is PI(4,5)P2 [2]. OCRL1 mutations in Lowe syndrome include deletions, premature stop codons, frameshift and missense mutations. Missense mutations are mostly located in the 5-phosphatase domain, consistent with a loss of 5-phosphatase activity causing the disease (Fig. 1).

Surprisingly, however, in most cases including missense mutations, patients' cells show strongly reduced or complete lack of OCRL1; this suggests that mutations lead to a decrease in protein or RNA stability and that loss of other domains of OCRL1, specifically the RhoGAP domain, contributes to the observed defects. Interestingly, Rac1, a Rho family GTPase, binds to the RhoGAP domain, raising the possibility of a dysregulation of Rac signaling in Lowe cells.

The bulk of OCRL1 is localized to the Trans Golgi Network (TGN) in many cell types [3]; OCRL1 has also been detected in early endosomes and in clathrin-coated vesicles, consistent with its reported interactions with clathrin and AP2. Finally, in growth factor-stimulated cells, a fraction of OCRL1 is translocated to membrane ruffles in a Rac-dependent manner (for a review on OCRL1 see [4]).

Due to the loss of PI(4,5)P2-5 phosphatase activity, patients' cells accumulate PI(4,5)P2, a major player in cell signaling, protein trafficking, and actin



**Lowe Syndrome. Figure 1** Exonic distribution of the known mutations along the *OCRL1* gene. Black bars represent nonsense, frameshift, and splicing mutations; white bars represent missense and in-frame deletions; horizontal bars represent genomic deletions.

polymerization. Anomalies in actin cytoskeleton, including loss of long actin stress fibers, increased sensitivity to actin depolymerizing agents and abnormal distribution of actin binding proteins have been observed in patients' dermal fibroblasts. In addition, alterations in TGN/endosome trafficking have been recently reported in OCRL1-depleted HeLa cells [4]. How these anomalies result in clinical features of Lowe syndrome is largely unknown.

Defective protein and solute reabsorption in the kidney proximal tubule (Fanconi syndrome) is a major symptom of the disease. A clue to the perturbation of the endocytic process in proximal tubule epithelium as a cause of Fanconi syndrome has come from the discovery of OCRL1 "loss of function" mutations in Dent disease [5]; this condition, an isolated renal tubulopathy, is typically due to mutations in the chloride channel ClC5 resulting in defective endocytosis-mediated protein uptake. This suggests a functional link between OCRL1 and ClC5 in tubule epithelial cells and a similar defect of endocytosis in Lowe tubular cells. The molecular and cellular basis of mental retardation and ocular symptoms remain poorly defined.

Why the loss of the ubiquitous protein OCRL1 results in defects to only eyes, central nervous system, and kidney proximal tubule in Lowe syndrome and in an even more restricted defect to kidney in Dent disease is an unsolved question. Loss of OCRL1 may be compensated in unaffected tissues by another type II PI-5-phosphatase called INPP5B, which is highly similar to OCRL1 in terms of domain organization and amino-acid sequence (45% identity). The finding that OCRL1 KO in mouse does not lead to Lowe phenotype and that KO of both OCRL1 and INPP5B results in embryonic lethality is consistent with the two proteins having overlapping functions. In humans, variability among tissues and individuals of the expression of the compensating enzyme would explain variations in the renal and neurological phenotypes in Lowe syndrome and also the lack of cataract and mental retardation in OCRL1-deficient patients presenting with Dent disease.

## Diagnostic Principles

The coincidence of bilateral cataract, hypotonia, and renal proximal tubular dysfunction in a male infant points to the disease. Assay for PI(4,5)P2-5 phosphatase in dermal fibroblasts obtained from a skin biopsy shows a strong defect or complete lack of activity that definitively set the diagnosis of Lowe syndrome. Extensive screening of the OCRL1 gene at the level of genomic DNA and/or RNA identifies point mutations and genomic deletions that allow genetic counseling and direct prenatal diagnosis.

Female carriers can be identified by detecting lenticular opacities in the eyes upon slit lamp examination and confirmed by DNA analysis. As in other X-linked diseases, one third of the identified mutations are neomutations and germinal mosaicism has been reported.

## Therapeutic Principles

Therapy of the renal disease is only symptomatic; electrolyte (bicarbonate, phosphate, calcium) and Vitamin D supplements are needed by many patients for treatment of the Fanconi syndrome. Water supply should avoid dehydration. Glomerular filtration deterioration is observed in young adults and needs specific care. Cataract requires therapy including surgical removal of lenses and use of glasses, as early as possible in childhood.

## Lung Abscess

Rade Tomic, Jesse Roman
Division of Pulmonary, Allergy and Critical Care Medicine and VA Medical Center, Emory University, Atlanta, GA, USA

### Definition and Characteristics

A lung abscess is a suppurative necrotic lesion of the lung characterized by the formation of a cavity that results from pulmonary infection [1]. Lung abscesses are typically polymicrobial with anaerobic bacteria predominating. They often complicate pneumonias caused by infectious organisms like pyogenic bacteria, mycobacteria, fungi, and parasites. Less frequently, lung abscesses may complicate pulmonary infarction, primary and metastatic malignancies, and necrotic conglomerate lesions of silicosis and coal miners' pneumoconiosis. It can be acute (<6 weeks) or chronic (>6 weeks).

### Prevalence

Lung abscess formation is seen in 0.2% of all cases of pneumonia, but is much more frequent in underdeveloped countries.

### Molecular and Systemic Pathophysiology

Of the factors involved in the development of a lung abscess, aspiration of oropharyngeal contents is considered an important one. Depression of consciousness and gag reflex due to such conditions as excess alcohol ingestion, drug overdose, neuromuscular disease, cardiac arrest, and cerebrovascular accidents are major precipitating factors. Esophageal conditions such as stricture, malignancy, and gastroesophageal reflux can predispose to aspiration and subsequent development of a lung abscess [2]. Bronchial obstruction due to malignancy, inflammation, or a foreign body is also an important risk factor because it impairs effective clearing of aspirated oropharyngeal fluid. Other risk factors include deficiencies in local and systemic immunity, immunosuppressive states of varying etiology, and chronic illness due to liver and kidney disease and diabetes mellitus. The processes that lead to tissue destruction and cavitation during abscess formation remain unclear, but both pathogen and host-derived products appear involved. In particular, the secretion of tissue destructive proteases from host cells is considered important.

### Diagnostic Principles

In most cases, the diagnosis of a lung abscess is made from chest radiography showing a round hyperluscent area of the lung surrounded by a thick rim and often containing fluid as demonstrated by the presence of an air-fluid level [3]. Although characteristic, these changes can be seen in other conditions such as in preexisting cysts or blebs. If the lung abscess is located on the periphery of the lung, it might be difficult to distinguish it from localized empyema using only chest radiography. The distinction, however, can be made with chest computer tomography [4]. The diagnosis of the specific cause(s) of lung abscess depends on definitive microbiological studies. In the absence of positive blood or pleural fluid cultures, identification of lung abscess may require obtaining respiratory tract specimen by an invasive procedure such as bronchoalveolar lavage or percutaneous lung aspiration.

### Therapeutic Principles

The main goal of therapy for patients with lung abscess is rapid eradication of the causative pathogen with appropriate therapy, adequate drainage of an associated empyema (if present), and the monitoring and prevention of complications. Antibiotics are the mainstay of treatment of lung abscesses. Antimicrobial therapy can consist initially of penicillin and metronidazole or clyndamicin. Treatment may require up to 6–8 weeks [5]. Serial chest radiographs are useful to follow the course of the disease and to document healing of the abscess cavity. Surgery is required in less than 10–20% patients with lung abscess. Surgical intervention is indicated in nonresolving lung abscesses or for relieving an underlying anatomic disturbance such as bronchogenic carcinoma or other bronchial obstructive lesions. Complications such as life-threatening hemoptysis, bronchopleural fistula and empyema also are indications for surgery. Aggressive expectoration, chest physiotherapy and postural drainage are often useful.

Laboratory of Respiratory Biology, NIH/NIEHS, Research Triangle Park, NC, USA

## Synonyms

Occupational lung disease

## Definition and Characteristics

Environmental lung disease encompasses a wide range of lung disorders resulting from inhalation of noxious environmental substances. The most common types of environmental lung disease are asthma, cancer and pneumoconioses (e.g., ►Asbestosis, ►Silicosis).

## Prevalence

The Prevalence of environmental lung diseases vary depending on the condition. Some diseases such as asthma are common (life time prevalence rate 10–12%), whereas other conditions such as silicosis are relatively rate.

## Genes

Genetic polymorphisms in several genes have been reported to increase the risk of environmental lung disease. Examples include tumor necrosis factor (TNF)-α polymorphisms which are associated with increased risk of asthma [1] and pneumoconiosis, and glutathione S-transferase polymorphisms which are associated with increased risk of lung cancer [2,3].

## Molecular and Systemic Pathophysiology

Environmental lung diseased is caused by inhalation of a wide variety of agents in the environment. Causative agents fall into one or more of the following categories: allergens, organic dusts, inorganic dusts, chemicals or gases/fumes (Table 1). Exposure to these agents may manifest in different types of lung disease, the major categories being asthma, hypersensitivity pneumonitis, pneumoconioses, lung cancer and chronic obstructive pulmonary disease (COPD). Occupational and environmental asthma can be caused and/or triggered by airborne allergens or irritants. High molecular weight compounds such as insect, animal or bird proteins induce asthma via specific IgE-dependent reactions. Inhaled allergen is taken up by professional antigen presenting cells in the lung such as dendritic cells, which then migrate to the T-cell

**Lung Disease, Environmental. Table 1** Causative agents of environmental lung disease

| Nature of agent | Examples | Disease manifestations |
|---|---|---|
| Allergens | Animal dander, pollens, excreta | Asthma |
| Organic dusts | Grain | Grain fever |
| | Cotton | Byssinosis |
| | Mold spores | Farmer's lung |
| Inorganic dusts | Asbestos | Asbestosis/cancer |

rich area of draining lymph nodes. Presentation of allergen to naïve T-cells by dendritic cells is a critical step in polarizing Th0 helper cells into either Th1 or Th2 effector cells. Dysregulation of the immune response resulting in an excess of Th2 cells is thought to be critical in the pathogenesis of allergic asthma. Upon subsequent exposure, inhaled allergens bind to specific IgE on the surface of various cell types within the airway, particularly mast cells. This leads to a cascade of events resulting in the release of preformed and rapidly synthesized mediators (including histamine, cysteinyl leukotrienes and prostaglandins) which cause bronchoconstriction and the release of selected cytokines/chemokines which orchestrate the allergic inflammatory process. Low molecular weight compounds, such as platinum salts and acid anhydrides, are too small to act as complete antigens, and thus may elicit an immunologic response by acting as haptens. Inhalation of a variety of organic dusts (e.g., mold spores, cotton, grain), inorganic dusts (e.g., asbestos, silica, coal dust) or chemical irritants (e.g., ammonia, sulfur dioxide) over a prolonged period of time may cause lung disease [5]. Inhaled dusts can accumulate in the alveoli causing cytokines and other profibrogenic mediators to be released locally. This stimulates an inflammatory response, which is followed by fibroblast proliferation, collagen deposition and development of lung fibrosis, which can compromise lung elasticity and compliance. Chemical irritants cause direct injury to the airways, thus altering neural and/or epithelial modulation of airway responsiveness. Asthma-like symptoms can persist in some individuals following acute irritant chemical exposures and this phenomenon has been termed reactive airways dysfunction syndrome (RADS). Prolonged inhalation of environmental agents such as tobacco smoke can lead to lung cancer [4]. The precise molecular mechanisms through which such agents cause lung cancer is not known; however, recent studies suggest that the generation of free radicals and oxidative stress may play a prominant role.

## Diagnostic Principles

Patients with environmental lung disease present with similar signs and symptoms to patients with lung disease of other etiologies. Asthmatics usually present with episodes of breathlessness, wheezing, chest tightness and cough. Early symptoms of pneumoconiosis include chest tightness and shortness of breath, which can progress to severe respiratory insufficiency. Lung cancer patients typically present with hemoptysis, breathlessness, signs of lung consolidation or collapse, and various systemic symptoms. A detailed medical and environmental exposure history combined with physical examination, chest radiograph, lung-function studies and serology testing for sensitization should complete the diagnostic evaluation. Lung biopsy may be necessary in selected cases.

## Therapeutic Principles

Environmental lung diseases are generally chronic but progression can frequently be halted by reduction in or elimination of exposure to the offending agents. Medication, physical therapy and oxygen may be required depending on the nature and severity of the disease.

# Lung Disease in EBV Infection

Hideto Kameda
Division of Rheumatology/Clinical Immunology, Department of Internal Medicine, Saitama Medical Center, Saitama Medical University, Saitama, Japan

## Synonyms

EBV

## Definition and Characteristics

Epstein-Barr virus (EBV) is a gamma-group herpes virus. Most childhood infections are either symptomatic or mild febrile illnesses. Sometimes primary

EBV infection is delayed to adolescence and infectious mononucleosis may develop. Almost all affected individuals become life-long carriers, although 75% of males carrying mutations in the X-linked lymphoproliferative disease (XLP) gene will die within a month of primary EBV infection due to massive invasion of liver and bone marrow by cytotoxic T cells, macrophages and EBV-infected B cells [1].

EBV preferentially infects B cells, but occasionally infects other cell types, especially epithelial cells, and activates and/or transforms them. Thus, EBV-associated lung diseases do not only include lymphoproliferative diseases (LPD) but also include interstitial pneumonia such as idiopathic pulmonary fibrosis (IPF) and lung carcinoma.

EBV-associated LPD may include Burkitt's lymphoma, Hodgkin's disease, pyothorax-associated lymphoma and lymphomatoid granulomatosis. Lymphomatoid granulomatosis is characterized by bilateral pulmonary infiltrates with a necrotizing angiocentric and angiodestructive infiltrative process composed of small lymphocytes, plasma cells, histiocytes and atypical lympho-reticular cells. It usually develops in transplant recipients treated with immunosuppressive drugs and patients with AIDS.

## Prevalence

EBV infects more than 90% of the human population until adulthood. IPF frequently develops in immunocompromized patients. On the other hand, IPF and lung carcinoma usually develop in apparently immunocompetent hosts. One study demonstrated that 44% and 48% of patients with IPF were EBV positive by immunohistochemistry and PCR, respectively, while 10% and 14%, respectively, in control subjects. Moreover, 61% and 59% of IPF patients were positive for a rearranged form of EBV DNA in lung tissue and buffy coat, respectively, while none of lung transplant recipients and only 4% of normal blood donors were positive for lung tissue and buffy coat analysis, respectively [2]. As for lung carcinoma, EBER1 was detected in all 5 cases of lymphoepithelioma-like carcinoma, 6 of the 43 squamous cell carcinoma cases, while none of 67 adenocarinoma cases and 12 large cell carcinoma cases [3].

## Genes

EBV has a 173-kb DNA genome for which the nucleotide sequence and predominant transcripts are well characterized. EBV encodes 9 latency-associated proteins. Six of them are localized in the nucleus, namely, EBV nuclear antigens (EBNAs) 1, 2, 3A, 3B, 3C, and LP (leader protein). Three proteins in the membrane are latent membrane proteins (LMPs) 1, 2A, and 2B. EBV also expresses a family of complementary strand transcripts (CSTs) also known as BamHI A rightward transcript, and EBV-encoded RNAs (EBERs) 1 and 2.

## Molecular and Systemic Pathophysiology

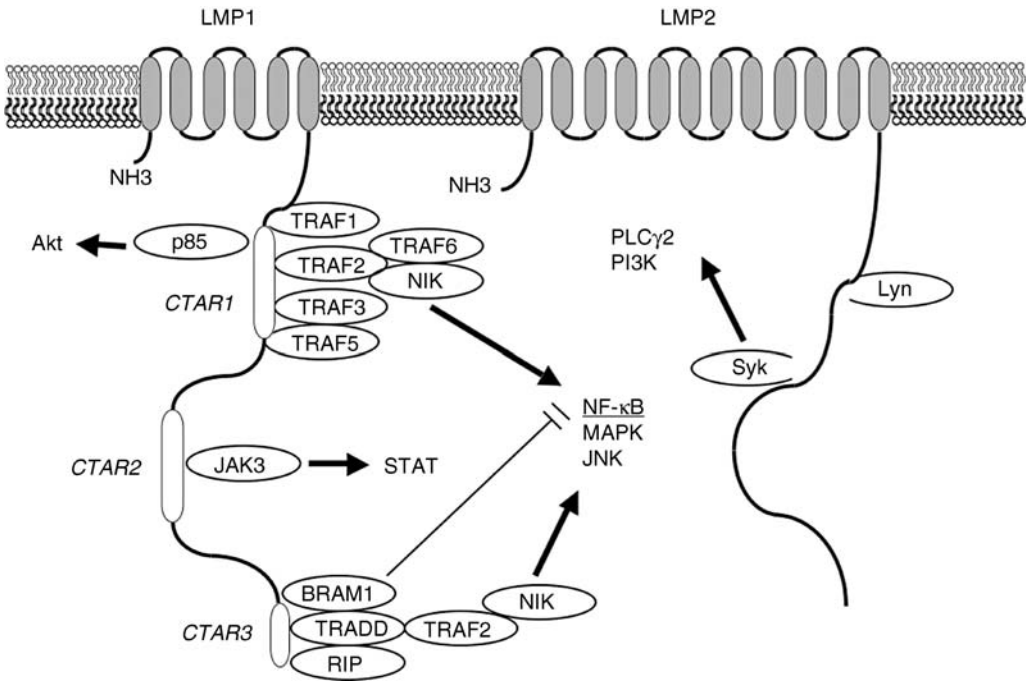
B cells require signals from T-helper ($T_H$) cells and through the B-cell antigen receptor (BCR) for survival. Key EBV proteins, LMP1 and LMP2A, mimic those activation pathways in a constitutively active ligand-independent manner (Fig. 1) [1].

The downstream signaling from LMP1 causes activation of nuclear factor-κB (NF-κB) inducing kinase (NIK) and subsequently NF-κB through C-terminal-activating region 2 (CTAR2) and, to a lesser extent, CTAR1. The activation of CTAR1 and CTAR2 is followed by the activation of p38/mitogen-activated protein kinase (MAPK) and c-Jun N-terminal kinase (JNK). On the other hand, CTAR2 is responsible for the activation of Janus-activated kinase 3 (JAK3) and signal transducer and activator of transcription (STAT). These signaling pathways are mostly shared with CD40 signaling cascade. The signaling from immunoreceptor tyrosine-based activation motifs (ITAMs) in the cytoplasmic domain of LMP2 includes Syk activation, followed by the activation of phospholipase Cγ2 (PLCγ2) and phosphatidylinositol 3 kinase (PI3K). In addition, the pathogenesis of lymphomatoid granulomatosis includes the recruitment and activation of cytotoxic T cells by monokine induced by interferon-γ (MIG) and inducible protein of 10 kD (IP-10).

Cellular activation and transformation through LMP1 signaling is also likely to be partly involved in the pathogenesis of IPF and some types of lung carcinoma. Indeed, cuboidal epithelial cells were positively stained with anti-LMP1 antibody exclusively in 9 of the 29 lung specimens from IPF patients, but not in those from 15 control subjects [4].

## Diagnostic Principles

In situ hybridization identifies EBER transcripts or EBV DNA in specific cell types, while immunohistochemistry identifies EBV protein expression and distinguishes latent from replicative infection based on expression profiles [5]. In EBV-infected tissues, 3 patterns of latent viral gene expression are observed: type 1 latency is characterized by the expression of only EBER transcripts, and EBNA 1 and LMP2A proteins; type 2 latency is characterized additionally by LMP1 and LMP2B coexpression; type 3 latency include the expression of all of the EBNAs, the LMPs, and EBER. Southern blot analysis assesses clonality of lesions with respect to EBV DNA structure and also distinguishes latent from replicative infection based on the episomal versus linear structure of the EBV genome. EBV viral load measurement by quantitative DNA amplification



**Lung Disease in EBV Infection. Figure 1** Structure of LMP1 and LMP2A and their associated signaling proteins. LMP1 consists of cytoplasmic amino-terminal and carboxy-terminal domains linked by 6 transmembrane sequences. It provides a surrogate $T_H$ cell signal. It interacts with tumor necrosis factor receptor (TNFR)-associated factors (TRAFs), TNFR-associated death domain protein (TRADD), JAK3, p85 subunit of PI3K and receptor-interacting protein (RIP). Bone morphogenetic protein receptor-associated molecule 1 (BRAM1) is considered to serve as a negative regulator of LMP1-mediated NF-κB signal pathways. Activated PI3K produces phospholipids that activate Akt, which suppresses apoptosis and promotes cell survival. LMP2A consists of cytoplasmic amino-terminal and carboxy-terminal domains linked by 12 transmembrane sequences. It interacts with members of the Src family of tyrosine kinases through possession of the same ITAMs found in the α- and β-chains of the BCR, and elicits signals in favor of B cell survival.

may be adequate to screen and monitor EBV expression in the blood or body fluid. Antibody assay for viral capsid antigen (VCA), EBNA, or early antigen (EA) distinguishes acute from remote infection.

### Therapeutic Principles

An established therapy for EBV-related lung diseases is not available. Corticosteroids, immunosuppressive/cytotoxic agents, or biologic response modifiers such as rituximab may be considered for some cases.

## Lung Disease in Hay Fever

Jonathan Corren
Allergy Research Foundation, Los Angeles, CA, USA

### Definition and Characteristics

IgE-mediated inflammation of the nose and lower airways caused by exposure to specific allergens.

### Prevalence

Approximately 25% of patients with allergic rhinitis have concomitant asthma [1]. In patients with rhinitis alone, nonspecific bronchial responsiveness to inhaled methacholine or histamine is elevated in 50–70% of patients. In this group of patients with airway hyperresponsiveness, FEF25–75% has been noted to be significantly lower and airway resistance significantly higher than values measured in allergic rhinitis patients with normal bronchial reactivity. Longitudinal studies

have demonstrated that patients with allergic rhinitis and no lower airway symptoms have a twofold to threefold higher risk of developing asthma than patients without rhinitis, and this risk is related to the severity and duration of nasal disease as well as the pre-existing level of nonspecific bronchial responsiveness [2].

## Genes

Genes coding for CD14, PTGD receptor, STAT 6, IL-4, IL-13 and VEGF receptor may all contribute to the susceptibility to allergy, bronchial hyperresponsiveness, and asthma [3].

## Molecular and Systemic Pathophysiology

Allergic rhinitis and asthma share a common immunopathology and pathophysiology [3]. In genetically susceptible individuals, allergen exposure induces $CD4^+$ T cells, and later other cells, to secrete IL-4, which promotes T-cell secretion of all $TH_2$ cytokines. The most central of these cytokines may be IL-13, which acts on smooth muscle cells, epithelial cells, vascular endothelial cells, fibroblasts, and nerve cells through STAT6 to promote airway hyperresponsiveness, goblet cell hyperplasia, chemokine production, inflammatory cell infiltration, and increased vascular permeability. Eosinophils represent the most prominent infiltrating cell, and following activation release a number of proinflammatory molecules including lipid-derived mediators (sulfidopeptide leukotrienes), cationic proteins (major basic protein, eosinophil cationic protein), and cytokines (IL-4, GM-CSF). In addition to shared elements of pathophysiology and immunopathology, nasal dysfunction may directly influence the lower airways. Nasal allergen challenge has been shown to cause immediate increases in nonspecific bronchial responsiveness as well as lower airway inflammation, while bronchial challenge with allergen has been demonstrated to induce nasal inflammation. In both cases, induction of inflammation at the other end of the respiratory tract occurs in the presence of blood eosinophilia, implying a systemic connection between these compartments [4].

## Diagnostic Principles

As a general rule, all patients with chronic rhinitis should be assessed for the presence of specific IgE to air-borne allergens by immediate skin testing or in-vitro analyses. In addition, all patients with persistent rhinitis should be evaluated for the possibility of concomitant asthma. A history of recurrent symptoms of wheezing, chest tightness, or cough or observation of wheezing on examination are strongly suggestive of bronchial asthma and should prompt the performance of spirometry (for assessment of the forced vital capacity, forced expiratory volume in one second, and flow rates occurring during the middle of forced expiration) in order to accurately characterize the degree of airways obstruction. In patients with recurrent chest symptoms, particularly isolated cough, and normal pulmonary function, it may be useful to assess bronchial responsiveness to inhaled methacholine or fractional expired nitric oxide as a guide to subsequent therapy.

## Therapeutic Principles

In patients who suffer from allergic rhinitis and asthma, both the upper and lower airways disease may benefit significantly from the use of intranasal corticosteroids. A number of small clinical studies have consistently demonstrated that intranasal corticosteroids improve bronchial hyperresponsiveness to inhaled bronchoconstrictor agents and large population-based studies have shown that intranasal corticosteroids cause significant reductions in asthma exacerbations requiring in-patient hospital care. The effects of systemic therapy with specific mediator antagonists have also been studied in patients with rhinitis and asthma. Oral H1 antihistamines, which may be moderately effective in allergic rhinitis, are only minimally effective in allergic asthma and have minor effects on pulmonary function. Leukotriene receptor antagonists, which are an established therapy for asthma, generally have only mild effects upon allergic rhinitis. Optimal pharmacologic results are most often obtained using a combination of intranasal and orally inhaled corticosteroids. In patients with allergic rhinitis alone, both sublingual and subcutaneous immunotherapy have been shown to reduce the development of asthma.

## Definition and Characteristics

While any subdivision of LE (lupus erythematosus) is arbitrary, a scheme based on the clinical presentation and disease course is practically useful despite the lack of a unifying etiology:

1. *Systemic lupus erythematosus* (*SLE*) (=lupus erythematodes disseminatus (LED)). The most serious and recognized subset, where immune-complex mediated inflammation can affect any organ system. Associated with increased mortality and antinuclear antibodies.
2. *Discoid lupus erythematosus* (*DLE*) (=chronic cutaneous LE (CCLE)). Characterized by typical discoid (=coin-shaped), scaling skin lesions that may result in severe scarring. Involves mostly the face, scalp, and neck (typical V-shape), but can occur in areas not usually exposed to sunlight. Erythematous and/or ulcerative mucosal lesions may be present. Antinuclear antibodies are found in a minority of patients, SLE developing in about 5%.
3. *Subacute cutaneous lupus erythematosus* (*SCLE*). An LE subset with typical widespread annular skin lesions, easily provoked by UV light exposition and associated with anti-SSA (Ro) antibodies. About half will have/develop SLE.
4. *Neonatal lupus erythematosus* (*NLE*). Passively transferred autoimmune disease, where maternal antibodies against SSA (Ro) can induce reversible skin and hematological manifestations and irreversible heart lesions (AV-block and cardiomyopathy) in the newborn.
5. *Drug-induced lupus erythematosus* (*DILE*). First described after hydralazine use, now associated with a long list of pharmaceutical drugs and environmental toxics; often presenting with joint and skin symptoms and associated with antibodies against the H2A–H2B subcomplex of the nucleosome. Rapid resolution after withdrawal of the offending drug is the rule.

## Prevalence

SLE: 1:1,000 adults among Caucasian females. Increased prevalence (and severity) in populations with non-Caucasian descent [1]. Female to male ratio about 10:1. Prevalence unknown for other subsets.

## Genes

LE is a polygenic disorder [2]. Strongest confirmed susceptibility genes for SLE are HLADR2 (DRB1*1501), HLADR3 (DRB1*0301), C1A*Q0, C2*Q0, C4A/B*Q0, FcγRIIA (H131R), FcγRIIA (F176V), PDCD1(PD1.3A).

## Molecular and Systemic Pathophysiology

LE is caused by an unexplained loss of tolerance to self-antigens leading to the activation of several immune cell types. This results in the production of characteristic autoantibodies, which may form immune complexes with specific or closely related antigens throughout the body and have the potential to induce inflammation. T cell-mediated activation of autoreactive B cells resulting in the production of nephritogenic anti-dsDNA antibodies through antibody maturation has been elucidated as a pathogenic pathway in SLE patients. Still unknown remain the eliciting antigen(s) (nucleosomes, possibly altered during inappropriate apoptosis, are a possible culprit) and the specifics of the interaction between immune complexes, intrinsic or planted antigens, and immune cell receptors. The traditional lupus band test (immune complex deposition in both affected and unaffected skin) and experimental models serve as reminders that immune complex deposition alone is not the only requirement for the development of skin and glomerular lesions [3,4].

## Diagnostic Principles

Due to the lack of a specific test (S)LE remains a clinical diagnosis based on the recognition of a complex of symptoms in the context of autoimmunity (Table 1).

While fulfilling four of the updated ACR criteria for the classification of SLE is generally accepted as specific enough for defining patient cohorts for scientific purposes, their retrospective design makes them less suitable for diagnostic purposes in clinical practice [5]. A widely applied strategy uses the presence of antinuclear antibodies (i.e., a positive

[a]For detailed definitions see http://www.rheumatology.org/publications/classification/SLE/1982Revised_Criteria_Classification_SLE.asp?aud = mem. X indicate criteria not included in that set. Sensitivity and specificity refer to data from the original US publication.

[b]Specificity was estimated against a control group of 118 patients with inflammatory joint disease and 36 patients with other types of connective tissue disease. NA, data not available.

ANA screening test by any assay) accompanied by three other ACR criteria as an alternative, but validated diagnostic approach [5]. A negative ANA-screening test using the sensitive, but unspecific immunofluorescence assay with HepG2 cells as substrate, rules out SLE (with the standard exceptions). Ideally, positive ANA-screening findings should be accompanied by the presence of more specific markers for SLE (antibodies against dsDNA, Sm, ribosomal protein P, or other ENA antibodies) to confirm the diagnosis, but this remains a matter of debate. Also, a considerable number of patients have other manifestations (e.g., Raynaud, hypocomplementemia, alopecia) and when not fulfilling the current ACR criteria, they are designated to have Lupus-like disease, incomplete LE, or undifferentiated connective tissue disease (UCTD). Management is, however, similar to patients fulfilling ACR criteria.

## Therapeutic Principles

There is presently no cure for SLE. The remarkable clinical efficacy of corticosteroid therapy in SLE has resulted in a lack of solid data on Prednisone usage for

SLE. Most randomized trials in SLE compared immunosuppressive drugs in proliferative lupus nephritis while disregarding the role of steroids. Observational studies have established the therapeutic efficacy of antimalarial drugs. Guidelines for SLE treatment in general are thus mostly eminence-based; physicians need to take into account the severity of current clinical symptoms and the risk for subsequent end-organ failure (i.e., hot and unpredictable versus mild and consistent lupus) while balancing drug efficacy against side-effects. Pharmaceutical options to suppress disease manifestations range from NSAID, corticosteroids (topical, oral, or i.v. push), and antimalarials to nonselective immunosuppressive drugs (cytotoxic drugs, cyclosporine/tacrolimus). Recently, more specific "biological" therapy with monoclonal antibodies resulting in B cell depleting (anti-CD20) or blockade of costimulatory signals (CTLA4-Ig) has been introduced for refractory cases and drugs targeting other mediators of inflammation (CD40L,CRP,IL-6, Blys) are likely to follow. Given the increased life expectations, close attention should be paid to the prevention of comorbid conditions that occur with increased frequency in SLE patients. This includes, reducing infections by an individually designed vaccination program and reducing the risk for accelerated atherosclerosis, thromboembolic disease, and osteoporosis by addressing the relevant risk factors.

## Lutembacher's Syndrome

Alexander Olivares-Reyes
Guerriari Heart & Cardiovascular Institute, Penisula Regional Medical Center, Salisbury, MD, USA

L

### Synonyms

Mitral stenosis; associated with atrial septal defect; ASD; both congenital and acquired; Lutembacher's disease; LBS

### Definition and Characteristics

The uncommon combination of an acquired or congenital mitral stenosis (generally rheumatic) and a congenital, or iatrogenic atrial septal defect, or even a patent foramen ovale (PFO), as well as any left-to-right shunt is known today as Lutembacher's syndrome (LBS) [1–3].

### Prevalence

Mitral stenosis (MS) is found in 4% of patients with an atrial septal defect. Congenital MS, itself, is very rare accounting for only 0.6% of congenital heart disease. The incidence of ASD in patients with MS is 0.6–0.7%. The association of MS and ASD was found in five cases (0.02%) in one US study of 25,000 autopsies. This syndrome is more commonly observed in adult females; reason being both ASD and MS are more frequent in females [1].

### Genes

Today, there is no known gene associated with this syndrome, however, familial occurrences have been reported but this is an isolated observation [4,5].

## Molecular and Systemic Pathophysiology

The etiology of ASD in this syndrome, like mitral stenosis, is recognized as being either congenital or acquired as associated with LBS. High left atrial pressure due to MS was thought to stretch open the patent foramen ovale causing a left-to-right shunt and providing another outlet for the left atrium [1–3]. The hemodynamic effects of this syndrome are a result of the interplay between the effects of ASD and MS. The direction of blood flow is determined largely by the compliance of left and right ventricles. Normally, the right ventricle is more compliant than the left ventricle. In the presence of MS, blood flows to the right atrium through the ASD instead of going into the pulmonary veins, thus avoiding pulmonary congestion. This causes progressive dilatation and ultimately, failure of the right ventricle and reduced blood flow to the left ventricle.

When mitral stenosis and ASD occur together, like in Lutembacher's syndrome, each lesion modifies the clinical and hemodynamic expressions of the other. The resulting clinical manifestations will depend mainly upon three conditions: (i) the size of the ASD, (ii) the severity of the MS, and (iii) distensibility characteristics of the right ventricle. The hemodynamic benefit of an ASD in the MS of a patient with LBS constitutes a second exit for left atrial blood; consequently, the typical hemodynamic effects of a tight mitral stenosis ameliorate proportionally to the size of the left-to-right shunting. In the same fashion, the increased pressure in the left atrium, the pulmonary veins, and the pulmonary capillaries decrease if the ASD is large. Likewise, classical symptoms associated with pulmonary venous congestion of important MS such as orthopnea, paroxysmal nocturnal dyspnea, hemoptysis, and pulmonary edema are attenuated and/or retarded. In contraposition, these symptoms are substituted by weakness and fatigue due to low systemic output.

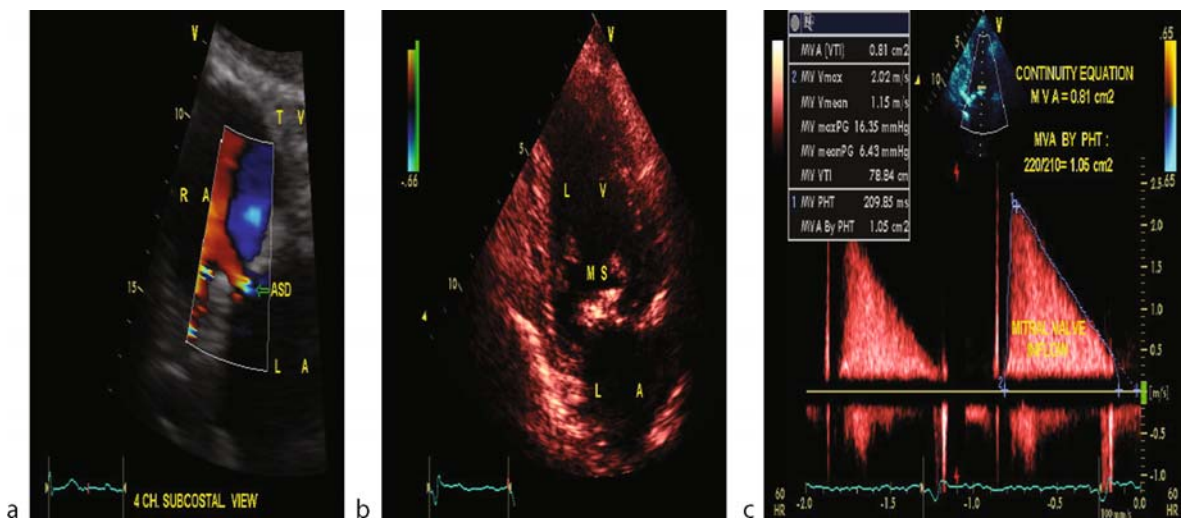
## Diagnostic Principles

The association of MS and ASD or PFO in a patient constitutes the Lutembacher's syndrome. This cardiohemodynamic abnormality could be diagnosed clinically and well confirmed by transthoracic or transesophageal echocardiography including color and spectral Doppler modalities (Fig. 1), as well as by cardiac catheterization.

This can evaluate the severity of the ASD, detect reversible pulmonary hypertension, measure the mitral valve area by the Gorlin formula, and evaluate the presence of coronary artery disease in high-risk patients.

## Therapeutic Principles

(i) Medical care for symptomatic relief include diuretics, digitalis, beta-blockers, calcium channel blockers, and antibiotics (as prophylaxis for sub-acute bacterial endocarditis). Patients with LBS, unlike those with isolated ASD, are at high risk for endocarditis owing to associated mitral stenosis. (ii) Diet: Patients should adhere to



**Lutembacher's Syndrome. Figure 1** Echocardiographic images of a patient with classic Lutembacher's syndrome. (a) shows a color Doppler flow crossing the interatrial septum from left atrium (LA) to right atrium (RA) in a subcostal view, demonstrating an atrial septal defect (ASD). (b) shows a 2D transthoracic echocardiogram in an apical two-chamber view evidencing the mitral valve thickening and calcification typical of mitral stenosis (MS), and in (c) there is a continuous wave Doppler image showing the continuity equation formula evidencing a severe mitral estenosis [mitral valve area (MVA) of 0.81 $cm^2$], as well as calculated valve area by pressure half time formula (PHT). The combination of ASD and MS constitutes the diagnosis of Lutembacher's syndrome. *LV* left ventricle; *TV* tricuspid valve.

a low-sodium diet. (iii) Activity should be as tolerated by the patient. (iv) Surgical care for opened mitral valve commissurotomy or valve replacement or for ASD closure. Surgery is now performed early rather than late because the rates of heart failure and cardiac arrhythmia increase with age. (v) Percutaneous mitral balloon valvuloplasty and/or the closure of ASD. In general, the prognosis of Lutembacher's syndrome is good and most patients live to adulthood. The causes of death are usually: (i) cardiac failure; (ii) paradoxical embolism (emboli pass through the left-to-right shunt); (iii) bacterial endocarditis; (iv) pulmonary hemorrhages incident to the pulmonary hypertension; (v) development of brain abscesses; and (vi) intercurrent systemic infections.

### Definition and Characteristics

Lyme neuroborreliosis (LNB) is a tick-borne disease of the peripheral and/or central nervous system caused by the spirochete Borrelia burgdorferi (Bb) sensu lato. Bb can be divided into four human pathogenic species: Bb sensu stricto (the only human pathogenic species present in the US), B. afzelii, B. garinii and B. spielmanii.

The infection by Bb is a complex process beginning with the translation from the gut to the salivary glands of the tick during the feeding process on the host. After invasion into the skin, Bb can cause a local infection called erythema migrans. During the second stage of Lyme borreliosis, Bb can spread from the site of the tick bite to various organs throughout the body, including the heart, joints and the peripheral and central nervous system (CNS) [1].

The most frequent manifestation of acute LNB in Europe is meningoradiculitis (Bannwarth's syndrome, BS), characterized by intense lancinating radicular pain especially at night, paresis of the extremities or of cranial nerves and inflammatory cerebrospinal fluid (CSF) changes [1]. In BS, the most frequent species isolated from the CSF is B. garinii. Accordingly, BS rarely occurs in the US, where meningitis is the predominant neurological manifestation, suggesting a certain organotropism of the different genospecies.

Chronic neuroborreliosis (stage 3) mainly includes chronic progressive encephalomyelitis, cerebral vasculitis and acrodermatitis chronica atrophicans associated polyneuropathy.

### Prevalence

No exact data, estimation: 2–10:100,000 (in endemic areas).

### Molecular and Systemic Pathophysiology

As there exists no murine model of LNB, most of the research has been done either in cell culture experiments or in the Rhesus macaque. Therefore, little is actually known about the exact pathogenesis of LNB.

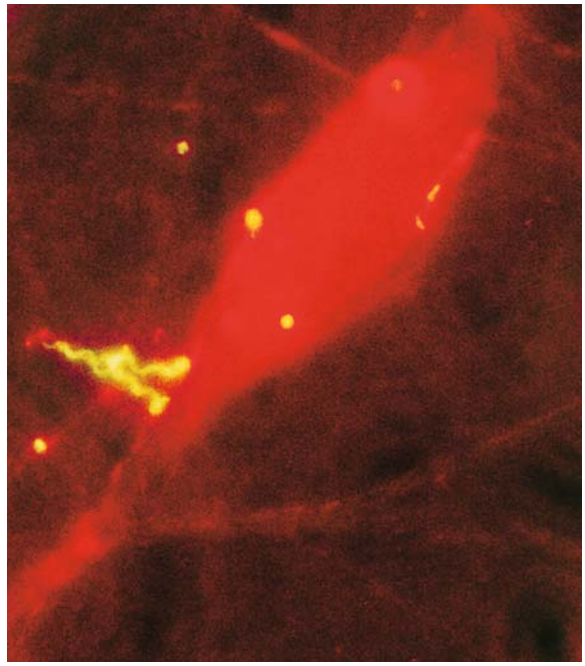
Borrelia have been detected at the sensory nerve roots and dorsal root ganglia (probable targets in BS) in the macaque [2]. In parallel, isolation of Bb from human CSF suggests a direct invasion of the nervous system. It is known from in vitro experiments, that Bb possesses the ability to adhere to endothelial cells. An interaction of the different outer surface proteins (Osp's) of Bb with E-selectin, P-selectin, ICAM-1 and/or VCAM-1 on the host cell appears to be involved in this adhesion process. In addition, the spirochete uses enzymes of the host such as plasmin to degrade the extracellular matrix and possibly to pass the blood-brain barrier (BBB). Once having entered the central nervous system (CNS), Bb elicits an inflammatory response, as high levels of several cytokines have been measured in the CSF of LNB patients [3] and the ability of Bb to induce cytokines in leucocytes has been shown in vitro.

One of these cytokines, CXCL13 (formerly B lymphotactic chemokine), might play a prominent role as (i) it has been detected at high levels in the CSF of LNB patients but not other inflammatory CNS diseases [3], (ii) this chemokine attracts B-lymphocytes, a dominant cell type in the CSF of LNB patients though rare in other inflammatory CNS diseases and (iii) the CXCL13 levels correlate well with the cell number in the CSF of these patients [3].

How exactly the borrelia elicit the observed clinical neurological symptoms is not yet fully understood. Typical forms of acute LNB like the BS respond well to antibiotic therapy, which hints at a direct effect of the spirochetes. As Borrelia are not known to produce toxins, the interaction and association of the bacteria with host cells is presumed to be important in the development of disease. In a recent study, we showed that B. garinii adhere to dorsal root ganglia cells (Fig. 1) [4] and exert a cytotoxic effect (unpublished).

In addition, the inflammatory reaction of the host could be neurotoxic through the production of oxygen radicals like NO. In cases of polyneuropathy, the degeneration of the axons was attributed to a vasculitis of the vasa nervorum. Finally, the presence of antineuronal antibodies has been demonstrated. This might be involved in the pathogenesis of chronic neuroborreliosis not responding to antibiotic therapy. However, it has to be kept in mind that cases of "chronic neuroborreliosis" without an adequate response to antibiotics most often represent a misdiagnosis rather than antibiotic refractory Borrelia infection [5].

A hallmark of LNB is the intrathecal production of Bb specific antibodies. However, these antibodies often fail to eliminate the spirocheteal infection, which might be attributed to the variability of the immunodominant Osp's. This could account for the development of chronic diseases in untreated patients.



**Lyme Neuroborreliosis. Figure 1** Two borrelia (yellow-green) adhere to a dorsal root ganglia cell (red) from a mouse fetus.

## Diagnostic Principles

The diagnosis of clinically suspected LNB is based on the presence of lymphocytic pleocytosis in the CSF and intrathecal Bb specific antibody production (expressed by the antibody index, AI) [1] which is positive in 70–90% of patients with a short disease duration and in nearly 100% with a disease duration of more than 6–8 weeks. However, the antibody production might be absent in early stages of the disease and antibiotic therapy has often to be initiated before the results of the AI are available. Other diagnostic tools such as culture of Bb from CSF or detection of Bb DNA by PCR have a high specificity but lack a sufficient sensitivity and are therefore not recommended for routine clinical use. A recently discovered additional CSF-marker, the chemokine CXCL13, appears to be a promising candidate as it is already highly expressed early in the disease and declines (in contrast to the AI) during treatment [3]. However, this marker has to be further validated in larger clinical studies.

## Therapeutic Principles

The therapy of choice for LNB is ceftriaxone 2 g/day intravenously for 2–3 weeks, the latter being recommended for chronic cases [5]. Doxycycline (dosage 200 mg/day orally) might be an alternative in early LNB especially in case of cephalosporin allergy. Treatment

failures are rare and suspected failures or relapses should question the diagnosis and lead to a further diagnostic workup.

## Definition and Characteristics

Lymphedema has been defined as a disease, arising from an accumulation of protein-rich interstitial fluid in soft tissues, and generally classified as primary or secondary. While primary lymphedema occurs rarely on idiopathic or developmental abnormalities in the lymphatic system, secondary lymphedema commonly develops when lymph transport is interrupted due to physical disruption or compression of lymphatics, or resection of lymph nodes in trauma, surgery, neoplasia, infection (recurrent erysipelas, filariasis), or radiation [1]. The dysfunctional lymphatics usually lead to disabling and disfiguring swelling of the extremities because of hydrostatic pressure and inefficient collateral lymph drainage in the terminal parts. Primary lymphedema shows an autosomal dominant pattern of inheritance with variable degrees of penetrance, and can be present at birth (congenital), at puberty (praecox) or, more rarely, at adulthood (tarda) (Table 1). Secondary lymphedema can be accompanied with original (causative) clinical features. The usual complications of lymphedema include fibrosis and cellulitis in the affected tissues.

## Prevalence

The estimated prevalence in primary lymphedema is 1:6,000–1:10,000. The incidence estimate of secondary lymphedema is difficult due to variability like extent of surgery or radiotherapy, and duration of follow-up.

## Genes

*MD*: FLT4 (136352), a gene encoding the vascular endothelial growth factor receptor-3 (VEGFR-3).
*ML, LDS, LP, and YNS*: FOXC2 (602402), the "forkhead" (or winged helix) gene family, originally identified in Drosophila, encodes transcription factors with a conserved 100-amino acid DNA binding motif.
*NS*: PTPN11 (176876), a gene encoding the nonreceptor protein tyrosine phosphatase SHP2.
*HLTS*: SRY-BOX 18; SOX18 (601618), the testis-determining gene SRY (480000) encodes a transcription factor characterized by a DNA-binding motif known as the high mobility group (HMG) domain. The SOX gene family consists of genes related to SRY, with a sequence identity of more than 60% to the SRY HMG box, (Table 1).

## Molecular and Systemic Pathophysiology

The accumulation of protein-rich interstitial fluid in lymphedema represents an imbalance between capillary

*Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim/).

filtration and lymph drainage. The causative factors resulting in insufficient lymph drainage mainly include obstruction, disruption, or dysplasia of functional lymphatics. In primary lymphedema, the lymphatics are usually hypoplastic or aplastic, and fail to transport lymph fluid into the venous circulation. In particular, inefficiency in the transport of interstitial macromolecules leads to an increase of oncotic pressure in affected tissues, inducing edema formation. The pathological conditions are further worsened due to lipid accumulation, lymphatic valvular abnormality, and reduced trafficking of immune cells. Lymphedema results in altered immunocompetence, partly because dendritic cells, T lymphocytes, and macrophages exert their immune effects by migrating from peripheral sites through lymphatics to regional lymph nodes for the establishment of adaptive/cellular immune responses. The modulation of extracellular matrix and glycosaminoglycans, chemokines, cytokines, growth factors, and adhesion molecules may have diverse effects on local tissue environment [2]. In the swelling tissues, stagnant protein provides an excellent medium for repeated bouts of cellulitis and lymphangitis, and progressively leads to irreversible interstitial fibrosis, hyperkeratosis and extensive remodeling (so-called elephantiasis). Recent insights into molecular genetic bases have shown an updated genotype–phenotype correlation between lymphangiogenesis, lymphatic function, and lymphedema. VEGFR-3 and FOXC2 have proven to be important factors of the genetic cascade linking to hereditary lymphedema, and embryonic and postnatal lymphatic development [3–5]. The mechanisms of hypoplasia or aplasia in lymphatic tissues may be a signaling response to a stable mutant form of the receptor on the cell surface [5]. The discovery of specific genes and signaling cascades involved in the regulation of lymphatic function and pathogenesis has provided a basis for developing novel targeted therapy for the disease.

## Diagnostic Principles

Lymphedema is initially detected as soft and pitting, and gradually becomes nonpitting, firm and brawny. Pain rarely occurs, but is related to conditions, such as infection, thrombosis, nerve injury, or tumor recurrence. There is not a unanimously accepted criterion to diagnose lymphedema. The arbitrary or subjective methods limit the possibility to make meaningful clinical comparisons or decisions. Lymphedema assessment is mainly depending on physical measures and imaging techniques. The physical evaluation includes circumferential and volumetric measurements, and skin/soft-tissue tonometry. Ultrasound examination, MRI, CT scanning, lymphangiography, or lymphoscintigraphy may help to confirm the diagnosis. The finding of germline mutations (VEGFR-3, FOXC2, PTPN11, SOX18) permits early diagnosis and treatment of hereditary lymphedema that is usually differentiated from secondary lymphedema by history as well. Thus, the medical and family history should not be neglected in a thorough clinical diagnosis.

## Therapeutic Principles

A rational therapy must be based on the knowledge of the pathophysiology to increase lymph transport

and remove excess interstitial fluid, to decrease oncotic pressure and blood vascular permeability, and to soften fibrotic induration. The complex decongestive physiotherapy is a basic therapeutic regimen for lymphedema, which includes manual lymph drainage, skin care, compression (pneumatic pumps, bandaging and garments), and remedial exercises. Medications (benzopyrones and diuretics), low level laser therapy, and lymphovenous anastomosis are also applied in some cases. Given the profound clinical and genetic heterogeneity in lymphedema, positional candidate gene analysis in affected families would facilitate the management of environmental factors influencing the expression and severity of lymphedema. Genetic counseling will benefit people with hereditary lymphedema and their families. Indeed, genetic identification of the FOXC2 and VEGFR-3 pathways has provided molecular clues to developing rational therapeutic approaches both for primary and secondary forms of lymphedema. The administration of VEGF-C to the affected tissues combined with other lymphangiogenic factors could be a powerful threapeutic tool. VEGF-C-induced lymphangiogenesis can improve overall lymphatic dysfunction and prevent chronic changes accompanied by lymphedema. However, high levels of VEGF-C may induce blood vascular growth and leakiness, aggregate edema and stimulate tumor lymphangiogenesis and metastasis [2]. Strategies to avoid these side effects have important implications for the development of new therapies for human lymphedema.

## Definition and Characteristics

Currently there are 40 inherited lymphedema (LE) syndromes and a few more of sporadic origin [1]. At least 36 have been studied in detail as regards specific organ/system involvement [2]. Classification is based on descriptive categories and severity is based on superficial external examination of the limb or torso. They present a wide spectrum of lymphatic and developmental growth disorders (Table 1).

LE is often mild and limited to below the knee but can be extensive with chylous ascites, pleural effusions or cystic hygromas, lymphangiomas, fetal hydrops and even fetal demise. Ocular anomalies (involving vision or structural defects such as hypertelorism, conjunctival abnormalities/edema ptosis, glaucoma) are found in almost 70% of the syndromes. More than 50% of the syndromes present dysmorphic facial features (most commonly flat/broad nasal bridge, deformed ears, cleft/high-arched palate, micrognathia). Thoracic and vertebral anomalies (pectus excavatum, scoliosis/kyphosis) are seen in about 50% of all LE syndromes. Growth retardation is present in almost half of the syndromes. Cardiac and pulmonary anomalies

(chylothorax, pulmonary lymphangiectasia) are seen in about 40% of all cases. Immune dysfunction (splenomegaly, IgG deficiency) and blood vessel and/or hematological abnormalities/malignancies (placental villous edema, single umbilical artery, venous varicosities) are seen in 30–40% of syndromes. Central nervous system abnormalities (most commonly hypotonicity, cerebral/cerebellar atrophy, seizures, spasticity,

impaired vision, deafness) and/or gastrointestinal anomalies (visceral lymphangiectasia, peripheral lymphedema) and/or genitourinary anomalies (kidney defects, genital edema) are seen in one third of all LE syndromes.

## Prevalence

LE on its own is not normally recorded at birth, but combined with Turner (XO) syndrome or trisomy 21 (Down syndrome) there can be several affected children/1000 live births. In USA, primary LE accounts for 10,000–100,000 cases; secondary LE cases (from trauma, cancer staging, invasion or treatment (surgery, irradiation)) are estimated at more than a million. World Health Organization estimates more than 100 million acquire LE from parasitic (filarial) infections worldwide.

## Genes

Of the 40 hereditary LE syndromes, 11 are autosomal dominant, 19 are autosomal recessive, 6 are X-linked and 4 show a sporadic pattern of inheritance. However, chromosome linkage and specific gene mutations have been identified in only three syndromes: Type I hereditary lymphedema or Milroy disease (chromosome 5q35.3; VEGFR-3 gene mutations), Lymphedema-distichiasis (chromosome 16q24.3 (inactivated due to translocation of Y); FOXC2 nonsense, frame-shift gene mutations) and Hypotrichosis-lymphedema-telangiectasia (chromosome 20q13.33; SOX-18 nonsense, mis-sense gene mutations). Transgenic and knockout animal models have implicated some other genes (e.g. VEGF-C, Angiopoietin2, EphrinB2, neuropilin2, Podoplanin, Prox-1, Integrin α9β1 and Net) in the development and/or maintenance of lymphedema but their exact role in humans is yet to be demonstrated [1].

## Molecular and Systemic Pathophysiology

Edema may be delayed in onset or may disappear for several months to years and reappear. Patients may present with or eventually develop massive lymphangiectasia, valvular destruction and retrograde flow [3]. The result is tissue swelling, scarring and disturbances in the immunological, nutritional and angiogenic pathways. In addition to high protein edema, fibrosis and fat deposition take place. Lymphangiogenesis and hemangiogenesis may become uncontrolled associated with vascular neoplasia including rapidly fatal angiosarcomas. The lymph stasis with eventual intractable edema leads to characteristic trophic skin changes (thickened toe skin folds (Stemmer's sign), warty overgrowth and brawny induration).

## Diagnostic Principles

There are four imaging techniques available: conventional oil-contrast lymphangiography (LAG), lymphangioscintigraphy (LAS), magnetic resonance imaging (MRI) and computerized tomography. LAS is considered a better choice than LAG as it is non-invasive, technically less demanding, less toxic, and offers better functional information [4]. High-resolution magnetic resonance lymphangiography, fluorescent/infrared and ultrasound imaging may become more useful in the future.

## Therapeutic Principles

Current therapies are mainly symptomatic and aim to ameliorate the external and internal, visceral manifestations of LE (soft tissue and organ swelling, serous effusions, tissue fibrosis and fat deposits, lymph fluid loss, malnutrition, imunodysregulation, neoangiogenesis) [5]. Physical manipulative treatments, such as CPT (multimodal combined physiotherapy utilizing compression bandages), MLD/MLT (manual lymph drainage/manual LE treatment utilizing gentle massaging) and compression garments, are widely practiced. Surgical treatments such as lymphatic-venous shunts, lymphatic transplantation, liposuction, and debulking of hypertrophic skin and excess subcutaneous tissues, are utilized in selected patients. Alternative medicine approaches remain controversial.

Looking ahead, LE syndromes need to be better defined in terms of the underlying pathophysiologic, genetic and molecular abnormalities along with more precise delineation of the lymphatic phenotype through refined higher resolution dynamic imaging in order to generate more effective management or prevention. The events associated with lymphatic failure (reduced lymphatic absorption/transport, lymphedema accumulation and its sequelae) await better understanding and quantitation. Molecular and cellular approaches to therapy, including gene therapy and protein replacement, stem cell therapy, and tissue engineering, should be developed and tested to achieve optimal lymphatic vessel growth and blood-lymph loop dynamics.

# Lymphocyte Leukemia, Large Granular

Lubomir Sokol
Division of Malignant Hematology, Department of Interdisciplinary Oncology, H. Lee Moffitt Cancer Center and Research Institute, University of South Florida, Tampa, FL, USA

## Synonyms

*Indolent:* T-cell LGL leukemia; Chronic natural killer (NK) cell leukemia/lymphocytosis; *Aggressive*: aggressive T-cell LGL leukemia; Aggressive NK cell leukemia

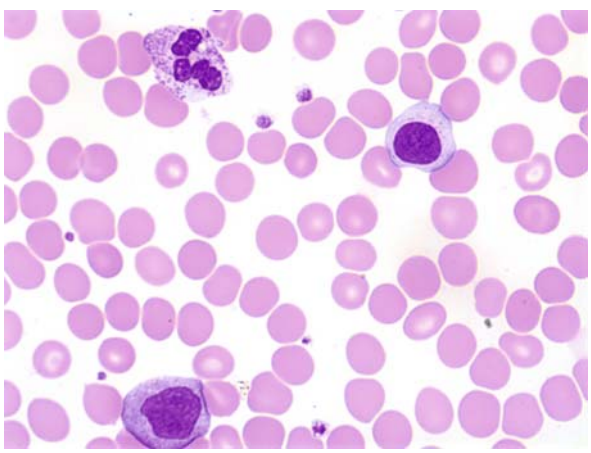
## Definition and Characteristics

Clonal disorders of large granular lymphocytes (LGLs) represent a biologically heterogeneous group of hematological diseases ranging from indolent to very aggressive [1]. LGLs are medium to large cells with eccentric nuclei and abundant cytoplasm with coarse azurophilic granules (Fig. 1).

Leukemic LGLs express a mature T cell (CD3+) or NK-cell (CD3−) immunophenotype. Most frequent immunophenotypic variants of indolent and aggressive LGL leukemia are described in Table 1.

## Prevalence

Disorders of LGLs are rare conditions representing only 2–5% of all T/NK-cell malignancies in the USA. Indolent T-cell LGL leukemia is the most frequent subtype diagnosed in Western countries. This entity manifests in older subjects with a median age of 60 years. The male to female ratio is equal. Prognosis is good with median survival over 10 years. Rare cases of aggressive T-cell LGL leukemia with poor prognosis have also been reported [2]. Chronic NK cell leukemia/lymphocytosis usually has an indolent course similar to indolent T-cell LGL leukemia. Aggressive NK cell leukemia typically occurs in younger subjects with a median age of 39 years. This condition with very poor prognosis has a higher prevalence in Asia and South America [1].



**Lymphocyte Leukemia, Large Granular.**
**Figure 1** Peripheral blood film of a patient with T-cell LGL leukemia. Two LGLs and a mature neutrophil (×100).

## Genes

A normal karyotype is most commonly encountered in indolent T-cell and NK-cell LGL leukemia. Rare cases with distinct chromosomal aberrations including trisomy 8 or inversions of chromosomes 7p and 14q have been reported. Clonal cytogenetic abnormalities, including duplication of 1q, rearrangement at 3q and deletion of chromosomes 10, 13 and Y have been detected in aggressive NK cell leukemia.

## Molecular and Systemic Pathophysiology

The etiopathogenesis of LGL leukemia is not well understood. However, chronic stimulation of LGLs with autoantigen or viral antigen derived from human T-cell lymphotropic virus – I/II (HTLV-I/II) has been suggested as a putative etiopathogenic mechanism in indolent T-cell and chronic NK cell LGL leukemias [1]. Epstein-Barr virus (EBV) infection of NK cells plays a role in the pathogenesis of aggressive NK cell leukemia. Dysregulation of several intracellular pathways, including Fas/FasL, rat sarcoma/mitogen activated protein kinase (ras/MAPK) and phosphatidylinositol 3-kinase (PI3K) was implicated in inhibition of apoptosis of leukemic LGLs in in vitro studies [3]. Constitutive over-expression of cytotoxic molecules, including granzymes and perforin and production of proinflammatory cytokines (IL-18, MIP-1β, RANTES) were also detected in malignant LGLs.

## Diagnostic Principles

1. Sustained expansion of LGLs in peripheral blood (>0.5 × $10^9$/L/ul). Bone marrow evaluation may be helpful in patients with smaller populations of circulating LGLs (<0.5 × $10^9$/L/ul) [4].
2. Determination of characteristic immunophenotype by multiparameter flow cytometry (Table 1).
3. Confirmation of clonality of malignant T-cells by detection of T-cell receptor (TCR) gene rearrangement using polymerase chain reaction (PCR) or Southern blot or detection of a restricted TCR Vβ repertoire using flow cytometry and a panel of monoclonal antibodies.
4. Cytopenias, splenomegaly and inflammatory arthritis support a diagnosis of indolent LGL leukemia. Acute illness with B-symptoms, hepatosplenomegaly,

**Lymphocyte Leukemia, Large Granular. Table 1** Most common immunophenotypes in LGL leukemia

| Cell lineage | Indolent | Aggressive |
|---|---|---|
| T cell | $CD3^+$, $CD8^+$, $CD56^-$, $CD57^+$ | $CD3^+$, $CD8^+$, $CD56^+$, $CD57^-$ |
| NK cell | $CD3^-$ $CD3\varepsilon^+CD56^+$ $EBV^-$ | $CD3^-$ $CD3\varepsilon^+$ $CD56^+$ $EBV^+$ |

lymphadenopathy, cytopenias and coagulopathy are common manifestations of aggressive T-cell and NK-cell leukemias.

## Therapeutic Principles

Asymptomatic patients with indolent T-cell and chronic NK-cell LGL leukemias can be observed. Single agent therapy with low dose methotrexate, cyclophosphamide and cyclosporine A is effective in approximately 50% of patients with clinically symptomatic disease [5]. Refractory cases may benefit from monotherapy with nucleoside analogs or targeted therapy with alemtuzumab. The efficacy of novel agents including anti CD2 monoclonal antibodies, tipifarnib and a MiK-beta-1 monoclonal antibody are being evaluated in clinical studies [3]. Aggressive T-cell and NK-cell LGL leukemias usually have a rapid progressive course with short survival. Induction chemotherapy with intensive acute lymphoblastic leukemia (ALL)-type regimens, followed by consolidation with hematopoietic stem cell transplantation in the first remission has been used with curative intention in a limited number of cases [2].

# Lymphocytic Colitis

Jürgen Schölmerich
Department of Internal Medicine I, University Medical Center Regensburg, Regensburg, Germany

## Definition and Characteristics

A disease with chronic or recurrent non-bloody watery diarrhea often associated with pain and weight loss. Fatigue, nausea and fecal incontinence may be other symptoms. Coincidence of other autoimmune disorders is frequent. The disease is not visible macroscopically but only found in biopsies. Together with collagenous colitis it is named microscopic colitis (Table 1).

## Prevalence

Previously considered rare, occurs mostly in Europe and North America. More recent data show annual incidence rates of 5–13/100,000/year in Olmstead County, USA and in Orebro, Sweden [1,2]. The disease manifests itself mostly between 50 and 65 years of age. Incidence has increased significantly during the last 20 years [1].

## Genes

There are no clear cut data regarding genetic predisposition. The family predisposition and an association with other inflammatory bowel diseases and celiac disease have been described. Data on human leucocyte antigen associations are not conclusive [2].

## Molecular and Systemic Pathophysiology

The course of lymphocytic colitis is unknown. It is presently considered to represent a specific mucosal response in predisposed individuals to various noxious luminal agents. Infectious agents such as Yersinia enterocolitica, Campylobacter jejuni and Clostridium difficile have been reported as inducing lymphocytic colitis. Several drugs such as NSAIDs, PPI and many others have been associated with an increased likelihood of lymphocytic colitis. Bile acid malabsorption can coexist with lymphocytic colitis in 9–60% of patients. The coexistence with other autoimmune diseases such as thyroiditis suggests an autoimmune process as basis of lymphocytic colitis [3]. No specific markers have been detected, although an increased prevalence of autoantibodies such as ANA has been reported [4]. Finally NO production is greatly increased in the colon of patients with lymphocytic colitis and the associated disorder collagenous colitis. The diarrhea is probably secretory in nature [2].

## Diagnostic Principles

As indicated by the name “microscopic colitis” microscopic assessment of colonic mucosal biopsies is the only means to verify the diagnosis of lymphocytic colitis (and of the related disease collagenous colitis) in patients with unexplained diarrhea. Neither stool tests nor

**Lymphocytic Colitis. Table 1** Microscopic colitides

| | Lymphocytic colitis | Collagenous colitis |
|---|---|---|
| Similarities | | |
| Watery diarrhea | 18/18 (100%) | 21/21 (100%) |
| Mean age at diagnosis | 53 ± 17 | 59 ± 16 |
| Colonoscopy normal | 18/18 (100%) | 21/21 (100%) |
| Increased intraepithelial lymphocytes | 18/18 (100%) | 9/12 (75%) |
| Differences | | |
| Female-to-male ratio | 1.3:1 | 20:1 |
| Increased subepithelial collagen | 1/18 (6%) | 20/20 (100%) |
| Autoantibodies | 6/12 (50%) | 1/11 (9%) |

laboratory parameters nor imaging is helpful. Histology reveals an increased number of intraepithelial lymphocytes (IEL) exceeding 20 IEL/100 surface epithelial cells compared to <5 IEL/100 in normal mucosa. Several other more rare forms of microscopic colitis in addition to lymphocytic and collagenous colitis have been described [2].

### Therapeutic Principles

Most recommendations are based on personal experience and include prednisolone, budesonide, 5-aminosalicylic acid (5-ASA), sulfasalazine, bismuth subsalicylate and probiotics. Antibiotics have been used as well [5].

### Synonyms

PCNSL, Diffuse large B cell lymphoma of the central nervous system

### Definition and Characteristics

Primary central nervous system lymphomas (PCNSL) are extranodal malignant B cell lymphomas of the diffuse large B cell type without any lymphoma manifestation outside the CNS at the time of diagnosis [1,2].

## Prevalence

The incidence of PCNSL has significantly increased world-wide, which is mainly due to the increased number of immunosuppressed, particularly HIV-infected patients. PCNSL account for 6.6% of all CNS neoplasms.

## Genes

Tumor cells carry somatically mutated immunoglobulin (IG) genes with evidence for ongoing mutation indicating germinal center B cells as their histogenetic origin. Further maturation steps of the IGM expressing tumor cells appear to be blocked. The lack of IG class switch recombination was attributed to internal switch μ deletions in the majority of the cases analyzed. Aberrant somatic mutations were introduced into the protooncogenes PIM1, c-MYC, RhoH/TTF, and PAX5 with evidence for ongoing mutation, indicating that the tumor cells may have participated in a prolonged germinal center reaction.

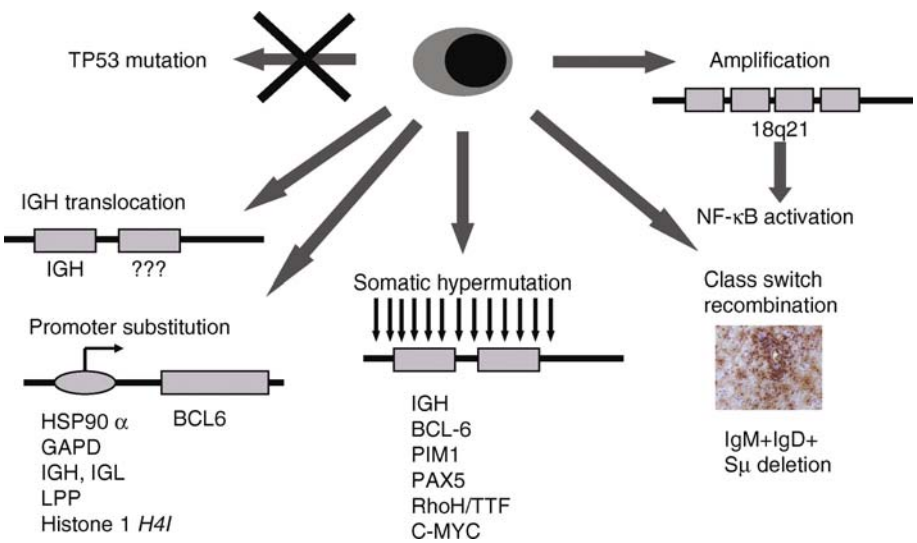
Clonal abnormalities and translocations have been reported. Recurrent translocations of the IG and BCL6 genes occur in approximately one third of PCNSL. While the translocation partners of the IG genes are still unknown, for the BCL6 gene IGH, IGL, histone 1H4I, GAPD, HSPCA (HSP90A), and LPP have been identified as reciprocal partner genes resulting in promoter substitution [3]. Amplification of 18q21 with gains of the MALT1 and BCL2 genes were the most frequent genetic alteration and may be associated with NF-κB activation. Genes of the NF-κB family as well as NF-κB-regulated genes including RELA, REL, and BCL2 are expressed in PCNSL [4].

FISH and CGH studies demonstrated gains of genetic material to be more frequent than losses. Loss of chromosome 6q was linked to a shorter survival. A variety of genes are aberrantly methylated (DAPK, TSP1, CRBP1, p16INK4a, p14ARF, MGMT, RARbeta2, TIMP3, TIMP2, p15INK4b, p73, hMLH1, RB1, GSTP1, HRK). A reduction in folate carrier gene expression by promoter methylation may be therapeutically relevant. PCNSL were distributed among the spectrum of systemic diffuse large B cell lymphomas of the activated B cell-like and germinal center type defined for systemic DLBCL as observed in a cDNA microarray study.

## Molecular and Systemic Pathophysiology

The pathogenesis of HIV-associated and HIV-unrelated PCNSL appears to be different. While the EBV genome is only exceptionally detected in PCNSL of immunocompetent patients, it is expressed in the malignant B cells of PCNSL in more than 95% of immunosuppressed patients and may exert NF-κB pathway activating properties. HHV-6, HHV-8, SV40, and BKV do not appear to play a role.

One major open question is whether PCNSL arise within the CNS or outside the brain. The latter hypothesis would suggest B cell transformation at any site with subsequent selective tumor cell homing to the CNS. However, selective adhesion molecules, chemokines or their receptors have not been identified for PCNSL so far. Lymphoma cells present systemically may be eliminated by the immune system, but survive in the CNS, which may be supported by astrocytic B cell-activating factor of the tumor necrosis factor family (BAFF). Alternatively,



**Lymphomas, Primary Central Nervous System . Figure 1** Model for pathogenesis of PCNSL in Immunocompetent patients.

a monoclonal B cell population may develop from a possibly unrecognized intracerebral polyclonal B cell infiltrate (Fig. 1).

## Diagnostic Principles

Patients (peak incidence in the sixth and seventh decade, male: female ratio of 3: 2) present with focal neurological and neuropsychiatric symptoms and signs of increased intracranial pressure. MRI is the standard in neuroradiological diagnosis. Neuropathologically verified diagnosis is required. Stereotactic biopsy is superior to open resection, which is not beneficial for the patient. Prior to biopsy, application of corticosteroids should be avoided unless herniation is imminent, as this may lead to nondiagnostic biopsies. Neuropathologically, PCNSL correspond to malignant non-Hodgkin's B cell lymphomas of the diffuse large B cell type with a high mitotic and proliferation activity. In the vast majority of PCNSL, the immunophenotpye of the tumor cells is assigned as $CD10^{-}CD19^{+}CD20^{+}$-$CD79a^{+}BCL6^{+}MUM1^{+}CD138^{-}$.

## Therapeutic Principles

Polychemotherapy has significantly ameliorated the poor prognosis of PCNSL [2]. The Bonn protocol achieved a median overall survival of 50 months with patients below 61 years having a more favorable prognosis (5-year survival: 75%). Patients <60 years with recurrent lymphoma, relapsing or refractory tumor may benefit from the inclusion of autologous stem cell transplantation. Radiotherapy alone is neither curative nor inducing durable remission. Radiotherapy with combined systemic and intraventricular polychemotherapy poses patients, in particular >60 years of age, at risk for development of long-term treatment-related neurotoxicity with severe leukencephalopathy and cortical/subcortical atrophy clinically manifesting as dementia. In HIV-associated PCNSL, the extremely poor prognosis has improved upon HAART and radiotherapy, reaching a median survival of 36 months.

# Lymphomatoid Papulosis

Werner Kempf[1,2], Reinhard Dummer[1], Günter Burg[1]
[1]Department of Dermatology, University Hospital Zurich, Zurich, Switzerland
[2]Kempf und Pfaltz, Histologische Diagnostik, Zurich, Switzerland

## Synonyms

LyP

## Definition and Characteristics

Lymphomatoid papulosis (LyP) belongs to the spectrum of primary cutaneous CD30+ lymphoproliferative disorders and is characterized by a chronic recurrent, self-healing papulo-nodular skin eruption with histologic features of a malignant pleomorphic or anaplastic lymphoma.

## Prevalence

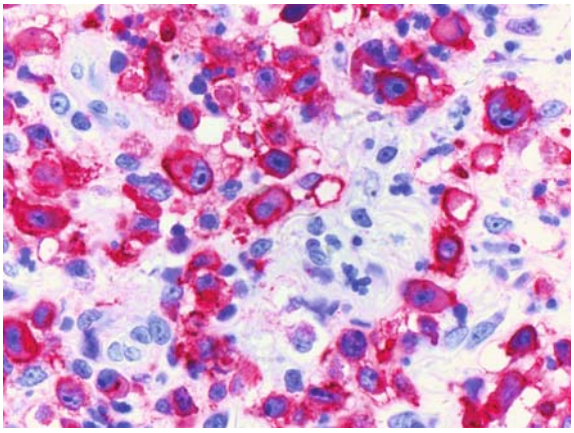
The prevalence of LyP is approximately 1 case per 1,000,000 inhabitants per year in Western countries.

## Genes

Cytogenetic studies demonstrated chromosomal deletions and rearrangements of chromosomes 1, 7, 9 and 10 [1]. The t(2;5) resulting in the npm/alk (p80) fusion protein which is commonly found in systemic CD30+ anaplastic large-cell lymphomas (ALCL), is not detected in LyP.

## Molecular and Systemic Pathophysiology

The tumor cells in LyP express a CD3+, CD4+, CD8-, CD30+, TIA-1+ phenotype and show additional expression of activation markers such as HLA-DR and CD25 (IL 2-receptor) thereby representing a proliferation of activated T-helper cells. Regression of tumoral lesions is a hallmark of LyP and is in part mediated by interaction of CD30 and its ligand, CD30L [2]. In contrast to primary cutaneous ALCL tumor cells in LyPexpress



**Lymphomatoid Papulosis. Figure 1** Lymphomatoid papulosis: CD30-positive tumor cells (red) intermingled with reactive cells such as neutrophils (magnification 400X).

MUM1 and TRAF1. Resistance to CD30L mediated growth inhibition provides a possible mechanism for tumor progression [3]. In addition, mutations of TGF beta receptors resulting in loss of TGF beta mediated growth inhibition have also been shown to contribute to tumor progression [3]. The expression of fascin was found to be significantly higher in LyP cases complicated by the development of systemic lymphomas [4]. The etiology of LyP is still unknown. There is no evidence for an etiologic role of human T-cell lymphotropic viruses (HTLV-1 or 2) or oncogenic human herpesviruses (e.g., Epstein Barr virus or human herpesvirus 8) in LyP. Recently, human endogenous retroviruses have been identified in tumor cell lines and tumor biopsies of LyP [5].

## Diagnostic Principles

Diagnosis is based on the characteristic clinical and histological features with self-regressing skin lesions and an infiltrate with CD30+ anaplastic T-cells (Fig. 1). Detection of clonal rearrangement of T-cell receptor genes is of limited diagnostic value.

## Therapeutic Principles

LyP exhibits a favorable prognosis with 5-year-survival rates of 100%. In 5–20% of patients with LyP, however, development of other cutaneous and nodal lymphomas is observed. Treatment includes heliotherapy, psoralen-UVA, retinoids (acitretin, bexarotene) as monotherapy or in combination with interferon-alpha. Alternatively, low dose methotrexate is effective. Experimental therapeutic strategies include anti-CD30 antibodies.

## Synonyms

Purtilo syndrome or Duncan disease; XLP

## Definition and Characteristics

XLP is principally characterized by a dysregulated immune response to Epstein Barr virus (EBV) infection. Two third of boys with XLP develop a fulminant infectious mononucleosis (FIM) with a

hemophagocytic syndrome. This clinical feature is often fatal. Other clinical manifestations are dysgammaglobunemia (30%), malignant lymphoma (30%), aplastic anemia (3%) and vasculitis (3%).

## Prevalence

1/1,000,000.

## Genes

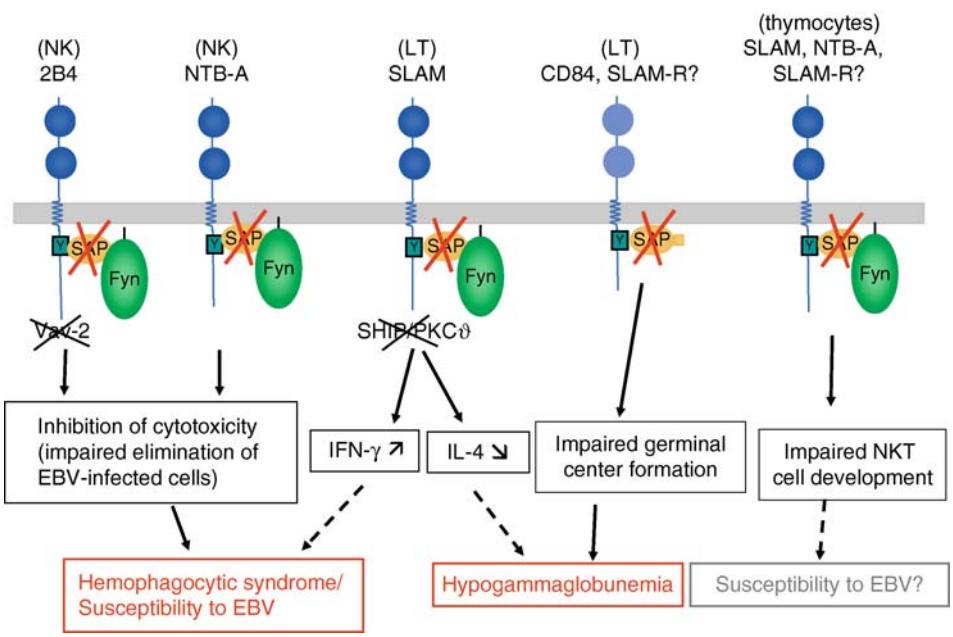
SAP or SH2D1A coding for SAP (SLAM-associated protein), localized on chromosome Xq25 mutated in 80% of patients with XLP (designated as XLP-1). BLRC4 coding for XIAP (X-linked Inhibitor of Apoptosis), localization in Xq25, mutated in 80% of patients with XLP (designated as XLP-2).

## Molecular and Systemic Pathophysiology

SAP is a small signaling adaptor protein that is mainly expressed in T and NK cells. SAP is composed of a unique SH2 domain and a short C-terminal extension. SAP binds by way of its SH2 domain with tyrosine-based motifs in the intracytoplasmic domain of a group of immune cell-specific receptors, the SLAM family. These include SLAM, 2B4, CD84 NTB-A and Ly-9. It has been established that SAP is a critical component of the signaling machinery used by the SLAM family receptors. The major function of SAP is to couple SLAM family receptors to intracellular signaling pathways by the ability of SAP to promote the recruitment and the activation of the Src-related protein tyrosine kinase FynT. Hence, immune dysfunctions seen in humans with XLP who lack SAP appear to be caused by alterations in the functions of SLAM family receptors, even though these are only beginning to be understood. Based on studies of SLAM-, SAP- and Fyn-deficient mice, it is proposed that a defect in SLAM signaling may contribute to the impaired Th2 response and the dysgammaglobunemia seen in XLP patients. Similarly, deficiencies in the functions of 2B4 and NTB-A may explain the reduced capacity of NK cells and CD8 + T cells from XLP patients to kill EBV-infected cells and may underlie the appearance of the hemophagocytic syndrome. Very recently, it has been also discovered that in the absence of SAP, the development of NK T cells is severely impaired both in mice and in humans. Hence, the deficiency of NK T cells found in XLP patients may contribute to the abnormal response to EBV (Fig. 1). However, signaling pathways other than apoptosis may be affected in the absence of XIAP. Both SAP and XIAP deficiencies are associated with a defect in a particular subpopulation of lymphocytes, the NK T cells. SAP and XIAP are required for the development and/or the homeostasis of NK T cells. Hence, the deficiency of NK T cells found in XLP-1 and XLP-2 patients might contribute to their susceptibility to EBV infection.

## Diagnostic Principles

Male patient with FIM, hemophagocytic syndrome, lymphoma, aplastic anemia, dysgammaglobulinemia (hypogammaglobulinemia) following acute EBV



**Lymphoproliferative Syndrome, X-linked. Figure 1** Model for defective SLAM receptor functions in the XLP pathophysiology.

infection. However, lymphoma and dysgammaglobulinemia could occur in XLP patients without evidence of EBV infection. The patient could have brothers, cousins, uncles and nephews with similar diagnoses indicating a family history. Detection of mutations in the SAP gene provides a definitive diagnosis of this rare X-linked disease.

### Therapeutic Principles

*Gene Therapy:* not available.
*Pharmacological Therapy:* Steroids, etoposide, cyclosporin A, immunoglobulin, antithymoglobulins (ATG), anti-CD20 antibodies.
*Dietary Therapy:* not available.
*Other Treatments:* The only definitive cure is the allogenic hematopoietic stem cell transplantation (HSCT).

## Lynch Syndrome

Karsten Schulmann, Christian Pox, Wolff Schmiegel
Medical Department, Ruhr-University Bochum, Bochum, Germany

### Synonyms

HNPCC; Hereditary nonpolyposis colorectal cancer

### Definition and Characteristics

Hereditary nonpolyposis colorectal cancer (HNPCC) is an autosomal dominant inherited disorder characterized by an increased risk of colorectal cancer and a variety of other neoplasms. The most common cancers are CRC (life-time risk, LTR 60–80%) and endometrial cancer (LTR 40–60%), followed by cancers of the stomach, ovaries, upper urothelial tract, hepatobiliary system (LTR each <20%), small bowel, skin, and CNS (LTR each <5%). HNPCC is a genetically heterogeneous disease. HNPCC is either defined clinically by fulfilment of the Amsterdam criteria (Table 1) [1] or through detection of a pathogenic germline mutation in a DNA mismatch repair (MMR) gene (mutation-positive HNPCC = Lynch syndrome). Furthermore HNPCC is characterized by a younger age at CRC diagnosis. Some patients may develop cancers in third decade of their life; however, a significant proportion of cancers are diagnosed in patients >60 years. The hallmark of classical HNPCC is the occurrence of microsatellite instability (MSI) in associated cancers [1]. A high level of MSI (MSI-H) can be detected in 80% of cases defined by the Amsterdam criteria and 30% of cases with positive Bethesda criteria (Table 1) [2].

MMR-proficient HNPCC (those without MSI) show a distinct phenotype. The genetic causes of this subtype have not been well-described yet.

### Prevalence

Lynch syndrome (mutation-positive HNPCC) accounts for approximately 0.8–3% of all CRC [3]. The mutation detection rate of patients with an MSI-H phenotype ranges from 50 to 94% depending on the applied diagnostic strategy.

### Genes

The underlying cause of classical HNPCC (Lynch Syndrome) is germline mutations in DNA mismatch repair (MMR) genes [4]. Approximately 85% of mutations are located in the MSH2 and MLH1 genes. Germline mutations in MSH6 account for 10% of cases, whereas PMS2 mutations are rare.

### Molecular and Systemic Pathophysiology

The hallmark of classical HNPCC is the occurrence of microsatellite instability (MSI) in associated cancers compared with normal tissue of probands. After development of somatic inactivating mutation of DNA MMR gene (second hit), cumulative DNA mismatches can not be repaired and accumulate in affected cells. MSI typically occurs in repetitive mono- or dinucleotid DNA sequences. Tumor suppressor genes with microsatellites such as TGFBR2 and BAX are involved in HNPCC-associated carcinogenesis. Approximately 12% of CRC are caused by epigenetic MLH1 inactivation caused by promoter hypermethylation. Those sporadic MSI-H cases are not linked to HNPCC and are typically found in older female patients with right-sided CRC.

**Lynch Syndrome. Table 1** Amsterdam I and Amsterdam II criteria, and Bethesda guidelines

| **Amsterdam I criteria** |
|---|
| At least three relatives with histologically verified CRC |
| 1. One is a first-degree relative of the other two |
| 2. At least two successive generations affected |
| 3. At least one of the relatives with CRC diagnosed at <50 years of age |
| 4. Exclusion of familial adenomatous polyposis (FAP) |
| **Amsterdam II criteria** |
| At least three relatives with an HNPCC-associated cancer (CRC, endometrial, ureter/renal pelvis, small bowel) |
| 1. One is a first-degree relative of the other two |
| 2. At least two successive generations affected |
| 3. At least one of the HNPCC-associated cancers should be diagnosed at <50 years of age |
| 4. Exclusion of familial adenomatous polyposis (FAP) |
| **Bethesda guidelines for microsatellite instability testing of CRC** |
| 1. CRC diagnosed before the age of 50 years |
| 2. Presence of synchronous or metachronous CRC, or other HNPCC-associated tumors, regardless of age |
| 3. CRC with MSI-H histology diagnosed before the age of 60 years |
| 4. CRC or HNPCC-associated tumor diagnosed before the of age 50 years in at least one first-degree relative |
| 5. CRC or HNPCC-associated tumor diagnosed at any age in two first- or second-degree relatives |

Hereditary nonpolyposis colorectal cancer (HNPCC)-associated tumors include colorectal, endometrial, stomach, ovarian, pancreas, ureter or renal pelvis, biliary tract, and brain (usually glioblastoma) tumors, sebaceous gland adenomas, keratoacanthomas, and carcinoma of the small bowel.

## Diagnostic Principles

Historically the diagnosis is based on family history (Amsterdam criteria), age at diagnosis (<50 years) and occurrence of multiple associated cancers in one patient. Patients with positive Bethesda criteria should be screened for MSI-H or immunohistochemical loss of MMR proteins (high-risk population-based approach). An alternative approach for the identification of HNPCC patients is the screening of all CRC for MSI-H or immunohistochemical loss of MMR proteins (population-based approach). Patients with MSI-H and/or loss of MMR proteins are candidates for germline mutation screening, preferentially of those genes which display loss of expression in the tumor tissue. Up to 18% of mutations are large genomic deletions which require a more extensive diagnostic strategy involving deletion screening, for example, using MLPA. If no tumor tissue is available, direct germline mutation screening of MLH1 and MSH2 may be appropriate.

HNPCC patients and their first degree relatives require an intensive cancer surveillance programme involving annual colonoscopy, esophagogastroduodenoscopy, and transvaginal as well as abdominal ultrasound [5]. Colonoscopy is usually starts at the age of 20–25 years. Surveillance colonoscopy every 2–3 years has demonstrated a significant reduction of CRC incidence and mortality through early cancer detection and polypectomy of premalignant adenomas; however, interval cancer occurred in 4% of patients, therefore annual colonoscopy is now frequently recommended.

## Therapeutic Principles

Treatment of associated cancers and premalignant lesions is identical to the corresponding sporadic lesions (i.e., oncological resection). Patients may undergo more extensive surgery, for example, subtotal colectomy at CRC diagnosis, although a benefit compared to surveillance has not been demonstrated. Prophylactic hysterectomy and bilateral salpingo-oophorectomy is an effective strategy for preventing endometrial and ovarian cancer in women with the Lynch syndrome and is suitable in postmenopausal patients or patients with completed childbearing. However, prophylactic surgery should be restricted to proven germline mutation carriers.

# LYP

►Lymphomatoid Papulosis

# Lysinuric Protein Intolerance

Laura M. Tanner
Department of Pediatrics, Turku University Hospital, Turku, Finland

## Synonyms

Familial protein intolerance; Hyperdibasic aminoaciduria type 2

## Definition and Characteristics

Lysinuric protein intolerance is a rare autosomal recessively inherited disorder in which the transport of cationic amino acids is defective. The defect is localized at the basolateral cell membrane of the intestine and the renal tubules. It leads to poor intestinal absorption and increased urinary excretion of three amino acids: lysine, arginine and ornithine. Decreased availability of arginine and ornithine, two urea cycle intermediates, leads to impaired function of the urea cycle and, subsequently, to the increase of blood ammonia concentration after protein-rich meals. Newborns with LPI are typically asymptomatic while they are breastfed because of the low protein content in human milk. Introduction of formula or supplementary high-protein foods leads to vomiting and diarrhea. Most patients therefore develop strong natural aversion to protein in early infancy. Later features of LPI include failure to thrive, growth retardation (Fig. 1), hepatosplenomegaly and osteopenia.

Mental development is normal in most patients but episodes of prolonged hyperammonemia may lead to moderate psychomotor retardation. Slight normochromic anemia, mild leukopenia and decreased platelet count are common findings in patients with LPI, and bone marrow abnormalities have been observed in some patients. Immunological abnormalities and exceptionally severe Varicella infections have also been described. The prognosis of LPI is rather good if the disease is diagnosed early and treated appropriately, and most of the patients are able to lead a nearly normal life. However, the risk of severe complications including pulmonary alveolar proteinosis and progressive nephropathy is increased and careful follow-up is therefore required [1]. The women with LPI are also at increased risk for toxemia and other complications during pregnancy [2].

## Prevalence

1:60 000 in Finland, clusters of LPI patients in Southern Italy and Japan.

## Genes

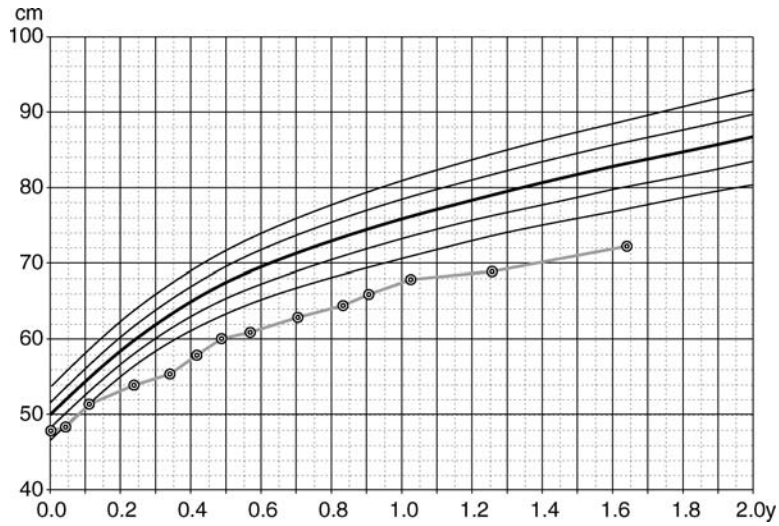
Mutations in SLC7A7 (14q11) encoding $y^+$ LAT-1, the light subunit of a heteromeric amino acid transporter [3,4]. To date, more than 30 different mutations have been found. LPI belongs to the Finnish disease heritage, and all Finnish patients share the same founder mutation ($LPI_{Fin}$). No genotype-phenotype association has been established as the same genotype may give rise to extensive clinical variability.

## Molecular and Systemic Pathophysiology

Lysinuric protein intolerance is caused by mutations in the $y^+$ LAT-1 protein, which combines in endoplasmic reticulum with the heavy chain of the surface antigen 4F2 (4F2hc) to form a heteromeric transporter for cationic amino acids. The transporter is expressed mainly in the epithelial cells of the renal tubules and the brush border of the small intestine. It transfers cationic amino acids from the cell into the extracellular space and neutral amino acids plus sodium back into the cell. Mutations in the $y^+$ LAT-1 protein lead to impaired assembly of the transporter complex and, subsequently, selective aminoaciduria and impaired intestinal absorption of cationic amino acids. No LPI-related mutations in the SLC3A2 gene encoding 4F2hc have been described [5].

## Diagnostic Principles

The diagnosis is based on characteristic clinical and laboratory findings: increased urinary excretion and decreased plasma levels of cationic amino acids, increased serum concentration of ferritin, increased serum lactate dehydrogenase activity, and hyperammonemia and



**Lysinuric Protein Intolerance. Figure 1** Growth curve of a Finnish girl with LPI.

increased urinary excretion of orotic acid after a nitrogen load. Genetic analysis may be used to confirm the diagnosis.

### Therapeutic Principles

The treatment is based on moderate protein restriction and daily oral supplementation with citrulline. Citrulline, a neutral amino acid, is partly converted to arginine and ornithine and thus improves urea cycle function and prevents postprandial hyperammonemia. The doses are adjusted to the protein content of the meals guided by postprandial orotic acid excretion. Oral sodium benzoate and sodium phenylbutyrate may be used to facilitate nitrogen excretion and reduce the need for citrulline. In acute hyperammonemic crisis, all nitrogen-containing substances should be removed from nutrition and ornithine, arginine or citrulline should be infused intravenously until the symptoms abate.

## Macroamylasemia

Mark Oette
Clinic for Gastroenterology, Hepatology, and Infectious Diseases, University Clinic Duesseldorf, Duesseldorf, Germany

### Definition and Characteristics

Macroamylasemia is defined as circulating complexes of amylase with other (macro-) molecules. The disorder does not cause symptoms.

### Prevalence

Macroamylasemia can be found in 0.1–1.5% of the nonalcoholic general population [1].

### Genes

The isoforms of amylase are coded on chromosome 1p21.

### Molecular and Systemic Pathophysiology

Amylase is an extracellular digestive enzyme that acts to cleave starch into di- and monosaccharides. The active cytoplasmatic form contains 496 amino acids with a molecular weight of around 54 kDa. A variety of organs produce amylase, such as pancreas, salivary glands, fallopian tubes, cyst fluid, lungs, thyroid, tonsils, mammae, and malignant neoplasms. The vast majority derives from pancreas and salivary glands. Thus, more than 99% of synthesized amylase is secreted into the gastrointestinal tract. In healthy individuals, 40–45% of serum amylase is derived from the pancreas, and 55–60% from the salivary glands. The mechanisms of amylase metabolism are not fully understood; however, the kidneys and the liver play an important role in amylase clearance. Hyperamylasemia is in majority a result of either pancreatitis or parotitis, decreased clearance, or amylase released from an involved organ.

Macroamylasemia results from the formation of complexes between amylase and other molecules, mostly immunoglobulins. Amylase is predominantly bound to the Fab-region of the immunoglobin (mostly IgA, <30% IgG, <5% others). Other partners that may form macro-amylase complexes are $\alpha_1$-antitrypsin, polysaccharides, or parenterally applied hydroxy-ethyl-starch (HAES). The molecular weight of such complexes usually exceeds 400 kDa. Therefore, the renal filtration and excretion is reduced with the result of a low urinary and high serum amylase activity.

Macroamylasemia may be associated with [1–3]:

- Non Hodgkin lymphoma
- Liver cirrhosis
- Celiac disease
- Ulcerative colitis
- Rheumatoid arthritis
- Multiple myeloma
- HIV infection
- Monoclonal gammopathy

### Diagnostic Principles

Macroamylasemia causes a high amylase blood level. The elevation usually does not exceed a fourfold increase. Lipase levels are not elevated. Serum isoamylase measurements to determine macroamylasemia, in contrast to either the salivary or pancreatic type of amylase, may complete the diagnostic workup when the etiology of hyperamylasemia is obscure [4].

Macroamylasemia may further be diagnosed by measuring amylase activity in the urine, where activities are low, compared with the increased activity in the serum. This is in contrast to acute pancreatitis, in which urine amylase levels will be high. More specific, the amylase-to-creatinine clearance ratio (ACR) can help to further differentiate hyperamylasemia. This ratio is calculated using the following equation: ACR = (amylase [urine] × creatinine [serum])/(amylase [serum] × creatinine [urine]) × 100. An ACR >5% suggests acute pancreatitis. An increased ACR may also occur in diabetic ketoacidosis, surgery, and renal disease. An ACR <1% suggests macroamylasemia. Due to limited clinical relevance, ACR

measurement has been abandoned, except to confirm a diagnosis of macroamylasemia.

Due to the association with the aforementioned diseases, concomitant paraprotenemia has to be excluded.

## Therapeutic Principles

Normally, a treatment of the benign disorder is not necessary. In cases with an association with celiac disease, macroamylasemia may resolve following a gluten-free diet.

# Macroglobulinemia, Waldenström

Marvin J. Stone
Baylor Sammons Cancer Center, Baylor University Medical Center, Dallas, TX, USA

## Synonyms

Waldenström's disease; Lymphoplasmacytic lymphoma

## Definition and Characteristics

A monoclonal gammopathy involving bone marrow lymphoid cells that normally synthesize and secrete immunoglobulin M (IgM). Lymph nodes, spleen and other organs may be affected.

## Prevalence

Waldenström's macroglobulinemia (WM) is about one-fifth as common as its closely related counterpart, multiple myeloma. It occurs principally in the elderly. An asymptomatic variant, IgM monoclonal gammopathy of undetermined significance (IgM MGUS), also has been recognized.

## Molecular and Systemic Pathophysiology

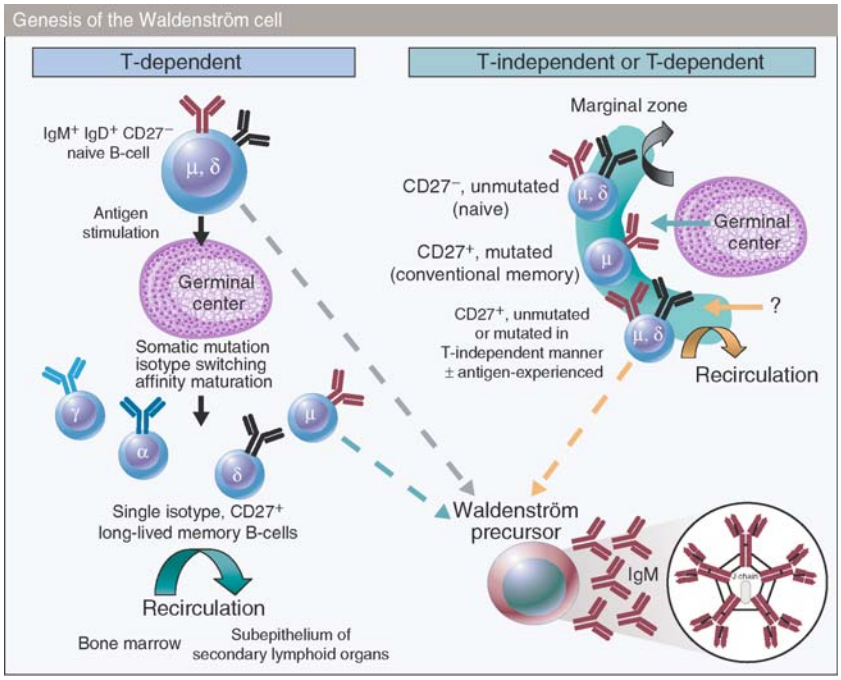
IgM is one of five classes of antibody molecules in humans. Its concentration in human serum is approximately 100 mg/dL (range 75–150). Waldenström macroglobulins and myeloma proteins from humans and mice have played a central role in elucidating immunoglobulin structure, genetics, and metabolism. Most of these monoclonal protein (M-protein) components have not been shown to possess functional antibody activity. Those that do react principally with antigens of autogenous or microbial origin. Proteins, polysaccharides, lipids, and nucleic acids are among the antigens identified. IgM is the first antibody produced phylogenetically and ontogenetically. IgM antibodies are often directed to bacterial polysaccharide antigens and are of low affinity and polyspecific. The genesis of the Waldenström cell is not totally clarified. It appears to be derived by more than one pathway, both T-dependent and T-independent (Fig. 1). The cells are positive for surface IgM and a single immunoglobulin light chain. Other B lymphocyte-derived markers (CD19, CD20) are also usually expressed. Lymphoplasmacytic lymphoma and splenic marginal zone lymphoma are histopathologic terms for the disorder.

IgM has a molecular mass of 900 kD; thus the term "macroglobulin" is apt since a mole of IgM weighs a ton. IgM is an 18S (Svedberg units) J (joining) chain-containing pentamer of four chain subunits with ten antigen-binding sites per molecule (Fig. 1).

This giant protein has a high intrinsic viscosity. Above an IgM concentration of 30g/L, serum viscosity rises steeply leading to hyperviscosity syndrome (HVS) in many patients. HVS is manifested by fatigue, skin and mucosal bleeding, and varied neurological symptoms, especially headache and visual disturbances. Coma occurs rarely. HVS can be diagnosed by the characteristic finding of marked retinal venous engorgement ("sausaging") on funduscopic examination. The syndrome is usually reversible by plasmapheresis which is particularly efficient since IgM is 80% intravascular. The Ostwald viscosimeter has remained a clinically valuable tool for monitoring relative serum viscosity in patients with WM and HVS. Each patient has a "symptomatic threshold" for hyperviscosity symptoms and signs. This threshold differs between patients but is generally reproducible within the same individual.

Cryoglobulins (immunoglobulins that precipitate or gel at temperatures < 37° and dissolve on rewarming) occur in some patients with WM. They may be single component (type I) IgM or mixed (type II) IgM-IgG.

IgM-related disorders include patients who have antibody activity associated with their monoclonal IgM. This activity produces signs and symptoms that alter the natural history of the disease. Examples include



**Macroglobulinemia, Waldenström. Figure 1** Immunoglobulin M-secreting cells may originate from naïve B-cells (IgM $^{+}$ IgD $^{+}$ CD27$^{-}$), from conventional memory B-cells (IgM $^{+}$ IgD$^{-}$ CD27$^{+}$), or from the IgM $^{+}$ IgD $^{+}$ CD27 $^{+}$ cell subset. Naïve B-cells recirculate through the blood, bone marrow, and follicular areas of secondary lymphoid organs. They may also be found in the marginal zone and express unmutated Ig genes. Conventional memory B-cells arise from germinal center reactions and express mutated Ig genes. They recirculate and may also be found in the marginal zone. The origin of IgM $^{+}$ IgD $^{+}$ CD27 $^{+}$ B-cells is unclear, but they are found in the marginal zone and recirculate in the periphery. These cells express mutated and unmutated Ig genes. Mutations occur independently of germinal center reactions. Each of the above cell types could give rise to the Waldenström cell. (Modified from [4]. Used with permission.)

**Macroglobulinemia, Waldenström. Table 1** Clinical Manifestations and Antigen Specificities of Human Monoclonal Macroglobulin Antibodies

| Syndrome | Autoantigen | Possible foreign antigen |
|---|---|---|
| Cold Agglutinin Immune Hemolytic Anemia | I/i red cell antigens | Bacterial LPS |
| Mixed Cryoglobulinemia | IgG Fc | HCV |
| Peripheral Neuropathy | Neural carbohydrate | Bacterial LPS |

**HCV* Hepatitis C virus; *LPS* Lipopolysaccharide.
From [4]. Used with permission.

cold agglutinin hemolytic anemia, mixed (type II) cryoglobulinemia, and certain peripheral neuropathies. The antibody activity in these IgM-related disorders is directed to autoantigens: cold agglutinin disease, IgM antibody to the I or i red cell antigen; mixed cryoglobulinemia, IgM antibody to autologous polyclonal IgG; and neuropathies, IgM antibodies to multiple neural carbohydrates. There is some evidence connecting foreign antigens to these processes as well. Bacterial lipopolysaccharide has been implicated in cold agglutinin disease and peripheral neuropathy while hepatitis C virus is closely associated with mixed cryoglobulinemia (Table 1).

Thus monoclonal IgM proteins having antibody activity not only influence clinical presentation and natural history of the disease, but also may provide a link between autoimmunity, infection, and lymphoproliferative disorders.

AL amyloidosis can occur rarely in WM; in these patients immunoglobulin light chain (Bence Jones protein) deposits in blood vessels and various tissues as fibrillar material.

### Diagnostic Principles

Symptoms/signs are variable and include fatigue, headache, bleeding, anemia, visual disturbance, cold sensitivity, neuropathy (peripheral or CNS), lymphadenopathy and hepatosplenomegaly. Some patients are asymptomatic. The characteristic finding of a tall homogeneous "church-spire" peak on serum protein electrophoresis which is monoclonal IgM (usually with kappa light chains) on immunofixation electrophoresis makes the diagnosis. Bone marrow examination usually discloses increased numbers of lymphoplasmacytic cells. Asymptomatic individuals with IgM serum M-components usually have IgM MGUS.

### Therapeutic Principles

WM is a low grade malignant B cell lymphoma with a median survival of 5–7 years. Treatment, when necessary, is directed towards reducing the IgM-producing monoclonal lymphoid cells with chemotherapy (alkylating agents such as chlorambucil or nucleoside analogues like fludarabine), corticosteroids, thalidomide and/or anti-CD20 monoclonal antibody. For patients with HVS, the physical removal of plasma (plasmapheresis) is effective in lowering serum viscosity temporarily. Persons with IgM MGUS do not require treatment but should be followed serially for change in clinical status.

### Synonyms

Age-related maculopathy; Aging macula disorder; AMD

### Definition and Characteristics

AMD is a genetically complex disorder of the photoreceptor-retinal pigment epithelium (RPE)-Bruch's membrane-choriocapillaris complex [1]. Early AMD is characterized by areas of increased pigment or hyperpigmentation (in the outer retina or choroid) and/or areas of depigmentation or hypopigmentation of the RPE, associated with intermediate or soft drusen (Fig. 1).

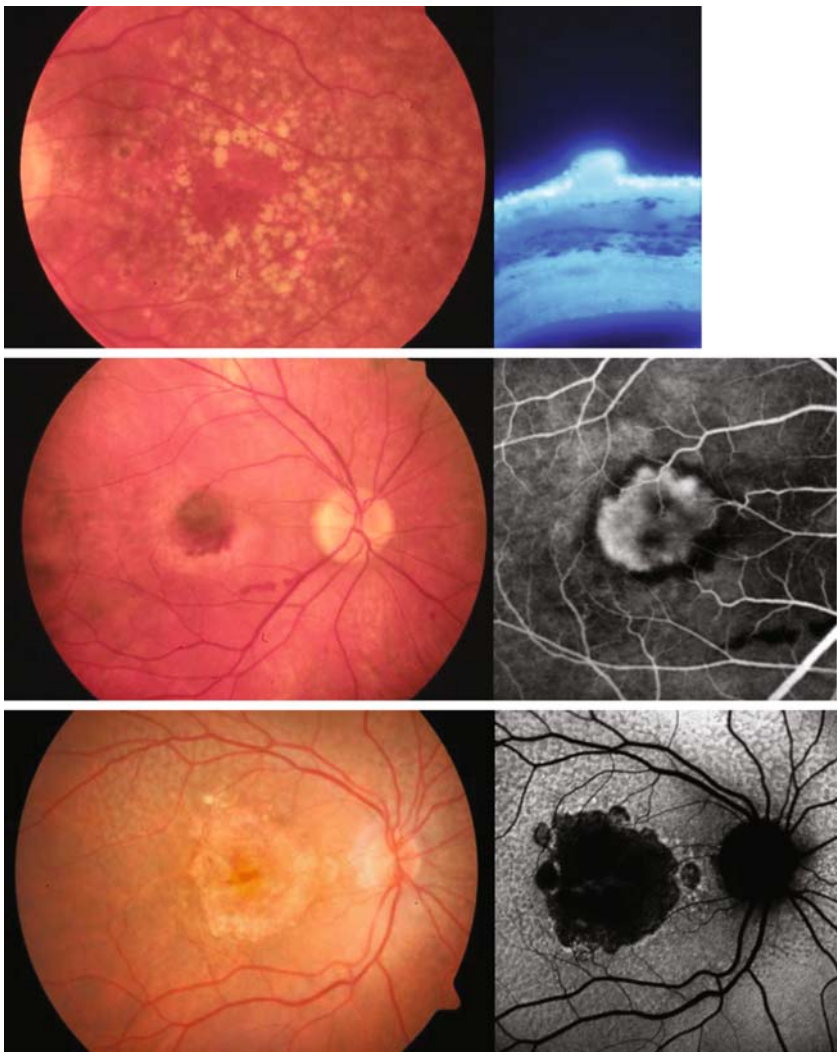
Late AMD includes geographic atrophy (GA) and choroidal neovascularization (CNV). The latter includes any of the following features: subretinal neovascular membranes, intraretinal or subretinal scars, RPE and neurosensory retinal detachments, hard exudates, and retinal hemorrhages (Fig. 1).

### Prevalence

Late AMD is now the most common cause of untreatable blindness in the Western world, with a prevalence of 0.05% before the age of 50 years and 11.8% after 80 years of age (Fig. 2).

### Genes

Family and twin studies have shown that the susceptibility for this disease is genetically influenced. The heritability has been estimated to be up to 71%. Linkage and association studies have identified several chromosomal regions that are likely to contain susceptibility loci with strongest evidence found on chromosome 1q31 and 10q26. Variants in the complement factor H (CFH) gene have been shown by several independent studies to be associated with an increased risk for AMD in Caucasian populations. The LOC387715/HTRA1 locus within 10q26 has been identified as a second major locus contributing to AMD pathogenesis. The two late forms of AMD, choroidal neovascularization and geographic atrophy, have not been found to be different in risk allele distribution. Variants within



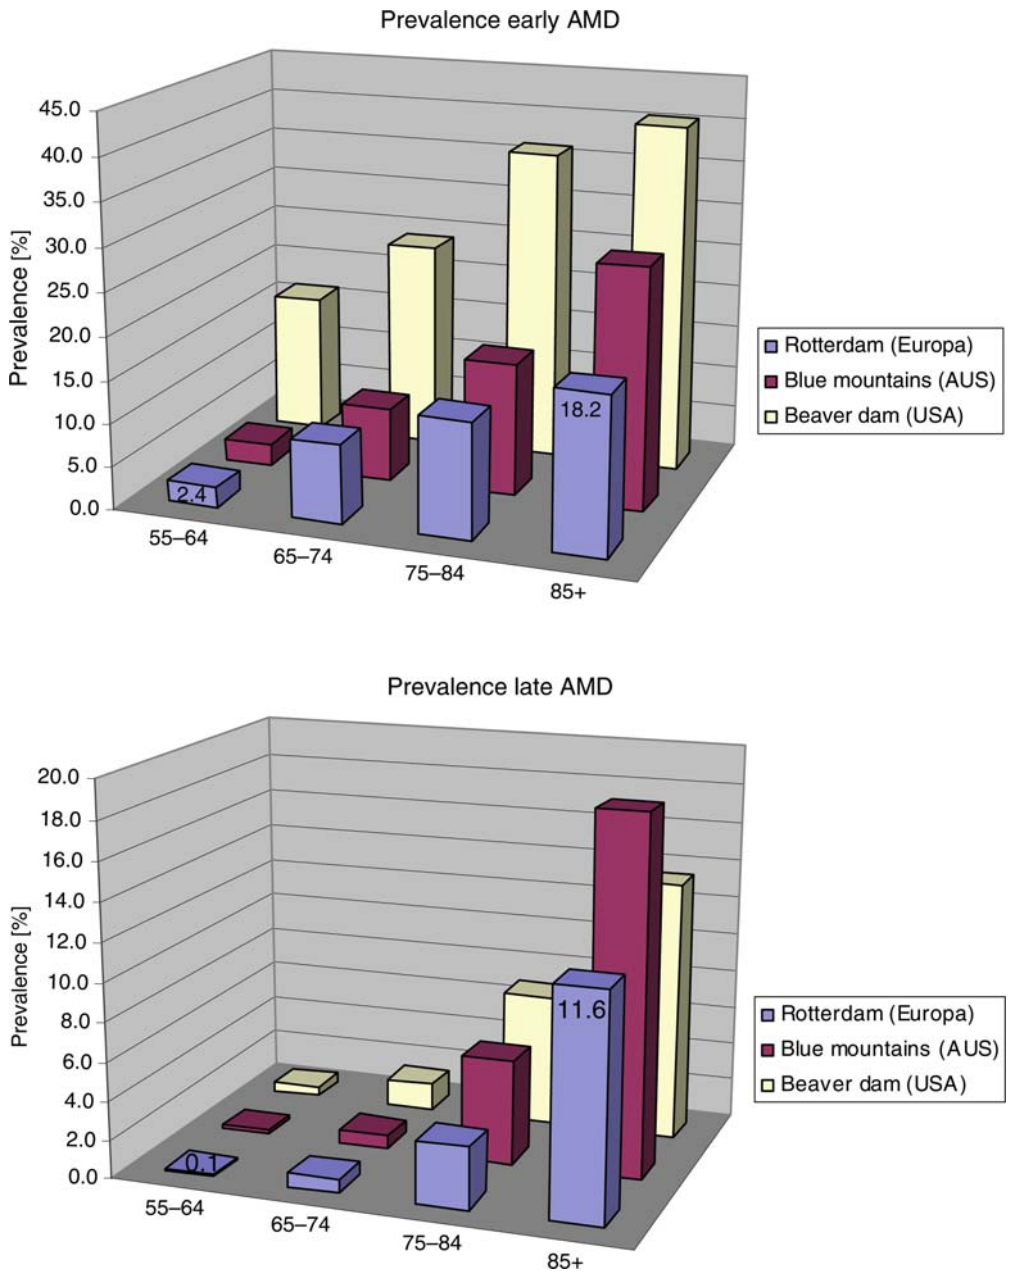
**Macular Degeneration, Age-related. Figure 1** *Top*: In vivo digital fundus photograph of early AMD with yellowish deposits in the extracellular matrix underneath the retina – so called "drusen" and brownish focal hyperpigmentations of the RPE (*left*). Ex vivo histopathology of a single druse between the RPE and Bruch's membrane (*right*). *Middle*: "Wet" AMD with edema and hemorrhages of the center of the retina (*left*). Digital fluorescein angiography (*right*) reveals a CNV below the neurosensory retina. Bottom: Late "dry" AMD with geographic atrophy (GA) of the RPE; digital fundus photograph (*left*) and digital fundus autofluorescence image (*right*) recorded with a confocal scanning-laser ophthalmoscope; the dark area corresponds to atrophy; retinal vessels and the optic nerve head also appear dark.

CFH and LOC387715/HTRA1 may contribute to the increased risk of late AMD largely or entirely through their impact on precursors, such as drusen and/or other RPE/Bruch's membrane changes [2].

An association with two other genes has also been reported that encode regulatory proteins acting along the same biological pathway as CFH. These two genes are factor B (CFB) and complement component 2 (C2). Very recently, a common functional polymorphism complement component C3 gene has been shown to be strongly associated with AMD. These findings imply that the innate immune system may play a significant role in AMD pathogenesis. Considering variants at CFH, LOC387715/HTRA1 and CFB, high-risk homozygotes at all three loci may have a 285-fold increased risk compared to baseline [3].

## Molecular and Systemic Pathophysiology

Underlying molecular mechanisms of the pathophysiology of AMD are yet incompletely understood. It is thought that the retinal pigment epithelium (RPE)



**Macular Degeneration, Age-related. Figure 2** Prevalence of early and late AMD in Europe, Australia and the USA for the age groups of 55–64 years, 66–74 years, 75–84 years and over 85 years. The data are derived from the "Rotterdam Eye Study," the "Blue Mountains Eye Study" and the "Beaver Dam Eye Study." Created from: Vingerling et al. (1995) The Rotterdam Study. Ophthalmology 102:205–210; Mitchell et al. (1995) The Blue Mountains Eye Study. Ophthalmology 102:1450–1460; Klein et al. (1992) The Beaver Dam Eye Study. Ophthalmology 99:933–943.

plays a key role in the disease process both in early and late forms of the disease. A hallmark of ageing is the accumulation of lipofuscin (LF) granules in the cytoplasm of RPE cells. Several lines of evidence indicate that adverse effects of excessive LF-accumulations represent a common downstream pathogenetic mechanism in various monogenic macular and retinal dystrophies and genetically complex retinal disorders. With the advent of novel imaging tools it has become possible to topographically map LF distribution at the level of RPE in-vivo by means of fundus autofluorescence (FAF) imaging (Fig. 1). Areas of GA are associated with RPE cell death as well as with collateral tissue layers, i.e. the outer neurosensory retina and the choriocapillaris.

With disappearance of RPE, LF is also absent resulting in a corresponding marked decrease in FAF intensity (Fig. 1).

The cell biology of choroidal new vessel (CNV) formation involves angiogenesis which is a multistep process involving angiogenic factor production and release, binding of angiogenic factors to endothelial cells, and intracellular signaling followed by complex changes, including alteration in the extracellular matrix, cell proliferation and migration, and association with other cells. Many different stimulators and inhibitors of ocular neovascularization have been identified. Vascular endothelial growth factor (VEGF)-A is a mitogen and a survival factor for endothelial cells. It also serves as a chemotactic factor and enhances vascular permeability. Multiple VEGF-A isoforms of different amino acid length are generated by alternative mRNA splicing. VEFG-A exerts its biological effects by binding to two cell surface receptors, VEGF receptor-1 (VEGFR-1) and VEGF receptor-2 (VEGFR-2). These proteins are tyrosine kinases, and agonist binding results in phosphorylation of intracellular proteins, which initiates a cascade of intracellular signaling. VEGFR-2 is probably the major mediator of VEGF-A-induced endothelial cell proliferation, survival, angiogenesis, and increased vascular permeability [4,5].

## Diagnostic Principles

Ophthalmoscopy and fluorescein angiography are the main diagnostic methods to visualize and differentiate different forms of AMD. Fluorescein angiography allows to detect CNV membranes and to visualize their dimensions. Recent developments in retinal imaging technologies have allowed for more accurate phenotyping and further insights in the diseases process. Abnormal fundus autofluorescence patterns in atrophic AMD and their impact on disease progression have been studied using scanning laser ophthalmoscopy (SLO) imaging. With the advent of optical coherence tomography (OCT), vertical sections of the retina can be obtained in vivo with visualization of microstructural alterations. The combination of the two technologies, cSLO imaging and spectral domain OCT, in one instrument together with real-time eye tracking now allows for accurate orientation of vertical OCT-scans at anatomic sites of interest with exact correlation, and therefore for three dimensional mapping of pathologic alterations within the retinal layers including the RPE.

## Therapeutic Principles

The Age-Related Eye Disease Study (AREDS) demonstrated that vitamin and mineral supplementation can reduce the risk of moderate visual loss among some patients with AMD. If patients had extensive intermediate-size drusen, noncentral geographic atrophy in one or both eyes, advanced AMD in one eye, or vision loss in one eye due to AMD and if they received daily supplementation with vitamin C (500 mg), vitamin E (400 IU), zinc oxide (80 mg), cupric oxide (2 mg), and beta-carotene (15 mg), then the risk of at least moderate visual loss was reduced from 29 to 23% and the risk of developing advanced AMD (i.e., subfoveal atrophy or CNVs) was reduced from 28 to 20% [5].

Visudyne (verteporfin), composed of benzoporphyrin derivative monoacid, circulates and complexes with low-density lipoproteins. Visudyne accumulates in neovascular tissue, which is rich in low-density-lipoprotein receptors. Nonthermal laser (689 nm) activation of verteporfin induces reactive oxygen species formation, endothelial damage with thrombus formation, and vascular occlusion. Verteporfin photodynamic therapy (PDT) reduces the rate of visual loss in AMD patients with subfoveal CNVs compared with sham-treated controls. At 2-years follow-up, the mean change in visual acuity is −2.3 lines with visudyne treatment vs. −4.5 lines among placebo-treated AMD patients with predominantly classic subfoveal CNVs. Verteporfin-PDT is palliative, with only approximately 9% of patients experiencing moderate visual gain at 2-years follow-up [5].

Ranibizumab is a humanized anti-VEGF-A recombinant Fab fragment that has been affinity-matured to increase its binding affinity for VEGF-A. In contrast to pegaptanib, an aptamer that binds specifically within the heparin-binding domain of VEGF-A, ranibizumab binds within the VEGFR-binding domain of VEGF-A. Thus, ranibizumab binds to all the biologically active isoforms of VEGF-A. Two randomized, double-masked, pivotal phase III clinical trials (MARINA and ANCHOR) have demonstrated that monthly intravitreal injection of ranibizumab is effective treatment for subfoveal CNVs in AMD patients. Consequently, the currently most effective proved therapy for AMD-associated CNVs is administered by repeated intravitreal injection of ranibizumab [5].

# Macular Dystrophy with Flecks

►Stargardt Disease

# Macular Dystrophy, Best's Vitelliform

Olaf Strauss
Experimental Ophthalmology, Department of Ophthalmology, University of Regensburg, Regensburg, Germany

## Synonyms

Morbus Best; Best's macular dystrophy (OMIM 153700)

## Definition and Characteristics

Best's vitelliform macular dystrophy [1] is a rare autosomal dominant inherited form of macular dystrophy with a central loss of vision and juvenile onset. Patients show a very heterogeneous penetrance and patterns of dystrophy. The dystrophy is characterized by five different phases of which one is the formation of a "bull's eye" or egg-yolk form of lesion in the macula and an early accumulation of lipofuscin. Hallmark of diagnosis is the reduced light-peak in the patient's electro-oculogram (Arden ratio <2). However, the reduction in the light-peak can occur before onset of the formation of a lesion or secondary to it. Furthermore, some patients show macular dystrophy without reduction in the electro-oculogram. The development of choroidal neovascularization is possible.

## Prevalence

Due to the heterogeneity and low penetrance of the disease, the prevalence not well described; an estimation: 60–80 per million (Sweden).

## Genes

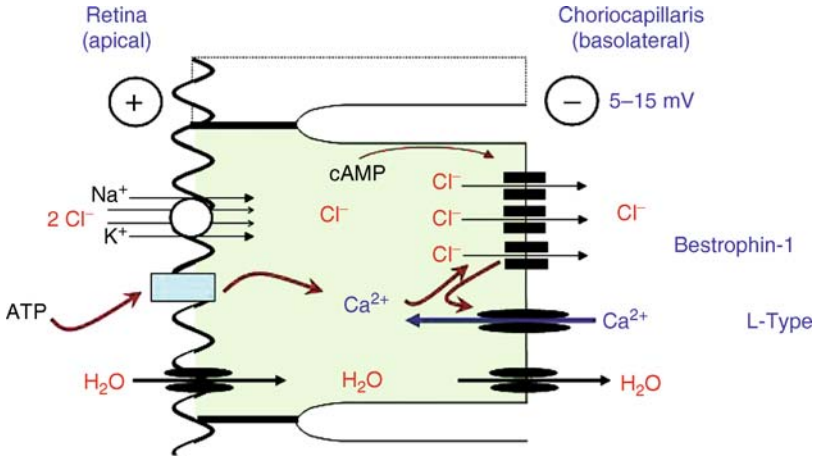
VMD2, vitelliform macular dystrophy-2 gene (GeneID 7439; OMIM 607854) on Chr. 11q13 encodes a transmembranal protein, bestrophin-1 [2,3]. The gene has 11 exons, the transcript encodes for a protein of 585 aminoacids. The amino acid sequence contains RFP domains, a sequence which is evolutionary highly conserved and defines the VMD2 gene product as member of the RFP domain (arginine-phenylalanine-proline tripeptide) family of proteins. VMD2 is the founder of a gene family with the members VMD2-like genes 1–3 (VMDL-1 to 3) encoding for the proteins bestrophin-2 to -4. So far, 89 different mutations have been discovered to cause Morbus Best. In the eye, bestrophin-1 is expressed in the retinal pigment epithelium. VMD2 mutations can also lead to adult vitelliforme macular degeneration or to ADVIRC (autosomal-dominant vitreoretinochoroidopathy).

## Molecular and Systemic Pathophysiology

In heterologeous expression systems, bestrophin-1 has been described as anion channel activated by increases in intracellular free $Ca^{2+}$ and as modulator of the activity of voltage-dependent $Ca^{2+}$ channels [4,5]. It physically interacts with the phosphatase PP-2A. It is a transmembrane protein with four membrane spanning domains.

Bestrophin-1 was found to be localised in the basolateral membrane of the RPE which displays a high $Cl^-$ conductance which is essential for a transepithelial transport of $Cl^-$ from retinal to blood side. The transport of $Cl^-$ drives a transepithelial transport of water from subretinal space to the blood side. Since bestrophin-1 function as $Cl^-$ channel it is likely that bestrophin-1 is involved in this transport process. Analysis of mutant bestrophin-1 showed in nearly all investigated cases the loss of $Cl^-$ channel function with dominant negative effects. The mutation A243V showed a moderate modulation of $Cl^-$ channel function in without dominant negative effects. Since the light-peak in the electro-oculogram correlates with an increase in the basolateral $Cl^-$ conductance the loss of $Cl^-$ channel function in the mutant forms would explain the changes in the patient's electro-oculogram. The loss of transepithelial transport of $Cl^-$ and water would lead to a disturbed interaction between photoreceptors and the retinal pigment epithelium and, thus, to loss of vision [4] (see Figure 1).

This model is challenged by analysis of a mouse model in which the VMD2 gene is inactivated [5]. These mice show no degenerative changes in the retina and larger light-peak amplitudes at low light intensities compared to wild-type mice. Thus, the lack of bestrophin-1 function seems not to have the expected effects on retinal function. Other lines of evidence point to another function of bestrophin-1 in addition as a $Cl^-$ channel. Mice lacking the $Ca_V1.3$ or of the β-4 subunit of voltage-dependent $Ca^{2+}$ channels show a reduction in the light-peak. A recent publication demonstrated a modulation of voltage-dependent $Ca^{2+}$ channels by bestrophin-1. Furthermore, two different mutant forms of bestrophin-1 showed individual effects on $Ca^{2+}$ channel activity indicating gain of function effects.



**Macular Dystrophy, Best's Vitelliform. Figure 1** Scheme illustrating bestrophin-1 function: $Cl^-$, accumulated by the activity of the apically located $Na^+/K^+/2Cl^-$ co-transporter, leaves the cell towards the choriocapillaris side through $Cl^-$ channels in the basolateral membrane. The resulting net transport of $Cl^-$ from retinal to blood side drives transport of water through aquaporines. Bestrophin-1 as $Ca^{2+}$ activated $Cl^-$ channel provides a transport route through the basolateral membrane. Furthermore, it modulates the activity of L-type $Ca^{2+}$ channels and, thus, the intracellular $Ca^{2+}$concentration which in turns regulates bestrophin-1 activity. Both, changes in $Cl^-$ channel activity or regulation of $Ca^{2+}$ channels might be involved in the chain of events leading to Best's macular dystrophy. Changes in the patient's electro-oculogram result from either ATP-dependent regulation of bestrophin-1 activity or by modulation of L-type channels.

## Diagnostic Principles

Together with standard ophthalmologic testing (visual acuity, perimetry and funduscopy) the recording of the electro-oculogram is required. Because of the heterogenous clinical picture VMD2 gene analysis is important.

## Therapeutic Principles

The patho-physiology of Best's vitelliform macular dystrophy is not fully understood. Thus a causative therapy does not exist. Since the patient's can develop a choroidal neovascularization a regular ophthalmic examination is important.

## Malabsorption

Jörg-Dieter Schulzke[1], Michael Fromm[2]
[1]Gastroenterology and Infectiology, Campus Benjamin Franklin, Charité, Berlin, Germany
[2]Clinical Physiology, Campus Benjamin Franklin, Charité, Berlin, Germany

### Definition and Characteristics

Malabsorption indicates a disturbed uptake of nutrients, ions, or water along the GI tract. Impaired small intestinal function can occur with and without morphological alterations of the intestinal mucosa. Thereby, disturbed digestion (maldigestion) and absorption (malabsorption) can work alone or together (malassimilation) which can also include pancreatic dysfunction. Maldigestion takes place, if congenital or acquired enzymatic activity of small intestinal mucosa or pancreas is reduced or due to intraluminal bile acid deficiency. Malabsorption occurs, when a primary transport disorder (without morphological changes) or a secondary transport defect due to morphological changes arises, when the absorptive area is reduced, or the transport of absorbed ingesta from the intestine is affected. Depending on localization and extent of the disturbance compensated, partial or global dysfunction takes place.

Furthermore, malabsorption is applied for malabsorption entities like, e.g., celiac disease or Whipple's disease, also called malabsorption syndromes. The latter usage is not ideal as it does not indicate the underlying etiology. Thus, in this sense malabsorption has to be considered as a symptom and the origin of the underlying malabsorption syndrome needs to be identified.

### Prevalence

Malabsorption syndromes comprise frequent disorders like, e.g., pancreatic dysfunction due to chronic pancreatitis, less frequent diseases as celiac sprue with a prevalence of about 0.5% in West-Europe and rare conditions like Whipple's disease as the result of a small intestinal infection with Tropheryma Whipplei.

### Molecular and Systemic Pathophysiology

Malabsorption is possible for all nutrients including proteins, carbohydrates, and lipids, for ions and water as

well as for vitamins and trace elements. The small intestine has a length of about 3–4 m, the large intestine 80–100 cm. Functional surface area is more than 600-fold higher as a tube of this length and diameter reaching a surface as big as a tennis court [1]. This is achieved by Kerckring' folds and haustra, villi, and crypts as well as microvilli. Thus, malabsorption can be due to lack of specific transporters or enzymes of the absorptive cell compartment, e.g., in villus, atrophy in celiac disease, intestinal inflammation or the absence of intestinal segments, e.g., after resective surgery. Depending on the site of disturbance along the gastrointestinal tract, it can differ to which extent the uptake of a single food component is affected. In Table 1, the uptake sites of different food components are shown. Resection of the respective intestinal segment causes malabsorption within this segment as, e.g., vitamin B12 and bile acids in the terminal ileum. The overall reserve capacity of the intestine, however, is rather high for nutrients, since as much as 70% of the mid-small intestine have to be usually resected, before global nutrient malabsorption causes weight loss [2].

Symptoms of malabsorption can comprise diarrhea, steatorrhea (fatty stool), weight loss, edema as the result of hypoproteinemia, osteopathia, anemia, and distinct deficiency due to partial uptake dysfunction (Table 2). Diarrhea starts only when the absorptive reserve capacity of the colon is reached. Physiologically <1 L of fluid passes the ileocecal valve at the end of the small intestine which is easily absorbed due to the osmotic force produced by electroneutral NaCl-absorption along the entire colon and by electrogenic Na-absorption which is only expressed in its distal parts. The intact colon is provided with a large absorptive reserve capacity of 6–8 L/day [3]. Only if this maximum is reached or colonic resection or inflammation hampers its function, diarrhea occurs. Interestingly, a watery diarrhea by itself causes some malabsorption by its rinsing effect and the reduced contact time of the ingesta with the mucosa. For example, watery diarrhea increases stool fat levels from 7 to 14 g/day [4].

The etiology of malabsorption is diverse. An overview is presented in Table 3. An identification of the underlying reason(s) is the first step toward therapy. A further hint for the etiology is available from a 24 h fasting period (see later).

**Malabsorption. Table 1** Absorptive sites along the GI tract

| GI segment | Absorption |
|---|---|
| Stomach | (None) |
| Duodenum, jejunum, ileum | Glucose, galactose, fructose, xylose |
| | Amino acids, dipeptides |
| | Medium chain fatty acids |
| | Diacylglyerol, long chain fatty acids (with micelles) |
| | Electrolytes, water |
| | Thiamin, riboflavin, pyridoxine, folic acid, vitamin C |
| | Calcium, magnesium, iron |
| Terminal ileum | Vitamin B12 |
| | Bile acids |
| Colon | Electrolytes, water |
| | Short chain fatty acids |

**Malabsorption. Table 2** Symptoms of malabsorption

| Deficiency | Symptom |
|---|---|
| Protein | Edema, hypoproteinemia |
| Fat | Steatorrhea |
| Carbohydrates | Weight loss |
| Iron | Anemia |
| Calcium, vitamin D | Osteopathia |
| Vitamin A | Night blindness |
| Vitamin K | Hemorrhage |
| Vitamin E | Brown bowel syndrome |
| Zinc | Acrodermatitis enteropathica |
| Vitamin B6 | Polyneuropathia |
| Vitamin B1 | Beri beri |
| Vitamin B12, folic acid | Pernicious anemia |
| Selenium | Heart failure, polyneuropathia |

## Diagnostic Principles

Indirect evidence for the etiology of malabsorption is available from a prolonged fasting period, as a result of which stool volume is reduced in case of malabsorptive diarrhea as, e.g., in case of lactase deficiency. In contrast, no change in stool volume points to a secretory or leak flux mechanism. Rarely, hormone release from neuroendocrine tumors can be triggered by food intake and miscellaneous pictures arise [5].

More specific evidence can be obtained from diagnostic procedures as endoscopy, X-ray, and laboratory tests. Starting with upper endoscopy which can identify celiac sprue, Whipple's disease, and several other small intestinal disorders like the blind loop syndrome. Colonoscopy can detect inflammatory bowel disease (IBD), microscopic colitis, and amyloidosis. Laboratory tests include tests for chronic pancreatic disease (elastase 1-test), neuroendocrine tumors (gastrin and VIP ELISAs), vitamin B deficiency (Schilling test), and lactase deficiency (hydrogen exhalation test with lactose). Micobiological testing

**Malabsorption. Table 3** Malabsorption syndromes

| Disease | Pathology |
|---|---|
| *Diffuse, specific* | |
| Whipple's disease | Lamina propria macrophages with PAS-positive material |
| Agammaglobulinemia | No plasma cells, either normal or flat mucosa due to lacking villi |
| Abetalipoproteinia | Normal villi, epithelial cells with fatty vacuoles postprandially |
| *Focal, specific* | |
| Intestinal lymphoma | Lymphoma cells in the lamina propria and submucosa |
| Intestinal lymphangiectasia | Dilated lymphatic ducts with distorted villi and partial villus atrophy |
| Eosinophilic gastroenteritis | Eosinophilic infiltrate in the lamina propria and submucosa |
| Amyloidosis | Amyloidal deposits |
| Crohn's disease | Skip lesions with detection of granulomas |
| Infectious diseases | Detection of microorganisms |
| Mastocytosis | Mast cell infiltrates of the lamina propria |
| *Diffuse, unspecific* | |
| Celiac sprue | Reduced or lacking villi, increased intraepithelial lymphocytes, crypt cell hyperplasia |
| Tropical sprue | Villus atrophy and folic acid deficiency |
| Giardia lamblia infection | Partial villus atrophy |
| Blind loop syndrome | Partial villus atrophy and increased intraepithelial lymphocyte count |
| Vitamin B12 deficiency | Villus reduction, megalocytosis |
| Radiation enteritis | inflammation of the intestine |
| Zollinger-Ellison syndrome | Ulcers and erosions of gastric mucosa and small intestinal partial villus atrophy |
| Malnutrition | Mucosal hypotrophy (villus and crypt reduction) |

**Malabsorption. Table 4** Therapy of malabsorption syndrome

| General therapy |
|---|
| Fiber-reduced diet (multiple small dinners) |
| Lactose-reduced diet |
| MCT-fat (medium chain fatty acids) – micelles-independent fat uptake |
| Cholestyramine – chelating bile acids |
| Loperamide – μ-opiate agonist inhibits propulsion |
| Parenteral nutrition |
| Small intestinal transplantation |
| **Specialized therapy** |
| Gluten-free diet |
| Antibiotics (Whipple's disease, Giardia lamblia, blind loop syndrome |
| Steroids (Crohn's disease, eosinophilic enteritis) |
| Chemotherapy (intestinal lymphoma) |

for chronic infectious agents such as, Giardia lamblia (indirect immuno fluorescence in stool), Yersinia enterocolitica (seologic testing), and Strongyloides stercoralis (stool examination) completes the diagnostic program.

## Therapeutic Principles

While for many entities specific therapeutic approaches are available, others, e.g., small intestinal resection can only be treated by unspecific procedures like a specialized diet and loperamide. A list of therapeutic procedures is presented in Table 4.

## Malignant Hyperthermia

Tommie V. McCarthy
Department of Biochemistry, University College Cork, Cork, Ireland

### Synonyms

Malignant hyperpyrexia; Hyperthermia of anaesthesia

### Definition and Characteristics

Malignant hyperthermia (MH) is an autosomal dominant pharmacogenetic disorder triggered in susceptible individuals by most of the commonly used volatile anaesthetic agents. A classical/fulminant MH episode is characterized by hyperthermia, skeletal muscle rigidity, tachycardia, and respiratory and metabolic acidosis. Fulminant MH has a mortality rate of more than 70% if left untreated. Susceptible individuals do not always develop symptoms of MH during anaesthesia and when the syndrome is triggered the symptoms that do develop can vary over a broad range.

### Prevalence

Prevalence of the clinical syndrome is 1 in 10,000 to 1 in 50,000 administrations of general anaesthesia. Prevalence of susceptibility to the malignant hyperthermia (MHS) is considered to be greater than 1 in 100. The large difference between clinical and susceptibility prevalence is not understood.

## Genes

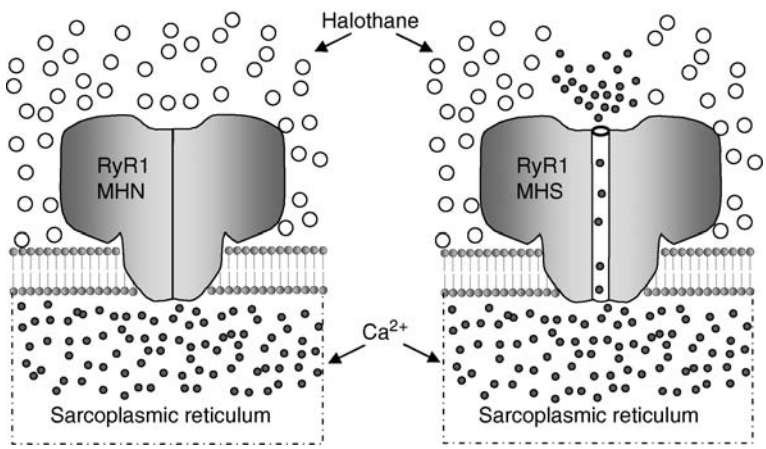
The majority of MH cases arise from mutations in the skeletal muscle ryanodine receptor calcium release channel gene (RYRI). Most mutations in the 15117bp coding sequence occur at a low frequency and result in single amino acid substitutions in the RyR1 protein [1]. A small number of in frame deletions have also been described. Three main clusters of RYR1 mutations are linked to MHS namely the N-terminal region (Cys35-Arg614), the central region (Asp2129-Arg2458) and the C-terminal region (Ile3916-Ala4942). A number of the RYR1 mutations (Gly341Arg, Arg614Cys, Gly2434Arg and Arg2458Cys/His) are relatively common and combined account for ~20% of cases. A low amount of genetic heterogeneity has been reported in MH [2]. Mutations in CACN1AS gene have been reported in a few isolated cases. This gene encodes the alpha1-subunit of the dihydropyridine receptor (DHPR) which interacts directly with the RyR1 channel in excitation – contraction coupling. A syndrome essentially identical to human MH and triggered by the same agents was identified in pigs in the late 1960s. Porcine MH is caused by an arginine to cysteine RYR1 substitution at amino acid 614. The identical MH mutation also occurs in humans. MH is closely related to central core disease(CCD) at the genetic level. Almost all individuals with CCD are susceptible to MH and carry mutations in the RYR1 gene.

## Molecular and Systemic Pathophysiology

This RyR1 protein plays a key role in excitation-contraction coupling and forms an elaborate tetrameric structure that acts both as a calcium release channel and "foot" structure bridging the gap between the sarcoplasmic reticulum (SR) and the t-tubule in skeletal muscle. Several proteins including the DHPR are tightly associated with RyR1. Biochemical studies have shown that calcium release from the SR mediated by the RyR1 channel is abnormal in skeletal muscle in the presence of trigger agents [3]. Mutations that cause MH enhance the sensitivity of the RyR1 channel to activation by a wide range of triggers including caffeine, 4-chloro-m-cresol and volatile anaesthetics such as halothane. These mutations are thought to disrupt a critical interdomain interaction that normally acts to stabilize the resting closed state of the release channel [4]. Hypersensitivity of the RyR1 channel to calcium release by halothane and other volatile anaesthetics offers an explanation for the symptoms of MH in that the "enhanced" calcium release would increase muscle contracture and ATP utilization, generate heat and activate enzymes. This would present as increased metabolism, elevated arterial $CO_2$ and lactic acid and could eventually cause death in the patient. Recent investigations have confirmed the association of the MHS with exercise-induced rhabdomyolysis and heat stroke. Interestingly another genetically distinct isoform of the ryanodine receptor (RYR2) is expressed in cardiac muscle. Mutations in RYR2 corresponding to RYR1 MH mutations have been reported in ventricular arrhythmias (catecholaminergic polymorphic ventricular tachycardia) and account for a portion of sudden death cases (Fig. 1).

## Diagnostic Principles

The MH in vitro contracture test (IVCT) is the standard test for susceptibility to MH. The IVCT is performed on a small section of skeletal muscle excised from the patient. The magnitude of contractures induced in strips of the muscle tissue in vitro by caffeine and independently



**Malignant Hyperthermia. Figure 1** Schematic diagram of the effect of halothane on calcium release from the SR into the myoplasm mediated by the RyR1 calcium release channel in normal individuals (MHN) and susceptible individuals (MHS). Mutations in the RYR1 gene lead to activation/opening of the RyR1 calcium release channel at clinically relevant concentrations of volatile anaesthetics such as halothane.

by the volatile anaesthetic halothane is measured. MHS muscle generates higher tension than MHN muscle in the presence of set concentrations of caffeine and halothane. Some individuals exhibit a higher than normal tension to one of the agents but not to both and are classified as MH equivocal (MHE). Genetic testing of MHS by screening for known MHS RYR1 mutations is possible in some families and guidelines in this regard have been published [5].

## Therapeutic Principles

MH can be avoided by using less common non triggering anaesthetic agents. Thus personal and family past history of adverse anaesthetic reactions should be explored in depth and anaesthetic agents altered accordingly. Careful monitoring of body temperature and respiratory carbon dioxide (capnography) are important for early detection of MH symptoms. If MH is suspected anaesthetic administration is stopped, and dantrolene is administered. Dantrolene is a selective inhibitor of RYR1 channel activity. It binds to RYR1 and inhibits $Ca^{2+}$ release from the sarcoplasmic reticulum in skeletal muscle.

# Malignant Melanoma

Meinhard Schiller[1], Stephan Grabbe[2], Cord Sunderkötter[1]

[1]Department of Dermatology, University Hospital of Muenster, Muenster, Germany

[2]Department of Dermatology, University of Mainz, Mainz, Germany

## Synonyms

Melanoma; Melanoma skin cancer

## Definition and Characteristics

Melanoma is an aggressive malignant tumor of pigment-producing cells (melanocytes) that differentiate from neural crest progenitor cells during embryonic development. It usually occurs in the skin, but rarely occurs in the uveal tract of the eye, the meninges and at different sides of the mucous membrane (~5%). Malignant melanoma (MM) accounts for 90% of the overall mortalities in skin cancer, and therefore, poses a major health threat worldwide [1].

## Prevalence

MM is less common than basal cell carcinoma (BCC) or squamous cell carcinoma (SCC) but its incidence is also increasing. MM are most common in light-skinned individuals with red or blond hair with high intermittent UV exposure. In Western Europe the incidence is 10–12/100,000, and in the USA 10–25/100,000 inhabitants per year. The highest incidence is reported from Australia with 50–60 new diseases per 100,000 inhabitants per year [1].

## Genes

Inactivation of tumor suppressor genes CDKN2A and activation of the potential oncogenes cyclin-dependent kinase 4 (CDK4), Nras, BRAF, and epidermal growth factor receptor (EGFR).

## Molecular and Systemic Pathophysiology

A role for solar UV in the etiology of MM is supported by a variety of evidence including latitude gradient, melanoma in xeroderma pigmentosum patients, and UV fingerprint mutations within the mutational spectrum of the cyclin-dependent kinase inhibitor 2a (CDKN2A) gene in patients with MM. The development of MM is believed to result from intermittent rather than cumulative UV exposure and in particular from severe sunburns during childhood. Solar radiation (UVB, especially from 290 to 320 nm) generates two major photoproducts in DNA: cyclobutane-pyrimidine dimers and 6–4 pyrimidine-pyrimidone (6–4PPs) [2]. In the absence of sufficient repair, this results in UV landmark transition mutation, C→T or CC→TT, leading in MM to inactivation of tumor suppressor genes (i.e., the CDKN2A gene encoding the $p16^{INK4A}$ (INK4A) and PTEN gene) and activation of potential oncogenes (i.e., CDK4, Nras, BRAF, and EGFR) [3].

While BCCs seem to develop de novo, development of some MM (and SCCs) is viewed as a multistep process. They either derive from malignant transformation of preexisting melanocytic naevi or appear on previously normal skin. In the model of melanoma progression from melanocytic nevi, benign melanocytic naevi are considered potential precursors of MM. An

early aberration is believed to occur in the tumor suppressor gene coding for INK4A. In unaltered cells, it binds to and inhibits CDK4, which drives entry of the cell into the cell cycle by phosphorylating the Retinoblastoma family of proteins (Rb). Activated Rb causes the release of E2F transcription factors and expression of E2F-regulated genes, thereby allowing progression from G1 to S phase. Melanoma predisposing mutations of the CDKN2A gene (mapping to 9p21) have been detected in as many as 25–40% of familiar melanomas and are frequently detected somatically in sporadic melanoma. In addition, melanoma-associated mutations (germline and sporadic) of CDK4 are found to disrupt INK4A–CDK4 binding.

After sufficient time, almost all MM proceed to the vertical growth phase (clinically manifesting in part as "nodular melanoma") and invade deep into the dermis, increasing the risk of metastasis. This growth phase is commonly associated with cytogenetic deletions and loss of heterozygosity on chromosome 10q as well as gain of 7q33 and of 8q. A candidate tumor suppressor, PTEN (a negative regulator of phospatidylinositol-3-kinase (PI3K)), was located to 10q23. Gain of 7q33 is associated with overexpression of c-MET, a thyrosine-kinase receptor for hepatocyte growth factor, which accounts not only for increased growth and motility but also for disruption of adhesion between keratinocytes and melanocytes through downregulation of E-cadherin and desmoglein 1. In addition, an activating mutation of c-myc was described in association with gain of 8q. Therefore, a high degree of genomic instability appears to be required for invasive melanoma. Activating mutations of the oncogenes Nras or BRAF, a downstream target of ras, are detected in more than 60% of melanocytic lesions, but appear to be a late event in melanoma progression [4].

## Diagnostic Principles

The diagnosis is usually made clinically; however, the use of a dermatoscope is helpful. The ABCDs – asymmetry, (irregular) border, (heterogeneous) color, diameter – can be used as a guide to differentiate melanoma from benign lesions. A histological confirmation of the diagnosis is mandatory, usually from a complete excision, or from a biopsy in certain cases such as lentigo maligna melanoma. In high-risk melanoma (especially after lymph node metastasis), a thorough investigation is necessary for detection of metastases, including imaging techniques such as CT scan or PET (Positron emission tomography).

## Therapeutic Principles

Standard procedure for primary MM lesions is a wide local excision. In Germany, a 0.5 cm margin of excision for melanoma in situ, a 1-cm margin of excision for melanoma ≤2 mm (Breslow depth), and a 2 cm margin for melanoma >2 mm are recommended. In Germany, a sentinel lymph node biopsy (SLNB) is routinely considered for primary melanomas deeper than 1.0 mm. For high-risk melanoma, treatment with IFN-α in the adjuvant setting is widely accepted; however, the optimal timing and dosing schedules and the best type of interferon (pegylated vs. conventional) are not yet defined. The optimal therapy for advanced melanoma depends to a great extent on the localization of the metastases (therapy options include surgical procedures, chemotherapy, immunotherapy, and/or radiation). Since the prognosis is poor once melanoma has metastasized [5], these patients should preferentially be treated in controlled clinical trials evaluating new approaches such as vaccination, antisense strategies, antiangiogenic therapies, and others.

# Malignant PKU

►Hyperphenylalaninemia

# Mallory-Weiss Syndrome

Gidon Almogy, Avraham I. Rivkind
Department of Surgery, Hadassah University Hospital, Jerusalem, Israel

## Synonyms

MWS

## Definition and Characteristics

Described in 1929 by George Kenneth Mallory and Soma Weiss of Harvard Medical School, Mallory-Weiss syndrome (MWS) was defined as upper gastrointestinal (UGI) bleeding caused by a mucosal tear at the gastro-esophageal junction [1].

## Prevalence

MWS is the cause of 5–15% of cases of upper gastrointestinal bleeding. Males are more commonly affected at a 7:1 ratio and the average age is 50 years [2]. Up to 15% of patients will suffer from concurrent liver disease, and 16–44% have a history of heavy alcohol abuse.

## Molecular and Systemic Pathophysiology

The mucosal tear is most commonly caused by prolonged vomiting and retching, classically described following binge drinking of alcohol. Other risk factors include pregnancy, biliary disease, peptic ulcer disease and certain medications (most notably polyethylene glycol for bowel preparation) have also been described. In 23% of patients there is no known risk factor.

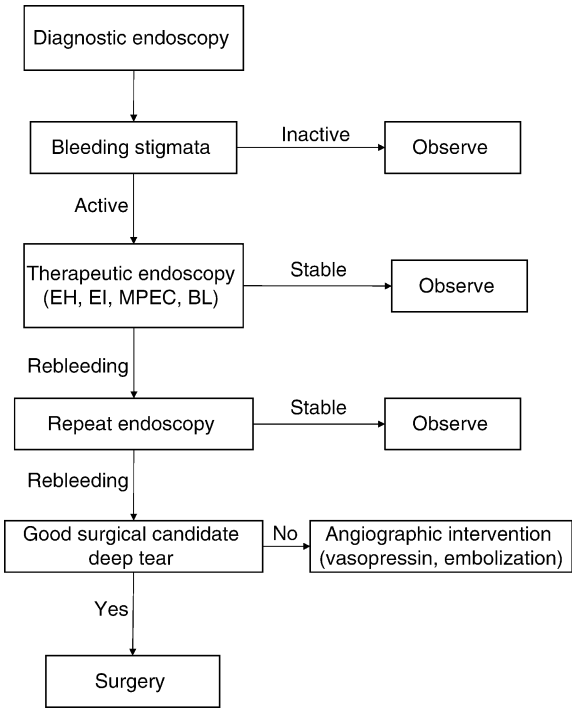
## Diagnostic Principles

Upper endoscopy is the most valuable tool in evaluating the presence of a mucosal tear at the gastro-esophageal junction. The findings are graded according to the stigmata for bleeding and the presence of blood vessels, and range from spurting vessel (grade I), oozing vessel (grade II), protruding vessel (grade III) and adherent blood clots (grade IV) [3]. Grades I and II are classified as active bleeding stigmata while grades III and IV are classified as inactive bleeding stigmata. The presence of active bleeding stigmata has been consistently shown to be the most significant predictor for rebleeding. Between 40 and 70% of patients will require a blood transfusion. A complicated course defined as requiring the transfusion of >6 units of blood, rebleeding, or the need for angiographic or surgical intervention can be predicted based on the presence of active bleeding on initial endoscopy and a low admission hematocrit [3].

## Therapeutic Principles

The majority of bleeding events are self-limited. Patients with inactive bleeding stigmata on initial endoscopy will rarely rebleed and do not require intervention. Patients with active bleeding stigmata require one of the following interventional techniques: upper endoscopy, trans-catheter embolization, systemic or selective infusion of vasopressin, or surgical intervention (Fig. 1) [4].

Past literature describes selective trans-catheter vasopressin infusion as the primary treatment method for massive UGI bleeding caused by MWS. Embolization of the left gastric artery is reserved for cases of vasopressin failure. More recent studies have shown the effectiveness of the various endoscopic techniques. These techniques include multipolar electric coagulation (MPEC), endoscopic hemo-clipping (EH), band



**Mallory-Weiss Syndrome. Figure 1** Therapeutic algorithm for the treatment of Mallory-Weiss syndrome. EH endoscopic hemoclip placement; EI endoscopic epinephrine injection; MPEC multipolar electric coagulation; BL band ligation.

ligation, and epinephrine injection. Using EH a mean number of 2.5 clips are applied to the bleeding vessel and surrounding tissue and it is emerging as a safe and effective technique [5]. It is probably safer than thermal endoscopic techniques in patients with deep tears as it will not cause esophageal wall perforation. There is controversy regarding whether rebleeding rates are influenced by the method of endoscopic intervention. In a recent study of patients with oozing vessels, rebleeding occurred in three of ten patients who underwent epinephrine injection and in none of the eight patients who underwent EH ($p < 0.05$) [2]. Other studies have not shown differences between the various endoscopic techniques [5]. The type of endoscopic intervention should therefore be individually based on the expertise of the endoscopist. Surgery is rarely necessary and is reserved for rebleeding and after repeated failure of endoscopic techniques.

# Malnutrition

Hideaki Kato
Internal Medicine and Molecular Science, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan

## Synonyms

Inadequate nutrition; Nutritional deficiency; Protein-energy malnutrition; PEM; Protein-caloric malnutrition; Starvation; Undernutrition; Marasmus; Kwashiorkor; Amenorrhea; Micronutrient deficiencies; Wasting

## Definition and Characteristics

Malnutrition may result from an inadequate food intake or poor dietary quality, digestive difficulties, absorption problems, presence of infection or other medical conditions. Malnutrition constitutes protein-energy malnutrition (PEM) and micronutrient deficiencies. PEM can be divided into three major forms; (i) marasmus, which is characterized by severe wasting, (ii) kwashiorkor, a malnutirition with edema, and (iii) marasmic kwashiorkor. Marasmus manifests typically triangular face, primary or secondary amenorrhea, extended abdomen, and anal or rectal prolapse. Kwashiorkor usually manifests with edema, changes of hair and skin color, anemia, hepatomegaly, lethargy, severe immune deficiency, and early death. Kwashiorkor is differentiated from marasmus by the presence of edema. The word kwashiorkor originates from the Ga language in Ghana; it implies "the disease that the young child developed when displaced from his mother by another child or pregnancy" [1].

Micronutrient deficiencies are diseases caused by a dietary deficiency of vitamins or microminerals, which are essential elements needed for life in small quantities.

## Prevalence

852 million people were estimated to be undernourished worldwide, and most (815 million) living in developing countries [1].

Approximately 9% of children below 5 years of age suffer from wasting and are at risk of death or severe impairment of growth and psychological development [2]. Malnutrition is directly responsible for 30,000 deaths every year in children younger than 5 years in developing countries.

Micronutrient deficiencies: overall 2 billion people worldwide, 740 million people are deficient in iodine and 1 billion people are deficient in iron. Vitamin A deficiency affects 250 million people.

## Genes

Specific gene mutation of PEM has not been identified.

## Molecular and Systemic Pathophysiology

Marasmus involves inadequate intake of protein and calories, whereas kwashiorkor is caused by inadequate protein intake in the presence of fair to good energy intake. It is still not unclear why some malnourished children developed kwashiorkor while others develop marasmus. The etiology of kwashiorkor is multifactorial and includes food insecurity, inadequate weaning and other feeding practices, infection, aflatoxins exposure, and possibly oxidative stress.

Nutrition regulates the synthesis of insulin-like growth factor 1 (IGF-1), a polypeptide growth factor important for the growth-promoting effects of growth

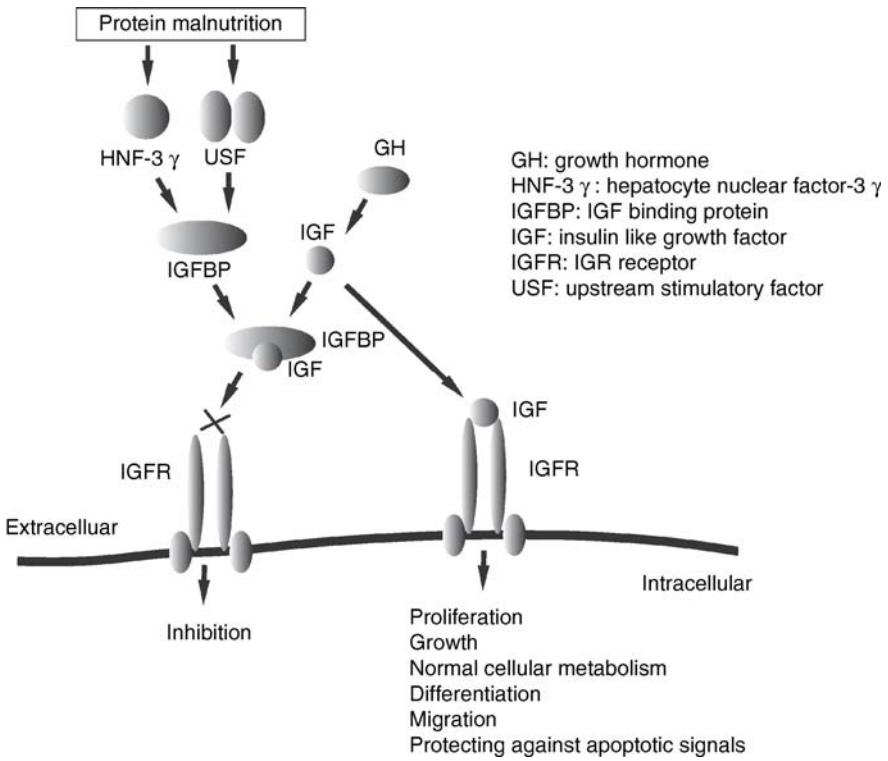
hormone (GH). Regulation of IGF-1 may be a key control point for nutritional regulation of growth. In children with growth arrest due to PEM, IGF-1 levels are decreased, and the decreased IGF-1 may be causally related to the growth arrest. The lowering of IGF-1 caused by nutritional insufficiency is dominant to the positive effects of pituitary GH. For example, in children with PEM, levels of IGF-1 are decreased even though the circulating GH is generally elevated. The decrease of IGF-1 by PEM is mediated by increase of IGF-binding protein-1 upregulation through increase of upstream stimulatory factor (Fig. 1).

## Diagnostic Principles

In children, PEM is defined by measurements that fall below 2 SD under the normal weight for age (underweight), height for age (stunting), and weight for height (wasting). Wasting indicates recent weight loss, whereas stunting usually results from chronic weight loss. Furthermore, severe acute malnutrition (SAM) is defined as a weight-for-height measurement of 70% or more below the median, or 3 SD or more below the mean reference values of National Center for Health Statistics, which is called "wastes"; the presence of bilateral pitting edema of nutritional origin, which is called "edematous malnutrition"; or a mid upper-arm circumference of <110 mm in children aged 1–5 years [3]. SAM should be differentiated from chronic malnutrition because of it has higher mortality rate, different causes, different indicators, and requires different interventions as chronic malnutrition.

## Therapeutic Principles

Most of severely malnourished children are complicated by concurrent infective illness, particularly acute respiratory infection, diarrhea, and gram-negative septinemia. Children with severe malnutrition should be treated according to WHO guidelines insofar as staffing levels allowed [2]. The core of WHO management protocol is ten steps in two phases (*initial treatment* and *rehabilitation*). *Initial treatment* includes the treatment of hypoglycemia, hypothermia, dehydration, electrolyte imbalance, and micronutrient deficiencies, whereas *rehabilitation* includes initial stabilization and catch-up growth.



**Malnutrition. Figure 1** The IGF system plays a pivotal role in normal growth throughout fetal and childhood development. In adult life, this system continues to function by regulating normal cellular metabolism, proliferation, differentiation and protecting against apoptotic signals via IGF and IGFR interaction. Bioavailability of IGF is regulated by IGFBP as binary complex of IGF and IGFBP is unable to bind IGFR. The gene encoding IGFBP is highly sensitive to nutritional status and protein malnutrition increases USF and HNF-3 γ, which lead to stimulation of IGFBP-1 gene transcription. As a result, protein malnutrition causes growth inhibition.

Since WHO management protocol requires many trained staff and substantial inpatient bed capacity, a community-based model for the management of acute malnutrition, called "community-based therapeutic care" has been adopted in a growing number of countries and international relief agencies. SAM is classified on the basis of whether there are coexistent life-threatening complications. Children with SAM complicated by life-threatening illness receive inpatient care according to the WHO treatment protocols. On the other hand, those with SAM without life-threatening complications are treated through weekly or fortnightly attendance in outpatient therapeutic programs. About 70% of patients were treated solely as outpatients and overall case-fatality ratio were about 5% [4].

Foods with a high content of absorbable micronutrients are considered the best means for preventing micronutrient deficiencies. In a circumstance where supplies of such food are unavailable, specific preventive and therapeutical interventions are required.

# mAMPD Deficiency

►Myoadenylate Deaminase Deficiency

# Manganese Deficiency

John W. Finley
Grand Forks Human Nutrition Research Center, ARS, USDA, Grand Forks, ND, USA

## Definition and Characteristics

Manganese (Mn) is an essential nutrient, and lack of Mn in the diet impairs the health of animals.

## Prevalence

Deficiency has not been reported in free-living humans, and is restricted to defined experimental or therapeutic diets.

## Molecular and Systemic Pathophysiology

Manganese (Mn), an essential metal and nutrient, enters the body through the diet or through inhaled Mn-laden dust. There is limited absorption of dietary Mn, but very little regulation of absorption via the lungs. Absorbed Mn moves to the liver and may be excreted into bile, or bound to transferrin or albumin for transport by systemic blood supply [1]. Alternatively, $Mn^{2+}$ may be converted to $Mn^{3+}$ (interconversion between $Mn^{2+}$ and $Mn^{3+}$ may be facilitated by ceruloplasmin) and bound to transferrin for transport. In cells, Mn is essential for activity of multiple proteins, including glutamine synthetase in the brain, glycosyl transferase, needed for sulfomucopoly-saccharide synthesis and cartilage/bone formation, and Mn superoxide dismutase, needed for anti-oxidant protection [2]. Animals deficient in Mn have impaired skeletal development and metabolic abnormalities, but this is unreported in humans [1] (Fig. 1).

## Diagnostic Principles

Manganese deficiency is rare; diagnostic criteria include transient dermatitis, slight reddening of the hair, hypocholestrolnemia and decreased levels of clotting proteins.

## Therapeutic Principles

Deficiency of Mn is corrected by addition of Mn to the diet; the Adequate Intake (AI, in mg/d) ranges from 1.2 (children) to 2.3 (adult men) and the Upper Limit ranges from 2 (children) to 11 (adults) [3].

# Manganese Excess

John W. Finley
Grand Forks Human Nutrition Research Center, ARS, USDA, Grand Forks, ND, USA

## Definition and Characteristics

Excessive exposure to Mn-laden dust results in debilitating toxicity.

## Prevalence

Mn-toxicity is well established in miners exposed to Mn-laden dust and possibly in subjects exposed to high concentrations in water. Toxicity is more likely in the very young, patients with hepato-biliary dysfunction, and/or patients with iron deficiency.

## Molecular and Systemic Pathophysiology

Toxicity from chronic exposure to Mn-laden dust (>1.0 mg Mn/m$^3$) is well reported. $Mn^{3+}$ bound to transferrin may cross the blood-brain barrier and be taken up by cells by using receptor-mediated endocytosis. Alternatively, free $Mn^{2+}$ may cross by the blood-brain barrier and be taken up into cells by using the divalent metal transporter DMT1. The exact mechanism of Mn toxicity is unknown but proposed mechanisms include oxidation of dopamine and inhibition of mitochondrial and/or synaptic cleft function [1]. Because healthy hepato-biliary activity and an integral blood-brain barrier are necessary for proper regulation of brain Mn, infants, very young children [2] and adults with liver disease may be more at risk for Mn toxicity. Also, Fe and Mn both utilize DMT1, thus Fe deficiency may increase Mn absorption and susceptibility to toxicity [3]. (see Fig. 1 in the chapter ►Manganese Deficiency).

## Diagnostic Principles

Manganese toxicity is indicated by progressive Parkinson-like neurological deterioration, bradykinesia, tremor, impaired postural reflexes and dystonia. Accumulation of Mn may be confirmed by excessive concentrations in the blood, and brain accumulation

M

may be visualized by T1 weighted relaxation of MRI images.

### Therapeutic Principles

Manganese toxicity is treated by removing sources of Mn exposure, and/or enhancing biliary excretion. Although neurological deterioration may not progress further, it is unclear whether neurological symptoms will reverse with treatment.

## α-Mannosidosis

Johannes Uhl[1], Jürgen Kopitz[2], Michael Cantz[2]
[1]Scil Proteins Production GmbH, Halle, Germany
[2]Institute of Pathology, University of Heidelberg, Heidelberg, Germany

### Synonyms

Lysosomal α-D-mannosidase deficiency; α-mannosidase B deficiency

### Definition and Characteristics

α-mannosidosis is an autosomal recessive disorder caused by the deficiency of the lysosomal enzyme α-mannosidase. This leads to the massive accumulation of partially degraded oligosaccharides in lysosomes with consequent enlargement and impaired function of varied cell types and organs, with a clinical picture resembling a mucopolysaccharidosis.

### Prevalence

Approximately 100 patients have been reported in the literature to date.

### Genes

Defective MAN2B1 gene coding for lysosomal α-mannosidase (EC 3.2.1.24) is localized on chromosome 19cen-q12 with a length of about 200 kilobases and consists of 24 exons.

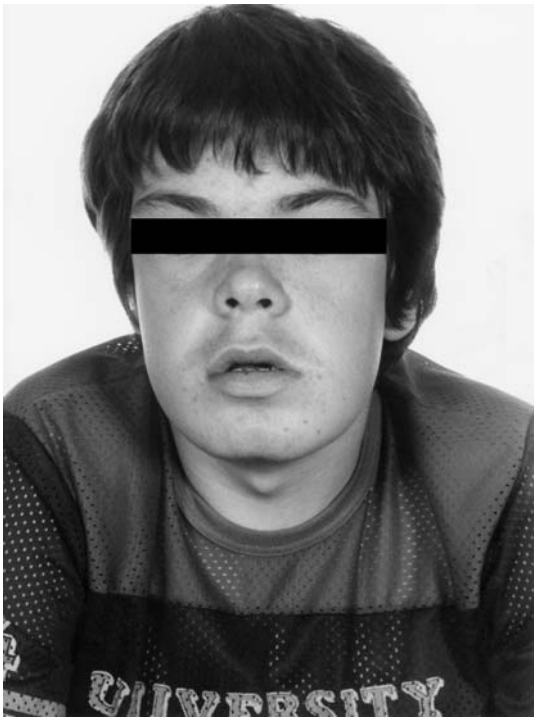
### Molecular and Systemic Pathophysiology

Lysosomal α-mannosidase is synthesized as a precursor protein consisting of 1,010 amino acids (113.67 kDa) which is first processed into three peptides of 70, 42, and 13/15 kDa, the 70 kDa piece being further cut into three smaller peptides, which are finally disulfide-linked. The processed protein is heavily glycosylated. α-mannosidase is necessary for the lysosomal degradation of N-linked carbohydrates released during glycoprotein catabolism, and cleaves all known types of α-mannosidic linkages [1]. The patients generally show severely decreased α-mannosidase activity (below 5%); however, there exist some patients with high residual activity. The consecutive cellular accumulation of partially degraded oligosaccharides leads to a disorder that has been grouped into a severe infantile form (type I) with rapid mental deterioration, inner ear hearing loss, hepatosplenomegaly, more severe dysostosis multiplex and death before the age of 12, or a milder juvenile-adult phenotype (type II, see Fig. 1), in which late-onset ataxia, retinal degeneration, and psychiatric symptoms may be found, adding to skeletal dysplasia, hearing loss, and cognitive impairment [2,3]. The three major urinary metabolites excreted are Man(α1 > 3) Man(β1 > 4)GlcNAc, Man(α1 > 2)Man (α1 > 3)Man(β1 > 4)GlcNAc, Man(α1 > 2)Man(α1 > 2) Man(α1 > 3)Man(β1 > 4)GlcNAc [2].

Many different causative gene mutations have been identified so far, including missense, nonsense, or splicing mutations, as well as deletions and insertions [1,4].

### Diagnostic Principles

Vacuolated lymphocytes, a granular or foamy cytoplasm in the hepatocytes, and marked and widespread ballooning of the nerve cells are indicative of a lysosomal storage disorder. TLC and HPLC can detect elevated amounts of oligosaccharides in urine and fibroblasts. The diagnosis must be confirmed by determination of lysosomal α-mannosidase activity in white blood cells, fibroblasts or serum. Prenatal diagnosis is



**α-Mannosidosis. Figure 1** Sixteen year old patient with α-mannosidosis exhibiting mildly coarsened facial features.

performed by enzyme activity determinations in cultured amniotic fluid or chorionic villus cells, as well as native chorionic villi [1,2]. Molecular genetic analysis should be attempted for confirmation of diagnosis and genetic counseling.

### Therapeutic Principles

Hematopoetic stem cell transplantation has been reported to halt the progressive cognitive loss in α-mannosidosis patients, early diagnosis and treatment being critical for best results [5].

# Marfan Syndrome

Philip F. Giampietro
Department of Medical Genetic Services, Marshfield Clinic, Marshfield, WI, USA

## Synonyms

MFS

## Definition and Characteristics

Autosomal dominant pleiotropic disorder of connective tissue with major clinical findings, including aortic root dilatation that may lead to dissection, ectopia lentis and dural ectasia [1]. Skeletal features, which may collectively represent a single major criteria and lead to earlier recognition of Marfan syndrome, include increased height and arm span, anterior chest deformity, joint laxity, scoliosis, pes planus, arachnodactyly, high arched palate, dental crowding and hammer toes. Craniofacial features associated with Marfan syndrome include downslanting palpebral fissures, malar hypoplasia, enophthalmos and retrognathia. A diagnosis of Marfan syndrome should be considered in individuals who present with spontaneous pneumothorax. Minor features in individuals with Marfan syndrome include inguinal hernia and striae atrophicae. Developmental dysplasia of the hip occurs with an incidence of 2%. Osteoporosis and osteopenia have been reported in Marfan syndrome. The clinical significance of this finding is uncertain at present.

## Prevalence

The prevalence of Marfan syndrome is approximately 2–3 per 10,000 individuals.

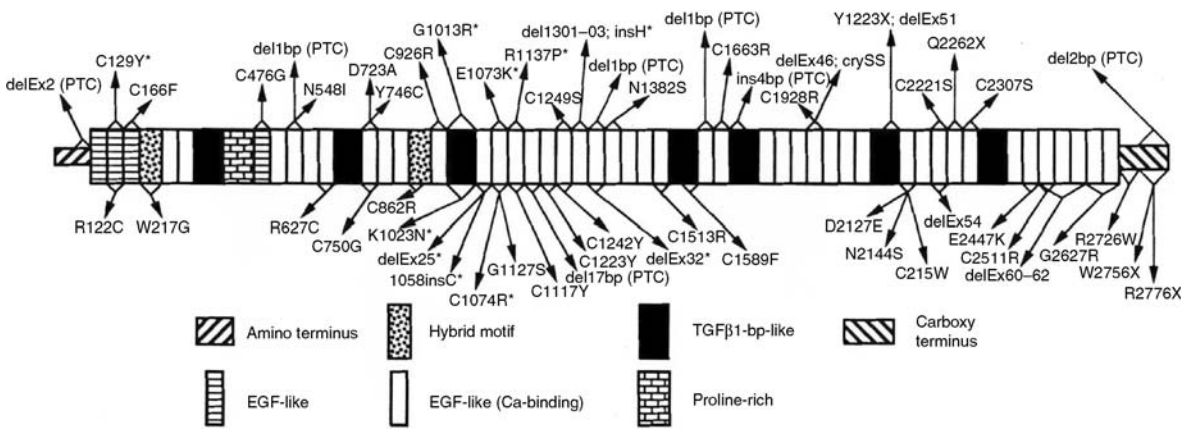
## Genes

Marfan syndrome is caused by mutations in the fibrillin-1 (FBN1) gene on chromosome 15q21.1.

## Molecular and Systemic Pathophysiology

Fibrillin-1, a glycoprotein with a molecular weight of 350 kDa represents the major component of microfibrils [2]. The FBN1 gene is composed of 65 exons encoding a series of 47 epidermal growth factor (EGF)-like domains, each containing six cysteine-repeats. Calcium binding is mediated by the presence of the EGF domain structure, three intradomain disulfide linkages, and negatively charged amino acid residues, including aspartic acid and glutamic acid. More than 500 mutations in the FBN1 gene have been identified [3]. Approximately 70% of FBN1 mutations are identifiable in individuals who satisfy the diagnostic criterion for Marfan syndrome. Missense mutations in FBN1 that affect cysteine residues important for proper EGF structure or amino acids involved in calcium binding act in a dominant negative fashion, usually resulting in a moderately severe phenotype. The severe neonatal form of the disease appears to be caused by missense mutations in exons 24–26 or skipping of exons 31 or 32.

FBN1 mutations have been identified in patients with the MASS (mitral valve prolapse, mild aortic root dilatation, striae and skeletal involvement) phenotype [4] and in several patients with Shprintzen-Goldberg syndrome. The identification of an in frame FBN1 deletion in affected family members with autosomal dominant Weill-Marchesani syndrome [5] and a mutation causing a single base substitution at codon 1796 in members of a three-generation kindred with kyphoscoliosis have widened the phenotypic spectrum associated with FBN1 gene mutations (Fig. 1).



**Marfan Syndrome. Figure 1** FBN1 gene containing 65 exons and various epidermal growth factor-like and transforming growth factor beta-like domains (Dietz HC, Pyeritz RE [1995] Mutations in the human gene for fibrillin-1 [FBN1] in the Marfan syndrome and related disorders. Hum Mol Genet 4 Spec No:1799–1809, with permission from Oxford University Press).

### Diagnostic Principles

For a clinical diagnosis of Marfan syndrome, in the absence of family history, an affected person should display major criteria in at least two organ systems (cardiac, eye, skeletal, dural ectasia) and involvement of a third organ system. In the presence of a positive family history, an affected person should display one major criterion in an organ system and involvement of a second organ system. Inability to detect a mutation in FBN1 or molecular abnormality of fibrillin-1 does not exclude the diagnosis of Marfan syndrome in a person who fulfills the clinical criteria.

### Therapeutic Principles

Early recognition and diagnosis of Marfan syndrome is important in order to enable implementation of treatment for cardiovascular symptoms. Beta-adrenergic blockers such as atenolol are used to decrease the rate of aortic root enlargement. Prophylactic repair of thoracic aneurysms is recommended when the diameter reaches between 5.0 and 5.5 cm. Patients should avoid contact sports and isometric exercise in order to minimize shearing forces on the aorta. Periodic ophthalmologic and orthopedic follow-up are necessary. Surgical correction of scoliosis may be necessary. As patients with Marfan syndrome survive longer, it is anticipated that degenerative arthritis of the hip, knees and other joints will represent new health concerns.

## Marinesco-Sjögren Syndrome

Inga Harting[1], Nicole I. Wolf[2]
[1]Department of Neuroradiology, University of Heidelberg Medical Centre, Heidelberg, Germany
[2]Department of Pediatric Neurology, University of Heidelberg Medical Centre, Heidelberg, Germany

### Synonyms

MSS; Hereditary congenital spinocerebellar ataxia accompanied by congenital cataract and oligophrenia

### Definition and Characteristics

Marinesco-Sjögren syndrome (MSS; OMIM 248800) is a rare, clinically defined disease entity characterized by the triad of ataxia, bilateral cataracts which have been observed to occur with a variable, early childhood onset, usually after the age of 3, and nonprogressive psychomotor retardation. Frequent additional findings include muscle hypotonia, muscle weakness, muscular atrophy, as well as short stature. Endocrinological abnormalities as hypergonadotropic hypogonadism have been found in a number of patients.

Laboratory investigations may reveal a slightly increased level of creatine kinase. The most common findings on brain imaging are cerebellar hypoplasia or atrophy, more pronounced in the vermis than the hemispheres. At least three syndromes with additional, untypical features have been identified and separated from the characteristic MSS, namely the syndrome of congenital cataracts, facial dysmorphism, and neuropathy (CCFDN; OMIM 604168), a syndrome with additional demyelinating neuropathy and recurrent episodes of myoglobinuria/acute rhabdomyolysis, and MSS with chylomicron retention disease and low vitamin E (OMIM 607692).

### Prevalence

Data on prevalence are missing. The disease is very rare.

### Genes

The pattern of inheritance with healthy parents, manifestation in both sexes, and the frequently reported

consanguinity implies an autosomal recessive disease. Homozygosity mapping localized a MSS locus on chromosome 5q31 and recently mutations in SIL1 have been identified in patients with classical MSS. SIL1 encodes a nucleotide exchange factor for the heat-shock protein 70 (HSP70) chaperone BiP, a key factor in regulating endoplasmatic reticulum functions. Classical MSS has therefore been proposed to represent a disorder of protein biosynthesis or processing in the endoplasmatic reticulum.

In contrast, linkage analysis in CCFDN and in MSS with demyelinating neuropathy and myoglobinuria localized to a 18qter region. CCFDN is caused by mutations in the gene coding for a protein phosphatase, CTDP1. MSS with chylomicron retention disease is due to mutations in SARA2 on chromosome 5q31.1 involved in intracellular trafficking of proteins.

### Molecular and Systemic Pathophysiology

Following the identification of a gene locus, classical MSS is currently thought to represent a disorder of protein biosynthesis or processing, though the underlying pathophysiology remains yet to be elucidated.

In the two reported cases with postmortem investigations, the most striking single abnormality was severe cerebellar atrophy. Histopathology of the cerebellum in a 4-year old boy demonstrated very severe atrophy of the cortical ribbon with almost complete absence of Purkinje and granule cells while cerebellar foliation was normally preserved. Nerve fibers were nearly completely lost in the cortex and severely reduced in the cerebellar white matter; in addition, gliosis of the cerebellar nuclei was noted. Atrophy and gliosis were also observed in pontine nuclei, transverse pontine fibers and descending tracts, as well as the inferior olivary nuclei. Biopsied muscle reveals a unique dense double membrane structure associated with the nuclei on electron microscopy. Less specific myopathic changes include variation in fiber size, internalization of nuclei, autophagic vacuoles, and accumulation of abnormal mitochondria in a subsarcolemmal localization.

### Diagnostic Principles

Diagnosis is based on typical clinical findings as described earlier. Mutation analysis of SIL1 confirms the diagnosis, as well as the presence of autophagic vacuoles and demonstration of unique dense membranous structures associated with cell nuclei in biopsied muscle.

### Therapeutic Principles

Therapy is supportive with operation of cataracts to restore/preserve vision and physiotherapy to prevent contractures.

## Maroteaux-Lamy Syndrome

►Mucopolysaccharidoses

## Mastocytosis

Jürgen Grabbe
Department of Dermatology, Medical University of Luebeck, Luebeck, Germany

### Definition and Characteristics

Mastocytosis is an heterogeneous group of disorders characterized by primary increase of tissue mast cells especially in skin and bone marrow. According to different patterns of organ involvement, five main categories are defined: (i) pure cutaneous mastocytosis (e.g., urticaria pigmentosa), (ii) systemic mastocytosis, especially of the bone marrow, without concomitant hematological disorder, (iii) mastocytosis with an associated clonal hematological, non-mast cell lineage disease, (iv) high-grade leukemic mast cell disease, and (v) unifocal mast cell sarcoma [1]. Clinical symptoms of mastocytosis are due to increased mast cell burden and release of mediators both in allergic reactions or even in the absence of immunological stimulation: e.g., histamine, prostaglandins and leukotriens are responsible for urticaria, dyspnoe, diarrhea and hypotension. A generally increased overall releasibility of mast cells is not definitively proven in mastocytosis.

## Prevalence

No reliable data are available. Masocytosis is generally regarded as a rare disease, although an unknown number of cases may be misdiagnosed or overlooked.

## Genes

"Regulatory" mutations, i.e., deletions or base exchanges in the juxtamembrane region encoded by exon 11 may result in loss of regulatory capacity and constitutive dimerization and activation of c-kit [2]. These mutations are found in many cases, e.g., gastrointestinal stromal tumors (GIST), but can be detected only in some cases of mastocytosis where their role is uncertain. Point mutations in the phosphotransferase domain coded by exon 17 leading to amino acid exchange (e.g., Asp816Val) cause c-kit activation in the absence of stem cell factor (SCF) even without receptor dimerization. Transfection experiments using c-kit variants which bear kinase domain mutations resulted in factor-independent survival, proliferation, and *in vivo*-tumorigenecity of murine mast cell lines. The Asp816Val exchange is detected in the vast majority of patients with cutaneous or systemic adult-onset mastocytosis, interestingly with the exception of cases of familial or aggressive mastocytosis. In extensive disease, the same c-kit mutations were also detected in blood mononuclear cells indicating that the affected clone shows variable expansion among bone marrow-derived lineages.

Other than in adult disease, "enzymatic" c-kit mutations affecting exon 17 were found in <50% of pediatric urticaria pigmentosa, and their presence could not be related to permanent or transient mastocytosis. This indicates mechanisms counteracting c-kit activation in spontaneous resolution or additional and alternative pathogenic events for autonomous mast cell growth.

## Molecular and Systemic Pathophysiology

SCF and its cellular receptor c-kit (CD 117) play a pivotal role in mast cell development. c-kit is expressed on hematopoietic progenitor cells, germ cells, and gastrointestinal stroma cells and belongs to the type III subfamily of receptor tyrosine kinases. These share an extracellular ligand-binding region with five immunoglobulin-like domains, a transmembrane part, and an intracellular domain bearing the kinase activity. A juxtamembrane region exerts a regulatory function preventing spontaneous kinase activity in the absence of SCF.

Ligand binding leads to dimerization of c-kit, induction of tyrosine kinase activity, and subsequent transphosphorylation of tyrosine residues. Phosphorylated tyrosines become docking sites for several intracellular signaling molecules, especially p85PIK leading to mast cell differentiation, survival, and activation.

## Diagnostic Principles

The diagnosis is based on clinical symptoms resembling type I allergic reactions, cutaneous signs (e.g., urticaria pigmentosa), histological proof of abnormal primary mast cell infiltration, and increased levels of mast cell tryptase (serum) or histamine metabolites (urine).

## Therapeutic Principles

Activity of mast cell mediators is blocked by specific inhibitors, mainly antihistamines. Interferon α may downregulate mast cell degranulation. Tyrosin kinase inhibitors are only clinically applicable in activating "regulatory" c-kit mutations as seen in GIST, whereas drugs affecting the "enzymatic" mutations of mastocytosis cells are not yet available for therapeutic purposes.

## McArdle Disease

Robert J. Beynon[1], Rosaline C. M. Quinlivan[2], Caroline A. Sewry[2]
[1]Department of Veterinary Preclinical Sciences, University of Liverpool, Liverpool, UK
[2]Centre for Inherited Neuromuscular Disorders, Robert Jones and Agnes Hunt Orthopedic and District Hospital NHS Trust, Oswestry, UK

### Synonyms

Glycogenosis V; Glycogen storage disease V; Myophosphorylase deficiency

### Definition and Characteristics

McArdle disease (MIM 232600) results from the almost complete absence of functional glycogen phosphorylase in skeletal muscle [1]. This enzyme is responsible for the breakdown of glycogen in the sarcoplasm via phosphorolysis of the substrate, glycogen, yielding glucose-1-phosphate. The condition is characterised by exertion-induced fatigue and myalgia and, under extreme exertion, painful muscle cramps and myoglobinuria with the attendant risk of renal failure. A marked characteristic of the disorder is the "second wind" phenomenon, which describes relief of symptoms with ongoing, prolonged exercise. There is marked heterogeneity in the presentation of this condition, such that some patients maintain a high level of muscle performance, whilst others of the same age and with the same genotype are severely limited by exercise intolerance. A significant proportion of patients will never experience myoglobinuria. The disorder may worsen with time; mild muscle wasting and weakness may develop from middle age. The onset is usually in childhood or adolescence although the diagnosis is rarely made before the third decade.

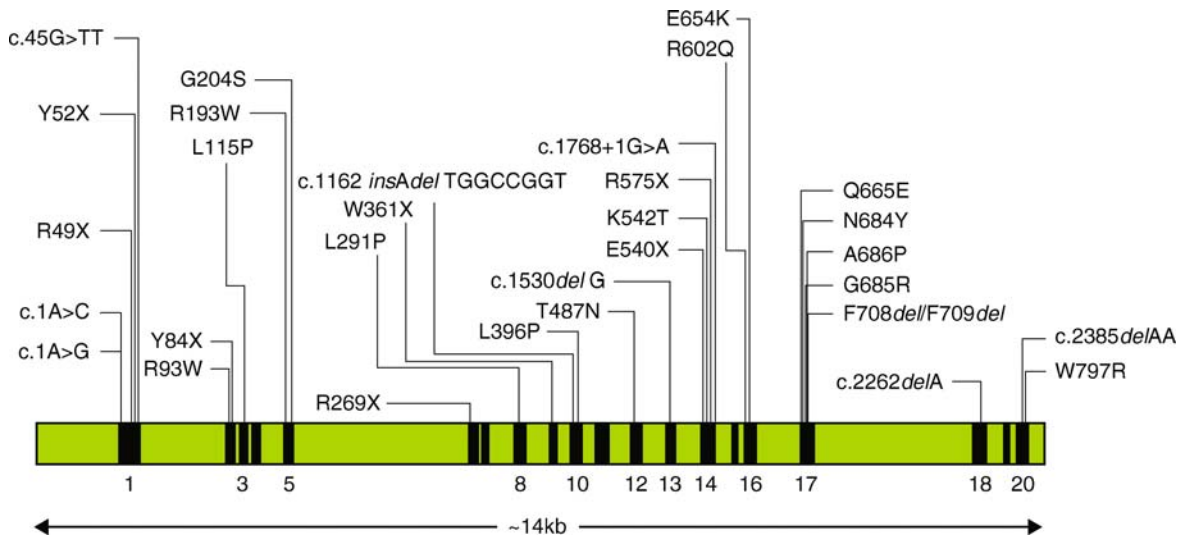
### Prevalence

Of the several metabolic myopathies caused by deficiencies in sarcoplasmic enzymes, McArdle disease is one of the most common. It is a rare autosomal recessive disorder. Precise epidemiological data are not available, although the prevalence in Texas is 1:100,000 [2].

### Genes

There are three isoenzymes of glycogen phosphorylase, the liver form (chromosome 14), the brain/foetal form (chromosome 20) and the muscle form (proximal part of 11q13). Only the last of these is affected in McArdle disease and with few exceptions, affected patients have virtually no detectable enzyme activity in muscle biopsies. There are over 80 reported mutations in the myophosphorylase gene ([3], Fig. 1).

In Caucasians, the most common mutation is an A–C mutation in codon 50, which causes the molecular phenotype commonly referred to as $Arg_{49}Ter$ or $R_{49}X$ (the discrepancy in the numbering system is a consequence of loss of the N-terminal methionine in the mature form of the protein as a co- or post-translational event). In southern European countries the preponderance of R50X is lower, and this mutation has never been seen in Japanese patients where F709del/F710del is commonly observed. In turn, this mutation has never been observed in non-Japanese patients. Recently, mutation analysis has shown apparently dominant cases to be pseudo-dominant with homozygous mutations occurring in more than one generation.



**McArdle Disease. Figure 1** Mutation in the myophosphorylase gene. The figure summarises representative mutations in the myophosphorylase gene. Because the protein sequence was previously counted from the second residue (the N-terminal methionine residue is removed from the mature protein), most mutation designations in the literature are displaced by one residue relative to the true length of the cDNA inferred sequence. Thus, the most common Caucasian mutation, R50X was previously known as R49X or R49TER. Mutations given with reference to the cDNA sequence are prefaced with "c".

An ovine and a bovine equivalent to McArdle disease are known [4].

## Molecular and Systemic Pathophysiology

The restriction to the muscle specific isoform means that there is no liver involvement. In the few patients that have been studied in detail, the lack of enzyme activity is coincident with a lack of immunoreactive protein or of mRNA. Lack of mRNA is a feature of the most common mutation, R50X, which, although a nonsense mutation, seems to bring about rapid degradation of mRNA as a consequence of early termination of translation. By contrast, a compound heterozygote of R50X/G205S revealed a strong mRNA signal on Northern blotting (unpublished data). In other groups of patients, a similar heterogeneity in myophosphorylase mRNA levels was observed, but these studies predated the discovery of mutations in the gene, and it is not possible to infer anything further about the relationship between genotype and molecular phenotype. Muscle phosphorylase cleaves glycogen to glucose-1- phosphate during anaerobic exercise. There is a secondary impairment of oxidative phosphorylation because of a virtual absence of the pyruvate normally produced through glycolysis. The second wind phenomenon occurs because of a shift in metabolism to fatty acid oxidation enabling exercise to continue.

## Diagnostic Principles

McArdle disease should be suspected when symptoms include exertion-induced fatigue and myalgia and, under extreme exertion, painful muscle cramps and myoglobinuria. Wasting of the upper body, especially around the paraspinal and scapular areas, may be seen. A raised serum creatine kinase (3×to 20× normal) is typical. An absence of lactate production in an ischaemic forearm test increases suspicion of McArdle disease, but a definitive diagnosis can only be obtained by muscle histochemistry. Although myophosphorylase is the key enzyme in sarcoplasmic glycogen degradation, deficiency of this enzyme is not always associated with a marked accumulation of glycogen, although there may be some sub-sarcolemmal accumulation. The commonly used diagnostic method relies on the activation of nascent enzyme in muscle and utilises the enzyme in the reverse direction (glycogen synthesis), monitoring the accumulation of glycogen as iodine-reactive material. The color development is not stable, so that it is essential to include a control sample in parallel with the test sample and to observe the outcome as soon as possible in order to avoid a false positive diagnosis. The commonly used histochemical technique also detects the brain isoform so that any regenerating fibers present in the sample will show enzyme activity. Similarly, activity of the brain isoform is also detected in spindle fibres and smooth muscle, but the majority of fibers have a complete absence of phosphorylase activity. The large number of rare mutations in this condition precludes DNA based diagnostics as a definitive test, although the most common mutations in certain ethnic groups (R50X) can sometimes be conclusive.

### Therapeutic Principles

At present there is no specific treatment for this disorder. Conditioning helped by a regular aerobic exercise programe will almost certainly improve patients' capacity to achieve a second wind and thus improve their exercise performance. Weight control is an important feature of management. A high protein or high fat diet, vitamin B6, glucagon and ribose administration have been tried in small and single case studies without evidence of benefit. So far, the only randomised controlled trial to demonstrate a statistically proven benefit in a small number of cases is low-dose creatine supplementation. The results, however, were not confirmed using a higher dose regimen and further work is needed to confirm this effect. Oral sucrose thirty minutes prior to planned exercise has been shown to improve exercise performance but regular sucrose supplementation for daily activities is not likely to be beneficial and may lead to unwanted weight gain and glucose intolerance [5]. Gene therapy techniques may provide a means for enzyme replacement in the future.

Naoto Kuroda
Department of Pathology and Clinical Laboratory, Kochi Red Cross Hospital, Kochi, Japan

### Synonyms

Meckel syndrome

### Definition and Characteristics

This syndrome is characterized by a triad of occipital encephalocele, bilateral polycystic kidneys, and postaxial polydactyly and generally exhibits the autosomal recessive inheritance [1–4]. This syndrome is a kind of congenital hepatorenal fibrocystic syndrome groups [2].

### Prevalence

The birth prevalence is estimated to be 1:3,500 in North America, 1:9,000 in Finland, 1:13,250 in the USA and 1:140,000 in the Great Britain [1,4].

### Genes

The candidate genes, namely MKS1, MKS2 and MKS3, of Meckel-Gruber syndrome (MGS) are mapped to chromosome 17q21-24 in Finnish kindreds, chromosome 13q13 in North African-Middle Eastern cohorts and 8q24 in consanguineous families originating from Pakistan and Northern India [1,2]. The karyotype is normal and this finding is important for the differential diagnosis of trisomy 13.

### Molecular and Systemic Pathophysiology

As a triad, occipital encephalocele (60–85%), bilateral polycystic kidneys (100%), and postaxial polydactyly (55%) are observed [1–4]. Oligohydramnios is frequently seen. Other associated central nervous system anomalies or abnormalities include prosencephalic dysgenesis, rhombic roof dysgenesis, cerebral and cerebellar hypoplasia, anencephaly, hydrocephaly, defects in the corpus callosum or olfactory bulbus, or hypopituitarism [3]. The kidneys are sometimes 10–20 times larger than normal. In the kidney, bilateral enlargement containing various-sized cysts is macroscopically seen [2,4]. Histologically, "renal dysplasia" characterized by cystic dilatation and primitive ducts surrounded by connective tissues are observed [2]. These connective tissues may contain myofibroblasts [4]. Corticomedullary differentiation is mostly absent [2]. Other associated renal anomalies include renal agenesis, renal hypoplasia, and ureteral duplication. The imbalance of proliferation and cell death causes the apical ridge to produce an additional digit during limb morphogenesis, resulting in polydactyly [2]. Regarding other digit anomalies, syndactyly or clinodactyly may be seen. In the liver, the ductal plate malformation can result in subsequent liver damage and inflammation can cause the formation of liver fibrosis. Malformed ductal plates have a low rate of apoptosis and an increase of proliferative activity [2]. In portal areas, the specific distribution of myofibroblastic cells is observed [4] and periportal fibrosis and biliary dysgenesis may be observed [2]. Other associated features of MGS include clubbed foot, short limbs, cleft palate or lip, short webbed neck, micrognathia, genital defects, accessory spleen, pulmonary hypoplasia, or cardiac malformations (ventricular or atrial septal defect, aortic hypoplasia or coarctation, aortic valvar stenosis, and rotational anomalies) [2–4].

### Diagnostic Principles

The coincidence of encephalocele, polycystic kidneys, and polydactyly points to the disease. In order to make a diagnosis of MGS, two of three major anomalies should be present. The systemic examination using an ultrasonography at the early gestation may detect these fetal developmental abnormalities [3]. Fibrocystic change of the liver may be often present. The differential diagnosis from Goldston syndrome, autosomal recessive polycystic kidney disease, Joubert syndrome and trisomy 13 is required [2,3].

The disease has a high risk of recurrence (about 25%) [4]. Most patients with this syndrome are stillborn or

die of respiratory or renal insufficiency in the neonatal period [2,4].

## Therapeutic Principles

Treatment is supportive.

# Mediterranean Fever, Familial

Cengiz Korkmaz
Department of Internal Medicine, Eskisehir Osmangazi University, Eskisehir, Turkey

## Synonyms

Recurrent polyserositis; Familial paroxysmal polyserositis; FMF (MIM249100)

## Definition and Characteristics

Familial Mediterranean fever (FMF) is an autosomal recessive disorder characterized by recurrent attacks of fever, peritonitis, pleuritis, arthritis and skin lesions. In some cases, it is complicated by secondary amyloidosis progressing to renal failure. It is primarily found in people of Jewish, Arabic, Turkish and Armenian ancestry.

## Prevalence

Its prevalence among susceptible ethnic groups varies between 1/500 and 1/2,000, and the carrier rate is about 20% in these populations.

## Genes

The FMF gene, denoted MEFV for Mediterranean fever, located at 16p13. More than 70 FMF gene mutations have been recorded to date. Five founder molecular alterations, E148Q in exon 2 and M680I, M694V, M694I, and V726A in exon 10, account for 70–80% of cases occurring in patients of Mediterranean ancestry [1].

## Molecular and Systemic Pathophysiology

The FMF gene, MEFV, encodes a protein called pyrin and is expressed predominantly in granulocytes, the most frequent cell in FMF inflammatory exudates, suggesting that pyrin plays some intrinsic role in regulating leukocyte function. Pyrin has been identified as a cytoplasmic protein and member of a family of proteins that all contain a domain first described in pyrin, the so-called pyrin domain. These proteins are involved in regulation of inflammation, apoptosis and/or cytokine secretion. The function of pyrin is more related to its N-terminal, which has a sequence of 90 amino acids and called pyrin domain. Others are death domain (DD), death effector domain (DED), and caspase activating and recruitment domain (CARD). Each domain can interact only with its similar counterparts, which is called homotypic interaction. These interactions are complex and not yet fully elucidated.

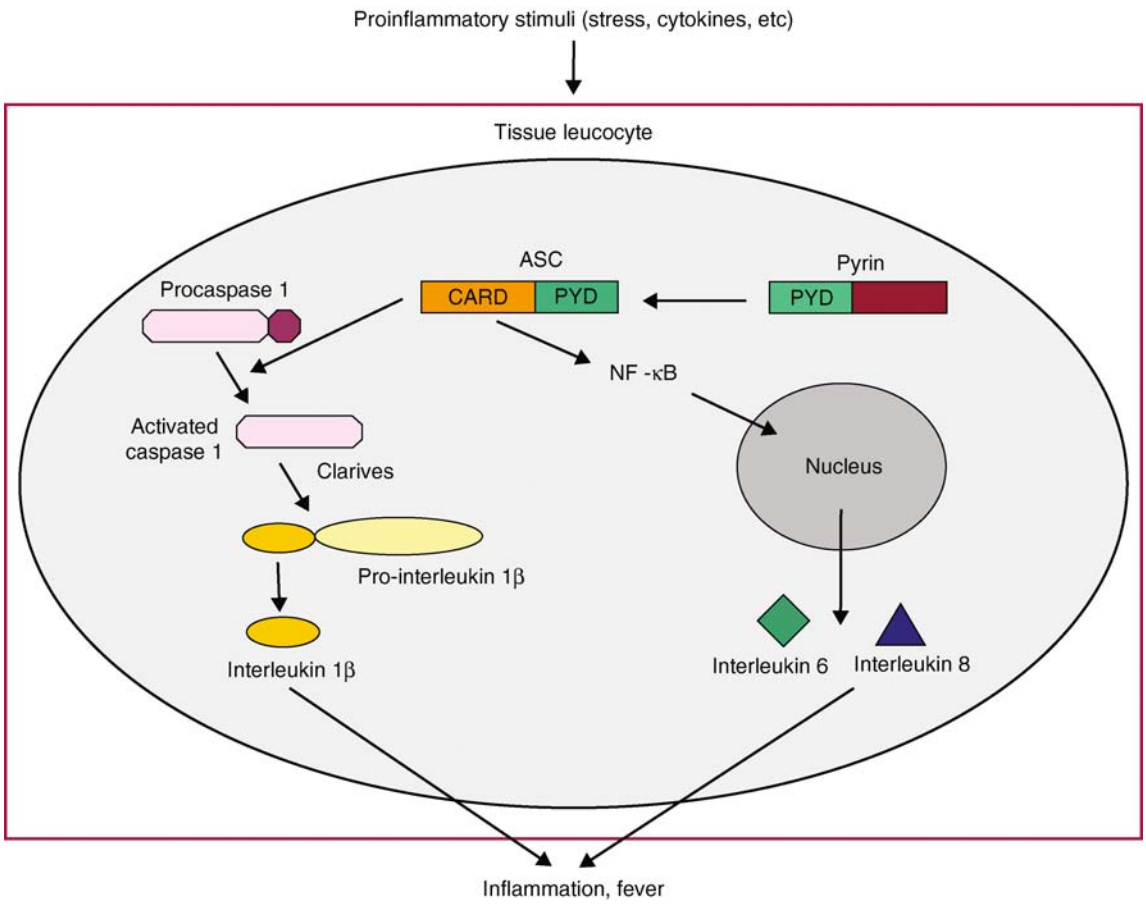
There is growing evidence that pyrin inhibits both NF-κB activation and apoptosis, induced by the apoptosis-associated speck-like protein containing a CARD (ASC), by disruption of the interaction between ASC and caspase-1. Pyrin is thought to indirectly regulate caspase-1 function, and therefore influences interleukin-1β processing and apoptosis. In patients with FMF, pyrin is defective, for which reason it interacts poorly with ASC, allowing it to react with procaspase, leading to IL-1 β production, NF-κB activation, inhibition of apoptosis and enhancement of the inflammatory burst [2,3] (Fig. 1).

## Diagnostic Principles

FMF is a clinical diagnosis, and the diagnostic criteria have been validated [4]. If a patient has a characteristic medical history and belongs to an ethnic group with a high prevalence of the disease, the diagnosis is easy to make. At the beginning of the disease, when clinical findings are not typical or when the familial history is lacking, genetic testing could be useful.

## Therapeutic Principles

The first-line treatment of FMF is colchicine. The adult dose is 1–1.5 mg daily and in non-responsive patients, it can be increased to 2 mg. Colchicine treatment is also necessary for protection against amyloid deposition that is likely to occur in kidney and other organs. In colchicine resistant patients, alpha



**Mediterranean Fever, Familial. Figure 1** Suggested mechanism of familial Mediterranean fever. Pyrin suppresses IL-1β processing and NF-κB through interactions with ASC. In patients with FMF, pyrin is defective, therefore it interacts poorly with ASC, allowing it to react with the procaspase, leading to IL-1β production, inhibition of apoptosis and enhancement of the inflammatory burst. interferon (3–5 million IU subcutaneous three times a week) can be a good adjunct to prevent attacks [5].

## Synonyms

Familial juvenile hyperuricemic nephropathy; Uromodulin associated kidney disease; Uromodulin storage disease

## Definition and Characteristics

An endosomal storage disease caused by mutations of uromodulin and leading to slow, progressive chronic kidney failure.

## Prevalence

While there has been knowledge of this condition for greater than 20 years, only recently have genetic advances allowed us to perform a complete clinical characterization. Unfortunately, many nephrologists still do not have a proper understanding of the clinical presentation of medullary cystic kidney disease (MCKD), hampering determination of prevalence rates. Approximately 100 families worldwide have been diagnosed with the condition, with approximately 60 families with a confirmed diagnosis of MCKD 2.

## Molecular and Systemic Pathophysiology

There are at least three subtypes of MCKD. All three conditions have an autosomal dominant inheritance pattern. MCKD types 1 [1] and 3 [2] have been linked to different areas of chromosome 1. Little is known regarding the pathophysiology of MCKD 1 and 3.

MCKD 2 is caused by a mutation in the gene producing uromodulin (Tamm Horsfall glycoprotein) [3]. Tamm Horsfall glycoprotein is produced exclusively in the thick ascending limb of Henle and is the most abundant protein in the urine of healthy individuals, though its function is not known. Thus, the manifestations of this disorder are strictly the result of abnormalities occurring in the tubulo-interstitium of the kidney. MCKD type 2 is an example of an endoplasmic reticulum storage disease. Mutations in one allele of the gene producing uromodulin result in a mutant uromodulin that is unable to fold correctly and deposits in the endoplasmic reticulum. Mutant uromodulin deposition prevents secretion of the wild-type uromodulin to a great extent, and affected individuals have very low urinary uromodulin levels. There are two clinical consequences: increased proximal tubular reabsorption of uric acid and slow, progressive chronic kidney failure.

In some way, absence of uromodulin or abnormal function of affected thick ascending limb cells results in increased proximal tubular reabsorption of uric acid. The mechanism for this abnormality has not been determined but must involve communication between the thick ascending limb and the proximal tubule.

Chronic kidney failure in this condition is associated with atrophy of thick ascending limb tubules. This tubular atrophy likely leads to secondary nephron death, resulting in slow, progressive chronic renal failure.

Individuals with MCKD type 3 have also been found to have abnormal uromodulin deposits in the thick ascending limb cells and decreased urinary uromodulin, though the mutation causing this sub-type is unknown.

## Diagnostic Principles

The autosomal dominant inheritance of progressive chronic kidney failure is the only key to diagnosis of this condition [3]. Individuals have a bland urinary sediment. Affected individuals usually start dialysis in the 4th through 7th decade of life. When found, precocious gout and gout in females is a diagnostic clue, but is not present in many families. Clinical suspicion and knowledge of the disorder are the key initial steps in pursuing the diagnosis. Medullary cysts are found in some individuals and families but are an inconstant finding – medullary cystic disease is therefore a misnomer. Patients with medullary cysts frequently do not have "medullary cystic kidney disease," and the absence of medullary cysts does not in any way rule out the presence of this condition.

For MCKD 2, mutational analysis verifies the diagnosis. The vast majority of mutations have been found in exons 4 and 5, but infrequent mutations have also been reported in exon 6. Urinary uromodulin levels will be low in MCKD 2 and MCKD 3, but these levels are also low in other forms of kidney failure. Immunohistochemical staining of the tissue with antibodies to uromodulin will reveal dense deposits in thick ascending limb tubules [4].

## Therapeutic Principles

Allopurinol will control gout and has been reported by some investigators to slow the progression of kidney disease [5]. It should be considered in all individuals with this condition, especially men with the disease who are likely to develop chronic, recurring, and tophaceous gout without treatment. ACE inhibitors have been used as a treatment in most individuals with chronic kidney disease. There is no known contraindication in patients with MCKD.

# Medullary Sponge Kidney

Michele Bisceglia[1], Carlos Galliani[2]
[1]Department of Pathology, IRCCS "Casa Sollievo della Sofferenza" Hospital, San Giovanni Rotondo, Italy
[2]Department of Pathology, Cook Children's Hospital, Fort Worth, TX, USA

## Synonyms

Maladie de Cacchi-Ricci; Lenarduzzi-Cacchi-Ricci disease; Papillary duct ectasia; Cystic disease of renal pyramids; MSK

## Definition and Characteristics

Medullary sponge kidney (MSK) is a developmental abnormality characterized by dilatation of the collecting ducts associated with defective urinary acidification and concentration [1]. MSK typically affects the collecting ducts of all papillae in both kidneys, but may be segmental, involve one or more renal papillae, one or both kidneys, or a horseshoe kidney. While dilatation of the collecting ducts is present at birth, clinical manifestations of hematuria, urinary tract infection, nephrocalcinosis, and nephrolithiasis emerge over a wide age range. Most MSK are sporadic, a few have autosomal dominant inheritance. Important associations of MSK include the Beckwith–Wiedemann syndrome/hemihyperplasia (13%), Ehlers-Danlos syndrome, autosomal dominant polycystic kidney disease, Caroli syndrome, hepatic fibrosis, Marfan syndrome, anodontia, growth failure, arterial fibromuscular dysplasia, congenital small kidney, congenital pyloric stenosis, hyperparathyroidism, multiple endocrine neoplasia type 2A, and Young's (immotile cilia) syndrome [1,2]. Four patients with MSK were found in a large kindred of northern European and Scandinavian ancestry with familial ureteral abnormalities syndrome.

## Prevalence

1 in 5,000–10,000, ~0.5% of patients undergoing intravenous urography, and 11–12% of patients with nephrocalcinosis and nephrolithiasis.

## Genes

Although the genetic basis and molecular mechanisms of many cystic diseases of the kidney have been elucidated, that of MSK is unknown. Based on the observation of a patient with MEN 2A who had MSK and that the RET gene plays an important role in renal development, the notion of a causal relationship has been advanced [1, and ref. 45 therein].

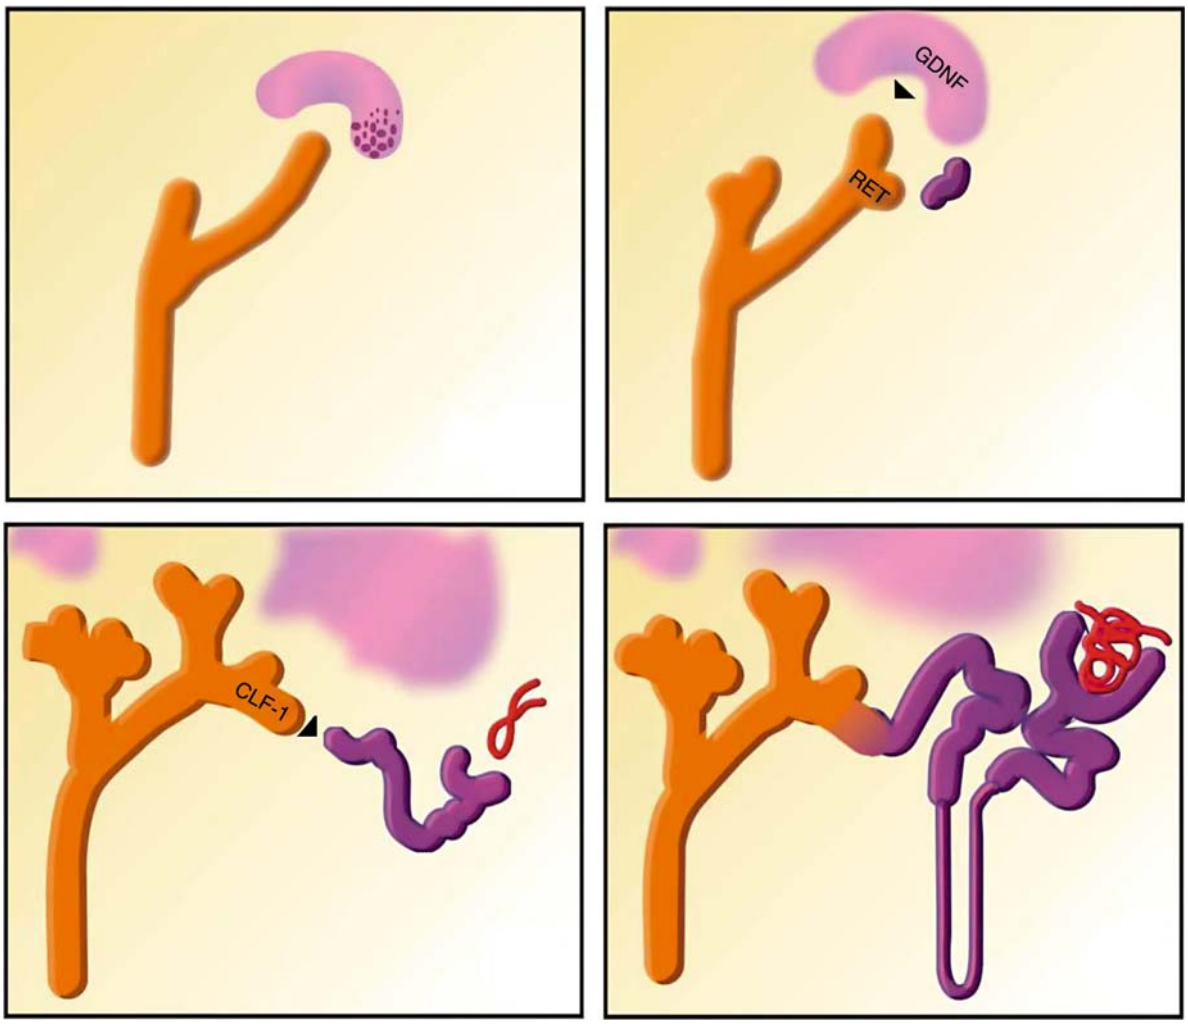
## Molecular and Systemic Pathophysiology

During development, the tips of the dichotomously branching ureteric buds exhibit distinct gene expression profiles and produce factors that induce cell conversion in the metanephric mesenchymal cap. In return, the metanephric cap exerts reciprocal induction to the ureteric buds. The end product of these interactions is the nephron with its collecting duct system [3] (Fig. 1).

It has been hypothesized that the medullary pyramid cysts result from ureteral bud/metanephric blastema disruption due to faulty signaling between RET tyrosine kinase receptor and glial-cell-line derived neurotrophic factor (GDNF), thus explaining the alterations both in the collecting duct and the nephron, an anatomical continuum of different embryological origins [1,4]. As a functional unit, the nephron produces urine by filtering waste, maintaining water/salt/mineral/acid/base homeostasis, vascular tone, as well as generating and being the target of multiple endocrine activities, including production of erythropoietin and calcitriol. Impaired urinary acidification and hypocitraturia contribute to precipitation of calcium in the collecting medullary tubules, and it is conceivable that MSK affects the tubules beyond the sixth order of branching and the inner medullary cells responsible for acid/base transport and salt and water absorption. Abnormal parathyroid function (primary hyperparathyroidism) is often seen associated with MSK and this could be also explained on the basis of some derangement in RET oncogene's role in controlling parathyroid cell proliferation [1]. The common association with Beckwith–Wiedemann syndrome/hemihyperplasia is of note, also in view of the frequent hypercalciuria and nephrocalcinosis affecting these patients.

## Diagnostic Principles

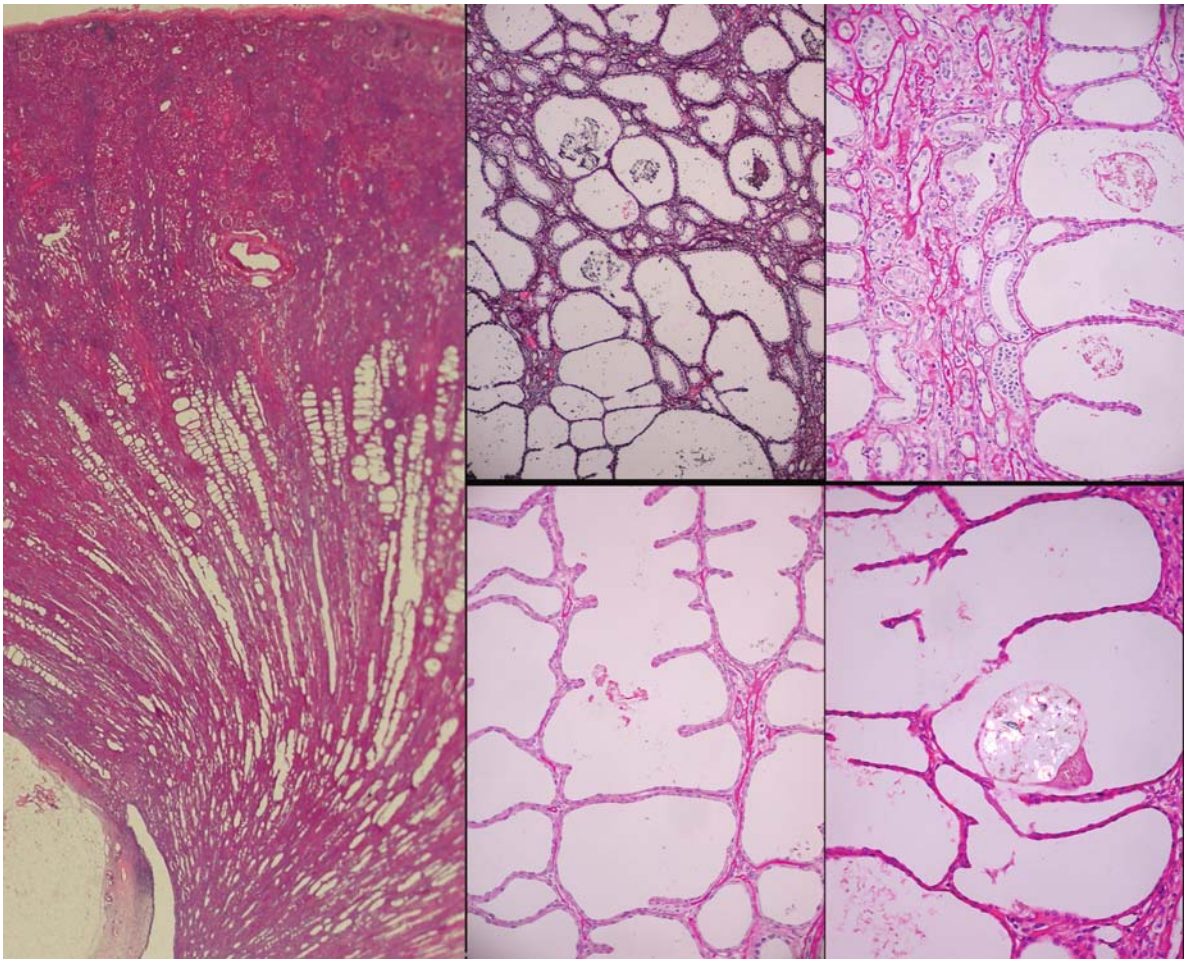
The diagnosis is almost always established radiographically. Excretory urography reveals radial linear striations in the papillae, often referred to as a "paintbrush" appearance. High-quality excretory urography with renal tomograms obtained before and after injection of contrast medium is considered to be the most accurate modality of identifying MSK. Abdominal plain film may reveal nephrocalcinosis/nephrolithiasis. Ultrasound may reveal hyperechoic medulla due to calcification. In early cases, the papillae of MSK without calcification may appear bright on ultrasound. A grading scheme based on intravenous urography, correlating with severity of disease, has been proposed. In regard to a 13% association with the overgrowth syndromes, when MSK is diagnosed in a child with subtle or overt signs pointing to these conditions, plans for imaging surveillance, chiefly focusing on intra-abdominal tumors, should be made. The gross



**Medullary Sponge Kidney. Figure 1** Sequential steps in the interdependent development of the collecting duct system (ochre), metanephric mesenchymal cap (pink-violet), and nephric vesicle (purple). Metanephric glial-cell-line derived neurotrophic factor (GDNF) from the metanephric mesenchyme activates the receptor tyrosine kinase RET located at the tips of paired outgrowths of the mesonephric wolffian duct, guiding its elongation and dichotomous branching (700,000–1,200,000 branches in each human kidney). In return, the ureteric bud tip derived cytokine CLF-1, required for secretion of the IL-6 family member CLC, guides epithelialization of metanephric mesenchyme during nephrogenesis. A complex array of gene expressions with overlapping molecular mechanisms activate reciprocal induction and regulatory processes, including the participation of elements derived from the neural crest, that play critical roles during nephrogenesis, eventually connecting tubules lined by epithelia of both ureteric bud and mesenchymal/blastemal derivation.

examination of most MSKs is unremarkable, a few are modestly enlarged, still others are shrunken and scarred due to chronic pyelonephritis. Characteristically, the cut surface reveals ectatic ducts and small cysts, sometimes containing calculi, dark brown or translucent mucus-like material, confined to the medulla, mostly toward the papillae. The histologic hallmark is the presence of ectatic collecting ducts extending to the draining pores in the papillae and calyces, with or without associated medullary interstitial inflammation and/or fibrosis (Fig. 2). Generally, the cortex is unremarkable.

Among the phenotypic mimics of MSK is familial juvenile nephronophthisis (NPHP1), caused by a mutation in the nephrocystin gene, located in chromosome 2q13, due to faulty mediator of focal adhesion signaling. This condition follows a progressive clinical course due to symmetrical tubulo/glomerular damage with cysts forming at the corticomedullary interface [5]. Potentially confused with MSK are medullary cystic



**Medullary Sponge Kidney. Figure 2** Histological features of MSK. Tubular dilatation of the collecting ducts in the inner medulla. Inserts (right panels) illustrate intraductal and interstitial mineral deposits. This is from a hypertensive female who had MSK associated with multivessel fibromuscular dysplasia.

kidney disease type 1 (MCKD1), an autosomal dominant tubulo-interstitial nephropathy that causes renal salt wasting, and end-stage renal failure in the 4th to 7th decade of life, localized to chromosome 1q21, and medullary cystic kidney disease type 2 (MCKD2), an autosomal dominant tubulointerstitial nephropathy with renal salt wasting, hyperuricemia, gout, and end-stage renal failure in the 5th decade of life, resulting from a mutation in the gene encoding uromodulin in chromosome 16p12.3 [5]. Benign tubular ectasia is noncystic and devoid of calcification.

## Therapeutic Principles

MSK is asymptomatic. Nephrocalcinosis and nephrolithiasis are common complications in MSK. Pyelonephritis may supervene. The treatment is directed at reducing the effects of defective urinary acidification and concentration by restoring urinary citrate excretion and reducing calcium excretion.

## Synonyms

Cerebellar (infratentorial) primitive neuroectodermal tumor; PNET

## Definition and Characteristics

Medulloblastoma, together with central nervous system (CNS) primitive neuroectodermal tumors and atypical teratoid/rhabdoid tumors compose a class of embryonal brain tumors according to the 2007 World Health Organization (WHO) classification of CNS tumors [1]. Medulloblastoma is a highly malignant tumor of the cerebellum (WHO grade IV) with preferential occurrence in children and a strong tendency to metastasize within the CNS via the cerebrospinal fluid (CSF). 5-year overall survival rates currently reach around 60–70%.

## Prevalence

Medulloblastoma comprises the most common malignant brain tumor in children and one of the leading causes of cancer-related mortality in this age group. The annual incidence in pediatric patients ranges from 0.48 in girls to 0.75 in boys per 100,000 children [2]. The peak age at presentation is 7 years. More than 80% of childhood medulloblastomas arise as midline tumors in the vermis of the cerebellum, whereas involvement of cerebellar hemispheres increases with age to reach around 50% in adult patients. Around 30% of children show evidence of disseminated disease at diagnosis.

## Genes

Medulloblastoma has been diagnosed in families with various inherited cancer syndromes characterized by germline mutations of centrally important genes, such as PTCH1 (Gorlin's syndrome/nevoid basal cell carcinoma syndrome), TP53 (Li-Fraumeni syndrome), APC (Turcot's syndrome), and CBP (Rubinstein-Taybi syndrome). Common genetic changes in sporadic medulloblastoma include isochromosome 17q (i17q) or isolated loss of 17p or gain of 17q, gain of chromosome 7, loss of chromosome 16q, 8p, 10q, and 11q, gain or loss of chromosome 6, and genomic amplification of the MYC and MYCN oncogenes. Monosomy 6 and i17q are mutually exclusive, and Wnt pathway activation has been found in virtually all tumors with monosomy 6, most frequently due to mutations of CTNNB1 [2,3]. This molecular subgroup shows a very good response to current standard treatment. Trisomies of chromosome 6 are typically associated with i17q formation and, together with tumors carrying MYC or MYCN amplifications, comprise a molecular subgroup with poor prognosis, independent of the presence of tumor dissemination. Tumors with i17q, but without accompanying trisomy of chromosome 6 or oncogene amplification, comprise a molecular subgroup with intermediate risk [4]. A proportion of mostly desmoplastic tumors with balanced chromosomes 6 and 17 displays activation of sonic hedgehog signaling, most frequently by loss of PTCH function, e.g., by deletion of chromosome arm 9q or inactivating gene mutations (Fig. 1).

## Molecular and Systemic Pathophysiology

Medulloblastoma is composed of densely packed layers of small round blue cells with hyperchromatic nuclei and scanty cytoplasm. Neuroblastic rosettes (Homer Wright rosettes) are observed in around 40% of cases. The most common type of differentiation is neuronal, reflected by immunopositivity for neuronal markers, such as synaptophysin. The 2007 WHO classification of CNS tumors defines five histological variants: (i) nodular/desmoplastic medulloblastoma, (ii) medulloblastoma with extensive nodularity, (iii) anaplastic medulloblastoma, (iv) large cell medulloblastoma, and (v) the classic variant, being by far the largest subgroup. Myogenic and/or melanocytic differentiation occur in different subgroups of medulloblastoma, and are no longer regarded as separate subgroups [1]. Classic, large cell and anaplastic medulloblastomas are thought to arise from the ventricular matrix, whereas desmoplastic tumors are derived from progenitor cells in the

Figure 1** Presumable cells of origin, histopathological designation, characteristic chromosomal aberrations, involved signaling pathways, typical tumor localization, and patient prognosis for different subgroups of medulloblastoma. Dashed lines indicate proportions <10% of cases.

M

external granular layer. Desmoplastic tumors are frequently encountered in adults (up to 50% compared with 15% in children), and are associated with better prognosis, whereas large cell and anaplastic tumors comprise the most aggressive variants and are associated with adverse clinical outcome.

## Diagnostic Principles

Presenting symptoms typically include occipital headaches, morning vomiting, and ataxia. Magnetic resonance imaging (MRI) of the brain shows a tumor in the posterior fossa. Definitive diagnosis is made by histological assessment of the tumor after resection. Metastatic spread is detected by craniospinal MRI and CSF cytology. Current risk stratification is based on age, presence of metastatic spread, histological subtype, and in some studies on the extent of surgical resection [3].

## Therapeutic Principles

Multimodal treatment for all patients consists of primary surgery followed by adjuvant (radio)-chemotherapy. Postoperative treatment in children of (2)–4 years or older, without dissemination at diagnosis, involves radiotherapy of the neuroaxis and a boost to the posterior fossa followed by a maintenance chemotherapy most commonly consisting of cisplatin, lomustine, and vincristine. Other frequently used drugs include cyclophosphamide and oral etoposide. For patients with disseminated disease at diagnosis, various different adjuvant treatment regimens are currently investigated in clinical trials, some of them applying chemotherapy prior to or before and after radiotherapy. Intravenous as well as intraventricular methotrexate (MTX) was added for high-risk patients in some studies, but the usefulness of intraventricular MTX remains to be determined. Other approaches for these patients include the use of myeloablative chemotherapy, followed by autologous stem cell rescue. Due to severe long-term neurocognitive deficits, radiotherapy is avoided in infants and small children before the age of (2)–4 years. Recently, excellent long-term survival for infants could be demonstrated with the use of a chemotherapy-only regimen, especially for patients with desmoplastic medulloblastoma [5].

## Melanonychia Striata

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

### Definition and Characteristics

The presentation can range from a narrow longitudinal streak to almost complete pigmentation of the nail plate [1]. The coloration can be tan, brown, or black (Fig. 1) [1,2].

Melanonychia striata is more common in the thumb, which is the most frequently used digit [3]. The index, middle, fourth, and fifth fingers are employed with decreasing frequency for grasping objects and demonstrate a correspondingly lower incidence of melanonychia striata. Involvement of the toes is unusual [3]. The involvement of multiple digits is rare [4].

### Prevalence

There is a marked racial variation on the occurrence of melanonychia striata. Melanonychia striata is noted in the more deeply pigmented race and is rare in white-skinned individuals. Leung et al examined 2,457 Chinese patients and found that melanonychia striata was not detected in patients under 20 years of age [3].

**Melanonychia Striata. Figure 1** Melanonychia striata presenting as brownish longitudinal bands in the thumbs of a 25-year-old female.

The condition was present in 0.6% of patients between 20 and 29 years. Thereafter, the prevalence increased gradually to 1.7% in patients aged 50 years and over. The prevalence in the Chinese population is higher than in the Caucasian populations, but appreciably less than in Japanese or black-skinned populations [3].

## Genes

The gene for melanonychia striata has not been identified.

## Molecular and Systemic Pathophysiology

Melanonychia striata is caused by an increased activity of melanocytes in the nail matrix with subsequent increased melanin deposition in the nail plate. Melanonychia striata may occur spontaneously or as a result of trauma, irradiation, or treatment with gold or cytotoxic agents. It may also be a sign of arsenic intoxication, hemochromatosis, Addison disease, or vitamin-$B_{12}$ deficiency.

## Diagnostic Principles

Melanonychia striata has to be differentiated from other causes of melanonychia. Probably the most common cause of melanonychia is a subungual hemorrhage. A subungual hematoma will migrate distally as the nail grows, whereas most of the other causes of melanonychia will remain stationary. A subungual melanoma should be suspected if there is an abrupt onset after middle age, rapid growth, variegated coloring, blurry edges, irregular elevation of the surface, and nail dystrophy. Hutchinson sign, periungual spread of pigmentation into the proximal and lateral nail folds, is highly suggestive of a subungual melanoma [4]. The sign, however, is not pathognomonic for subungual melanoma. Other differential diagnosis includes nail matrix melanocytic nevus, lentigo, and lentinginosis of various types [5]. Dermoscopy provides useful information to help the clinician to decide if a nail matrix biopsy is required [5]. The presence of a brown pigmentation overlaid by longitudinal lines irregular in their thickness, spacing, color, or parallelism is highly suggestive of a subungual melanoma [5].

## Therapeutic Principles

Melanonychia striata is essentially a benign condition. Rarely, spontaneous regression has been reported. The benign nature is suggested by an early age of onset, stable character of the lesion, occurrence in dark-skinned individuals, and/or multiple digital involvement. Most investigators advocate a wait-and-see approach. Prolonged follow-up is mandatory for early detection of possible malignant changes.

## Definition and Characteristics

Melorheostosis is a rare skeletal dysplasia characterized by a hyperostosis of cortical bone [1,2]. The hyperostotic bone lesions have a linear pattern and are mainly located along the diaphyses of tubular bones. They can extend internally into the medullary canal or externally with periosteal involvement resulting in the characteristic wavy outline of the affected bone. In some patients smaller, spotty lesions, reminiscent of osteopoikilosis, can be observed in the epimetaphyseal regions of the affected bones. Melorheostosis lesions are most frequently found in the appendicular skeleton. They usually show an asymmetric distribution with involvement of one or more bones located in an area innervated by the same spinal sensory nerve. Melorheostosis can also affect the surrounding soft tissues including the subcutis, muscles and blood vessels. Soft tissue calcification, fibrosis and blood or lymphatic vessel anomalies resulting in edema can be present. Sclerodermatous skin lesions or indurations and joint contractures are frequently observed and are usually the presenting symptoms. The disorder can be asymptomatic but usually causes chronic pain and functional limitations because of joint contractures, bone deformities and limb length discrepancy. Melorheostosis is predominantly a sporadic disorder. However, individuals with melorheostosis have been observed in families with autosomal dominant osteopoikilosis.

## Prevalence

The estimated prevalence is 1:1,000,000.

## Genes

Heterozygous loss-of-function mutations in the LEMD3 gene can cause osteopoikilosis and the Buschke-Ollendorff syndrome [3]. Osteopoikilosis is a benign autosomal dominant skeletal dysplasia characterized by multiple small and round hyperostotic lesions in different parts of the skeleton (usually the epimetaphyseal regions of the tubular bones). The Buschke-Ollendorff syndrome is the association of osteopoikilosis and dermatofibrosis lenticularis disseminata. Inactivating germline mutations in the LEMD3 gene have also been identified in a few melorheostosis patients that belong to a family with either osteopoikilosis or the Buschke-Ollendorff syndrome [3,4]. However, in the vast majority of sporadic patients with isolated melorheostosis, no germline LEMD3 mutations have been identified so far. In a few cases, the possibility of a somatic LEMD3 mutation has been investigated but not found [4]. Despite the evidence that haploinsufficiency for LEMD3 acts as a predisposing factor for the development of melorheostosis, the precise role of LEMD3 in the pathogenesis of isolated and sporadic melorheostosis is not yet fully understood.

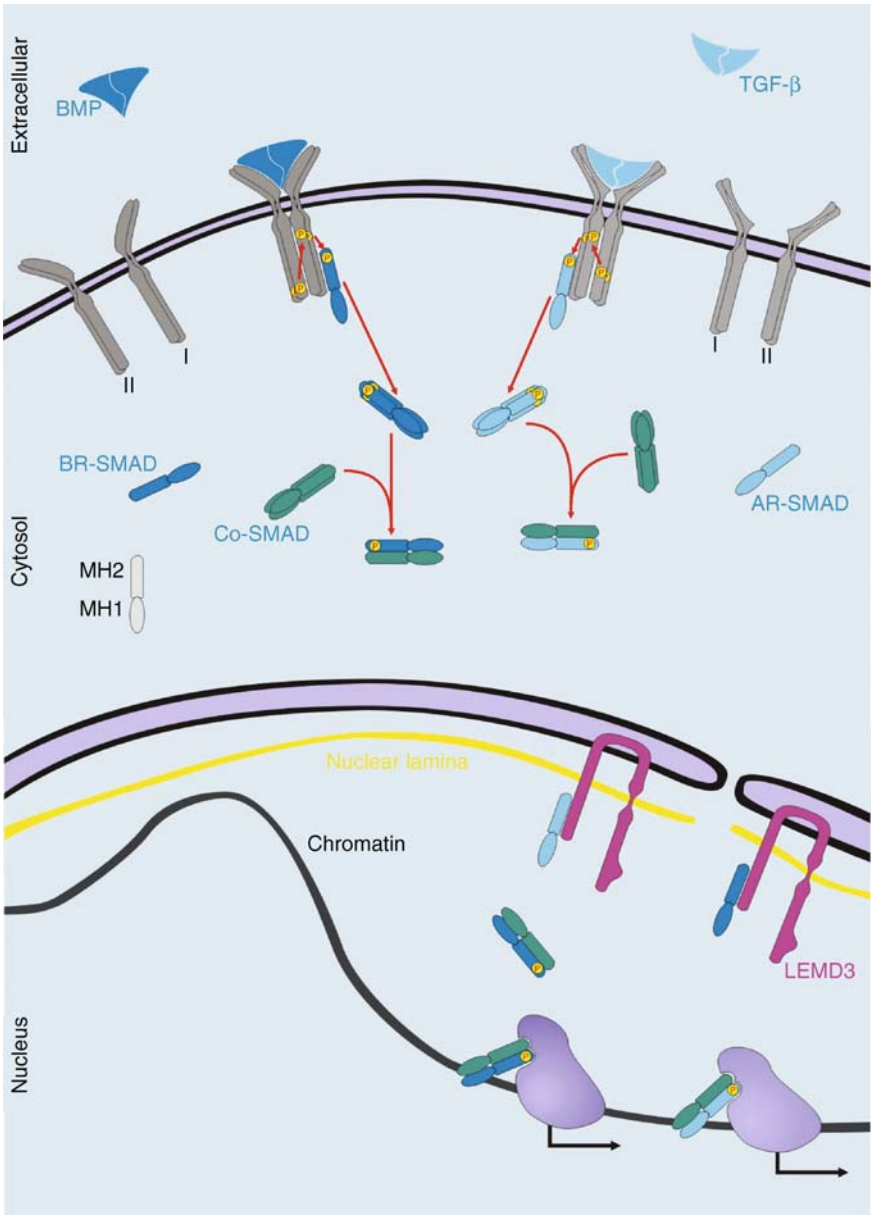
## Molecular and Systemic Pathophysiology

The LEMD3 gene is located on chromosome 12q14, contains 13 exons and has a size of 4,744 bp. It codes for the LEMD3 protein which contains 911 amino acids. LEMD3 is an integral protein of the inner nuclear membrane and has a molecular mass of about 100 kDa [5]. It is composed of a nucleoplasmic N-terminal domain, a first transmembrane segment, a luminal loop, a second transmembrane segment and a nucleoplasmic C-terminal domain. LEMD3 was previously known as MAN1 but recently renamed as LEMD3, herewith referring to the LEM domain in the N-terminal portion of the protein. The LEM domain is a conserved globular motif of approximately 40 amino acids found in several inner nuclear membrane and nucleoplasmic proteins. The N-terminal domain of the protein binds to lamin A, lamin B1 and the barrier-to-autointegration factor (BAF). This binding seems to be important for retention of LEMD3 in the inner nuclear membrane. The C-terminal domain contains a winged helix motif, required for DNA binding and a SMAD interacting domain. In humans, LEMD3 interacts with the MH2 domain of both BMP-specific and TGFβ-specific receptor activated SMAD proteins (R-SMADs). LEMD3 does not affect the expression or stability of R-SMADs, but reduces the amount of phosphorylated SMADs in the nucleus and blocks hetero-oligomerization of R-SMADs with SMAD4. Through its interaction with the R-SMADs, LEMD3 acts as a specific repressor of TGFβ and BMP signaling (Fig. 1).

Loss-of-function mutations in the LEMD3 gene will result in an increase in transcriptional activation of TGFβ, activin or BMP responsive promoters. These pathways have been shown to be very important in the regulation of bone mineral density and control of fibroblast activity.

## Diagnostic Principles

The diagnosis of melorheostosis is usually based on clinical evaluation and the finding of the characteristic radiographic abnormalities. Plain radiographs are usually sufficient to confirm the diagnosis. Scintigraphy



**Melorheostosis. Figure 1** The LEMD3 protein is an integral protein of the inner nuclear membrane. It can antagonize the TGFβ and BMP signaling by interacting with the MH2 domain of R-SMADs.

reveals increased tracer uptake in the affected bone and soft tissue areas. Computed tomography and magnetic resonance imaging (MRI) are usually not needed for diagnosis. The bone and soft tissue lesions have low signal activities on all MRI sequences.

## Therapeutic Principles

The disease can be progressive with periodic exacerbations. There is currently no cure for the disorder. Surgery is possible to correct bone deformities and asymmetric bone growth. However, bone healing after osteotomy can be problematic in melorheostosis patients. Soft tissue releases in children have a high failure rate and are often complicated by abnormal scar formation. Contracture releases are more effective in adults and the outcome seems to improve with the use of rotation flaps. Prior to surgery, the application of external fixators spanning the contracture area should be considered and this may even be the sole treatment. Pain management is usually a challenge because of the chronic and progressive character of the disorder.

## Ménétrier's Disease

►Menetriere's Disease

## Menetriere's Disease

Marcus Schmitt
Gastroenterology, Hepatology and Infectiology, UKD, Heinrich-Heine-University, Duesseldorf, Germany

### Synonyms

Ménétrier's disease; Giant hypertrophic gastritis; Protein losing gastropathy; Hyperplastic gastropathy

### Definition and Characteristics

To avoid confusion the distinction between hyperplasia and hypertrophy has to be made. Both conditions can lead to enlarged gastric folds. Menetriere's disease is a

form of hyperplastic gastropathy. Hyperplastic gastropathy refers to conditions confined to the rugae in the gastric body and fundus, which are associated with an excessive number of mucosal epithelial cells. Menetriere's disease is characterized by epithelial hyperplasia of the gastric mucosa (increased mucosal thickness more than 10 mm, marked foveolar hyperplasia, and atrophy or normality of the oxyntic glands), thus resulting in an increased production of mucus, reduced acid secretion, and severe hypoproteinemia (selective serum protein loss across gastric mucosa). However, some authors do not add hypoproteinemia and reduced acid secretion to the definition.

## Prevalence

This condition is rare and only about 300 cases are mentioned in the literature.

The mean age of patients with Menetriere's disease is 40–60 years. The male-to-female ratio shows a trend to the males.

## Molecular and Systemic Pathophysiology

Since Menetriere's original description of the syndrome [1], (Pierre Eugene Menetrier (1859–1935) first description 1888), the exact pathophysiology remains unknown but human and animal studies suggest a role for elevated levels of transforming growth factor (TGF-alpha) in gastric mucous cells. TGF-alpha binds to the epidermal growth factor receptor, thus increasing gastric mucous production and cell renewal, while inhibiting acid secretion [2]. Furthermore elevated levels of the epidermal growth factor in the saliva are discussed. Menetriere's disease in twins suggest that at least some cases have a genetic cause.

## Diagnostic Principles

Menetriere's disease is diagnosed by the demonstration of extreme foveolar hyperplasia with glandular atrophy in a full-thickness biopsy (by endoscopic snare or suction biopsy). This confirms the suspicious enlargement of gastric folds or rugae seen on endoscopy or barium radiography. The enlarged folds are confined to the body and fundus. The folds are usually enlarged symmetrically, although asymmetric polpoid enlargement may occur.

Clinical signs impress as epigastric pain, substantial weight loss, nausea, vomiting, gastrointestinal bleeding, diarrhea, and protein-losing gastroenteropathy. Hypalbuminemia is common in approximately 80% of patients.

## Therapeutic Principles

*General Therapeutic Recommendations*: Correction of albumin, iron, and calcium.

*Drug Therapy*: Proton pump inhibitors, H2-receptor antagonists and in some cases octreotid were used but there are no guidelines for therapy. In infected patients therapy directed against Helicobacter pylori may heal the disease though this entity of enlarged gastric folds may be different from Menetriere's disease [3]. Two patients improved clinically after therapy with a monoclonal antibody directed against the epidermal growth factor receptor.

*Interventional Therapy*: Gastrectomy has been advocated for patients with intractable pain, hypoalbuminemia with edema, hemorrhage, pyloric obstruction, and for those in whom a malignancy cannot be excluded.

# Ménière's Disease

Markus Pfister, Hans-Peter Zenner
Department of Otolaryngology and Head and Neck Surgery, University of Tuebingen, Tuebingen, Germany

## Definition and Characteristics

Ménière's disease is an inner ear disorder that can affect both hearing and balance (see [1,2]). It can cause episodes of vertigo, hearing loss, tinnitus and the sensation of fullness in the ear. It is named after the French physician Prosper Ménière, who first reported that vertigo was caused by inner ear disorders in an article published in 1861.

The symptoms of Ménière's disease occur suddenly and can arise daily or as infrequently as once a year. Vertigo, often the most debilitating symptom of Ménière's disease, typically involves a whirling dizziness that forces the sufferer to lie down. Vertigo attacks can lead to severe nausea, vomiting and sweating and often come with little or no warning.

Attacks can also start with tinnitus (ear noises), a loss of hearing or a full feeling or pressure in the affected ear. It is important to remember that all of these symptoms are unpredictable. Typically, the attack is characterized by a combination of vertigo, tinnitus and hearing loss lasting several hours.

## Prevalence

Ménière's disease has a prevalence of about 200 cases/100,000 persons in the United States, or about 0.2% of the population (see [2]). The prevalence varies internationally.The prevalence increases with age, rather linearly, up to the age of 60.

## Molecular and Systemic Pathophysiology

The exact cause of Ménière's disease is not known, but it is believed to be related to endolymphatic hydrops or excess fluid in the inner ear. It is thought that endolymphatic fluid bursts from its normal channels in the ear and flows into other areas causing damage. This may be related to swelling of the endolymphatic sac or other issues in the vestibular system of the inner ear, which is responsible for the body's sense of balance. The physiological role of AQP2 (aquaporin 2) in water transport and its expression pattern in the cochlea suggests an important role for AQP2 in fluid homeostasis of the inner ear; however, its role in the pathogenesis of Ménière's disease remains to be established.

## Diagnostic Principles

1. Otolaryngological examination (see [1]).
2. Pure tone audiometry, immittance audiometry battery consisting of tympanometry, static compliance and acoustic reflex testing.
3. In case of hereditary hearing loss a high resolution CT can be performed to rule out other malformations of the middle and inner ear e.g., Pendred.

## Therapeutic Principles

There is no cure for Ménière's disease. However, the symptoms of the disease are often controlled successfully by reducing the body's retention of fluids through dietary changes (such as a low salt or salt free diet and no caffeine or alcohol) or medication (diuretics). Changes in medications that either control allergies or improve blood circulation in the inner ear may help. Eliminating tobacco use and reducing stress levels are more ways in which some people can lessen the severity of their symptoms.

Different surgical procedures have been advocated for patients with persistent, debilitating vertigo from Ménière's disease. These include labyrinthectomy (removal of the inner ear sense organ), exposition of the endolymphatic sac or vestibular neurectomy. Recently, the administration of the ototoxic antibiotic, gentamycin directly into the middle ear space has gained popularity worldwide for the control of the vertigo of Ménière's disease [1].

# Meningioma

Markus J. Riemenschneider,
Guido Reifenberger
Department of Neuropathology,
Heinrich-Heine-University, Duesseldorf, Germany

## Definition and Characteristics

Meningiomas originate from the meningeal coverings of the spinal cord and the brain. They are typically associated with symptoms of gradually increasing intracranial pressure, headaches, seizures and focal neurological symptoms, depending on the location of the tumor. On MRI, meningiomas are isointense to cerebral cortex on T1- and T2-weighted images and avidly contrast-enhancing.

Meningiomas are classified in three histological grades according to the WHO classification of tumors of the nervous system [1,2]: WHO grade I (benign), WHO grade II (atypical) and WHO grade III (anaplastic). About 80% of all meningiomas are slowly growing benign tumors of WHO grade I with a 5-year recurrence rate of only 5%. Atypical meningiomas of WHO grade II constitute 15–20% of meningiomas, their 5-year recurrence rate after gross total resection is about 40%. Anaplastic meningiomas account for 1–3% of all cases. They exhibit a clinical behavior similar to other malignant neoplasms with the ability to widely infiltrate neighboring tissues and form metastatic deposits. Anaplastic meningiomas are associated with recurrence rates of up to 50–80% after surgical resection and median survival times are less than 2 years.

Meningiomas are the hallmark tumors of neurofibromatosis type 2 (NF2), an autosomal dominantly inherited disorder caused by germ line mutations in the NF2 tumor suppressor gene on chromosome 22q [3].

## Prevalence

Approximately 30% of all primary brain tumors, annual incidence rate of about 4.5:100,000, female:male rate approximately 3:1.

## Genes

*Meningioma initiation: NF2 (22q)*: Most important and most frequent alteration involved in meningioma initiation. Allelic losses on chromosome arm 22q in approximately half of meningiomas. *NF2* gene mutations in all NF2-associated meningiomas and about 50% of sporadic meningiomas. *NF2* mutation or promoter methylation leads to reduced expression of the NF2 gene product merlin, a protein 4.1 superfamily member [3].

*Other protein 4.1 superfamily members:* Loss of protein 4.1B (DAL-1), TSLC1 (tumor suppressor in lung cancer-1) and protein 4.1R expression in subsets of meningiomas.

*Activation of growth factor receptors*: EGFR and PDGFRB activation [2].

*Progression-associated changes*: Frequent losses on 1p (second most frequent alteration), 6q, 10, 14q (NDRG2 hypermethylation), 18q, 9p (CDKN2A, $p14^{ARF}$ and CDKN2B deletion) as well as gains on 1q, 9q, 12q, 15q, 20q and gain or amplification on 17q (PS6K, other possible target genes). Loss of progesterone receptor expression. Telomerase/hTERT activation. Notch, WNT, IGF signaling pathway activation [2,4] (Fig. 1).

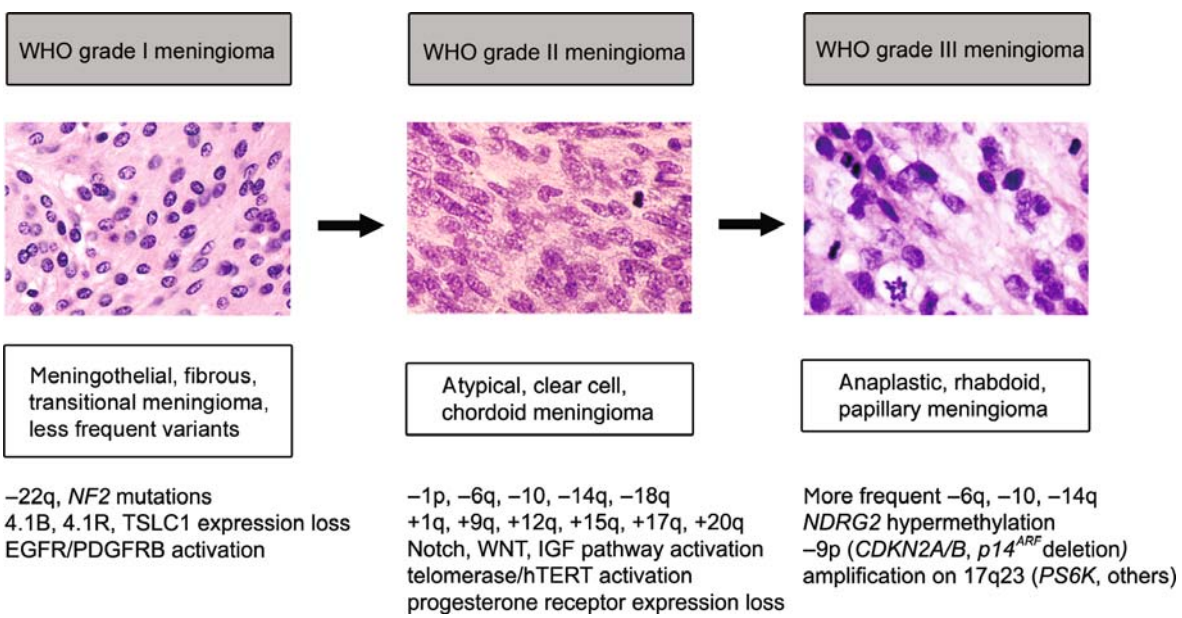
## Molecular and Systemic Pathophysiology

*Merlin function and its role in meningioma initiation*: Merlin links integral membrane proteins to the cytoskeleton and is localized to the cell membrane at regions which regulate cell–cell contact and motility. Merlin binds to cell-surface proteins, such as CD44 and ß1-integrin, molecules involved in cell-cytoskeleton dynamics (ßII-spectrin, paxillin, actin and syntenin) and molecules regulating ion transport (sodium hydrogen exchange regulatory factor, NHE-RF) as well as endocytosis (hepatocyte growth factor-regulated tyrosine kinase substrate, HRS). The functions of many of these interactions have not been studied *in vivo* yet, however there is recent evidence that the CD44-merlin interaction, which is tightly regulated by protein phosphorylation, affects merlin-mediated inhibition of cell proliferation and cell motility [3].

*Pathways to meningioma progression*: Impairment of retinoblastoma protein (pRB)-dependent and p53-dependent cell cycle regulation is common in anaplastic meningiomas. Homozygous deletions or mutations of CDKN2A (gene product $p16^{INK4a}$) and CDKN2B (gene product $p15^{INK4b}$) lead to activation of cell cycle progression at the $G_1$/S-phase checkpoint through loss of negative effects on the cyclin-dependent kinases Cdk4 and Cdk6, thereby phosphorylating pRB and releasing E2F transcription factors. Deletions or mutations of $p14^{ARF}$ positively regulate the MDM2 oncoprotein and result in p53 degradation [2].

## Diagnostic Principles

*WHO grade I meningiomas*: Histological signs of atypia or anaplasia are absent. Characteristic uniform tumor cells forming lobules surrounded by thin



**Meningioma. Figure 1** Genetic alterations associated with meningioma initiation and progression. Benign meningiomas of WHO grade I most commonly show losses on chromosome 22q, *NF2* mutations as well as loss of expression of other members of the protein 4.1 superfamily pointing to a role of these molecular alterations in meningioma initiation. Many additional molecular changes and genetic pathways have been identified conveying the progression from benign to atypical (WHO grade II) and anaplastic (WHO grade III) meningiomas.

collagenous septae with fuzzy ill-defined cell borders and eosinophilic nuclear pseudoinclusions (meningothelial variant), spindle-shaped cells resembling fibroblasts, forming intersecting fascicles embedded in a collagen- and reticulin-rich matrix (fibrous variant) or a mixture of both features often with extensive whorl formation (transitional variant). Additional less frequent histological variants can be distinguished (psammomatous, angiomatous, microcystic, secretory, lymphoplasmcyte-rich, metaplastic meningioma).

*WHO grade II meningiomas*: Histologically, presence of any of the three following criteria leads to the diagnosis of atypical meningioma of WHO grade II: (i) mitotic index ≥4 mitoses/10 high power fields (HPF), (ii) at least three of the following five parameters: increased cellularity, high nuclear/cytoplasmic ratio ("small cells"), prominent nucleoli, uninterrupted patternless or sheet-like growth, foci of spontaneous necrosis (i.e., not induced by embolization or radiation) or (iii) brain invasion. Intracranial clear cell meningioma (with a clear, glycogen-rich cytoplasm) and chordoid meningioma (with a chordoma-like growth of tumor cells in a myxoid matrix) are associated with a higher likelihood of recurrence even in absence of the criteria described above and are graded as WHO grade II by definition.

*WHO grade III meningiomas*: Histologically, either of two criteria is diagnostic for anaplastic meningioma of WHO grade III: (i) mitotic index ≥20/10 HPF, or (ii) frank anaplasia (sarcoma, carcinoma, or melanoma-like histology). Rhabdoid meningioma (containing large rounded tumor cells with excentric nuclei) and papillary meningioma (demonstrating a pseudopapillary growth pattern) are consistently associated with malignant behavior and correspond to WHO grade III by definition [1,2].

## Therapeutic Principles

Surgical resection is the treatment of choice. For benign lesions complete resection is often curative. Tumors that have been resected incompletely or recurrent lesions may be treated by means of radiotherapy or radiosurgery, which may also be the first choice in patients in poor general condition or when tumors are located in surgically inaccessible or high-risk locations. Chemotherapy has a limited role, i.e., trials of different hormonal or chemotherapeutic agents have been performed with only partial success. Hydroxyurea has been reported to show some efficiency [5].

# Meningomyelocele

►Myelomeningocele
►Spina Bifida

# Menkes Disease

Julian F. B. Mercer, Sharon La Fontaine
Centre for Cellular and Molecular Biology, School of Life and Environmental Sciences, Deakin University, Burwood, VIC, Australia

## Synonyms

Menkes steely hair disease; Kinky-hair syndrome; Trichopoliodystrophy; X-linked copper deficiency

## Definition and Characteristics

Menkes disease (MD) (MIM#309400) and its allelic variants are X-linked recessive copper deficiency diseases characterized by a systemic disturbance in copper transport and consequent maldistribution of body copper. There are three distinct clinical phenotypes, the severe classical MD, mild MD and occipital horn syndrome (OHS, also known as X-linked cutis laxa or Ehlers-Danlos type IX). The classical form is usually fatal in early childhood and was described in 1962 by John Menkes as an X-linked syndrome of growth retardation, brain degeneration and unusual hair. Patients with mild MD are mildly mentally retarded and survive into adult life. OHS is primarily a connective tissue disorder. Classical MD was described as a copper transport disorder by David Danks in 1972. Excellent reviews of the clinical features of MD and its variants are available [1,2].

## Prevalence

Estimates of incidence range from 1 in 100,000 to 1 in 250,000 live births [2]. One third of cases are due to new mutations.

## Genes

ATP7A (MNK, MIM300011) is the gene affected in MD. The gene is located on Xq13.3, and was isolated by three groups using a positional cloning approach [3]. The gene spans about 150 kb and has 23 exons [3]. The mRNA is expressed in most tissues except the liver. The protein product is a transmembrane copper-transporting P-type ATPase (ATP7A, or MNK) closely related (56% amino acid identity) to the protein affected in Wilson disease, ATP7B. ATP7A has eight predicted transmembrane domains that form a channel for the transport of copper across cell membranes driven by the hydrolysis of ATP. A wide range of mutations have been found to cause MD, including splice site, insertions/deletions, missense and nonsense mutations [4].

## Molecular and Systemic Pathophysiology

In the more severe classical MD, serum copper is low (<70 ug/dL), the hair is abnormal and fragile, and the patients have abnormal facies and exhibit progressive cerebral degeneration, hypopigmentation, osteoporosis, arterial rupture and hypothermia. The deficiency of ATP7A causes reduced intestinal uptake of copper and maldistribution of copper in the body, which leads to low activity of essential copper-dependent enzymes. The clinical features of the disease are explained by deficiencies in many of these important copper enzymes, principally cytochrome c oxidase, which probably accounts for the impairment in neurological function, and lysyl oxidase, which is responsible for the connective tissue defects. Paradoxically, certain tissues such as the kidney, intestinal enterocytes and fetal placenta of Menkes patients have higher than normal levels of copper, despite the deficiency of copper-dependent enzymes. The small amount of copper that reaches the circulation (perhaps by ATP7A-independent mechanisms) becomes trapped in some cells such as those in the proximal tubules of the kidney, because ATP7A, which is normally required for copper efflux, is absent or defective [1,2].

ATP7A actively effluxes copper across the plasma membrane of cells for transport of copper across epithelial barriers, such as the intestinal enterocyte and the cells of the blood brain barrier. ATP7A is also required for delivery of copper to secreted cuproenzymes such as lysyl oxidase. The dual role of copper efflux across the plasma membrane and delivery of copper to enzymes in the secretory pathway is achieved by changes in the location of the protein in the cell in response to copper. The protein traffics from the transGolgi network to the plasma membrane when intracellular copper levels increase [5].

It is not completely clear from the mutation studies why the clinical presentations of the allelic variants of MD are so distinct. The mutations that result in severe classical MD are predicted to prevent formation of any functional protein and hence reduce copper transport activity to a very low level. In contrast the mutations that cause OHS are often splice site variants that allow the production of only small amounts of an otherwise normal protein [5]. In one mild MD patient, a missense mutation prevented copper-induced trafficking of ATP7A but the reduced disease severity suggested that the protein retained some activity. One model to explain the pronounced connective tissue defects in OHS is that the residual protein is constitutively located on the plasma membrane and not in the transGolgi network. ATP7A on the plasma membrane allows a limited amount of copper efflux and distribution in the body, ameliorating the severity of the disorder, but lysyl oxidase (required for the cross-linking of collagen and elastin) is severely affected because copper cannot be supplied to the apoenzyme in the transGolgi network [5]. Thus the clinical phenotype of MD patients seems to be determined by the effect of the mutation on the amount of protein produced, the level of activity of the protein, its correct location in the cell and its ability to traffic in response to copper.

## Diagnostic Principles

Clinical features in males with classical MD include poor weight gain, loss of early developmental milestones, hypothermia and marked neurodegenerative features with seizures often in the first year of life. Profound hypotonia is apparent. Characteristic facies with pudgy cheeks, sagging jowls and abnormal eyebrows are useful diagnostic guides. The hair is sparse and coarse with pili torti on microscopic examination. White matter abnormalities due to defective myelination and tortuosity of cerebral blood vessels are visible on magnetic imaging of the brain (reviewed by Danks [1] and Kaler [2]). Abnormalities of the bones are also present, with wormian bones in the skull and metaphyseal spurring of the long bones. Low serum copper and ceruloplasmin are characteristic, but are unreliable indicators in the first year of life. Diagnosis is confirmed by detection of impaired copper efflux from cultured fibroblasts or mutation detection in the ATP7A gene. Prenatal diagnosis using these techniques applied to amniocytes or chorion villus cells is possible if indicated by a family history of the disease.

## Therapeutic Principles

The response to parenteral administration of various forms of copper has been variable but in general relatively unsuccessful [1,2]. A few cases have responded well to copper histidine administration, but many patients continue to deteriorate despite early intervention. Treatment by oral ingestion of copper is ineffective because of the block in intestinal transport of

copper. The reason for therapeutic success or failure has not been established, but one suggestion is that the effectiveness of copper replacement may depend on the presence of some functional ATP7A protein, which in turn is dependent on the type of mutation [2]. However, it is clear that treatment as soon as possible after birth is essential to avoid irreversible neurological damage. Even when patients respond to copper, the connective tissue defects are not corrected probably because copper is not available to lysyl oxidase. The connective tissue abnormalities may become disabling later in life. Symptomatic treatment with midodrine and fludocortisone or L-threo-3,4-dihydroxyphenylserine (L-DOPS) has been used for controlling the hypotension and diarrhea.

## Merkel Cell Carcinoma

Ingrid Moll
Department of Dermatology and Venerology, University Hospital Hamburg-Eppendorf, Hamburg, Germany

### Synonyms

Neuroendocrine carcinoma of skin; Merkel cell tumor; MCC

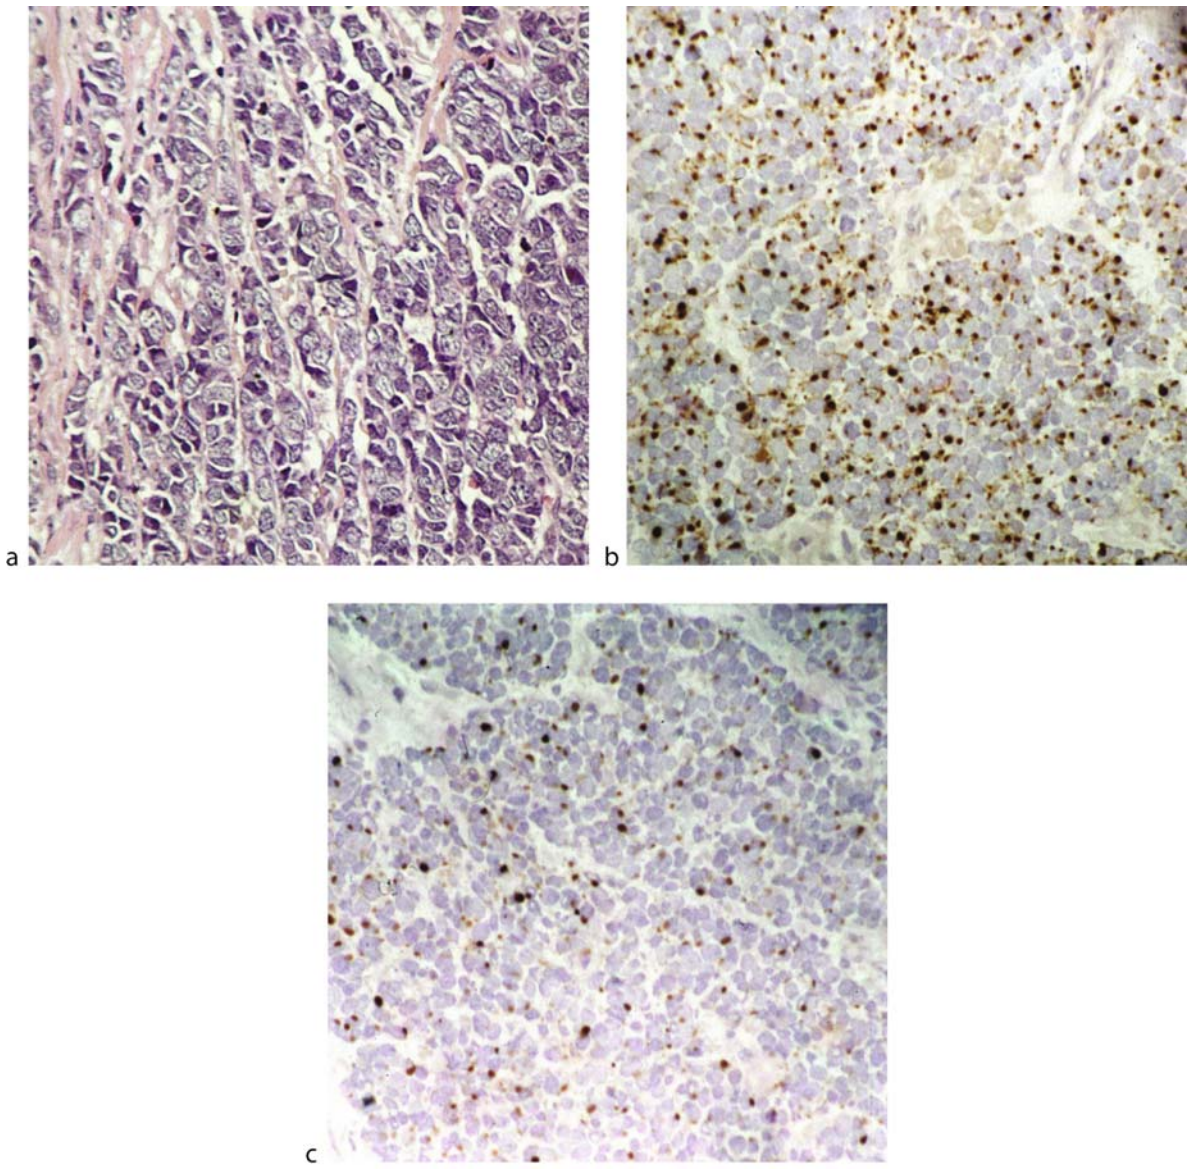
### Definition and Characteristics

MCC I is a highly aggressive tumor with a 3-year survival of only 31% [1]. Its typical clinical appearance is a blue-reddish, dome-shaped nodule with a shiny surface. In histopathology, MCC exhibits solid formations of rather uniform tumor cells with round to oval nuclei and scant cytoplasms, separated by fine connective tissue strands (Fig. 1a).

Because of these unconspicious clinical and microscopic features differential diagnosis of MCC is often difficult. Ultrastructure of tumor cells shows within cytoplasm typical dense-cored granules (diameter: 100 nm) and fibrous bodies composed of intermediate filaments (IF). Recently immunocytochemistry became of major diagnostic importance for MCC using neuronal/neuroendocrine and intermediate filament marker proteins [2]. Broadly expressed neuronal/neuroendocrine markers, such as NSE, chromogranin A, synaptophysin, protein gene product 9.5, are mostly and neuropeptides are variably detectable in MCC. IF turned out to be most important in diagnosis for MCC: Keratins (CK) of low-molecular weight (CK 8, CK 18, CK 19, and CK 20) are present in MCC. Among them CK 20 is highly specific because it is restricted to MCC (Fig. 1b) and virtually absent from small cell carcinomas of other organs and from lymphomas. The staining pattern characteristically shows both, a filamentous cytoskeleton and paranuclear plaques. Neurofilaments are in addition present in MCC, but mostly at a lower level (Fig. 1c). Thus the coexpression of CK 20 and neurofilaments is highly specific for MCC. The absence of TTF-1 is typical.

### Prevalence

In Caucasians, the incidence of MCC is about 0.3/100,000/year doubling within the last 10 years. Moreover frequency is rising with solar UVB index and in immunoincompetent individuals. Ninety-five percent of patients are older than 50 years. The preferential localization is face and neck.



**Merkel Cell Carcinoma. Figure 1** (a-c) H&E staining of MCC (a) showing uniform cells with a pale round relatively large nuclei and scanty cytoplasm together with scarce stromal tissue. Immunohistochemistry of MCC using antibodies selective for CK20 (b) and for neurofilaments (c). Both antibodies decorate a filamentous cytoskeleton and paranuclear plaques.

## Genes

Deletions and unbalanced translocations of 1p and 3 q, gains of 5 p, and 8q21-q22, loss of 4p15-pter and trisomies of chromosomes 1,6 and 11 have been described as well as UVB-type-specific mutations in the Harvey-ras and the p53 genes.

## Molecular and Systemic Pathophysiology

Some data on the molecular and genetic mechanisms involved in the development and progression of MCC are not yet available. Most MCC express the tyrosine kinase receptor KIT, but activating mutations in the C-KIT patho-oncogenes are missing. The same is true for the most common mutation of BRAF. Moreover, frequently in cancers mitogen-activated protein kinase (MAPK) pathway is inactive in MCC, and in good concordance B-Raf and Ras mutations are absent. Thus, the molecular mechanisms of MCC need further clarification.

Systemic manifestations of endocrine symptoms are very rare since tumor cells do not secrete relevant amounts of neuroendocrine substances despite their neuroendocrine nature.

### Diagnostic Principles

The clinical appearance of a rapidly growing nodule, uniform round cells in routine histology (H&E), and immunocytochemistry showing a cytoskeleton and paranuclear plaques composed of CK 20 and neurofilaments are the main stays in diagnosis.

### Therapeutic Principles

The therapy mostly comprises excision with wide surgical margins (mostly 2–3 cm), with histological margin controls. Primary site should undergo an adjuvant radiation therapy which has been shown to reduce local and regional recurrence rates [3], and possibly also to improve survival time [1]. The inclusion of the draining lymph nodes is still unclear. Sentinel node biopsy is recommended for exact nodal staging; however, its prognostic value as well as the additional total lymph node dissection are in discussion [4]. Distant metastases are treated by various, still controversial chemotherapeutic protocols mostly including doxorubicin, cyclophospamide, vincristine, and platinum-based compounds [5]. A somatostatin analogue, octreotide has been used but its effects are not yet clear.

### Synonyms

Intestinal ischemia; Gut ischemia

### Definition and Characteristics

Acute mesenteric ischemia (AMI) and infarction represents a complex of diseases that share clinical features caused by insufficient blood perfusion to the intestine,

reperfusion injury, bacterial translocation, and the systemic inflammatory response syndrome. Chronic mesenteric ischemia is typically caused by severe obstructive atherosclerotic disease of two or more splanchnic vessels.

## Prevalence

Although it accounts for only 1–2% of gastrointestinal diseases, the incidence of AMI is increasing and mortality rates still exceed 60%. The most common form of AMI is superior mesenteric artery (SMA) embolism, followed by SMA thrombosis, nonocclusive mesenteric ischemia, acute SMA thrombosis, focal segmental ischemia, and mesenteric venous thrombosis.

## Genes

NF-κB, heat shock factor-1, Hsp70, endothelin, platelet activating factor, complement, P-selectin, metalloproteinase-9, leukotrienes, histameine, RANTES, TNF-α, IL-6, Syk kinase, heme oxygenase-1.

## Molecular and Systemic Pathophysiology

Mucosal necrosis, with injury of the enterocytes of the intestinal villi, submucosal edema, hemorrhage and ulceration are seen with subacute or transient AMI. Transmural necrosis, or bowel infarction, resulting from more significant or prolonged ischemia, may lead to gangrene or perforation. Intermediate grades of injury may also be observed. Mestenteric I/R injury can be viewed conceptually as proceeding in three phases. The initial gut ischemia results in sublethal cell injury, which renders the gut vulnerable to additional waves of damage caused by maladaptive inflammatory and cytotoxic injury cascades activated during reperfusion. Once adequate perfusion is restored, a second phase, I/R injury, ensues, which, in experimental models, is characterized by a biphasic activation pattern of NF-κB p50 homodimers, in the enterocytes and heat shock factor-1 transactivation of Hsp70 synthesis in the mucosal and muscular layers of the gut. The activation of NF-κB is mediated by distinct pathways for IκBα serine and tyrosine phosphorylation, Numerous mediators have been implicated in I/R injury to the gut, including reactive oxygen and nitrogen species, endothelin, platelet activating factor, complement, arachidonic acid metabolites, metalloproteinase-9, leukotrienes, adenosine, histamine, and other components of resident mast cells, macrophages, T cells, and recruited leukocytes. E-selectin, ICAM-1, and platelet-associated P-selectin alter leukocyte-endothelial cell adhesion and contribute to the recruitment of leukocytes in the postischemic tissue and the microvascular and inflammatory responses of the intestine to I/R. CD4+ and CD8+T-cells also modulate the recruitment of leukocytes in a process dependent on endothelial MAdCAM-1. A third phase of gut I/R injury, mediated principally by activated resident and recruited leukocytes in the lamina propria, Peyer's patches, and muscularis, as well as enterocytes, involves the local synthesis and release of cytokines, including TNFα, IL-6, RANTES, and MCP-1, which invokes a maladaptive, sustained inflammatory response that exacerbates gut injury. The resultant mucosal barrier dysfunction, ileus, and failure of intestinal defense mechanisms perpetuate the hyperinflammatory response and increase susceptibility to bacteremia and endotoxemia.

## Diagnostic Principles

Most patients experience abdominal pain, with SMA embolism usually associated with a more acute onset. In the early stages of AMI, the abdomen may be benign, but distention and severe tenderness with rebound may indicate bowel infarction. Most patients experience occult bleeding in the stool, whereas gross bleeding is uncommon and usually indicates right colon involvement. In the elderly, AMI more commonly presents with nonspecific symptoms than with abdominal pain. Late findings may include fever, nausea, vomiting, hematemesis, back pain, bowel obstruction, and shock. Nonocclusive mesenteric ischemia is typically seen in patients with low-flow splanchnic circulation, often undergoing treatment with vasopressors. Duplex ultrasonography, multidetector row computed tomography, and magnetic resonance angiography aid in establishing the diagnosis. Plasma D-dimer has been suggested as an early marker of acute ischemia. Favorable outcomes are dependent on a high index of suspicion and prompt management. Chronic mesenteric ischemia often presents with postprandial pain and weight loss.

## Therapeutic Principles

Volume resuscitation and treatment with broad-spectrum antibiotics, as well as correction of potential underlying causes of AMI, such as arrhythmias or congestive heart failure, are mainstays of treatment. Intraarterial vasodilators have been used for treatment primarily of nonocclusive AMI. Thrombolytics have been used on a limited basis as treatment of occlusive AMI. Surgery is mandated in the presence of peritoneal signs if it can be tolerated. Protective or interventional therapies for AMI targeting components of early, branching pathways of I/R injury have been described in animals. Chronic mesenteric ischemia is typically treated by either surgical revascularization or percutaneous angioplasty and stenting.

Several agents offering partial protection in experimental gut I/R have been studied in rodents, including inhibitors of xanthine oxidase, inducible nitric oxide synthase, complement components, NF-κB, superoxide anion, and iron chelators. In the rat SMA I/R model, α-melanocyte stimulating hormone (α-MSH), even when given one hour after the initial ischemia, limited

mucosal injury and leukocyte influx, and abrogated the activation of NF-κB, ICAM-1, and IL-6, while promoting heme oxygenase-1 expression, in enterocytes of the postischemic ileum, Combined use of α-MSH with an inhibitor of serine phosphorylation of IκBα resulted in gut protection at early and late phases of reperfusion. Studies in cultured intestinal epithelial (IEC-6) cells indicate that oxidative stress activates Syk tyrosine kinase to tyrosine phosphorylate IκBα, a process that is blocked by α-MSH. Studies in scrape-wounded IEC-6 cells exposed to oxidative stress indicate that α-MSH also accelerates intestinal epithelial cell restitution through blockade of Syk tyrosine kinase. Direct cooling of the small intestine during the ischemic period also protects against experimental gut-I/R injury in part through the induction and maintenance of heme oxygenase-1 expression. Similarly, ischemic preconditioning limits gut injury, intestinal hyperpermeability, and bacterial translocation. Adenosine, NO, protein kinase C, and heme oxygenase-1 have been implicated in the protective response.

# Mesenteric Lipodystrophy

Stephan vom Dahl
Department of Internal Medicine, St. Franziskus-Hospital, Cologne, Germany

## Synonyms

Lipogranuloma of the mesentery; Liposclerotic mesenteritis; Mesenteric panniculitis; Panniculitis mesenterica; Retractile mesenteritis; Retroperitoneal xanthogranuloma; Sclerosing mesenteritis

## Definition and Characteristics

Mesenteric lipodystrophy is a clinical entity. It is characterized by an enlargement of mesenteric fat (Fig. 1, [1,2]) and, histologically, by inflammatory signs, fibrosis, and retraction, yielding it mesenteric panniculitis or retractile mesenteritis.

The disease has to be differentiated from familial partial lipodystrophy type 2, a defect of the LMNA gene, which is coding for lamines A and C, characterized by a loss of subcutaneous tissue of the lower limbs, often associated with profound insulin resistance and diabetes.

## Prevalence

Currently, fewer than 300 cases have been reported.

## Genes

Genetic analysis has not widely been performed in mesenteric lipodystrophy. In two cases, the disease has phenotypically been associated with ►Cholesterol Ester Storage Disease and (CESD) with one case showing decreased lysosomal acid lipase activity in fibroblasts, a homozygous lysosomal acid lipase-1 exon 8 splice junction mutation and increase of plasma chitotriosidase, a macrophage-derived enzyme, which is characteristically elevated in many lysosomal storage disorders, especially ►Gaucher disease [1].

## Molecular and Systemic Pathophysiology

Currently, there is no distinct molecular understanding of the disease. The enlargement of the mesenteric fat is due to proliferation of lipid-laden macrophages, different from the lymphocytic infiltration of Weber–Christian disease. In more severe cases, cystic necrosis, lipid-filled macrophages with multi-nucleated giant

**Mesenteric Lipodystrophy. Figure 1** Mesenteric lipodystrophy, visible as enlargement of mesenteric fat in abdominal CT. From [1].

cells and fibrosis occur. It has been associated with CESD, ►Sweet's Syndrome, repetitive abdominal trauma, ischemia, and infection. The disease is often associated with malignancy, predominantly Non-Hodgkin's lymphoma [2], but also solid tumours of breast, lung, colon, ovaries and kidney. A similarity of the disease to Ormond's retroperitoneal fibrosis has been discussed. Males are affected 2–3 times more often and peak occurrence is between the 5th and 7th decade. Fatal courses have been described. Transformation into malignant lymphoma is not frequent.

### Diagnostic Principles

Most cases present with no or mild abdominal pain and a palpable abdominal mass [3,4]. Sometimes, presentation can be with an acute abdomen. Additionally, weight loss, nausea, and diarrhea may be the first symptoms. The diagnosis resides on the findings of lipomatous thickening of the mesentery by computed tomography (Fig. 1) and non-specific inflammatory findings upon biopsy. Sometimes, mesenteric calcifications, visible on plain radiographs and computed tomography, are present. If associated with hepatosplenomegaly, Gaucher disease, CESD and other macrophage-derived lysosomal diseases have to be excluded biochemically.

### Therapeutic Principles

Treatment is still symptomatic. The disease follows a benign course and prognosis is generally favorable. Successful treatment has been reported with the use of progesterone (10 mg/d) for 6 months, corticosteroids in combination with colchicine and immunosuppressive drugs like azathioprine. A recent study reported a high response rate in individuals treated with 200 mg thalidomide nightly for a period of 12 weeks [5]. In case of severely symptomatic patients or bowel obstruction, debulking surgery is required, usually with good success and little relapse rates.

## Synonyms

Dysmetabolic syndrome X; (metabolic) Syndrome X; Insulin resistance syndrome; Reaven's syndrome; CHAOS (Australia); Abdominal obesity-metabolic syndrome; Deadly quartet; Metabolic vascular syndrome

## Definition and Characteristics

The metabolic syndrome clusters a variety of cardiometabolic risk factors such as hyperinsulinemia, dyslipidemia, essential hypertension, abdominal obesity, and glucose intolerance in individuals with insulin resistance predisposing to diabetes and cardiovascular disease [1,2].

## Prevalence

It has been estimated that the prevalence of the metabolic syndrome amounts to 25% in the North American population [3]. The prevalence of the metabolic syndrome and of its components varies substantially among ethnic groups, with the highest rates in Mexican American women.

## Genes

The complexity in underlying disturbances strongly points at a polygenic background of the metabolic syndrome. Genetic studies have linked certain quantitative trait loci (QTL) such as 3q27 and 4q22–q24 to components of the metabolic syndrome [4]. A range of genes were also found to be associated with metabolic syndrome partly in a gender-specific manner. These include LDLR, GBE1, IL1R1, TGFB1, IL6, COL5A2, SELE, and LIPC [4].

## Molecular and Systemic Pathophysiology

The etiology of the metabolic syndrome is complex involving genetic and environmental factors, which include age, smoking, alcohol, diet, and physical inactivity. There is debate of whether obesity, especially visceral obesity, or insulin resistance are causally related to the metabolic syndrome or whether they are merely a consequence of a more far-reaching metabolic derangement. Systemic inflammation and related oxidative stress is closely associated with the metabolic syndrome and both are discussed as potential contributors. C-reactive protein, fibrinogen, interleukin (IL)-6, tumor necrosis factor-α and others are usually found in higher concentrations and IL-10 in lower concentrations in individuals with the metabolic syndrome.

## Diagnostic Principles

There is a range of diagnostic criteria and guidelines for the metabolic syndrome developed by different organizations such as World Health Organisation (WHO), International Diabetes Federation (IDF), National Cholesterol Education Program (NCEP), and European Group for the Study of Insulin Resistance (EGIR).

*WHO*: The WHO criteria (1999) require the presence of either diabetes mellitus, impaired glucose tolerance, impaired fasting glucose or insulin resistance, and two of the following criteria:

- blood pressure: ≥140/90 mmHg
- dyslipidaemia: triglycerides (TG) ≥ 1.695 mmol/L and/or high-density lipoprotein cholesterol (HDL-C) ≤0.9 mmol/L (male), ≤1.0 mmol/L (female)
- central obesity: waist-hip-ratio >0.90 (male), >0.85 (female), and/or body mass index >30 kg/m$^2$
- microalbuminuria: urinary albumin excretion ratio ≥20 mg/min or albumin–creatinine ratio ≥30 mg/g

*EGIR*: The EGIR criteria (1999) require insulin resistance defined as the top 25% of the fasting insulin values among non-diabetic individuals and two or more of the following criteria:

central obesity: waist circumference ≥94 cm (male), ≥80 cm (female)
dyslipidaemia: TG ≥ 2.0 mmol/L and/or HDL-C < 1.0 mg/dL or treated for dyslipidaemia

- hypertension: blood pressure ≥140/90 mmHg or antihypertensive medication
- fasting plasma glucose ≥6.1 mmol/L

*NCEP-ATP III*: The National Cholesterol Education Program Adult Treatment Panel III (2001) requires at least three of the following criteria:

- central obesity: waist circumference ≥102 cm (male), ≥88 cm (female)
- dyslipidaemia: TG ≥1.695 mmol/L (150 mg/dl)
- dyslipidaemia: HDL-C <40 mg/dL (male), <50 mg/dL (female)
- blood pressure ≥130/85 mmHg
- fasting plasma glucose ≥6.1 mmol/L (110 mg/dl)

*American Heart Association (AHA)/Updated NCEP*: The updated NCEP ATP III criteria by AHA require the presence of at least three of the following components:

- Elevated waist circumference: ≥ 102 cm (male), ≥ 88 cm (female)
- Elevated TG: ≥150 mg/dL
- Reduced HDL-C < 40 mg/dL (male), < 50 mg/dL (female)
- Elevated blood pressure: ≥ 130/85 mmHg or use of medication for hypertension
- Elevated fasting glucose: ≥100 mg/dL (5.6 mmol/L) or use of medication for hyperglycemia

## Therapeutic Principles

The first-line therapy targets weight reduction by lifestyle changes (i.e., caloric restriction and physical activity), which is frequently complemented by drug treatment. The individual disturbances that comprise the metabolic syndrome are in general treated separately with multi-drug regimens being applied more frequently. There are currently no recommendations for the use of agents that target insulin sensitivity and beta cell function, e.g., metformin, incretin mimentics and thiazolidinediones, but preliminary data from clinical trials are promising.

# Metachromatic Leukodystrophy

Volkmar Gieselmann
Institute of Physiological Chemistry, University Bonn, Bonn, Germany

## Synonyms

Sulfatide lipidosis; MLD

## Definition and Characteristics

Autosomal recessive defect in the arylsulfatase gene leading to inability to degrade sulfated glycolipids in particular the sphingolipid 3-0-sulfogalactosylceramide (sulfatide). Lysosomal storage disease. A rare variant form of the disease is caused by defects in the saposin B portion of the prosaposin gene [1].

## Prevalence

The prevalence is unknown. Estimations about the frequency among newborns vary in between 1:40,000 and 1:160,000 newborns [2,3]. Higher frequencies were observed in Habbanite Jews, Christian Arabs, Eskimos and Navajo Indians.

## Genes

The arylsulfatase A gene is a small gene of 3 kb and consists of eight exons localized on chromosome 22 q 13. Around 100 disease causing mutations have been identified. Only three of these have a frequency worth mentioning, others are rare, most mutations are private.

## Molecular and Systemic Pathophysiology

Arylsulfatase A is a lysosomal enzyme catalyzing the first step in the degradation pathway of the membrane lipid 3-0-sulfogalactosylceramide (sulfatide). This

reaction depends on the presence of another protein saposin B. Thus, either the deficiency of Arylsulfatase A or saposin B leads to the lysosomal storage of sulfatide in various tissues. Storage in brain causes progressive demyelination which leads to multiple neurologic symptoms, such as ataxias, paresis and mental regression. The disease is lethal.

Clinically the disease is heterogeneous. The most frequent form of the disease is late infantile MLD which starts usually between the age of 18 and 24 months. Late onset starting in juvenile or adult age has been also observed.

### Diagnostic Principles

Leading initial symptoms in infants are progressive weakness, ataxias and gait disturbances. In late onset forms, psychiatric symptoms may prevail initially. MRI showing white matter lesions is important in the diagnosis of leukodystrophies in general. Arylsulfatase A activity can be determined in leukocytes or in cultured fibroblasts. Excess of sulfatide can be demonstrated in urine. It is important to emphasize that a deficiency of ASA is not a diagnostic proof for MLD. ASA pseudodeficiency must be excluded [1].

### Therapeutic Principles

Therapy is restricted to symptomatic interventions. In late onset patients, bone marrow transplantation can be considered in early stages of the disease.

## Metatropic (-like) Dysplasia

David Genevieve, Martine Le Merrer
Département de Génétique, INSERM, Hôpital Necker Enfants-Malades, Paris, France

### Synonyms

Metatropic dwarfism; Metatropic dysplasias; Fibrochondrogenesis; Schneckenbecken dysplasia

### Definition and Characteristics

Metatropic dysplasia (MD – MIM: 156530 and 250600) is a severe chondrodysplasia, described in 1966 by Maroteaux et al. and characterized by short limbs with enlargement and stiffness of joints and usually severe kyphoscoliosis. The diagnosis is based on radiological manifestations including severe platyspondyly, metaphyseal enlargement and shortening of long bones. The Greek term "metatropos" and emphasizes the progressive changes in the body proportions of patients with MD. Several phenotypes are described taking account of the severity and the likely mode of inheritance.

### Prevalence

The prevalence of the disease is very low, less than 100 patients were described in the literature.

### Genes

A previous classification was proposed by Beck et al., based on the radiological anomalies to distinguish three different types: a lethal autosomal recessive form, an autosomal recessive nonlethal form and a nonlethal autosomal dominant form with less severe X-ray manifestations and better clinical outcome. However, taking into account long-term follow up of a severe form autosomal dominant mode of inheritance with some cases with germinal mosaicism is likely. Neither the gene nor the chromosomal localization are known for metatropic dysplasia.

Fibrochondrogenesis and Schneckenbecken dysplasia are probably inherited in the autosomal recessive mode.

## Molecular and Systemic Pathophysiology

The disease could be discovered during pregnancy on IUGR or shortness of femora but hydramnios and fetal ascitis have been also observed. Birth measurements, including head circumference were normal in almost all cases. At birth, kyphoscoliosis and thorax narrowing are frequently noticed and associated with joint limitation and caudal appendage (1/5 of patients described in the literature). Fingers are long and thin. Other anomalies as cleft palate, cryptochidism, or sensorineural hearing loss are also described [1].

Specific radiological features are observed in MD: short diaphyses with wide "mushrooming shape" metaphyses leading to the classical dumbbell aspect, narrow iliac notches and delayed ossification of ischiopubic bones, kyphoscoliosis with severe platyspondyly with very thin (Fig. 1), "wafer" and dense vertebral bodies with coronal cleft. Odontoid hypoplasia with vertebral cervical subluxation could be responsible for medullar compression.

During the evolution, the striking aspect present in the newborn could modify with significant improvement of the platyspondyly and stabilization of the scoliosis and improvement of the growth of the long bones [1].

A lethal form, previously called hyperchondrogenesis showed marked features: poor or absent ossification of vertebral bodies with bulky and well-ossified pedicle and narrow interpedicular distances; short ribs with cupped anterior ends, "halberd" appearance of iliac wings with medial spurs of acetabula contrasting with very well-ossified ischia and pubic rami; the long bones are extremely expanded and dumbbell shaped on the lower limb and trumpet appearance of the upper limb. The phalanges are short with wide and sclerotic metaphyses (Fig. 2).

Variant metatropic dysplasias are fibrochondrogenesis and Schneckenbecken dysplasia, described as specific lethal chondrodysplasias. They have been recently included in metatropic dysplasia group in the International Classification of Skeletal Dysplasia [2,3].

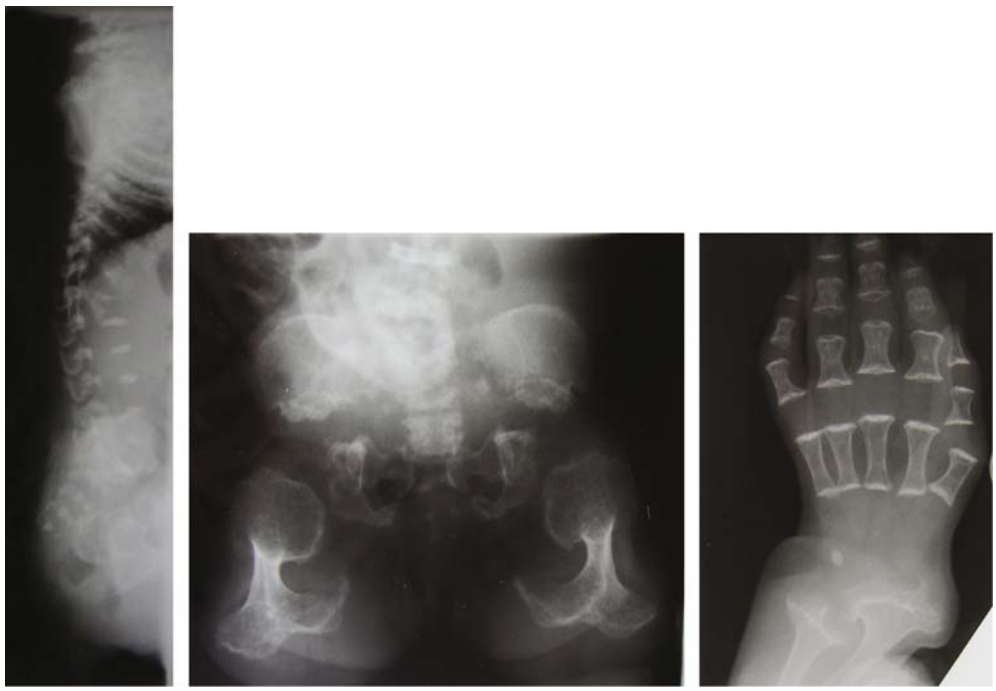
Fibrochondrogenesis is radiologically defined on the pear shape of the vertebral bodies on a lateral projection and small iliac wings. Histopathological findings are unique with interwoven fibrous septa and fibroblastic dysplasia of chondrocytes [4].

Schneckenbecken dysplasia is characterized by a snail-shaped iliac bone with medial extension, very flattened, on lateral view, oval-shaped vertebral bodies, and short long bones with mild flared metaphyses [5].

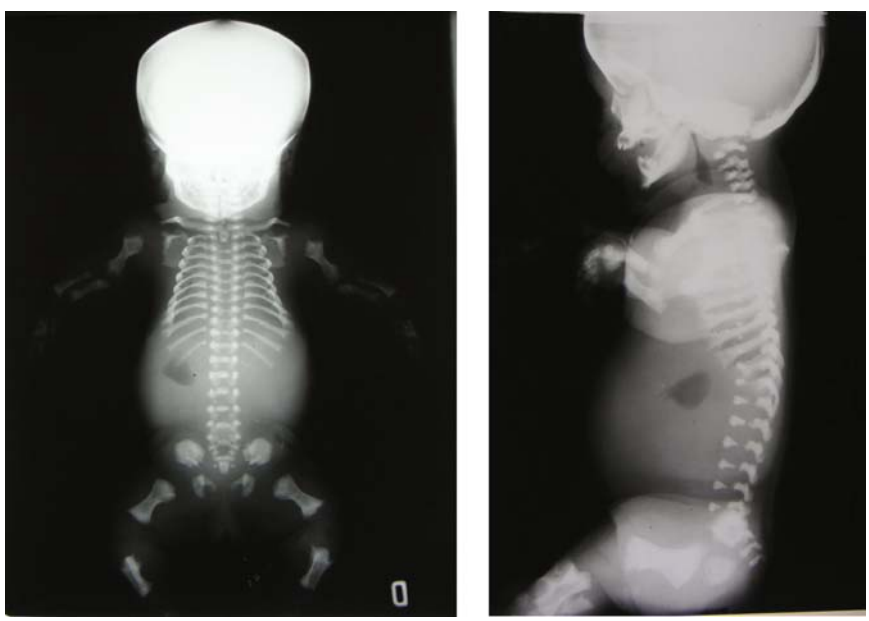
## Diagnostic Principles

The diagnosis lies on clinical and radiological examination: Long thorax, severe platyspondyly with enlarged and sclerotic metaphyses of the long bones, halberd shaped iliac wings with well-ossified ischia and pubic rami, irregular and squared calcaneum bones are the recognizable features.

**Metatropic (-like) Dysplasia. Figure 1** Mild metatropic dysplasia: note platyspondyly, enlarged metaphyses of the long bones and short phalanges with flaring of the metaphyses.



**Metatropic (-like) Dysplasia. Figure 2** Severe neonatal metatropic dysplasia: note the dum-bell shape of the long bones, wafer vertebral bodies, and sclerotic and wide phalanges.



**Metatropic (-like) Dysplasia. Figure 3** Fibrochondrogenesis: short long bones with flat and pear shape vertebral bodies.

## Therapeutic Principles

There is no pharmacologic or gene therapy for this condition. Orthopaedic and neurological follow up is required. Instability or stenosis of the cervical spine need fast and early surgery [6]. The kyphoscoliosis is precocious and need to be treated by brace along the growth. Epiphyseal dysplasia of the hip and the knee could be responsible for deformations (coxa vara, genu

valgum), which need orthopaedic surgery. Physiotherapy is useful to improve joint restriction and muscular function (Fig. 3).

## Definition and Characteristics

Congenital or acquired condition in which methemoglobin (Hb-$Fe^{3+}$), which cannot bind oxygen, is increased leading to asymptomatic cyanosis at concentrations of ±20%, fatigue, exertional dyspnea at ±35% and concentrations higher than ±60% lead to coma and death [1,2].

## Prevalence

There is a worldwide distribution of congenital forms, exact data are lacking.

## Genes

Hereditary methemoglobinemia is due to deficiency of cytochrome b5 (18q23) and deficiency of cytochrome b5 reductase (cb5r; 22q13.31-qter), both inherited via an autosomal recessive manner [1,2].

## Molecular and Systemic Pathophysiology

When oxygen ($O_2$) binds heme-iron in the hemoglobin molecule (oxygenation), an electron is passed from iron in the ferrous form ($Fe^{2+}$) to $O_2$, resulting in $Fe^{3+}$:$O_2^-$ (ferric superoxide). Upon deoxygenation the electron is passed back to the ferric ($Fe^{3+}$) iron, reducing it to the ferrous form in 97–99.5% of hemoglobin. The remainder is methemoglobin, which is normally reduced to hemoglobin via the cb5r pathway, in which NADH (generated from glycolysis) transfers electrons via cytochrome b5 (catalyzed by cb5r) to methemoglobin [1,2]. NADPH, which is generated in the hexose monophosphate shunt (and is G6PD dependent) can also serve as an electron donor (a "reducing agent") to reduce methemoglobin, but in red blood cells there is no electron carrier available to interact with NADPH. However, administration of exogenous electron carriers can activate this reducing pathway (see Therapeutic principles). Methemoglobinemia is mostly acquired due to exogenous agents (such as nitrates or sulfons), both in excessive doses and

M

in a normal dose. The latter occurs especially in infants, as cb5r activity is about 50% of adult activity and in individuals with partial cb5r deficiency. Cb5r deficiency gives rise to two distinct syndromes; deficiency solely in red cells results in life-long cyanosis with methemoglobin levels as high as 30%, whereas deficiency in all cells (due to a nucleotide substitution) also results in mental retardation, spasticity, growth retardation and microencephalopathy. In methemoglobinemia, the affinity of normal hemoglobin for $O_2$ is increased, so that the $O_2$-dissociation curve is shifted to the left resulting in a decreased $O_2$ delivery to tissues next to a reduced $O_2$ carrying capacity. This results in functional anemia with (sometimes) compensatory erythrocytosis. Other disease states that give rise to cyanosis are hemoglobin M disease and sulfhemoglobinemia [1,2].

## Diagnostic Principles

Co-oxymetry detects methemoglobin at its peak absorption of 631 nm. As sulfhemoglobin or methylene blue can give rise to false positives, confirmation should be obtained by adding cyanide to the specimen (which binds methemoglobin shifting the peak wavelength at 635 nm in direct correlation with methemoglobin concentration). Addition of ferricyanide converts the entire specimen to cyanomethemoglobin for measurement of the total hemoglobin concentration. Methemoglobin can then be calculated as percentage of the total hemoglobin level [1,2].

## Therapeutic Principles

For cosmetic purposes methylene blue and ascorbic acid can be given to reduce cyanosis. Both serve as exogenous electron carriers thereby activating the NADPH dependent (and thus G6PD dependent) methemoglobin-reducing pathway. Intravenous administration of methylene blue in case of dangerously high methemoglobinemia concentrations is indicated in individuals without G6PD deficiency. Clinically important methemoglobinemia in individuals with concomitant G6PD deficiency should be treated by exchange transfusion [1,2].

# Methylenetetrahydrofolate Reductase Deficiency

Katrin Beyer
Department of Pathology, Hospital Universitari Germans Trias i Pujol, Badalona, Barcelona, Spain

## Synonyms

MTHFR deficiency; MTHFR deficiency, thermolabile type

## Definition and Characteristics

MTHFR deficiency is an autosomal recessive inborn error of folate metabolism. Patients with severe MTHFR deficiency present homocysteinuria as well as high homocysteine and low methionine concentrations in plasma. Homocysteinuria is accompanied by neurological (developmental delay during first years of life, mental retardation), skeletal and muscular (osteoporosis), ophthalmologic (ectopia lentis) and vascular features (thromboembolic events during adulthood). Moreover, reduced cerebrospinal fluid levels of both methionine and adenosylmethionine, brain demyelination and spinal cord degeneration have been observed. The severity of the clinical course correlates with onset of symptoms and with residual MTHFR activity. Mild MTHFR deficiency, with onset at adult age, is characterized by homocysteinemia and much less pronounced clinical features. The TT genotype corresponding to thermolabile MTHFR has been associated with vascular and coronary heart disease, ischemic stroke [1], neural tube defects, cleft lip/paladar, migraine, cancer [2] and schizophrenia [3].

## Prevalence

*Severe MTHFR deficiency*: unknown.
*Mild MTHFR deficiency* : (homozygosity for thermolabile MTHFR): 15% in European, Middle Eastern and Japanese populations, 1.4% in African Americans.

## Genes

MTHFR (1p36.3); two common polymorphisms: C677T (A222V, thermolabile MTHFR) and A1298C. Severe MTHFR deficiency: 29 missense/nonsense mutations on MTHFR (correlation between location and onset/severity of the disease), two splicing mutations, two deletions; combination of heterozygotes for two separate mutations; in some cases further combination of mutations and deleterious alleles [4].

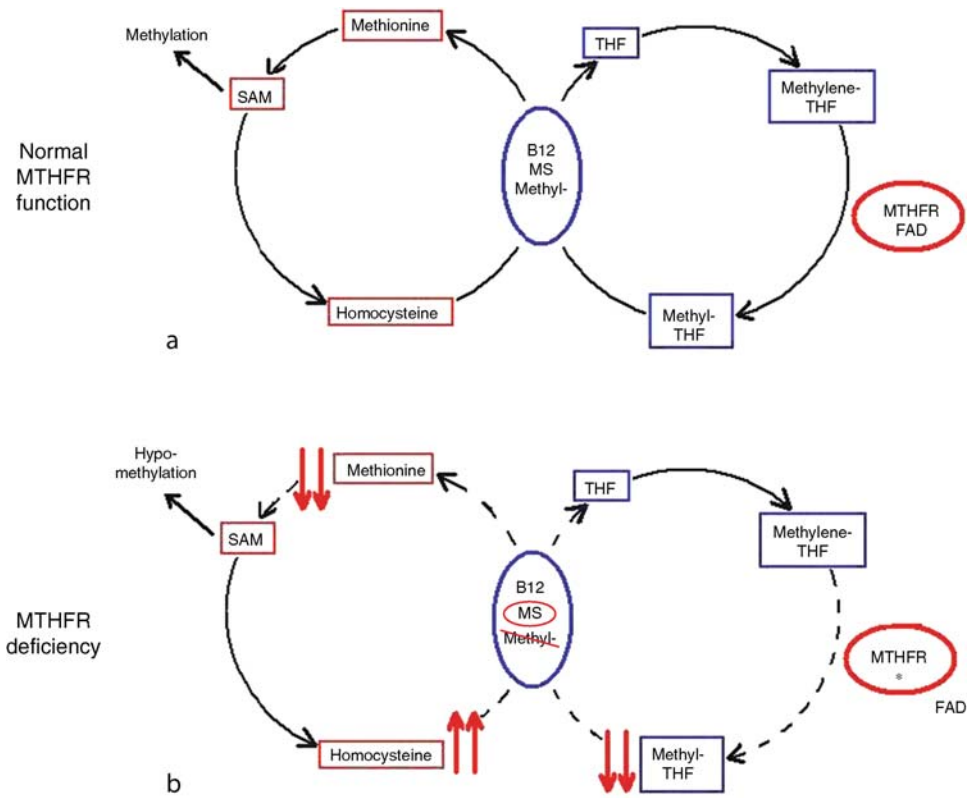
Mild MTHFR deficiency: T/T-homozygotes at C677T [5]; combination of both T667 and C1298 alleles (rare cys-haplotype).

## Molecular and Systemic Pathophysiology

The homocysteine metabolic pathway comprises two arms: the remethylation pathway regenerating methionine and the transsulfuration pathway degrading homocysteine into cysteine.

In the remethylation pathway MTHFR reduces methylene-tetrahydrofolate (THF) into methyl-THF that represents the active form of folic acid. MTHFR requires riboflavin in the coenzyme form of flavin adenine dinucleotide (FAD). The transfer of the methyl group from methyl-THF regenerates methylcobalamin, which then acts as a coenzyme for methionine synthase in the methylation of homocysteine to synthesize methionine (Fig. 1a).

In severe MTHFR deficiency several point mutations within the MTHFR gene, and in mild MTHFR deficiency the homozygous thermolabile variant lead to impaired enzyme activity [5]. The loss or diminution of MTHFR activity is caused by the enhanced ability of the mutated enzyme to dissociate from FAD, but FAD binding can be stabilized by folate administration. In the presence of mutated MTHFR forms, THF (Fig. 1b) cannot be converted to MTHF. The reduced MTHF synthesis leads to insufficient levels of methylcobalamin, a cofactor for methionine synthase, and finally methionine synthase function is impaired. Results are, on one hand, the increase of homocysteine and, on the other hand, the decrease of methionine levels. Whereas the accumulation of homocysteine is associated with widespread toxic effects, methionine is the most important methyl-group donor in cellular metabolism. Low methionine levels affect widespread methylation processes, such as the stabilization of many proteins, DNA methylation and the synthesis of molecules including creatine, phosphatidylcholine, melatonin and others.



**Methylenetetrahydrofolate Reductase Deficiency. Figure 1** The homocysteine remethylation pathway. (a) Normal MTHFR function. (b) MTHFR deficiency. Interrupted lines indicate affected reactions. Mutated MTHFR (MTHFR*) has impaired ability to bind FAD resulting in reduced enzyme activity. MTHFR dysfunction reduces methyl-THF levels that lead to insufficient methionine synthase functioning and than to homocysteine accumulation and methionine decrease, followed by hypomethylation. FAD flavin adenine dinucleotide; MS methionine synthase; SAM S-adenosil-methionine; THF tetrahydrofolate.

### Diagnostic Principles

The latest diagnostic techniques used to identify a deficiency in MTHFR begin with the test of homocysteine concentration in plasma from whole blood or from cell free amniotic fluid. If elevated levels are detected, a direct assay of fibroblasts and/or blood cells is done to determine the specific activity level of MTHFR. When abnormally low MTHFR activity is detected, direct sequencing for mutation detection is carried out.

### Therapeutic Principles

*Mild MTHFR deficiency*: treatment generally consists of diet control and folate supplementation. Those will protect mild MTHFR mutant proteins from losing their FAD and restore enzyme function.

*Severe MTHFR deficiency*: treatment must be more aggressive, but even so it is not always effective. The treatment uses a combination of therapies, on one hand, to decrease homocysteine levels, and, on the other hand, to maximize any residual enzyme activity. Folate compounds are used to protect the enzyme from loosing its crucial FAD cofactor and MTHF compensates for MTHFR inability to generate this product. Whereas the additional treatment with methionine has been effective in some patients, betaine (a substrate for betaine methyltransferase, an enzyme that provides an alternate route for the conversion of homocysteine to methionine) restores cerebrospinal fluid S-adenosylmethionine levels to normal and prevents the progress of neurological symptoms in all patients in whom it has been tried.

## 3-Methylglutaconic Aciduria Type I

►3-Methylglutaconyl-Coenzyme A Hydratase Deficiency

## 3-Methylglutaconyl-Coenzyme A Hydratase Deficiency

Elardus Erasmus, Lodewyk J. Mienie
School of Biochemistry, North-West University, Potchefstroom, South Africa

### Synonyms

3-Methylglutaconic aciduria type I; 3-MG-CoA-hydratase deficiency; 3-MGA-type I

### Definition and Characteristics

An autosomal recessive inherited defect in the leucine catabolic pathway. 3-methylglutaconyl CoA hydratase normally converts 3-methylglutaconyl-CoA to 3-hydroxy-3-methylglutaryl-CoA. In 3-methylglutaconic aciduria type I the hydratase [1] is deficient, causing accumulation and excretion of high concentrations of 3-methylglutaconic acid and 3-hydroxyisovaleric acid.

### Prevalence

Type I 3-methylglutaconic aciduria is very rare with less than 20 cases described internationally.

### Genes

The type I-gene for 3-MGA is assigned to chromosome 9q22.2.

### Molecular and Systemic Pathophysiology

3-Methylglutaconic aciduria type I is caused by a primary enzyme deficiency of the mitochondrial hydratase enzyme in the leucine catabolic pathway, leading to the accumulation of the cis–trans isomers of 3-methylglutaconic acid. It was recently shown that 3-methylglutaconyl-CoA hydratase is encoded by the AUH gene [2]. Type I is also the only 3-methylglutaconyl aciduria variant in which 3-hydroxyisovaleric acid is produced. This is the result of reversibility of the enzyme reaction to 3-methylcrotonyl-CoA. Some patients excreted small amounts of the hydrogenation product of 3-methylglutaconic acid, 3-methylglutaric acid in the urine. Hydratase enzyme activity in this variant of the disorder is normally below 30% with one family having sibs with activity below 3% of normal activity [3].

### Diagnostic Principles

Clinical symptoms range from mild to severe. This may include acidosis, microcephaly, hypotonia, hepatomegaly, macrocephaly and in some cases spastic quadriplegia. Severe cases of 3-methylglutaconic aciduria were accompanied by dystonia and episodes of irritability

and self-mutilation [4]. Fasting has produced hypoglycemia and acidosis in some patients. MGA has been identified in asymptomatic individuals. Excretion of 3-methylglutaconic acid has been associated with mitochondrial dysfunction, urea cycle defects and hypercholesterolemia. Diagnosis of 3-methylglutaconic aciduria type I is normally based on the detection of the cis- and trans isomers of 3-methylglutaconic acid accompanied by high levels of 3-hydroxy isovaleric acid. Confirmation of the diagnosis is based on activity assays of 3-methylglutaconyl-Co A hydratase.

### Therapeutic Principles

Treatment of the patients is based upon modest limitation of leucine intake. Carnitine supplementation has been shown to contribute in the excretion of carnitine conjugates of 3-methylglutaconate and 3-methylglutarate [5].

## MHC Class I Deficiency

Jan Bubeník, Jana Šímová
Department of Tumor Immunology, Institute of Molecular Genetics, Academy of Sciences of the Czech Republic, Prague, Czech Republic

### Synonyms

MHC class I down-regulation

### Definition and Characteristics

Down-regulation of MHC class I molecule expression is a widespread phenomenon used by tumor cells and virus infected cells to escape T-cell mediated immune responses.

## Genes

Classical MHC class I molecules, HLA-A, -B and -C in humans are composed of polymorphic heavy chains non-covalently associated with $\beta_2$-microglobulin. These molecules are coded for by the respective HLA-A, -B, -C and $\beta_2$-microglobulin genes. The function of each of the respective genes can either be down-regulated or absent. MHC class I molecules HLA-A, -B and -C are coded by genes localized on human chromosome 6 and the $\beta_2$-microglobulin is coded by the gene localized on chromosome 15.

## Molecular and Systemic Pathophysiology

The polymorphic classical MHC class I (MHC I) molecules are integral membrane proteins that bind a diverse group of peptides and display these peptides for recognition by cytotoxic T lymphocytes (CTL). MHC I antigens are found on nearly all nucleated cells in the body [1], but the relative level of their expression varies amongst the different tissue types. Certain reproductive and developmental tissues lack the expression of MHC I molecules, as do cells of the nervous system and the eye. The richest source of MHC I molecules are the cells of the immune system which employ the MHC I molecules for the induction of adaptive immune responses. Down-regulation or deficiency of the MHC I molecules on the surface of a large proportion of tumor cells (for a review see [2]) and on the surface of some virus infected (cytomegaloviruses, human T-cell leukemia virus, human immunodeficiency virus-1, human herpesvirus-8 and others) or other pathogen infected (Legionella pneumophila, Trypanosoma cruzi and others) cells, mediates the escape of these cells from immune surveillance or substantially diminishes the efficacy of T-cell mediated immune responses, since the sensitized CD8+ CTL can recognize the "foreign" cell surface antigens only when these antigens are presented in the context of MHC I molecules (MHC class I restriction of the CD8+ CTL function, for a review see [3]).

## Therapeutic Principles

From the therapeutic point of view, the conventional types of MHC class I defects described in human tumors as total, locus, allele and haplotype loss can be classified as irreversible defects, such as $\beta_2$-microglobulin and MHC I heavy chain gene disabling mutations or reversible defects. The reversible defects involve all levels of the MHC class I restricted antigen presentation machinery and can be repaired in preclinical settings by local therapeutic procedures, such as peritumoral administration of interferon (IFN) or tumor necrosis factor alpha. The IFN, particularly IFN gamma, therapy can prospectively be performed also as local gene therapy using irradiated tumor vaccines carrying an inserted IFN gene and producing this cytokine constitutively (for a review see [4]).

## Definition and Characteristics

Major histocompatibility complex (MHC) class II deficiency is a genetic disease of autosomal recessive inheritance that is defined by absence or strong reduction of MHC class II (HLA-DR, DP, DQ) expression on peripheral blood cells [1]. The major clinical manifestations of MHC class II deficiency present themselves during the first year of life as septicemia and recurrent infections of the gastrointestinal, pulmonary, upper respiratory, and urinary tracts. These infections can be of bacterial, fungal, viral, and protozoan origin. If untreated the disease aggravates over time and leads to

an early death between 6 months and 5 years of age [2]. Historically, MHC class II deficiency has been divided into four complementation groups A–D: MHC class II expression of cells from a patient (e.g., group A) could be rescued only by fusion with cell lines derived from patients that belonged to another complementation group (e.g., groups B,C,D) thus complementing for each others gene defect [1].

## Prevalence

Less than 100 patients have been formally reported worldwide (with 70% belonging to complementation group B).

## Genes

*Complementation group A*: Mutations in the CIITA gene (16p13) encoding for the MHC class II transactivator protein.

*Complementation group B*: Mutations in the RFXANK gene (19p12; syn: BLS, RFX-B, ANKRA1) encoding for the regulatory factor X-associated ankyrin-containing protein.

*Complementation group C*: Mutations in the *RFX5* gene (1q21) encoding for regulatory factor X 5.

*Complementation group D*: Mutations in the RFXAP gene (13q14) encoding for regulatory factor X-associated protein.

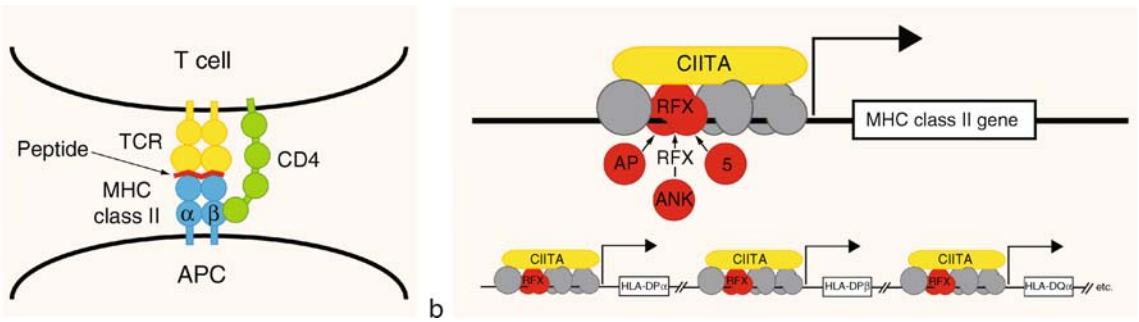
## Molecular and Systemic Pathophysiology

Classical MHC class II molecules (HLA-DP, DR, and DQ in the human) are expressed at the surface of antigen presenting cells (e.g., dendritic cells, B lymphocytes, macrophages) and activated T cells. They display peptide antigens derived from phagocytosed pathogens to the T cell receptor of CD4-expressing helper T lymphocytes. This leads to activation of the antigen-specific T helper cells, which in turn proliferate clonally and promote specific immune responses by the release of cytokines and expression of costimulatory molecules. The defects in immune functions resulting from the absence of MHC class II are twofold: (1) failure of the proper development of MHC class II-restricted T-helper cells due to lack of MHC class II in the thymus and (2) absence of MHC class II-dependent antigen presentation due to lack of MHC class II expression on peripheral antigen presenting cells (Fig. 1a). Taken together the genetic defects result in a virtually complete absence of T helper cell mediated immune defense mechanisms exemplified by impaired delayed type hypersensitivity and reduced humoral immune responses.

Despite the absence of MHC class II expression patients have considerable frequencies of $CD4^+$ T cells. It is unclear how these cells are generated in the thymus and whether they play any functional role in an environment devoid of MHC class II.

MHC class II deficiency is caused by mutations within genes involved in the transcriptional regulation of the promoter common to all human MHC class II genes. The mutations may affect the transcriptional regulator CIITA or one of three components of the DNA-binding RFX complex (RFXANK, RFX5, or RFXAP) [1] (Fig. 1b).

Mouse models of MHC class II deficiency have been generated by gene targeting of either CIITA or RFX5. They essentially confirmed the observations made in human patients but also revealed an unexpected residual expression of MHC class II on dendritic cells and B cells, allowing these animals to generate T cell dependent immune responses when properly selected CD4 T cells are provided [3]. Whether this constitutes



**MHC Class II Deficiency. Figure 1** Molecular and cellular mechanism of MHC class II deficiency. (a) MHC class II molecules present peptide antigen derived from phagocytosed proteins to CD4-expressing T helper lymphocytes. Triggering of the T cell receptor (TCR) results in activation of the T lymphocyte, which in turn proliferates clonally, and by secretion of cytokines enables the subsequent mounting of immune effector functions. (b) Expression of the different MHC class II molecules is enabled by a common promoter complex. Deficiency in any of the molecules unique to this promoter complex (i.e., the RFX molecules and CIITA) results in absence of any MHC class II expression and thus profound immune deficiency due to lack of T helper cell functions.

a true species difference or whether residual MHC class II expression on certain antigen presenting cells from patients may have escaped attention remains to be shown.

### Diagnostic Principles

Patients present clinically with recurrent bronchopulmonary infections and chronical diarrhea at infancy, triggered by bacterial, viral, or fungal infections. The clinical course is characterized by failure to thrive, frequently complicated by hepatitis and cholangitis, viral meningoencephalitis and autoimmune phenomena. T- cell counts in peripheral blood are normal, but variable $CD4^+$ lymphopenia and hypogammaglobulinemia are found. The lack of MHC class II expression is confirmed by flow cytometric analysis of HLA-DP, DQ, and DR on peripheral blood cells. Identification of genetic complementation groups can be performed by transduction of lymphocytes with lentiviral vectors encoding CIITA, RFXANK, RFX5, or RFXAP [4].

### Therapeutic Principles

Symptomatic treatment includes intravenous gammaglobulin, prophylactic use of antibiotics, and parenteral nutrition. For curative treatment, allogeneic bone marrow transplantation is the current therapy of choice, although the success rate seems to be lower compared to other immunodeficiencies [2,4,5]. This is not fully understood but may be due to the requirement of MHC class II expression by thymic epithelium for the selection of functional $CD4^+$ T cells are from the transplanted bone marrow [3]. In future, gene therapy of hematopoetic stem cells and thymic epithelial cells may thus constitute an alternative [4].

## Microdeletion 5q15-q22 with Familial Adenomatous Polyposis

Shirley Hodgson
Department of Cancer Genetics, St. George's Hospital, University of London, UMDS, London, UK

### Synonyms

FAP

### Definition and Characteristics

The major features of this microdeletion are developmental delay of variable degree and familial adenomatous polyposis (FAP) caused by deletions in the adenomatous polyposis coli (APC) gene on chromosome 5q [1]. The latter is an autosomal dominant condition caused by mutations or deletions and characterized by the development of hundreds to thousands of adenomatous polyps in the large bowel, usually from the teenage years, causing a very high risk of colorectal carcinoma, which is almost inevitable in an untreated affected person, (average age at diagnosis 40 years.) without prophylactic surgery [2].

Other features include benign proximal gastric polyps, adenomas of the distal stomach and of the duodenum, desmoids, sebaceous cysts, osteomas, and congenital hypertrophy of the retinal pigment epithelium (CHRPE). There is also an increased risk of hepatoblastoma in early childhood, brain tumors (medulloblastomas and astrocytomas) and thyroid cancer (cribriform variant papillary histological type). Gardner's syndrome was a term used to describe FAP with the extracolonic features, including exostoses, supernumerary and unerupted teeth, fibromas, epidermoid cysts, in addition to those mentioned above [3].

Further variably associated findings are likely to be due to haploinsufficiency of genes other than the APC gene. They include a pattern of facial dysmorphic features (blepharophimosis, large nose, prominent mandible), ocular coloboma, cleft palate, heart defects, hiatus hernia and hypothyroidsm, and renal malformations.

### Prevalence

Interstitial deletions of chromosome 5q are rare (reviewed in [4]).

## Genes

Deletion of genes localized at 5q15-q22.

## Molecular and Systemic Pathophysiology

Only patients with deletions encompassing the APC locus have FAP; other cases tend to be described in children with very variable phenotypic abnormalities, including psychomotor retardation, failure to thrive, club feet, dislocated hips, cleft palate, renal malformations and minor facial dysmorphism, and short stature with growth hormone deficiency, malformed ears and short neck has been described in a case with del(5)(q13.1-q15). Deletions of the entire APC gene are thought to result in typical FAP, although a few reports suggest that such patients have a lower number of polyps (but usually over 100), with sigmoid sparing and some sessile adenomas, and this has been ascribed to a "dominant negative" effect of the gene. However other cases with whole gene deletions have been shown to be associated with florid polyposis. Using real-time quantitative multiplex PCR to detect exon 14 deletions, seven (12%) of 60 classical FAP cases were shown to have deletions, and six of these encompassed the entire locus [5]. CHRPE occurs in cases with whole gene deletions where documented.

Submicroscopic deletions encompassing the APC gene tend to be associated with mild to moderate developmental delay, depending on the extent of the deletion. A familial deletion 5(q15-q22) was associated with FAP in a mother and two children who also had I.Q.'s of 50 recorded, and epidermal cysts were noted. Hodgson et al described two cases with FAP and mild mental handicap, with del (5)(q21.3-q23.1) in one case and del (5)(q15-q23.1) in the other, similar to a familial deletion described in a nephew and aunt with FAP and more severe mental handicap, with del(5)(q22-q23.2). A further case with profound mental retardation had the deletion del(5)(15-q22.3). A familial translocation, t(5: 10)(q22;q25) resulted in mild adenomatosis with fewer than 1,000 colonic polyps in two affected relatives. Very mild adenomatous polyposis with normal intelligence was described in carriers of a familial submicroscopic deletion del(5)(150kb:ex11-3′), and Pilarski described a case with a de novo deletion del (5)(q22-q23.3) who had FAP and was institutionalised because of special needs, with hypothyroidism and hyperlipidaemia.

Cases with FAP and small deletions in the APC gene do not appear to have developmental delay, although some cases with mild delay and arachnoidactyly have been described, associated with larger deletions. One of the cases described with a larger deletion (del(5)(q15;q22.3 or 23.1) had a marfanoid habitus and mild developmental delay, but the fibrillin 2 gene (in which mutations cause Beal's syndrome) was shown to be present using in-situ hybridization. Congenital contractures reported in a case with del(5)(q22.3;q31.1) could have resulted from deletion of this gene, which has been mapped to 5q23-31. Other features of individuals with deletions within this region include speech defect, frontal bossing, macrocephaly, epicanthic folds, and a high arched palate. One case had Caroli's disease.

## Diagnostic Principles

Typical FAP is diagnosed by the presence of at least 100 colorectal adenomas. Nearly 95% of patients present in this way by the age of 35 years.

## Therapeutic Principles

It is important to be aware of the possibility of the presence of FAP in individuals with deletions in proximal chromosome 5q encompassing 5q22.

## Definition and Characteristics

Acute or recurrent infection the middle ear may result in a permanent perforation of the tympanic membrane (Fig. 1a). Ears with chronic perforations without cholesteatoma may be chronically or intermittently infected and commonly exhibit discharge [1].

## Prevalence

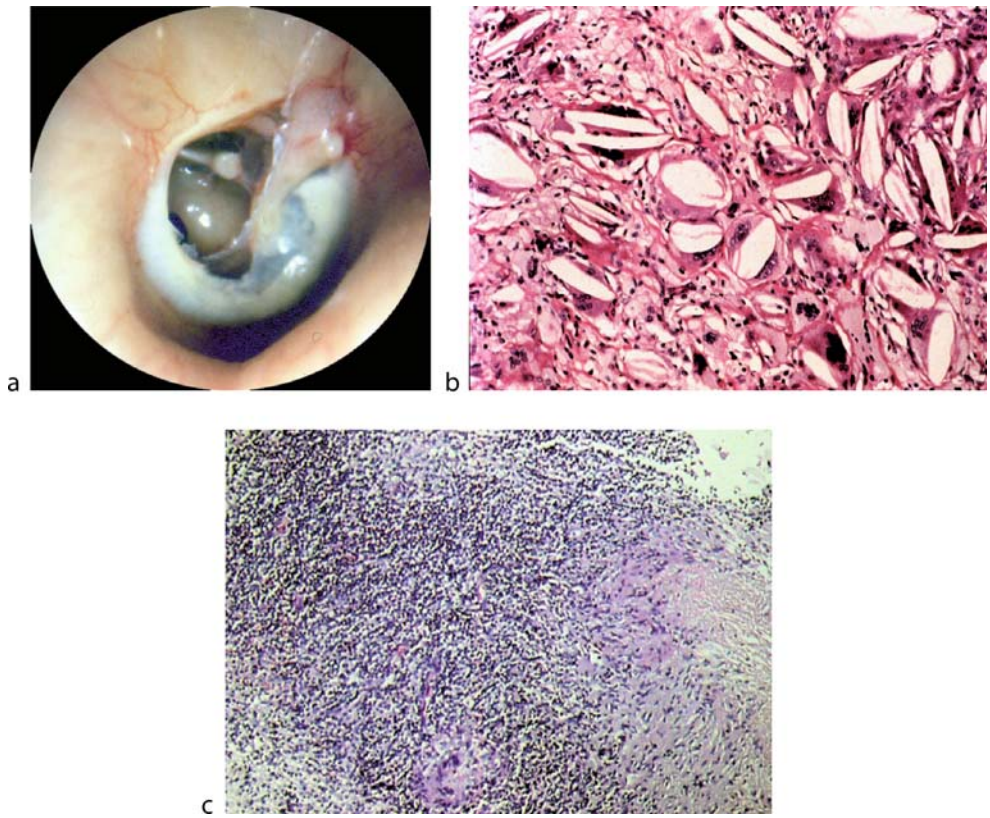
Exact details on the epidemiology of chronic middle ear disease are not available for several countries including Germany.

## Molecular and Systemic Pathophysiology

Chronic otitis media without cholesteatoma is characterized by the presence of irreversible inflammatory changes within the middle ear and mastoid. The factors that allow acute infections within the middle ear and mastoid to develop into chronic infections are not fully understood [2]. An important feature of chronic otitis media is the variation in the degree and extent of the inflammatory reaction. da Costa et al. observed granulation tissue in 96%, ossicular changes in 96%, tympanosclerosis in 43%, cholesteatoma in 36%, and cholesterol granuloma in 21% of the temporal bones of those with chronic otitis media with perforated tympanic membrane [2]. Tympanosclerosis, a special from of fibrosis, is a complication of otitis media in which acellular hyalin and calcified deposits accumulate within the tympanic membrane and the subepithelial connective tissue of the middle ear mucosa (see: tympanosclerosis). Ventilation of the middle ear, antrum, and mastoid depends on the uninhibited passage of air from the eustachian tube into the mastoid air cells. In the human temporal bone, air must travel around the ossicles in the epitympanic space to get into the antrum. The middle ear is divided from the antrum not only by the ossicles but also by mucosal folds. There were two constant openings, the space between the tendon of the tensor tympani muscle and the stapes and between the short process of the incus and the stapedial tendon [2]. Therefore, edema and inflammation with granulation tissue may block these interconnected openings, prevents drainage of the antrum and mastoid. Chronic obstruction of the attic and antrum with infection leads to permanent alterations in the mucosa and bone of the antrum and mastoid. Bone erosion in chronic otitis media is more prevalent in ►Cholesteatoma, but it still occurred in the absence of cholesteatoma. Granulation tissue within the temporal bone also can lead to bone erosion. Cholesterol granuloma develops as a giant cell reaction to the deposition of cholesterol, generally found in areas blocked from aeration mostly in the mastoid, rarely within the middle ear (Fig. 1b).

Sometime it leads to recurrent secretion of a brown liquid originating from retentions in the middle ear. Between the spells of secretion the tympanic membrane closes and may have a dark brown-blue appearance as seen in some cases of middle ear effusions. The retentions in the middle ear cause conductive hearing loss [1,2].

Tympanic membrane perforation may result from acute otitis media (AOM), chronic otitis media, and/or trauma. In some cases, a dry, simple perforation will result from a single bout of AOM, like necrotizing otitis media. Perforation of the tympanic membrane, especially involving the tympanic annulus, may allow immigration of the keratinizing epithelium of the



**Middle Ear Disease, Chronic. Figure 1** (a) Microphotograph of a perforated tympanic membrane in the posterior superior quadrant and tympanosclerosis. (c) Tuberculosis of the middle ear. Epitheloid cells, lymphocytes and scattered langhans giant cells are present.

ear canal or tympanic membrane, leading to cholesteatoma. An ear with a simple perforation may become infected because of contamination from the ear canal and/or because of a smoldering infection in the mastoid. Chronic otitis media may also occur after insertion of tympanostomy tubes. Drainage may be due to complication of tympanostomy tube insertion and has been reported to occur in ~10–35% of children undergoing this procedure. Chronic otorrhea that is resistant to therapy has been reported to occur in ~6% of children with tubes [1,2]. It is unclear whether such chronic infection is a result of the indwelling tube or of the drainage of an already smoldering infection. The risk of otorrhea on the second postoperative day was significantly increased by the presence of a bacterial pathogen in the ear canal or in the middle ear effusion and by the presence of inflamed middle ear mucosa at tympanostomy tube insertion.

Middle ear tuberculosis often has a typical whitish appearance and its granulations have a little tendency to bleed; histologically typical Langerhans cells are found (Fig. 1c).

Sarcoidosis may be seen in patient with pulmonary affection. Actinomycosis of the middle ear has been described. Wegener's granulomatosis is a systemic inflammatory condition affecting nose, kidneys, lungs, and other organs and may affect the middle ear [1].

## Diagnostic Principles

The patient's history should exclude other possible causes for secretion out of the ear canal. The diagnosis is based on microscopical otoscopy after cleaning of the ear canal. A cholesteatoma should be excluded. Central perforations of varying size are found.

In case of tympanosclerosis, the prognosis for hearing improvement by surgery is poor, if the ossicular chain is involved. Sometimes, parts of the ossicular chain are visible, especially the region of the long process of the incus informing the surgeon about the necessity for ossicular reconstruction. Improvement of hearing after covering the perforation indicates an intact chain. There are no reliable tests for the function of the Eustachian tube. Valsalva maneuver should be performed. A negative

Valsalva, however, is not a contraindication against surgery. As audiometrical test, pure tone audiometry is sufficient. A simple perforation commonly presents as a low-frequency conductive hearing loss clinically. The tympanic membrane velocity was found decreased in the low frequency in a small perforation and in the high and low frequencies in a large perforation [3]. A speech audiogram can be used for verification. It should be controlled by the tuning fork tests Weber and Rinne. Imaging is of little importance in normal cases. Schüller's X-ray informs the surgeon about the position of the sinus, the medial fossa, and the approximate size of the mastoid. Computerized tomography or/and NMR should be reserved for complications and exceptional for more extended surgery. Specific middle ear infections like tuberculosis and actinomycosis are generally not expected before surgery but diagnosed by histology. Cultures may not confirm tubercle bacilli, therefore identification of middle ear tuberculosis by polymerase chain reaction (PCR) has become of high diagnostic value. Postoperative general examination of the patient mostly shows other manifestations of the tuberculosis. Positive c-ANCA tests do not prove but point at Wegener's disease of the middle ear. Sarcoidosis should be considered in patients with lung disease.

## Therapeutic Principles

The main concept of treating a draining ear is closure of the perforation [4,5]. Most infected perforations can be controlled conservatively with topical antibiotics. Antibiotic ear drops with or without hydrocortisone usually are effective and should be chosen to eradicate the most common pathogens, like Pseudomonas aeruginosa and Staphylococcus aureus. In those with recurrent or chronic infections, cultures should be used to adjust antibiotics. Irrigation of an infected ear with a perforation with a dilute acidic or fuchsin solution is often effective in refractory cases. Many topical otic antibiotic solutions contain potentially ototoxic substances, including aminoglycoside antibiotics and propylene glycol. Although there are reports suggesting that sensorineural hearing loss may occur after topical use of these preparations, no conclusive evidence is available proving ototoxicity of commercially available otic preparations in humans. Topical antibiotics and steroids also can be applied in powder form by insufflation. A variety of substances have been utilized individually or in combination, including boric acid, sulfamethoxazole, chloramphenicol, and hydrocortisone. Systemic antibiotics should be used in refractory cases when specific pathogens are found on culture. Several quinolones like ciprofloxacin, floxacin, and norfloxacin may be helpful in these patients. In ears that become repeatedly infected but clear between episodes, tympanoplasty should be recommended [4]. In some patients, chronic infection with otorrhea, but without cholesteatoma, will continue despite intense medical treatment. In these cases, two options should be considered: long-term intravenous antibiotics or tympanomastoid surgery [4,5]. Repetitively local debridement is required. The goals of tympanomastoidectomy include aeration of the middle ear and mastoid, removal of irreversibly diseased tissue, closure of the middle ear, and reconstruction of the sound-conducting mechanism. These goals are not always achieved in a single stage. If there is no intention to preform a mastoidectomy, like in tympanoplasty type I, an endaural incision is generally chosen. A postauricular approach should be preferred, and mastoidectomy is expected in order to expose the mastoid plain widely. A tympanomeatal flap is formed detaching only the posterior part of the meatal skin. An underlay or medial graft technique is used routinely, but techniques may differ based on experience. This prevents anulus cholesteatomas, lateralization of the graft, and blunting of the anterior tympanomeatal angle [5]. The undersurface is scarified to provoke a slight bleeding to improve the attachment to the graft. It normally sticks to the undersurface without support. If necessary, small pieces of gelfoam are used taking care to leave arreation to the Eustachian tube to improve postoperative aeration. Temporalis fascia or perichondrium is generally used as graft material. Larger defects are additionally covered with meatal skin or split thickness skin grafts to speed up epithelization. If fascia is not available, perichondrium from the tragus or the posterior side of the concha is a good, stable alternative. The fascia is placed under the handle of the malleus whenever possible. If the handle is close to the promontory, cutting off the tensor tympani tendon allows more space. The mucosa of the middle ear should not be removed to prevent adhesions [5]. The production of mucus by the goblet cells of the inflamed mucosa serves as a good protection against adhesions. Polyps have to be removed. In rare cases, a small piece if silicone is placed on the promontory avoiding contact with the graft. Cartilage is an excellent material if stiffness of the graft is needed, especially for total or subtotal perforations and for cases of extensive adhesive otitis, when depleted areation is expected in the middle ear. The use of cartilage is mostly performed by employing Heermann's palisade technique using stripes of cartilage placed aside of each. Its application in underlay technique is also possible [5].

Chronic suppurative otitis media frequently leads to a destruction of the ossicular chain, typically of the incus. For the reconstruction of the ossicular chain, a large variety of materials has been described. Among biological materials ossicles, bone cartilage and teeth have to be mentioned, among alloplastics there are metals, hydroxyapatites of different density, carbons, ceramics, polyethylene and dental cement. A complete evaluation is challenging since no author can evaluate and compare all proposed materials. The use of these

materials has either become routine application as the use of ossicles or they did not give stable satisfying long-term results. Therefore it seems reasonable to employ only few materials like titanium that have proven to give satisfactory results in animal experiments and clinical observations until sufficient support for better alternatives are established [4,5].

The following situations of ossicular chain defects can de distinguished, like (i) a simple perforation with an intact ossicular chain, or (ii) the incus is partially or completely missing. This is the most common situation requiring reconstruction. In the majority of cases, the long process of the incus is absent, allowing its reuse. Otherwise the head of the malleus is utilized. If the head of the stapes is sufficient, a piece of cartilage can be interposed. Alloplastic material, like partial ossicular replacement prosthesis (PORP) can also be used. (iii) If only the stapes is preserved, a stapes elevation technique is required. Besides the reuse of ossicles, stapes elevation by cartilage or a titanium allograft are further options. Allografts have to be covered by cartilage in order to prevent extrusion. (iv) In the rare situation of a preservation of the malleus or handle of malleus preserved and missing incus and stapes, suprastructure reconstruction is achieved by a titanium allograft (TORP, total ossicular replacement prosthesis) with cartilage preventing extrusion. (v) In a condition where all ossicles except stapes footplate are destroyed, total or subtotal perforation is generally present. Reconstruction in one stage is relatively unstable but should be tried. Using cartilage palisade tympanoplasty can result in a good stability of the drum and reinforcement for the titanium allograft. Surgery of the mastoid in draining ears is performed by most ear surgeons under the assumption that the inflammatory process has to be removed from the mastoid [2,4,5].

Reconstruction of the ossicular chain can be performed in one stage or two stages. Revision surgery may become necessary for insufficient hearing improvement. According to histological observations, the middle ear mucosa needs at least 6 month to recover, loosing the previous density of goblet and ciliated cells. Therefore, revisions for hearing improvement should not be accomplished earlier. In revision surgery, displaced grafts, anchylosis of reimplanted ossicles or partial adhesions between graft and the promontory can be observed. Reconstructing in a less inflamed environment improves the outcome. Reperforations are reported in the literature at a frequency of 5–15%. In these cases, reoperation should be considered half a year to one year after prior surgery. Depending on the situation cartilage techniques are more frequently used [5]. Split thickness cartilage prevents adhesions to the promontory and is expected to give more resistance to subsequent further inflammations. The surgical outcome does not differ in comparison to cases of unspecific infection if sufficient medical treatment is started immediately after diagnosis.

# Migraine

Peter J. Goadsby
Headache Group, Department of Neurology, University of California, San Francisco, CA, USA

M

## Synonyms

None in modern use

## Definition and Characteristics

Migraine is an inherited, highly disabling, episodic disturbance involving head pain with nausea and sensitivity to sensory input, such as to light, sound and head movement (Table 1).

*Triggers Believed to Precipitate Migraine Attacks*:

- Altered sleep patterns: becoming tired or oversleeping
- Skipping meals
- Over-exertion
- Weather change
- Stress or relaxation from stress
- Hormonal change, such as menstrual periods
- Excess afferent stimulation: bright lights, strong smells
- Chemicals: alcohol or nitrates

There are two common types, migraine with aura and migraine without aura. The aura consists of neurological symptoms, often a visual disturbance, such as zigzag flashing lights or visual loss, which occur for up to an

hour and is usually followed by the headache [1]. Migraine without aura is more common.

## Prevalence

Migraine has a 1-year prevalence of 12–15% in North America and Western Europe. Migraine occurs in some 6% of children, and becomes more common in females after puberty, reaching a peak at age 41 when three times more females than males have migraine [2].

## Genes

No genes have as yet been identified for the common forms of migraine. Studies in twins and clinical experience indicate migraine has a very important inherited component. Familial hemiplegic migraine, a rare form of autosomal dominant migraine, has three identified genes (see below), which have not been directly implicated in common forms of migraine [3].

## Molecular and Systemic Pathophysiology

The expression of migraine involves three distinct phases, the beginning of the attack, which for one quarter of patients involves the migraine aura, and for many more a premonitory phase even before the aura, the attack proper and a resolution or post-dromal phase. Patients have inter-attack changes in their brain physiology with the general principle that there is reduced habituation to sensory stimulation. During the attack there is activation, or the perception of activation, of the nociceptive trigeminal afferents and abnormal perception of light and sound as well as significant nausea. Each of these manifestations may result from abnormal activity of brainstem and diencephalic control pathways that normally modulate sensory traffic. This pan-sensory disturbance explains the very many symptoms that migraine patients identify in and around their attacks [4]. The most effective acute attack therapy, the triptans (see below), act to modulate pain traffic at serotonin receptors in the trigeminocervical complex, in the dorsal midbrain and in the thalamus.

## Diagnostic Principles

The diagnosis of migraine is made by a careful history and normal physical examination. The sub-types of the disorder can be classified and described, based on the well established diagnostic criteria of the International Headache Society [5]. The main criteria are listed in Table 1. An essential point is that migraine is identified by its behaviour and the symptom complex and thus not all symptoms are required in each attack. In particular only one quarter of patients have aura symptoms.

## Therapeutic Principles

Migraine treatment begins with a good explanation of the nature of the disorder and from this it follows that regulation of behaviour, such as regular meals, sleep, and exercise are all helpful. Migraine is a largely inherited tendency so it cannot be cured with current knowledge, although its very disabling manifestations can most often be controlled. In therapeutic terms, the options are preventive medicines that reduce the frequency and severity of the disorder and acute attack medicines [4]. Examples of preventive medicines are beta-blockers, serotonin antagonists and neuromodulators, while examples of acute treatments are analgesics, such as paracetamol (acetaminophen), aspirin, non-steroidal anti-inflammatory drugs and triptans. Triptans are relatively specific for migraine, also being used in ▶Cluster headache and act on the serotonin, 5-$HT_{1B/1D}$, receptors to terminate acute attacks.

# Migraine, Familial Hemiplegic

Karin Jurkat-Rott, Frank Lehmann-Horn
Department of Applied Physiology, Ulm University, Ulm, Germany

## Synonyms

There are four genetic types of familial hemiplegic migraine (FHM). No all-encompassing synonyms are in

use, however, the phenotypes include subphenotypes: FHM1 includes sporadic hemiplegic migraine with progressive cerebellar ataxia and FHM2 includes forms of basilar migraine. FHM3 has no additional synonyms.

## Definition and Characteristics

Individuals affected by autosomal dominant FHM present with characteristic unilateral migrainous headaches accompanied by nausea, phono- and photophobia. Episodes are typically precipitated by an aura with symptoms of both hyper- and underexcitability such as aphasia, dysarthria, vertigo, homonymous hemianopsia, cheiro-oral paresthesia, and some degree of mainly unilateral paresis. The aura may be prolonged and confusion and loss of consciousness may occur. In the interval, some families additionally present with epilepsy, retinal degeneration, hypakusis, persistent cerebellar dysfunction with Purkinje cell atrophy.

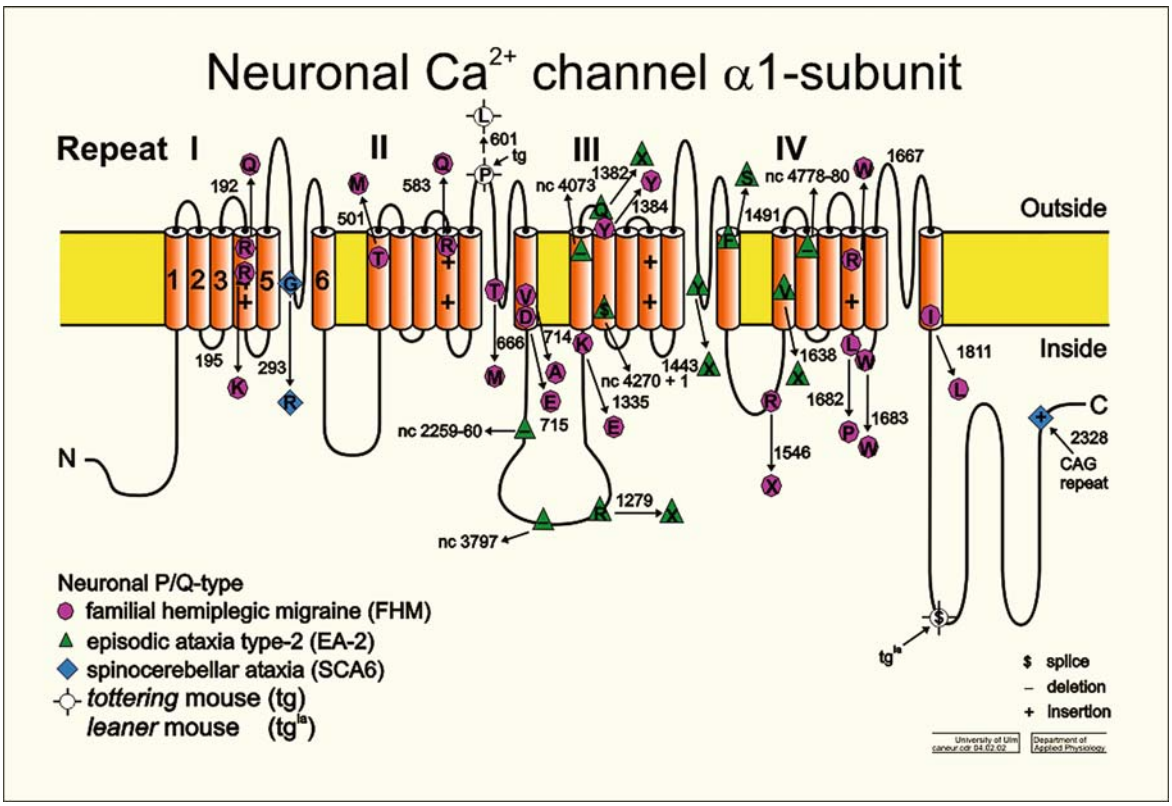
## Prevalence

FHM prevalence has been estimated in Denmark. It is approximately 0.005% with a male to female sex ratio of 1:3. Of the FHM, up to 50% of cases are FHM1 and 20–30% FHM2 [1]. FHM3 is rare.

## Genes

FHM1 is caused by mutations in the CACNA1A on chromosome 19p13 encoding the neuronal voltage-gated P/Q-type calcium channel alpha1 subunit, Cav2.1 [2]. Until now, 18 missense mutations have been described, that primarily lead to gain of Cav2.1 function. Episodic ataxia type 2 and spinocerebellar ataxia type 6 are allelic and caused mainly by loss-of-function nonsense and repeat expansion mutations respectively (Fig. 1).

FHM2 is caused by mutations in the ATP1A2 gene on chromosome 1q21–23 encoding the alpha2 subunit of the astrocytic $Na^+/K^+$-ATPase [3]. As yet, 23 missense mutations have been detected that all lead to loss of ATPase function. FHM3 is caused by mutations in the SCN1A gene on chromosome 2q24 encoding the neuronal voltage-gated sodium channel alpha1 subunit, Nav1.1 [4]. Just one Nav1.1 mutation is known which increases function by decreasing the refractory period.



**Migraine, Familial Hemiplegic. Figure 1** Cav2.1 channel. The model shows the Cav2.1 neuronal P/Q channel alpha1 subunit. It consists of four highly homologous domains (repeats I–IV) containing six transmembrane segments each (S1–S6). The S5–S6 loops and the transmembrane segments S6 form the ion selective pore, and the S4 segments contain positively charged residues conferring voltage dependence to the protein. Mutations associated with channelopathies are indicated by conventional one-letter abbreviations for the replaced amino acids.

## Molecular and Systemic Pathophysiology

The current pathogenesis models of migraine suggests cortical spreading depression (CSD) which consists of an initial brief spike of increased neuronal activity followed by long-lasting suppression of excitability spreading across the cortex at 1–3 mm/s. The CSD wave is associated with long-lasting depolarization and changes in ion concentration gradients (elevation of extracellular $K^+$ and intracellular $Na^+$). Its progress correlates to the succession of symptoms during the aura initiating the migraine attacks. Functional magnetic resonance imaging and magnetoencephalography show similarities between migraine aura in humans and experimentally induced CSD in rodents. CSD then activates the trigeminovascular system leading to trigeminally mediated migraine headache. Gain-of-function mutations in Cav2.1 (FHM1) may increase synaptic glutamate transmitter release initiating CSD. This agrees nicely with the naturally occurring mice strains tottering and leaner (Fig. 1) which both show a loss of Cav2.1 function and elevated thresholds for CSD. Similarly, in FMH3, gain-of-function Nav1.1 mutations may facilitate neuronal firing which increases glutamate in the synaptic cleft reducing threshold and increasing velocity of CSD. Finally, loss-function mutations of the astrocytic $Na^+/K^+$-ATPase (FHM2) may increase extracellular $K^+$ enhancing CSD depolarization.

## Diagnostic Principles

The diagnosis of FHM relies upon revised clinical criteria of the international headache society [5]. HM are recurrent, fully reversible attacks of migraine with aura whereby the aura contains motor weakness and either visual, sensory, or speech disturbance. At least one aura symptoms develops gradually or in succession (CSD), lasts less than 24 h and, ideally, is associated with headache not attributable to another disorder. FHM additionally requires that at least one other close relative is affected. In 40% of FHM1 patients, interictal cerebellar signs such as progressive ataxia with or without nystagmus may be found [2]. In contrast, FHM2 patients may suffer more frequently from epileptic seizures than other FHM [1, 3]. The phenotype for FHM3 is not yet distinct due to the low number of cases.

## Therapeutic Principles

Many drugs are used for preventing migraine attacks. These include beta-blockers such as metoprolol or propranolol which depress thalamocortical relay neurons via beta1-adrenoceptors and reduce CSD migration velocity by inhibiting cAMP-dependent glutamate release. Additionally, anti-epileptic agents such as valproate or topiramate are employed. Valproate enhances inhibitory GABAergic transmission and reduces the concentrations of excitatory amino acids. Topiramate decreases firing rate of the trigeminal neurons by blocking $Na^+$, $Ca^{2+}$, and glutamate receptor channels, and by enhancing GABAergic activity. Lastly, tricyclic anti-depressants such as amitryptiline, and $Ca^{2+}$ channel blockers like flunarizine which decrease neutotransmitter release are in use. All these drugs require administration for at least 6–8 weeks to effectively reduce the occurrence of migraine attacks.

## Milk Alkali Syndrome

John Logan, Bernadette McGuinness
Belfast City Hospital, Belfast, UK

### Synonyms

Burnett's syndrome

### Definition and Characteristics

A sub-acute or chronic condition with variable severity of hypercalcemia, alkalosis and renal failure, caused by the excessive ingestion of absorbable calcium and alkali [1]. Symptoms include lethargy, headache, vomiting and leg pain.

### Prevalence

Rare but possibly under-diagnosed. Was commoner when milk and alkalis were the only treatments for gastric and duodenal ulceration and indigestion. Prevalence may be increasing because of increased use of calcium carbonate in the prophylaxis and treatment of osteoporosis [2].

### Genes

No underlying genetic abnormality has been recognised.

### Molecular and Systemic Pathophysiology

There is some uncertainty about the exact pathophysiology of the milk alkali syndrome. While a high intake of calcium and alkali (at least 10 g of calcium carbonate a day) is needed for its development, only some patients on a standard regime will develop the syndrome. This is not necessarily due to their absorbing a greater percentage of the dose [3]. Those who have had it once may develop it again. Whether those unaffected would develop it with larger doses is unknown. The central abnormality is the inability of the kidneys to excrete the ingested calcium load. Pre-existing renal disease and the use of thiazide diuretics increase susceptibility.

Single doses of calcium carbonate of 8 g or above can produce transient hypercalcemia [3]. Any rise in calcium will stimulate the extracellular calcium-sensing protein in the parathyroid glands, renal tubules and renal collecting ducts [4]. The response of this protein, a member of the G protein-coupled receptor family, is enhanced by alkalosis. Activation of the sensor in the parathyroids and renal tubules causes a reduction in parathormone level and a reduction in renal tubular calcium reabsorption. The former then enhances the latter. These changes will tend to restore the plasma calcium level to normal [4].

The ability of even normal kidneys to excrete calcium is not unlimited, however, and that ability is reduced in the milk alkali syndrome. Activation of the calcium sensor in the collecting ducts blocks the effect of anti-diuretic hormone, while the reduced tubular calcium reabsorption is accompanied by reduced tubular sodium reabsorption [4]. The resulting polyuria reduces vascular volume and renal perfusion. As glomerular filtration rate falls, the kidneys' ability to excrete calcium falls. Vomiting often accompanies the milk alkali syndrome and this reduces vascular volume further. Vomiting and the ingestion of alkali both contribute to the development of alkalosis and alkalosis tends to increase tubular reabsorption of calcium.

The net effect in a susceptible individual with a sufficiently high intake of calcium and alkali is the development of hypercalcemia, alkalosis and renal impairment. The latter may be completely reversible particularly if the illness is of short duration but nephrocalcinosis and renal failure can occur.

### Diagnostic Principles

Specifically ask about intake of calcium and alkali, both prescribed and over-the-counter. Establish the presence of hypercalcemia, alkalosis and renal impairment. Exclude other conditions.

### Therapeutic Principles

First and foremost, stop the intake of calcium and alkali. Ensure adequate hydration and urinary output. A loop diuretic may help but steroids and bisphosphonates probably do not. Once the intake of calcium and alkali ceases and rehydration starts, nothing is left to drive the level of calcium up and transient hypocalcemia is sometimes seen.

It is essential that excess calcium is avoided in the future. The usual maximum recommended dose of calcium carbonate is 3.5 g per day; for those who have had the milk alkali syndrome it might be safest to take none.

# Miller-Dieker Lissencephaly Syndrome

►Miller-Dieker Syndrome

# Miller-Dieker Syndrome

Maria Isabel Melaragno[1], Marcial Francis Galera[2]
[1]Universidade Federal de São Paulo, São Paulo, Brazil
[2]Faculdade de Medicina, Universidade de Cuiabá, Cuiabá, Brazil

## Synonyms

MDS; Miller-Dieker lissencephaly syndrome; Microdeletion 17p13

## Definition and Characteristics

Miller-Dieker syndrome (MDS – MIM 2477200) is a rare condition manifested by classical lissencephaly and dysmorphic features.

Lissencephaly is characterized by a smooth cerebral surface and encompasses varying degrees of agyria or pachygyria, a thickened cortex with four rather than six layers, agenesis/hypoplasia of the corpus callosum, generalized neuronal heterotopias and enlarged ventricles. Patients with lissencephaly usually present microcephaly, severe mental retardation and epilepsy, spasticity, and reduced life span. Type I, or classical lissencephaly, when observed as an isolated finding, is referred to as isolated lissencephaly sequence (ILS – MIM 607432).

In MDS patients, several dysmorphic facial features have been observed: prominent forehead, bitemporal hollowing, midface hypoplasia, depressed nasal bridge, anteverted nares, prominent upper lip with thin vermillion border, and micrognathia. Other abnormalities can also occur, such as congenital heart defects, renal agenesis, genital anomalies, sacral dimples, and growth deficiency.

## Prevalence

MDS is estimated to be present in less than one in 100,000 births.

## Genes

MDS is a microdeletion syndrome resulting from the deletion of several, unrelated genes that are physically close to each other at band q13.3 in the long arm of chromosome 17 (17p13.3). Almost all patients with MDS and 10–40% of patients with ILS have deletions involving 17p13.3. In MDS patients, the deletions are generally larger and more distal than those of patients with ILS. By mapping the extent of the deletions and narrowing down the critical region for the lissencephaly phenotype, a candidate gene, known as LIS1 or PAFAH1B1, was isolated. Patients with ILS and 17p13.3 deletions show no evident differences in clinical features compared to those with point mutations in the LIS1 gene. It appears that deletion of or mutation in the LIS1 gene are responsible for the lissencephaly, while facial dysmorphism and other anomalies found in MDS are the consequence of the deletion of additional genes distal to LIS1, including genes 14-3-3-epsilon, CRK, PRP8, RILP, SREC, PITPNα, SKIP, and MYO1C.

## Molecular and Systemic Pathophysiology

Lissencephaly results from defects in neuronal migration events that normally occur at 9–13 weeks of embryonic development. The LIS1 gene, responsible for lissencephaly, encodes the subunit of the platelet-activating factor acetylhydrolase, brain isoform, which inactivates the platelet-activating factor (PAF), a neuroregulatory molecule. Haploinsufficiency of the LIS1 gene and a reduction in LIS1 protein, named PAFAH1B1, seem to impair the neuroblast migration process, diminish cell proliferation and increase cell death rates. The PAFAH1B1 protein is required for optimal neuronal migration by two proposed mechanisms: as a microtubule-associated protein and as one subunit of the enzyme. Deletion of LIS1 alone appears not to be sufficient to cause the severe lissencephaly phenotype seen only in MDS. Deletion of genes 14-3-3ε and/or CRK in addition to LIS1 may contribute to the most severe form of classical lissencephaly.

## Diagnostic Principles

MDS may be suspected in a newborn or infant with characteristic dysmorphic facial features and hypotonia. Neuro-imaging studies are recommended, since CT scan and MRI can reveal a smooth brain surface with complete agyria, and mixed areas with agyria

and pachygyria. The lissencephaly seen in MDS is usually more severe than that seen in ILS, and in ILS dysmorphic facial features or anomalies are mild to absent. Children with MDS have severe neurological impairment, characterized by mental retardation, hypotonia in early life and spasticity when the patients grow older. These children are unable to learn, to sit or walk. Their development landmarks remain at the 3–6 months' level. Seizures can occur at birth and during the first 6 months of life, often including infantile spasms. Severe feeding and swallowing problems are frequent, and can be complicated by pneumonia. Since the 17p13.3 deletions are usually submicroscopic, the most sensitive and efficient method of cytogenetic diagnosis is fluorescent in situ hybridization (FISH) analysis, using a specific probe for the Miller-Dieker region and a control probe for chromosome 17 identification. Since several familial cases have been described, FISH studies are recommended in both parents of probands, in order to exclude a balanced translocation or inversion, which would represent a substantial risk of producing unbalanced offspring.

## Therapeutic Principles

Clinical care of individuals with MDS is supportive and symptomatic. Feeding and swallowing problems can result in complications such as malnutrition and pneumonia due to aspiration. Nasogastric tubes and gastrostomies can be used in these cases. Seizure control has to be performed. Medical treatments are available for complications affecting kidneys, heart and other organs. The neurological prognosis varies, depending on the degree of brain malformation. Many patients with MDS die before the age of 2, due to intractable seizures and respiratory problems (aspiration and pneumonia). However, with improved clinical care and a surgical approach (feeding tubes), children with MDS can achieve a longer survival.

# Milroy Disease

Alexander K. C. Leung, Hardally R. Hegde
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Nonne-Milroy lymphedema; Hereditary lymphedema I; Primary congenital lymphedema

## Definition and Characteristics

Milroy disease is characterized by congenital lymphedema of the lower limbs having onset at or near birth and has an autosomal dominant mode of inheritance (Fig. 1) [1].

Anatomically, the disease is characterized by hypoplasia or aplasia of the lymphatics [2]. The edema is confined to the legs and feet. Over time, the edema becomes nonpitting. The overlying skin becomes fibrotic with fissures and the underlying tissue fibrotic. Prominent wide caliber veins in the legs and feet are characteristic and help to distinguish Milroy disease from other causes of congenital lymphedema [3]. Other associated features include intestinal loss of protein, hypoproteinemia, pleural effusion, chylous ascites, papillomatosis, and upslanting toenails [3]. In males, hydroceles and scrotal edema may be present [3]. Patients with Milroy disease have poor wound healing and are susceptible to infection (cellulitis, lymphangitis) in the affected limb. Lymphangiosarcomas and squamous epidermoid carcinomas are potential complications in adulthood.

## Prevalence

The incidence is 1:60,000 live births [4]. The female to male ratio is ~1.5:1 [2].

**Milroy Disease. Figure 1** A male neonate with Milroy disease. Note the congenital edema of both feet.

M

### Genes

Mutations in FLT4, coding for vascular endothelial growth factor receptor-3 (VEGFR-3), have been identified as a cause of Milroy disease [3]. The gene locus has been mapped to 5q34–35.3 [4].

### Molecular and Systemic Pathophysiology

Vascular endothelial growth factor C (VEGF-C) and D (VEGF-D) have been found to be important in the formation of the lymphatic system through their receptor VEGFR-3. Lymphedema results from abnormal accumulation of protein-rich fluid (lymph) in the interstitial space that cannot return to the vascular compartment as a result of lymphatic hypoplasia/aplasia. The accumulation of lymphatic fluid in the interstitial space leads to proliferation of fibroblasts, giving rise to firm, non-pitting edema.

### Diagnostic Principles

Milroy disease should be differentiated from other types of primary lymphedema such as lymphedema praecox (Meige disease) which typically occurs during adolescence or in association with pregnancy and lymphedema tarda which usually develops after age 35 years. Differential diagnoses of congenital lymphedema include Turner syndrome, Noonan syndrome, yellow nail syndrome, microcephaly-lymphedema syndrome, lymphedema-microcephaly-chorioretinopathy syndrome, lymphedema-distichiasis syndrome, Aagenaes syndrome (cholestasis-lymphedema syndrome), and Hennekan lymphangiectasia-lymphedema syndrome [1]. Radionuclide lymphoscintigraphy has proved extremely useful for differentiating lymphedema from other causes of swelling in the lower limb and for depicting the specific lymphatic abnormality [4].

### Therapeutic Principles

Conservative treatment includes optimal skin care, antibiotic therapy for skin infection, elevation of the limbs whenever possible, exercise, massage, physical therapy, compression with hosiery, and intermittent pneumatic compression. Surgery should be considered for selected patients with disfiguring deformities who do not respond to the conservative treatment. Surgery can take the form of removing the excess skin and subcutaneous tissue in the lymphedematous limb or microsurgery to create lymphaticovenous anastomosis to augment the return of lymph to the circulatory system [4].

## Minicore Myopathy

►Central Core and Multi-Minicore Disease

## Minimal Change Nephrotic Syndrome

Hannu Jalanko
Hospital for Children and Adolescents, University of Helsinki, Helsinki, Finland

### Synonyms

Steroid sensitive nephrotic syndrome; MCNS

### Definition and Characteristics

A common pediatric kidney disease characterized by repeated episodes of heavy proteinuria, hypoalbuminemia, and edema.

### Prevalence

Approximately 2–16 per 100,000 children. Occurs also rarely in adults.

### Molecular and Systemic Pathophysiology

Episodic leakage of plasma proteins in the urine is caused by defective function of the glomerular filtration barrier located in the capillary wall of the kidney glomerulus. This filter is composed of three layers: the fenestrated endothelium, the glomerular basement membrane, and the epithelial layer consisting of epithelial cell (podocyte) foot processes and the slit diaphragms connecting the foot processes. Disorganization of the podocyte foot processes as well as distortion of the slit diaphragm is typically seen in electron microscopy during a nephrotic episode. These findings, however, are not specific for MCNS. The molecular basis of the pathophysiology of MCNS is not

known. T-lymphocyte mediated immunological attack against the glomerular filter has been suggested but not verified [1].

### Diagnostic Principles

The diagnosis in pediatric patients is mostly based on typical clinical findings: heavy proteinuria (>4 g/L), hypoalbuminemia (often <20 g/L), oliguria, edema, and weight gain, normal or only slightly elevated serum creatinine and normal or slightly elevated urinary erythrocyte count [2]. Renal biopsy and histological examination are performed, if the clinical findings or the patient's age (adolescents and adults) is not typical for MCNS. Moreover, kidney biopsy is performed to those who do not respond to therapy. Light microscopy shows normal kidney histology or mild expansion of glomerular mesangium.

### Therapeutic Principles

The nephrotic episodes respond well to corticosteroid therapy [3]. Relapses, however, occur in 80% of the children. Other immunosuppressive drugs (e.g., cyclophosphamide, cyclosporine A) are used in patients, who show frequent or steroid-resistant relapses or are steroid dependent.

## Mitochondrial Cytopathies

Maria Judit Molnar
Clinical and Research Center of Molecular Neurology, Semmeiwers University, Budapest, Hungary

### Definition and Characteristics

Mitochondrial cytopathies represent a heterogeneous group of multisystem disorders which often affects skeletal muscle and nervous system and is mostly due to dysfunction of the mitochondrial respiratory chain [1,2]. A variety of organs may be affected by mitochondrial dysfunction (Table 1). The disorders are caused either by mutations of the maternally inherited mitochondrial genome (Table 2), or by nuclear DNA (nDNA) mutations (Table 3) [2]. Today ~200 different disease-causing mutations of mitochondrial DNA (mtDNA) are known and due to the increased knowledge about nuclear genetics during the last few years, more and more nuclear mutations are being described [3]. Owing to the unequal distribution of mitochondria in the different tissues and the co-existence of mutant and wild type mtDNA in these organelles, these disorders may present with a huge variety of symptoms, even if the same mutation is involved.

### Prevalence

Combining the results of the epidemiological data on childhood and adult mitochondrial disease suggests that the minimum prevalence is at least 1 in 5,000 and could be much higher. The first population based study of all mitochondrial disorders estimated a mtDNA mutation prevalence of 12.48/100,000, and a disease prevalence of 6.57/100,000 [4].

### Genes

On the inner mitochondrial membrane about 80 different polypeptides form the respiratory chain organized in four complexes (complex I-IV). The vast majority of these polypeptides are synthesized in the cytosol from nuclear gene transcripts, but 13 subunits are encoded by the mtDNA [2], by a small 16.5 kb molecule of double-stranded DNA. Two ribosomal RNA genes (12S and 16S rRNA), and 22 transfer RNA genes are interspaced between the protein-encoding genes of the mtDNA. These provide the necessary RNA components for intramitochondrial protein synthesis. $O_H$ and $O_L$ are the origins of heavy- and light-strand mtDNA replication. The D-loop (noncoding region) is involved in the regulation of transcription and replication of the molecule, and it is the only region not directly involved in the synthesis of respiratory chain polypeptides. NDNA encodes ~1,000 mitochondrial proteins, among them only 67 are coding respiratory chain subunits, others are important for proper assembly and functioning of the respiratory chain, including components of the mitochondrial protein import machinery, enzymes involved in phospholipids synthesis and enzymes necessary for the replication integrity of mtDNA itself, and mitochondrial motility, fusion and fission [1]. The nDNA-encoded proteins are synthesized in the cytoplasm and they are imported into the mitochondrion via specific transport systems. The known mitochondrial disorders due to nDNA mutations are listed in Table 3.

**Mitochondrial Cytopathies. Table 1** Clinical symptoms associated with mitochondrial dysfunction

| Organ system | Possible symptom |
|---|---|
| Central nervous system | Epileptic seizures, myoclonus, stroke, cluster headache, migraine, spastic paraparesis, dystonia, tremor, chorea, myelopathy, psychomotor delay, mental retardation, affective disorders |
| Peripheral nervous system | Axonal neuropathy, demyelinating neuropathy |
| Skeletal muscle | Myopathy, fatigue, muscle weakness, exercise intolerance, myalgia, rhabdomyolysis, myoglobinuria |
| Cardiac muscle | Conduction abnormalities, Wolff-Parkinson-White syndrome, cardiomyopathy, ischemic damage, sick sinus syndrome |
| Eye | Ophthalmoplegia, ptosis, optic atrophy, pigmentary retinopathy, choroideremia like fundus, cataract, macular pattern, retinal dystrophy |
| Ear | Senso-neural hearing loss, ototoxicity susceptibility |
| Liver | Hepatopathia, chronic renal failure |
| Kidney | Renal tubular dysfunction, tubulointestinal nephropathy, Toni-Fanconi-Debre syndrome, glomerulopathy, Barth syndrome, aminoaciduria |
| Pancreas | Diabetes mellitus, exocrine pancreatic dysfunction |
| Endocrine | Short stature, recurrent hypoglycemia, hypoparathyroidism, hypothyroidism, ACTH deficiency, cryptorchidism |
| Hematopoetic system | Sideroblastic anemia, pancytopenia, megaloblastic anemia, thrombopenia, myelodysplastic syndrome |
| GIT | Intestinal pseudoobstruction, episodic nausea, vomiting, dysphagia, duodenal atresia |
| Dermatological signs | Lipomatosis, fatty infiltration of skin, vitiligo, mottled pigmentation, palmoplantar keratoderma, dry brittle hair |

## Molecular and Systemic Pathophysiology

Mitochondrial function depends on the coordinated expression of genes encoded in the nucleus and mitochondrion. This is evident from the makeup of several mitochondrial complexes, including the translational machinery that involves nuclear-encoded polypeptides and mitochondrially encoded rRNAs and tRNAs as well as large respiratory complexes that have subunits encoded in each of the genomes [1,2]. Besides their fundamental role in the cellular energy metabolism, mitochondria seem to be involved in a number of other cellular processes. Moreover mitochondrial defects seem to contribute to the pathogenesis of many degenerative diseases, to aging and cancer. It is important to know: the most oxidative tissues (brain, retina, muscle and kidney) are the most vulnerable to OXPHOS defects. Increased oxidative stress (i.e. fever, hypoxia) can trigger or aggravate tissue damage and may put OXPHOS impairment above a threshold level. In postmitotic cells there is a progressive, cumulative effect of the deleterious consequences of mitochondrial defects. Cross-talk between the nuclear and mitochondrial genomes is crucial for mitochondrial biogenesis and function, and the two genomes are probably subjected to co-evolutionary processes. The defect of intergenomic signaling can affect mtDNA quantitatively (mtDNA depletion) and qualitatively (multiple mtDNA deletion). Disturbances of the nucleotide pool available for mtDNA replication, as well as abnormalities in either the mitochondrial helicase or DNA polymerase, are likely to affect the rate or processivity of DNA replication, which could ultimately lead to the exaggerated production of rearranged mtDNA molecules. Proper balance of the mitochondrial deoxynucleotide pools is also essential in the maintenance of mtDNA copy number. This idea is supported by the discovery that defects in mitochondrial deoxyguanosine kinase, thymidine kinase and, possibly, the mitochondrial deoxynucleotide carrier lead to depletion of mtDNA. These enzymes are involved in the salvage pathways of mitochondrial deoxynucleotides or in the control of the mitochondrial dNTP pool, which is the major source of mtDNA precursors in stable tissues such as liver, brain, and muscle. There are more mutations in nDNA causing isolated respiratory chain complex deficiencies (Table 3). Some of them seem to be tissue specific disorders as SURF1 brain specific in Leigh syndrome, SCO2 and COX15 in infantile cardiomyopathy and brain disease, COX 10 in kidney disease and SCO1 in liver disorders. Other mitochondrial defect can alter the mitochondrial membrane structure (Barth syndrome), mitochondrial protein importation (deafness and dystonia syndrome – DDP protein), mitochondrial motility

(optic neuropathy – OPA1) and neurodegenerative disorders (Friedreich ataxia, spastic paraparesis).

## Diagnostic Principles

In some individuals the clinical picture is characteristic of a specific mitochondrial disorder (e.g. SCO2) and the diagnosis can be confirmed by molecular genetic testing of DNA extracted from a blood sample. In many individuals this is not the case and a more structured approach is needed, including family history, blood and/or CSF lactate concentration, neuroimaging, cardiac evolution and muscle biopsy for histological, histochemical and biochemical evidence of mitochondrial disease and DNA mutational analysis [5]. Molecular genetic testing includes Southern blot analysis using a range of enzymes and probes, point mutation analysis and sequencing of the entire mitochondrial genome or the culprit nuclear gene.

## Therapeutic Principles

*Gene Therapy*:

1. Gene shifting (decreasing the ratio of mutant to wild type mt genomes)
2. Converting mutated mtDNA genes into normal nDNA genes (allotopic expression)
3. Importing cognate genes from other species (xenotopic expression)
4. Correcting mtDNA mutations by importing specific restriction endonucleases
5. Selecting for respiratory function
6. Inducing muscle regeneration

*Pharmacological Therapy*: Dichloracetate to reduce serum and tissue lactate level.
*Dietary Therapy*: No fasting. Ketogenic diet, no glutamate, fat instead of carbohydrates.
*Other Treatments*: Surgical therapy of the ptosis.
Supplementation therapy with coenzyme Q10 and carnitine.
Free radical scavengers, idebenone (vitamin C, K).

# Mitochondrial Disorders

Danae Liolitsa, Charungthai Dejthevaporn, Michael G. Hanna
Centre for Neuromuscular Disease and Department of Molecular Neuroscience, Institute of Neurology, University College London, London, UK

## Synonyms

Mitochondrial cytopathies; Mitochondrial oxidative phosphorylation (OXPHOS) disorders; KSS; Kearns-Sayre syndrome; Leigh's syndrome; Subacute necrotizing encephalomyopathy; LHON; Leber Hereditary optic neuropathy; MELAS; Mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes; MERRF; Myoclonus epilepsy with ragged-red fibers; MNGIE; Myogastrointestinal encephalomyopathy; NARP; Neuropathy, ataxia and retinitis pigmentosa; PEO; Progressive external ophthalmoplegia; Pearson syndrome

## Definition and Characteristics

A heterogeneous group of disorders characterized by defects in mitochondrial respiratory chain function due to mutations in the genes of the mitochondrial and/or nuclear genomes. The spectrum of clinical phenotypes is quite broad and there is evidence for a role of mitochondrial dysfunction in common diseases such as diabetes, hypertension, neurodegenerative diseases and cancer.

## Prevalence

Estimates from British epidemiological studies have shown that approximately one in 3,500 individuals either have an mtDNA disease or are at risk of developing it [1]. The prevalence may be even higher if the more common diseases are included.

## Genes

*MtDNA genes and inheritance*: MtDNA molecules are present in multiple copies and pathogenic mutations usually affect only a proportion of mtDNAs (heteroplasmy). A minimum critical percentage of mutated mtDNAs have to be present in order to impair oxidative phosphorylation (threshold effect). Additionally, heteroplasmy has been considered as an essential prerequisite for an mtDNA mutation to be considered pathogenic. More recently however, homoplasmic mutations have also been found to cause disease. Defects in mtDNA are classified into a) mutations that affect protein synthesis such as rearrangements and point mutations in tRNAs and rRNAs genes and b)

**Mitochondrial Disorders. Table 1**

| Structural genes | | Import, processing and assembly genes | |
|---|---|---|---|
| Complex I genes | | SURF1 | Leigh syndrome |
| NDUFS1 | Leigh syndrome | SCO2 | Cardioencephalopathy |
| NDUFS2 | Hypertrophic cardiomyopathy | SCO1 | Hepatic failure and encephalopathy |
| NDUFS3 | Leigh syndrome | COX10 | Leigh and Toni-Fanconi syndrome |
| NDUFS4 | Leigh-like syndrome | COX15 | Leigh syndrome |
| NDUFS6 | Leigh syndrome | BCS1L | Tubulopathy, encephalopathy and liver failure |
| NDUFS7 | Leigh syndrome | TIMM8A | X-linked deafness dystonia |
| NDUFS8 | Leigh syndrome | SPG7 | Hereditary spastic paraplegia |
| NDUFV1 | Leukodystrophy and epilepsy | HSP60 | Hereditary spastic paraplegia |
| NDUFV2 | Cardiomyopathy and encephalopathy | **Intergenomic communication genes** | |
| Complex II genes | | ANT1 | AD-PEO with mtDNA deletions |
| SDHA | Leigh syndrome | TP | MNGIE |
| SDHB | Phaeochromocytoma/paraganglioma | TK2 | Hepatoencephalopathy |
| SDHC | Paraganglioma | DGUOK | Mitochondrial depletion syndrome |
| SDHD | Paraganglioma | **MtDNA replication genes** | |
| Complex III gene | | LRPPRC | Leigh syndrome |
| UQCRB | Hypoglycaemia and lactic acidosis | Twinkle | AD-PEO with mtDNA deletions |
| | | POLG | AD-PEO with mtDNA deletions |

**Mitochondrial Disorders. Table 2**

| Disease | Onset | Characteristics |
|---|---|---|
| KSS: Kearns-Sayre syndrome | Before age 20 | Blindness, eye muscle paralysis (ophthalmoplegia), short stature, cardiac abnormalities, ataxia, psychomotor retardation and coma |
| Leigh's syndrome: Subacute necrotizing encephalomyopathy | Infancy; progression can be fast or slow | Epilepsy, movement disorder, psychomotor retardation myopathy, vomiting, dysphagia, cardiomyopathy |
| LHON: Leber Hereditary optic neuropathy | Before age 20 | Subacute visual failure particularly in males, dystonia |
| MELAS: Mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes. | Before age 20 | Short stature, migraine, seizures, stroke-like episodes, dementia, sensorineural deafness, muscle weakness, exercise intolerance, diabetes mellitus, intracerebral calcification, cerebral atrophy |
| MERRF: Myoclonus epilepsy with ragged-red fibers | Usually before adolescence; variable progression | Myoclonus epilepsy, ataxia, dementia and muscle weakness and wasting, deafness, retinal pigmentary degeneration |
| MNGIE: Myogastrointestinal encephalomyopathy | Before age 20 | Ophthalmoplegia, muscle weakness, gastrointestinal disorders, loss of coordination and brain abnormalities |
| NARP: Neuropathy, ataxia and retinitis pigmentosa | Infancy or childhood | Impaired vision, ataxia, psychomotor retardation. This syndrome may represent a less severe form of maternally inherited Leigh's syndrome |
| PEO: Progressive external ophthalmoplegia | Usually in adolescence or early adulthood; slow progression | Ophthalmoplegia, drooping eyelids (ptosis), muscle weakness, exercise intolerance, intracerebral calcification, white matter abnormalities on MRI |
| Pearson syndrome. | Childhood | Severe anemia and pancreas malfunction; children who survive the disease may develop KSS as adolescents |

mutations in protein coding genes which may be multisystemic or tissue specific. Since the first discovery that mtDNA deletions may cause CPEO [2] more than 100 mtDNA mutations have been reported [3]. The standard model of mtDNA inheritance is through the maternal lineage. Single large-scale deletions are spontaneous events found in sporadic patients although it is increasingly recognized that a high percentage of point mutations also appears *de novo*.

*Nuclear genes and inheritance*: Over 30 nuclear genes known to cause respiratory chain disorders have been identified and it is expected that an even greater number is yet to be discovered (reviewed in [4]). Table 1 summarizes the genes bearing mutations linked to OXPHOS disease, classified according to the functional role of the proteins encoded. Most of the nuclear gene defects cause autosomal recessive diseases, but autosomal dominant and X-linked disorders can also occur [5].

## Molecular and Systemic Pathophysiology

There are more than 40 different types of diseases that are attributed to defects in respiratory chain function. The "classic" neurological syndromes and their clinical characteristics are summarized in Table 2.

## Diagnostic Principles

Mitochondrial disease is diagnosed by a variety of clinical and laboratory investigations:

Lactic acidosis, abnormalities on MRI, abnormal muscle biopsy associated with ragged red fibers or cytochrome c oxidase-deficient fibers and demonstration of biochemical defects in enzyme components of the respiratory chain on muscle homogenate. In addition, genetic diagnosis may be made based on mutational screening of the mtDNA sequence on muscle tissue-extracted DNA of the affected individual. Typically diagnostic centers test for a limited number of "common" mtDNA mutations that give rise to classic mtDNA syndromes. The yield of a positive result for these mutations ranges from 10 to 40% [6].

## Therapeutic Principles

Unfortunately there remains no curative treatment. Non-pharmacological interventions include aerobic exercise and pacemaker insertion. Pharmacologic treatments made by coenzyme Q and other quinones, vitamins, corticosteroids or administration of carnitine, succinate, creatinine, chloramphenicol and dichloroacetate. Finally, gene therapy is currently under investigation and includes genetic and protein complementation techniques, sequence-specific inhibition, induced muscle regeneration, preimplantation selection and forced paternal inheritance (reviewed in [7]).

# Mitochondrial Encephalomyopathy

Josef Finsterer
KA Rudolfstiftung, Vienna, Austria

M

## Synonyms

Mitochondrial cytopathies; Mitochondrial disorders; Encephalomyopathies; Respiratory chain disorders; Metabolic myopathies; Primary mitochondriopathies

## Definition and Characteristics

In a narrow sense mitochondrial disorders are due to defects of the mitochondrial respiratory chain (RC), resulting in impaired oxidative phosphorylation (OXPHOS) and thus reduced energy (ATP) output [1]. RC defects are due to mutations in mitochondrial or nuclear genes, encoding for: subunits of RC complexes; proteins required for RC assembly and folding; proteins of intergenomic signaling and replication and integrity of nDNA and mtDNA; proteins involved in mitochondrial motility, fission, and fusion; components of the mitochondrial import/export machinery; and enzymes involved in phospholipid synthesis (Table 1) [1–3].

Mitochondrial disorders are clinically extremely heterogeneous, ranging from single-organ affection to severe multi-organ disease [2,4]. Organs/tissues most frequently affected are the skeletal muscle (ptosis, ophthalmoparesis, limb weakness, myoglobinuria, exercise intolerance), peripheral nerves (polyneuropathy), CNS (stroke, seizure, dementia, migraine, movement disorder, ataxia, basal ganglia lesions, myelopathy, aseptic pleocytosis), endocrinological system (hypophysial insufficiency, thyroid dysfunction, hypoparathyroidism, diabetes, exocrine

pancreas insufficiency, hypocorticism, hypogonadism, infertility, osteoporosis, hyperhidrosis), heart (cardiomyopathy, impulse generation or propagation disturbances), ears (hypoacusis, tinnitus), eyes (cataract, glaucoma, retinopathy, optic atrophy), guts (emesis, hepatopathy, diarrhea, hypomotility, pseudo-obstruction), kidneys (nephropathy, cysts), bone marrow (pancytopenia, anemia, thrombopenia), or dermis (lipoma, skleroderma). Various combinations of organ affection constitute either nonspecific mitochondrial disorders or typical syndromes, for which specific acronyms have been coined (MERRF, MELAS, KSS, CPEO, PS, LHON, LS, MILS, MNGIE, NARP, SNHL, FBSN, SANDO, ARCO, GRACILE, DIDMOAD, MIDD, MSL syndrome). Pediatric patients usually present with psychomotor delay, generalized hypotonia, lactic acidosis, and cardiorespiratory failure. Adult patients most frequently present with myopathy and/or encephalopathy [3]. One of the leading symptoms in pediatric and adult cases is exercise intolerance.

## Prevalence

In adults the prevalence is estimated to be 12–48/100,000 and in children 4–7/100,000 [2]. Nowadays, mitochondrial disorders are amongst the most common inherited human diseases. The prevalence of single deletion disorders is 1–2/100,000 [2].

## Genes

Formation of RC complexes I, III, IV, or V is under the control of a genetic mosaic of nuclear and mitochondrial genes. Mitochondrial genes encode for 3 COX, 1 cytb, 7 NADH, and 2 ATPase subunit(s), 22 tRNAs, and 2 rRNAs (Table 1). Nuclear genes encode for the remaining subunits of RC complexes and other essential components for RC maintenance (Table 1) [2]. mtDNA is unique because: it contains only exons (except D-loop); the genetic code differs from the universal code; it is maternally inherited; it depends on nuclear genes for its replication, transcription, translation, and repair; it is present in multiple copies (polyplasmy, polyploidy), which are identical (homoplasmy); usually, pathogenic mutations affect only a portion of it (heteroplasmy); a minimum critical percentage of mutated mtDNA is required to impair OXPHOS (threshold effect); during subsequent cell generations the level of heteroplasmy (mutation load) may change (replicative segregation, mitochondria are randomly distributed to daughter cells), resulting in varying clinical disease expression [1,2,5]. About two thirds of the mitochondrial disorders are due to tRNA mutations.

## Molecular and Systemic Pathophysiology

mtDNA mutations comprise large-scale rearrangements (deletions, duplications), which usually are heteroplasmic and occur sporadically, or point mutations, which usually are maternally inherited and either heteroplasmic (MELAS, MERRF, NARP) or homoplasmic (LHON, SNHL) [3]. Homoplasmic mutations often result in single organ affection with incomplete penetrance, requiring additional environmental factors, polymorphisms, or nuclear genes for disease expression (nuclear background) [3,5]. Recurrence risk of rearrangements is estimated to be 5% [3]. For OXPHOS failure due to rearrangements or tRNA point mutations a threshold of 60–90% is required. tRNA mutations

impair the overall non-protein synthesis, whereas mutations in protein encoding genes specifically affect the function of RC complexes. Some nDNA mutations cause multiple deletions or depletion of mtDNA [1]. The same mutation or different mutations in the same gene may present with different phenotypes (phenotype heterogeneity), while the same phenotype may be caused by different mutations (genetic heterogeneity) [2].

## Diagnostic Principles

The diagnosis is based on the history, clinical presentation, chemical investigations of blood (muscle enzymes, lactate stress test, ischemic forearm test, hormone levels), urine analysis (inorganic acids, amino acids), imaging studies (CT, MRI, PET), magnetic resonance spectroscopy, histological, immune-histochemical, and biochemical muscle biopsy investigations, ATP-production in skin fibroblasts, and molecular genetic investigations [4]. Diagnostic algorithms, like Walker's criteria, Bernier's criteria, or modified Bernier's criteria, rely on these investigations [1]. However, molecular investigations fail to identify the responsible genetic defect in 50% of the adult cases and in 80–90% of the pediatric cases [3]. Morphological hallmarks of mitochondrial disorders on muscle biopsy are ragged-red fibers (RRFs), COX-negative muscle fibers, and ultrastructurally abnormal mitochondria. Usually, RRFs are COX-negative [2]. MILS patients may have COX-negative fibers but no RRFs [2]. In myopathic patients with ND or cytb mutations RRF fibers are COX positive [5]. Many patients with complex I or III defects may have normal muscle biopsy.

## Therapeutic Principles

Therapy of mitochondrial disorders is symptomatic, supplementary, supportive, and should be individualized [4]. There is no gene therapy available yet. Dietary may help in single cases. Antioxidants such as vitamins A, C, or E, selenium, β-carotene, zinc, copper, manganese, *N*-acetylcystein, glutamine, glutathion, L-arginine, citrulline, taurine, creatine, or tea polyphenoles may be beneficial in single cases. Symptomatic drug therapy is indicated in case of epilepsy, stroke-like-episodes, dementia, Parkinson syndrome, migraine, spasticity, dystonia, neuropathic pain, muscle cramps, myalgias, restless-leg syndrome, dorsalgia, endocrinological disturbances, cardiac rhythm abnormalities, heart failure, glaucoma, vertigo, emesis, diarrhea, pseudo-obstruction, renal insufficiency, lactic acidosis, anemia, or thrombopenia. There is some evidence for a beneficial effect of dichloracetic acid, but polyneuropathy can be a severe side effect [3]. Coenzyme-Q10 supplementation is only effective in primary CoQ10-deficiency. Carnitine may help in cases with secondary carnitine deficiency. Surgical therapy is available for ptosis, cataract, glaucoma, pituitary tumor, hypo- or anacusis, (cochlear implant), thyroidectomy, intractable dilative cardiomyopathy (heart transplantation), renal insufficiency (nephrectomy, kidney transplantation), or secondary orthopedic problems. Drugs, known to impair RC function, like valproic acid, acetyl salicylic acid, corticosteroids, barbiturates, biguanides, tetracyclines, chloramphenicol, zidovudin, local anesthetics, volatile anesthetics, or doxorubicin should be avoided [4].

# Mitochondrial Myopathy, Encephalopathy, Lactic Acidosis and Stroke-like Episode

YU-ICHI GOTO
Kodaira, Tokyo, Japan

## Synonyms

MELAS

## Definition and Characteristics

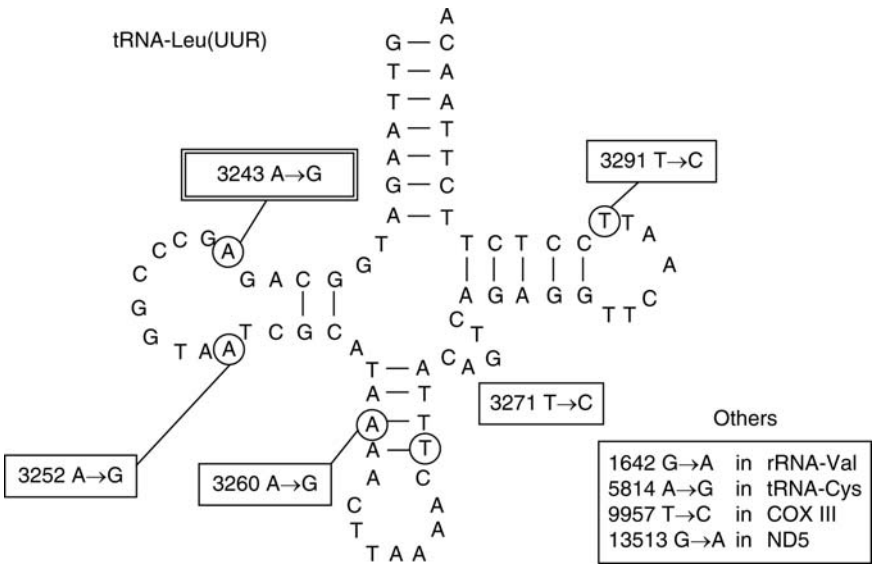
A clinical entity of mitochondrial disease characterized by stroke-like episode and multiple organ involvement based on mitochondrial dysfunction.

## Genes

Approximately 80% of the patients have a point mutation at nucleotide pair 3243 in mitochondrial tRNA-Leu(UUR) gene (Fig. 1).
Rare mutations are also reported in the same tRNA, other tRNA genes, or some protein-coding regions of mitochondrial DNA.

## Molecular and Systemic Pathophysiology

Stroke-like episode including convulsion, unconsciousness, visual disturbance, paralysis, and focal regions on cranial CT/MRI imaging is characteristic. Recurrent



**Mitochondrial Myopathy, Encephalopathy, Lactic Acidosis and Stroke-like Episode. Figure 1** Point mutations in the mitochondrial DNA associated with MELAS. Approximately 80% of the patients have 3,243 mutation.

headache and vomiting are also a frequent accompanying symptom. Encepahlopathy with mental retardation, dementia, ataxia, psychiatric symptoms, and generalized atrophies of cerebrum is frequently observed. Involved are also other organs such as heart (cardiomyopathy and conduction block), skeletal muscle (weakness, hypotonia and hyperCKemia), ear (sensorineural deafness), eye (ophthalmoplegia and optic nerve atrophy), pancreas (diabetes mellitus), endocrine (short stature), gastrointestinal tract (diarrhea and constipation), kidney (glomerular sclerosis and renal tubular dysfunction) and skin (hypohidrosis and hypertrichosis). These manifestations result from the defect in energy metabolism attributable to mitochondrial abnormality. The most major cause is an A-to-G point mutation in the mitochondrial tRNA-Leu(UUR). Because of thousands of mitochondrial genomes in a cell, the mutant genomes detected in the samples from the patients exist together with wild type known as heteroplasmy. The proportion of the heteroplasmy is essential for the threshold effect; once the proportion is over the threshold, cells show the defect in energy metabolism (i.e., complex I and/or IV deficiency) and the abnormal pathology (i.e., ragged-red fiber and strongly succinate-dehydrogenase-reactive blood vessel in skeletal muscle).

## Diagnostic Principles

Clinical manifestations of stroke-like episode such as unconsciousness, visual disturbance, hemiparesis and convulsion, and focal regions on CT/MRI are requirements. Recurrent headache and vomiting accompanied with mental retardation, dementia, or psychiatric symptoms are hallmarks for encephalopathy of this MELAS. Diagnosis is confirmed by at least two of three lines of evidence for mitochondrial abnormality based on pathology, biochemistry, and molecular genetics.

## Therapeutic Principles

Drugs (coenzyme Q10, multi-vitamins, succinate, carnitine, etc.) are used to activate energy metabolism. Palliative therapy for specific organ involvement is also important, such as antiepileptic drugs for convulsion, insulin for diabetes mellitus, and so on.

# Mitochondrial Oxidative Phosphorylation Disorders

►Mitochondrial Disorders

# Mitral Regurgitation

Lucia K. Ma[1], Patrick T. S. Ma[2], Alexander K. C. Leung[3]
[1]Royal College of Surgeons, Dublin, Ireland
[2]Department of Cardiac Sciences, Foothills Hospital, The University of Calgary, Calgary, AB, Canada
[3]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Mitral regurgitation (MR) is characterized by an apical systolic murmur radiating to the left axilla and can be accompanied with signs and symptoms of congestive heart failure. Elevated jugular venous pressure secondary to right ventricular dysfunction is common in severe MR. The left ventricular apical pulse is displaced laterally and right ventricular heave may be appreciated. A S3 and S4 are common in severe MR. The aetiology of MR can be inflammatory (rheumatic heart disease, systemic lupus erythematosus.), degenerative (mitral valve prolapse, mitral annular calcification, Marfan syndrome), infectious or structural (hypertrophic cardiomyopathy, paravalvular prosthetic valve leak).

An important cause of chronic MR is functional MR from ischaemic and cardiomyopathic heart disease.

## Prevalence

Mitral valve prolapse occurs in 2.4% of the population.

## Molecular and Systemic Pathophysiology

The mitral value (MV) consists of the anterior and posterior leaflets, which are attached to the saddle-shape annulus. The posteromedial papillary muscle receives its blood supply from either the left circumflex or the right coronary artery; its single blood supply makes it more prone to papillary muscle dysfunction or rupture during myocardial ischemia. MR causes left ventricle and left atrial volume overload. As the severity of MR increases there is progressive enlargement of the left ventricular left artium (LA) and left ventricle (LV) to compensate for the regurgitant volume. LV dilatation occurs as a result of remodeling of the extracellular matrix with rearrangement of myocardial fibers, in association with the addition of new sarcomeres in series and the development of eccentric LV hypertrophy [1]. In patients with severe MR the LA is markedly dilated and atrial compliance is increased. Although there is fibrosis of the atrial wall, LA pressure can be normal or only slightly elevated. The left ventricular ejection fraction (LVEF) may be normal or even hyperdynamic as the LV empties into the lower pressure LA. The increase in end diastolic volume and the small end systolic volume help to maintain a normal forward stroke volume. Over time the LV progressively dilates. During this decompensated phase, there is significant LA enlargement, increase in capillary wedge pressure, and development of pulmonary hypertension and right ventricular dysfunction. It is important to point out that a recognized drop in LVEF is a late event, and when the LVEF falls below 60% then there is definite LV dysfunction.

## Diagnostic Principles

The diagnosis of MR is mainly clinical. However, transthoracic echocardiogram with or without transesophageal echocardiography remains the gold standard for diagnosing MR. The severity of MR may be assessed by semi-quantitative methods based on the size of the regurgitant jet or the width of the vena contracta, or alternatively by quantitative techniques that attempt to quantify the mitral regurgitant volume and fraction, and the size of the mitral regurgitant orifice area [2,3]. Stress echocardiography can be used to determine the functional significance of MR. An increased end systolic volume with exercise is also a predictor of diminished postoperative ejection fraction. Transesophageal echocardiogram is especially helpful in cases of suboptimal windows to define the size and extent of the defective MV structure.

## Therapeutic Principles

The American Heart Cessociation has recently issued new and dramatically restricted recommendations for the chemoprophylaxis of infective endocarditis in patients with mitral regurgitation [4]. All patients with significant MR and structurally abnormal MV should receive antibiotics prophylaxis before dental and other nonsterile invasive procedures [4]. Optimal blood pressure control with beta-blockers, angiotensin converting enzyme inhibitors or angiotensin receptor blockers is important. Restricted physical activity is recommended only in symptomatic patients and in those with demonstratable left ventricular dysfunction. The most important goals of surgical intervention are improvement of symptoms, preservation of left ventricle function, avoidance of chronic anticoagulation, and atrial fibrillation. Definite indications for surgery in severe MR are the presence of heart failure symptoms and objective parameters of LV dysfunction (LVEF less than 0.60, LV end systolic dimension greater than 40–45mm² or a drop of LVEF with exercise). Surgery should also be considered for patients with severe MR and new onset atrial fibrillation. MV repair is preferable to MU replacement.

# Mitral Stenosis

Toshio Nishikimi
Department of Hypertension and Cardiorenal Medicine, Dokkyo Medical University, Mibu, Tochigi, Japan

## Definition and Characteristics

Mitral stenosis is an obstruction to left ventricular inflow at the level of the mitral valve as a result of a structural abnormality of the mitral valve apparatus, which prevents proper opening during diastolic filling of the left ventricle. The predominant cause of mitral stenosis is rheumatic carditis. Congenital mitral stenosis is very rare.

## Prevalence

Although there has been no apparent or documented decline in group A streptococci pharyngitis, the incidence of acute rheumatic fever in developed countries has dropped precipitously to below 1/100,000, whereas in developing countries it exceeds 100/100,000 [1]. Although these differences may in part reflect less overcrowding and more effective antibiotic treatment of group A streptococci pharyngitis in developed countries, differences both in the frequency of infection with rheumatogenic M-protein serotypes and in their virulence may be important.

## Genes

Genetic association is shown with different HLA class II antigens in several populations: DR4 in Caucasian-American, DR2 in African-American, DR4 in Arabians, DR3 in Indians, DR1 and DR6 in Africans and DR5 in Turks with a relative risk of 2–14. The most consistent HLA class II allele associated with the rheumatic heart disease is DR7. HLA-DR53 is another class II molecule always associated with DR4, DR7 and DR9 molecules. Since several HLA class II antigens are associated with the development of rheumatic heart disease in different countries, different strains of group A streptococci could be implicated in the development of rheumatic heart disease in different countries. The variable association may also be due to the important role that HLA class II antigens play in antigen presentation to the T cell receptor [2].

## Molecular and Systemic Pathophysiology

Rheumatic fever, which is a main cause of mitral stenosis, is an inflammatory disease mediated by humoral and cellular autoimmune responses that occurs as a delayed consequence of Streptococcus pyogenes infection in 3–4% of susceptible and untreated children and adolescents. Carditis affects 30–45% of rheumatic fever patients and is the most serious manifestation of the disease, leading to valvular lesions mainly in the mitral and aortic valves. Although the pathogenic mechanisms involved in the development of rheumatic fever/rheumatic heart disease are not completely understood, recent studies suggest that the molecular mimicry mechanism is responsible for the cross-reactions between streptococcal antigens, mainly M-protein epitope, and human heart tissue proteins in susceptible individuals. The rheumatic heart disease is considered to be mediated by both humoral and cellular immune responses and that the cellular immune response is more involved in the development of rheumatic heart disease [2].

Neurohumoral factors, such as natriuretic peptides, adrenomedullin, endothelin, nitric oxide, etc. contribute to the pathophysiology of mitral stenosis according to the severity of the disease and these measurements are often used as index of severity [3].

## Diagnostic Principles

The diagnosis of mitral stenosis is readily made by two-dimensional echocardiography, which shows restricted motion and doming of mitral valve leaflets. The orifice can be imaged directly and measured by this technique. Two-dimensional echocardiography also provides useful information about the pliability and extent of calcification of the valve and subvalvular tissue. As the evaluation of the severity of mitral stenosis, the transmitral gradient is measured by Doppler echocardiography. The severity of mitral stenosis is also evaluated by the simultaneous measurement of the pressure in the left ventricle and the left atrial during right and left heart catheterization.

## Therapeutic Principles

The treatment options for mitral stenosis include medical management, surgical replacement of the valve, and percutaneous balloon valvuloplasty. In patients with a mild to moderate condition and no symptoms, the regular medical checkups to carefully monitor the mitral heart valve is recommended. If appropriate, medications such as digitalis, diuretic, anticoagulant medicine, etc

are prescribed. The indication for invasive treatment with either a mitral valve replacement or valvuloplasty is recommended for the patients with NYHA functional class III or IV symptoms [4].

# Mitral Valve Prolapse

Patrick T. S. Ma[1], Siobhan D. Ma[2], Alexander K. C. Leung[3]

[1]Heart Health Institute and Department of Cardiac Science, The University of Calgary, Calgary, AB, Canada

[2]Royal College of Surgeons, Dublin, Ireland

[3]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Barlow's syndrome; Floppy-valve syndrome; Billowing mitral leaflet syndrome; Systolic click-murmur syndrome; MVP

## Definition and Characteristics

Mitral valve prolapse (MVP) is defined anatomically as billowing of the mitral valve (MV) leaflet posterior to the mitral annular plane, usually secondary to softened and redundant MV leaflets and chordae tendineae as a result of myxomatous degeneration and increased concentrations of acid mucopolysaccharide. Patients however fall into a spectrum between two opposite forms of MVP. The common benign form usually occurs in young females with mild buckling of an otherwise normal MV. The rarer serious form occurs in middle aged males with severely thickened and redundant myxomatous changes in the MV resulting in significant mitral regurgitation (MR) and heart failure. Most patients with MVP, especially the benign form are sporadic, have no significant comorbidities other than an asthenic built. The more serious form may be associated with Ehlers-Danlos syndrome, Marfan syndrome, acute rheumatic carditis and various congenital heart diseases. Clinically, there are one or multiple mid-systolic clicks resulting from tightening of the chordae tendineae where the MV billows posteriorly. This click occurs after the onset of the carotid pulse, and follows by a mid to late apical systolic crescendo murmur. In general, the longer the murmur, the more severe is the MR. Maneuvers, such as Valsalva that reduce left ventricular (LV) cavity size, move the click and murmur earlier. Maneuvers that increase LV size do the opposite. Most benign forms of MVP are asymptomatic. Various symptoms such as anxiety, easy fatigability, palpitations, orthostatic hypotension, and chest pain may occur.

## Prevalence

MVP occurs in 2–4% of population.

## Genes

The rare familial form of MVP has an autosomal dominant mode of inheritance with variable penetrance. The MMVP1gene locus has been mapped to chromosome 16p.11.2 – p.12.1 [1] and a second locus, MMVP2 gene locus to chromosome 11p15.4 [2].

## Molecular and Systemic Pathophysiology

MVP is associated with fragmentation and reduction of production of collagen fibrils. MVP may lead to excessive stress and ischaemia in the papillary muscle and subjacent ventricular myocardium, thereby causing angina and ventricular arrhythmias which may lead to an increased risk of sudden death especially in patients with chordal rupture and severe MR. Supraventricular arrhythmias such as atrial fibrillation can occur especially in patients with increased sympathetic

tone. Transient cerebral ischaemic attacks secondary to emboli from the dysfunctional endothelium of the MV may occur, and the dysfunctional endothelium may predispose these patients to infective endocarditis. Progression to severe MR may occur in 10% of patients who are male, older (> 50 years), obese, and hypertensive. There is progressive dilatation of the left atrium, which can also predispose the patient to supraventricular dysrhythmias such as atrial fibrillation. Dilatation of the LV and significant LV dysfunction occur when the left ventricular end systolic dimension (LVESD) exceeds 40–45 mm and the left ventricular ejection fraction (LVEF) drops below 60%.

## Diagnostic Principles

The diagnosis of MVP is suspected from its clinical features and can be confirmed by echocardiography in demonstrating posterior displacement of one or both MV leaflets beyond the mitral annular plane into the left atrium in the parasternal long axis view. Echocardiography can estimate the severity of MR and LV dysfunction by measuring the LVESD, LVEF, mitral regurgitant volume, the size of the mitral regurgitant orifice area, and demonstrating the presence of chordal or papillary muscle rupture and flail MV leaflets [3]. An increased LVESD and reduced LVEF with exercise during stress echocardiography is a predictor of diminished postoperative LVEF and poor outcome [4]. Transoesophageal echocardiogram is especially helpful in cases of suboptimal windows and for a better definition of the defective MV especially in preoperative settings.

## Therapeutic Principles

The indications for antibiotic prophylaxis in patients with MVP to prevent infective endocarditis has been changed dramatically [5]. Currently, the only cardiac conditions which require antibiotic prophylaxis prior to dental/surgical procedure are restricted to prosthetic cardiac values, previous infective endocarditis, various congenital heart diseases, and cardiac transplantation recipients who develop cardiac valvulopathy [5]. Beta-blockersare useful for the control of chest pain and arrhythmia. Antiplatelet agents such as aspirin or anticoagulants should be given to patients with transient cerebral attacks. With significant MR, surgery should be considered when heart failure symptoms develop and/or objective parameters of LV dysfunction are reached (LVEF < 0.60, LVESD > 40–45 mm, a drop of LVEF with exercise or mitral regurgitant orifice area > 40 $mm^2$) or when atrial fibrillation and flailed MV leaflets develop. MV repair is superior to MV replacement, and the durability of MV repair is better for the posterior than the anterior MV leaflet.

# Mixed Connective Tissue Disease

Andrew Rozelle, Eliza F. Chakravarty
Division of Immunology and Rheumatology, Stanford University School of Medicine, Palo Alto, CA, USA

## Synonyms

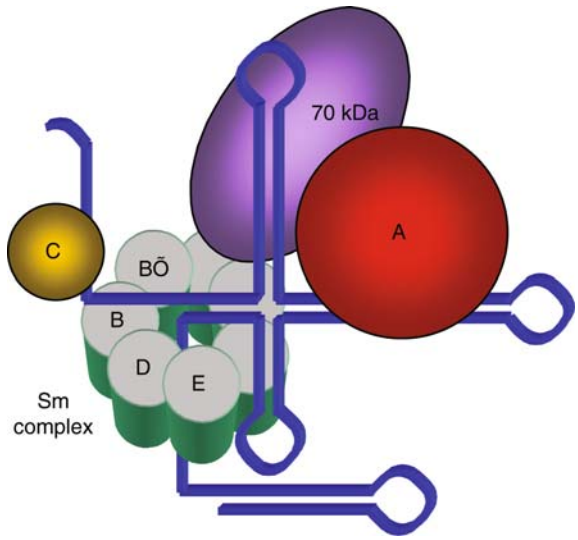
MCTD; (distinctions should be made between MCTD and "overlap syndrome," which indicates the simultaneous presence of ≥2 separate CTDs, as well as between MCTD and undifferentiated CTD (UCTD))

## Definition and Characteristics

Although several definitions exist for MCTD, they are all constructed around the initial observation that a subset of patients presenting with a particular type of antinuclear antibody (ANA) called anti-U1-RNP and features of connective tissue disease appear to segregate into a unique category. The U1-RNP is a RNA-protein complex that forms a subunit of the spliceosome (Fig. 1) and is composed of the specific U1-RNA stem as well as three specific protein subunits known as the A, C, and 70 kD subunits.

Another group of proteins in this structure, the Smith complex, is also found in other nuclear structures. The most sensitive and specific definition for MCTD holds that patients must have high titer antibodies to U1-RNP as well as three of the following five features: hand edema, Raynaud's phenomenon, acrosclerosis, synovitis, and myositis, with one of the latter two always being present.

Holman and colleagues observed in their initial description of MCTD that the symptoms experienced by this group of patients "suggest the presence of several coexistent rheumatic diseases," the most prevalent being polyarthritis, hand edema with Raynaud's phenomenon, and myositis [1]. Serological profiles of these patients demonstrate high titer anti-U1-RNP



**Mixed Connective Tissue Disease.**
**Figure 1** The U1-RNP complex is composed of the specific U1-RNA stem as well as three specific protein subunits known as the A, C, and 70 kD subunits. Another group of proteins in this structure, the Smith complex, is also found in other nuclear structures. The combination of epitope targets within this complex that compose the clinical anti-U1-RNP response differs between individual patients and also shows different patterns among diseases such as MCTD and SLE.

antibodies in the absence of significant titers of anti-Smith antibodies, the latter being highly specific for systemic lupus erythematosus (SLE).

Indeed, the early symptoms experienced by patients with MCTD often suggest an overlap of RA, systemic sclerosis, inflammatory myositis, and SLE. In decreasing order of prevalence, patients may have polyarthritis of the hands (55–95%) [1], hand edema or "puffy hands" with Raynaud's phenomenon (60–90%), myositis (~50%), and skin rash (~50%) [2]. These are not often present simultaneously, but manifest within a few years of each other.

It was originally thought that MCTD comprised a group of patients who were quite responsive to steroids and experienced a more benign course than those with classical lupus or scleroderma. However, follow-up of the original cohort proved this not to be the case, and long term morbidity and mortality estimates may actually be worse than those for either of the two other diseases.

The major cause of morbidity and mortality in MCTD appears to be pulmonary involvement, which can be due to both interstitial lung disease (ILD) and pulmonary hypertension (pHTN). Prevalence estimates vary widely based on different diagnostic techniques and different definitions used to identify cases, but recent studies of two relatively large cohorts estimate the figures for ILD and pHTN to be 66 and 19%, respectively [2,3]. In a long-term follow-up of nearly 50 patients with MCTD, pulmonary HTN was present in 23% and was responsible for 80% of the 11 deaths over this time [2].

The clinical course of MCTD is characterized by inflammatory symptoms in the early phase, which then progress to more fibrotic conditions including acrosclerosis and pulmonary fibrosis. A significant percentage of patients ultimately meet diagnostic criteria for scleroderma (SSc), which has fueled the argument that MCTD is not so much a separate entity but rather an undifferentiated CTD in evolution. However, several long-term follow-up studies indicate that while significant numbers of patients do ultimately meet criteria for either SSc or SLE (15–30%), a large proportion (30–45%) do not evolve in this way and instead continue to meet classification parameters for MCTD. These observations, as well as serological and genetic profiles (see below) that suggest a unique pathophysiology for MCTD, argue in favor of the separate classification given to this condition.

## Prevalence

The prevalence of MCTD is unknown.

## Molecular and Systemic Pathophysiology

While the pathogenic mechanisms of nearly all connective tissue diseases remain incompletely understood, central themes involve a breakdown in tolerance to self and amplification of this autoimmunity by the innate immune system. Reactivity to host proteins, including U1-RNP subunits, may be initiated in apoptosis when novel peptides are generated by proteases, with the subsequent presentation of these epitopes to naïve B cells. In addition, memory cells may recognize particular sequences that mimic antigenic targets from previous viral infections. In the case of MCTD, the 70 kD protein subunit of U1-RNP has a motif that resembles a sequence of a CMV peptide, while the B/B' subunits of the Smith complex may mimic a peptide from EBV [4].

Generation of high-titer IgG antibodies to subunits of the U1-RNP complex requires that appropriate costimulatory signals complement the initial engagement of the B-cell receptor. These signals may be provided by the binding of the RNA component of U1-RNP to toll-like receptors (TLRs) on antigen presenting cells. Normally, microbial-derived nucleic acids activate these innate immune sensors, resulting in increased expression of proinflammatory cytokines and costimulatory signals. In MCTD, this antimicrobial response mechanism may be subverted by U1-RNA binding to TLRs-3, 7, and 8, leading to T cell recruitment and generation of highly specific antibodies to the nucleoprotein complex [4].

### Diagnostic Principles

A major argument against the classification of MCTD as a unique clinical entity is the fact that antibodies to the U1-RNP complex are seen in other diseases such as lupus. Nonetheless, it is observed that among MCTD and SLE patients with anti-U1-RNP, individual autoantibody profiles to the different subunits show different patterns between the two diseases. This preference for certain epitopes, as well as the association of MCTD with certain DR4 alleles that are not linked to SLE, scleroderma, or the inflammatory myopathies, argues that a distinct immune response is the etiology of this clinical entity.

Only preliminary evidence exists for a directly pathogenic role played by anti-U1 RNP in MCTD, and the presence of these antibodies is not always associated with the clinical features of the disease. Immunization of mice transgenic for HLA-DR4 with the 70 kD U1-RNP protein subunit results in high titer antibodies to this complex, and the requirement for Freund's adjuvant in this reaction can be obviated by co-immunization with U1-RNA alone [5]. A significant proportion of these animals subsequently develop interstitial lung disease. Furthermore, follow-up of clinic patients with anti-U1-RNP antibodies but not fulfilling MCTD criteria indicates that 75–100% of patients ultimately do develop a well-defined CTD, with MCTD being the most frequent.

### Therapeutic Principles

Management of individual tissue manifestations in MCTD is the same as the management for these conditions when they present in the context of any of the other well-defined CTDs.

## MODY

Stefan R. Bornstein[1], Sven Schinner[2]
[1]Medical Clinic III, University Hospital Dresden, Dresden, Germany
[2]Department of Endocrinology, Diabetes and Rheumatology, University Hospital Duesseldorf, Duesseldorf, Germany

### Synonyms

Maturity onset diabetes of the young

### Definition and Characteristics

A group of monogenic, autosomal dominant pancreatic beta cell defects leading to the onset of nonketotic diabetes mellitus before the age of 25.

### Prevalence

1–5% of all cases of diabetes mellitus.

### Genes

*MODY-1*: HNF-4a (hepatocyte nuclear factor-4a) is localized on chromosome 20
*MODY-2*: Glucokinase is localized on chromosome 7
*MODY-3*: HNF-1a (hepatocyte nuclear factor-1a) is localized on chromosome 12
*MODY-4*: IPF-1 (Insulin Promoter Factor-1) is localized on chromosome 13
*MODY-5*: HNF-1b (hepatocyte nuclear factor-1b) is localized on chromosome 17
*MODY-6*: NEURO-D1 (neurogenic differentiation factor-1), also known as BETA2 (beta-cell E-box transactivator-2) is localized on chromosome 2.

### Molecular and Systemic Pathophysiology

HNF proteins (hepatocyte nuclear factors) are transcription factors that were first described in the liver. They are highly expressed in pancreatic beta cells, where they not only play a pivotal role during embryonic development, but also regulate (either directly, or indirectly as in the case of HNF4) the transcription of the insulin gene or genes involved in insulin secretion. Similary, Neuro D1 (BETA2) and IPF-1 are transcription factors regulating both, islet development and insulin gene transcription, in the adult.

Glucokinase forms glucose-6-phosphate by catalyzing the transfer of phosphate from ATP to glucose. Thereby, glucokinase acts as a glucose sensor in beta cells regulating insulin secretion.

*MODY-1*: HNF-4 is a transcription factor expressed in pancreatic beta cells. HNF-4 regulates the expression of HNF-1. Mutations in HNF-4 are very rare and lead to impaired insulin secretion and decreased beta cell mass, but lead to mild elevation of fasting glucose at young age. However, hyperglycemia tends to deteriorate later in life, making oral hypoglycemic drugs or insulin necessary.

*MODY-2*: Glucokinase shows highest expression levels in pancreatic beta-cells and in the liver. For generating glucose-6-phosphate, the first step in glycolysis, glucokinase is a key enzyme for glucose sensing in beta cells. The final product of glycolysis and the Krebs cycle is ATP, which in turn triggers insulin release from secretory granules. In the liver, glucokinase regulates glycogen-synthesis. Accordingly, glucokinase mutations cause defects in insulin secretion as well as glycogen storage in the liver. The relatively common heterozygous glucokinase mutations show a mild phenotype, generally without typical complications of diabetes mellitus. Fifty percent of women with heterozygous glucokinase mutations develop gestational diabetes. Homozygous mutations lead to permanent neonatal diabetes mellitus.

*MODY-3*: HNF-1a mutations are the most common form of MODY in most populations. MODY-3 is characterized by mild elevation of fasting glucose, which tends to deteriorate with time, making oral hypoglycemic drugs or insulin necessary.

*MODY-4*: IPF-1 mutations are extremely rare. They are characterized by mild fasting hyperglycemia.

*MODY-5*: HNF-1b mutations are associated with mild diabetes mellitus and renal cysts, as well as internal genital malformations in some cases.

*MODY-6*: Neuro D1/BETA2 associated diabetes mellitus is very rare and normally requires insulin treatment.

*Systemic Pathophysiology*: In most cases, MODY leads to mild, often asymptomatic, hyperglycemia. Although the manifestation of MODY occurs during childhood or adolescents in most of the patients, the diagnosis is made relatively late as mild hyperglycemia remains undiagnosed for years. Characteristically, those patients in whom penetrance of MODY is as high as >80% show a strong family history of diabetes

mellitus. Compared with type-2 diabetics, MODY patients are generally younger (<25 years) and do not exhibit typical features of the metabolic syndrome, such as obesity, hypertension, or dyslipidemia.

### Diagnostic Principles

Clinical features and subsequent genetic screening for mutations in the respective genes.

### Therapeutic Principles

Typically, a correction of fasting hyperglycemia can be achieved without insulin for at least 2 years following diagnosis.

## Mohr-Wreidt Type Brachydactyly

►Brachydactyly Type A

## Molybdenum Cofactor Deficiency

Marinus Duran
Department of Clinical Chemistry, University of Amsterdam, Amsterdam, The Netherlands

### Synonyms

Sulfite oxidase deficiency; Xanthine dehydrogenase deficiency

### Definition and Characteristics

Autosomal recessive defect of the biosynthesis of the molybdenum cofactor that is essential for the functioning of sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase. Affected patients have severe neurological abnormalities with convulsions, microcephaly, mental retardation [1]. They may die early. Isolated sulfite oxidase deficiency due to mutations of the apoenzyme has similar clinical features. Xanthine dehydrogenase deficiency is quite harmless, but may result in the formation of kidney stones.

### Prevalence

More than 100 patients with Mo-cofactor deficiency have been reported, and the number of patients with isolated sulfite oxidase deficiency is considerably lower. The disorder may be underdiagnosed because of the diagnostic problems [2].

### Genes

A relatively small number of mutations of the genes MOCS1, MOCS2, and GEPH have been described; in some populations a founder effect could be established.

### Molecular and Systemic Pathophysiology

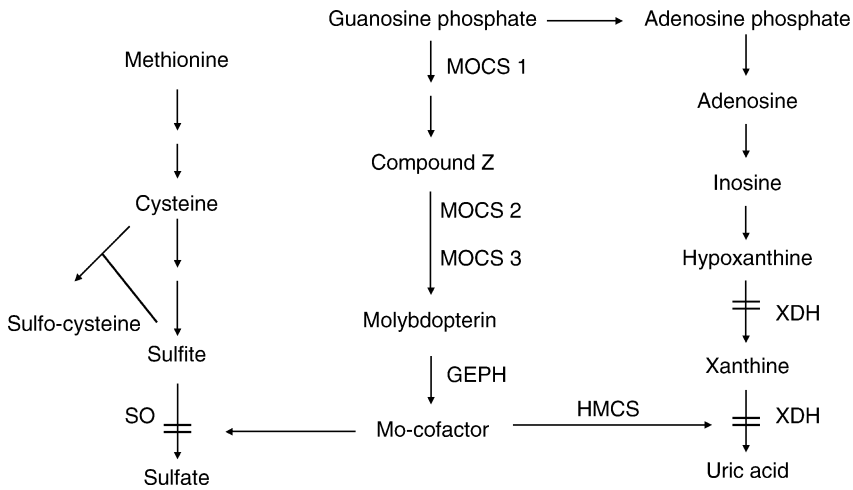
The enzymes, viz. sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase require the presence of the so-called molybdenum cofactor for their functioning (Fig. 1). This unstable compound has a pterin-like structure and is synthesized endogenously from guanosine triphosphate. Thus far at least four genes encoding biosynthetic enzymes have been characterized in this pathway. These genes are called MOCS1, MOCS2, MOCS3, and GEPH [3]. Each of the genes MOCS1 and MOCS2 produce two different enzyme proteins, the mechanism of which has not been fully elucidated. GEPH encodes for the protein gephyrin, it is involved in the insertion of Mo in the active cofactor. The latter is also called molybdopterin. Molybdopterin synthase (MOCS2A and B) has to be activated by a sulphotransferase (MOCS3).

Inability of the formation of the Mo-cofactor or failure to incorporate molybdenum results in hypouricemia and low sulfate levels. The accumulating xanthine and sulfite leads to urolithiasis and neurosulfite intoxication, respectively.

An animal model has been made showing similar biochemical findings as in the human. Knock-out mice die very early in life.

### Diagnostic Principles

Affected patients generally have a characteristic microcephaly, severe mental retardation, and convulsions.



**Molybdenum Cofactor Deficiency. Figure 1** Metabolic pathways showing the degradation of cysteine and adenosine as well as the effect of the various mutations in the Mo-cofactor metabolism on the functioning of sulfite oxidase (SO) and xanthine dehydrogenase (XDH). The relevant genes involved in the modulation of the molybdenum-cofactor are explained in the text.

Mo-cofactor deficiency leads to low uric acid, enhanced xanthine and hypoxanthine and accumulation of urinary sulfite (to be detected with a dipstick) and the abnormal amino acid S-sulfocysteine as well as taurine. Plasma cystine and homocysteine may be exceptionally low. Sulfite oxidase can be assayed in cultured fibroblasts. Mutations of MOCS1, MOCS2, and GEPH could confirm the diagnosis.

## Therapeutic Principles

Truly effective therapy is not available. Mildly affected patients may benefit from a diet, which is low in both the amino acids methionine and cystine, the precursors of sulfite. Theoretically only the patients with GEPH mutations are expected to benefit from treatment with molybdate.

# Mongolian Spots

Alexander K. C. Leung[1],
William Lane M. Robson[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]The Childrens' Clinic, Calgary, AB, Canada

## Synonyms

Congenital dermal melanosis; Congenital dermal melanocytosis

## Definition and Characteristics

Mongolian spots are congenital hyperpigmented macules or patches of varying size and shape [1]. Mongolian spots are usually grayish and vary from gray to gray-blue to gray-black; the younger the child, the darker the color [1]. Mongolian spots are most common in the sacrococcygeal area, followed by the gluteal and lumbar areas (Fig. 1) [2].

Lesions are less common on the upper back, occur even less frequently on the abdomen, thorax, and limbs, and are rare on the scalp and face [3,4]. Mongolian spots are usually round or oval, but they can be triangular, heart-shaped, or horseshoe-shaped. Lesions might be single or multiple. The spots vary in size. Most spots are small and measure 1–4 cm in diameter, but occasionally the lesions can be quite extensive [2].

**Mongolian Spots. Figure 1** Extensive Mongolian spots in the sacrococcygeal, gluteal, and lumbar areas.

## Prevalence

Mongolian spots are very common in children of Asian and African descent but are rare in Caucasians [1,2]. The spots are present in all newborn Chinese, Japanese, and Mongols [1]. Both sexes are affected, with a slight male predominance [1]. Mongolian spots usually fade during the first few years of life and are rare in children older than 10 years [5].

## Molecular and Systemic Pathophysiology

During fetal development, dermal melanocytes migrate from the neural crest to the dermoepidermal junction. Dermal melanocytes are present in the dermis of embryos from the 10th week of gestation, migrate to the epidermis between the 11th and 14th week, and gradually disappear from the dermis after the 20th week. A Mongolian spot is thought to be the result of the failure of dermal melanocytes to migrate to the epidermis [2]. Histologically, the lesions are characterized by spindle-shaped melanocytes in the lower layers of the dermis. The disappearance of Mongolian spots at a later age is caused either by the subsequent migration of these dermal melanocytes to the epidermis or by removal by macrophages.

## Diagnostic Principles

A Mongolian spot should be distinguished from a nevus of Ota and a nevus of Ito. A nevus of Ota is characterized by benign melanosis of the skin around the eye, which is supplied by the ophthalmic and maxillary divisions of the trigeminal nerve. The color of the affected skin might be light or dark-brown, blue-black, or slate. The lesion is usually unilateral. Ocular melanosis is a common finding in patients with nevus of Ota, especially in moderate or severe cases. Ocular involvement ranges from a black or gray-blue discoloration of the sclera alone, which is present in about two thirds of cases, to hyperpigmentation of the entire uveal tract, conjunctiva, and optic nerve. A nevus of Ito is a variant of nevus of Ota. In nevus of Ito, the pigmentation occurs in the acromioclavicular region and is more diffuse and less mottled. Unlike Mongolian spots, both nevus of Ota and nevus of Ito persist through adult life. A bruise can look similar to a Mongolian spot. A bruise is tender at the onset. The color of a bruise evolves from blue-black or purple to yellow-green, and the lesion disappears over several weeks. A Mongolian spot is never tender and the color is usually homogeneous.

## Therapeutic Principles

When Mongolian spots are confused with a bruise, there might be medico-legal implications [2]. Misdiagnosis is more common if the child is comatose and the Mongolian spot is found in an unusual site, such as the scalp or face, or has an abnormal shape [3,4]. Horizontal and linear Mongolian spots have been reported that simulate bruises inflicted with a stick. Mongolian spots that are extensive, that occur in an unusual site, or have an unusual shape should be documented [2]. Mongolian spots are otherwise benign, asymptomatic, and most often self-limited, and treatment is therefore not necessary.

# Mongolism

►Trisomy 21

# Monilethrix

Christine Liang, Julie V. Schaffer
Department of Dermatology, New York University School of Medicine, New York, NY, USA

## Synonyms

Congenital beaded hair; Moniliform hair; Nodose hair; Aplasia pilorum intermittens

## Definition and Characteristics

The term monilethrix is derived from *monile* (Latin), meaning necklace, and *thrix* (Greek), meaning hair. This condition is characterized by fragile hairs with a beaded appearance due to elliptical nodes of normal thickness alternating with narrow-diameter internodes where the hair is weakened and prone to breakage (Fig. 1a) [1]. Ultrastructural findings include an abnormal fibrillar structure and vacuolation of lower hair cortex cells.

The dystrophic alopecia of monilethrix appears as short or "stubbly," brittle, lusterless terminal hairs (Fig. 1b). The clinical spectrum ranges from a mild form in which only occipital hairs are affected to a more severe variant involving the entire scalp, eyebrows, eyelashes and secondary sexual hair [1]. The condition usually becomes apparent in infancy, and improvement may be noted after puberty or during pregnancy. Individuals with monilethrix often have follicular hyperkeratosis and perifollicular erythema favoring the neck, upper outer arms and thighs as well as the scalp. Although monilethrix is classically an autosomal dominant disorder with high penetrance and variable expressivity, the genetic basis of an autosomal recessive form (which overlaps with localized autosomal recessive hypotrichosis [LAH]) has recently been elucidated [2,3].

## Prevalence

Rare, exact prevalence unknown.

## Genes

*Autosomal dominant monilethrix*: KRT81 (hHb1), KRT83 (hHb3) and KRT86 (hHb6) on chromosome 12q13, which encode keratins 81, 83 and 86, the major type II (basic) hair cortex keratins [4,5].

**Monilethrix. Figure 1** Clinical features of monilethrix. (a) Typical moniliform hairs with elliptical nodes regularly separated by constricted internodes. (b) Short sparse hairs, stubble and follicular papules on the scalp of a young girl with autosomal recessive monilethrix due to *DSG4* mutations.

*Autosomal recessive monilethrix*: *DSG4* on chromosome 18q12.1, which encodes desmoglein 4, a member of the desmosomal cadherin family of transmembrane cell adhesion molecules that is expressed primarily in the hair cortex [2,3].

## Molecular and Systemic Pathophysiology

Keratin intermediate filaments form a cytoplasmic network that extends from the nuclear periphery to the plasma membrane, where interactions with desmosomal proteins are crucial to maintenance of cell and tissue integrity. Expressed in a tissue and differentiation-specific fashion, keratin intermediate filaments are composed of heterodimeric subunits formed by the pairing of a type I keratin (acidic; KRT31-KRT40 in the hair shaft) and type II keratin (basic-neutral; KRT81-KRT86 in the hair shaft) [1]. Each keratin protein contains a central α-helical rod domain flanked by helix initiation and helix termination motifs. The latter motifs play a critical role in intermediate filament assembly, are highly conserved among different keratins, and represent "hot spots" for mutations in hereditary keratin disorders including monilethrix. Such mutations are typically dominant negative, since the defective keratins bind to and disrupt the function of normal keratins.

The most common underlying defects in patients with autosomal dominant monilethrix are missense mutations located in the helix termination motifs of the hair cortex keratins KRT86 and (less frequently) KRT81 (Glu413Lys in KRT86 > 81; Glu402Lys in KRT81/86) [1,4]. To date, a mutation in KRT83 (Glu407Lys, the equivalent of Glu402Lys in KRT81/86) has been reported in only one family [5]. Although a genotype-phenotype correlation has generally not been observed in monilethrix and clinical manifestations often vary within affected families, in one large pedigree severely affected individuals were found to have a Glu402Asp mutation in both KRT86 alleles (rather than one allele as in more mildly affected family members), thus demonstrating semidominant inheritance (i.e. an intermediate phenotype in heterozygotes) [1].

Mutations in DSG4 underlie an autosomal recessive form of monilethrix as well as LAH, a disorder that is clinically similar to monilethrix but lacks the microscopic finding of a beaded hair shaft. In both of these conditions, mutations cluster in the extracellular domain of DSG4, which is necessary for cadherin-cadherin binding between cells [2,3]. In particular, the mutations affect highly conserved amino acids that represent phosphorylation sites or components of calcium-binding domains in desmosomal cadherins, the loss of which abrogates their adhesive function.

Interestingly, the autosomal recessive lanceolate hair phenotype in mice and rats is due to loss-of-function mutations in the orthologous Dsg4 gene [2,3]. Affected animals display sparse, short, fragile hairs with a "lance head"-like bulbous swelling at the distal tips of broken hairs. The swelling originates in the lower portion of the anagen hair follicle, where "blebs" have also been described in scalp biopsies from patients with autosomal recessive monilethrix and LAH [2,3]. This is thought to reflect intermittent perturbation of keratinocyte differentiation in the setting of disrupted cell-cell adhesion due to defective DSG4, which represents the principal desmosomal cadherin in the hair follicle. Without functional DSG4, precortical cells may be torn away from their neighbors and subsequently undergo premature, abrupt and abnormal keratinization, with decreased expression of hair cortex keratins. Follicular dystrophy and the formation of lanceolate/monilethrix hairs underscore the important function of cell-cell adhesion mediated by DSG4 in providing structural integrity to the hair follicle and coordinating hair shaft differentiation. DSG4 is also expressed in the suprabasal epidermis, accounting for the observation of congenital scalp erosions (reflecting transient pre-/neonatal skin fragility) in three siblings with autosomal recessive monilethrix due to DSG4 mutations [3].

All of the proteins shown to be defective in monilethrix (KRT81, KRT83, KRT86 and DSG4) belong to the desmosome-keratin complex that joins hair cortex cells. This explains how perturbation of keratinocyte adhesion and differentiation due to DSG4 dysfunction can lead to a hair shaft abnormality identical to that resulting from a direct hair keratin defect. The sudden, early differentiation that occurs in the lower hair follicle due to DSG4 defects may also provide a clue to the etiology of the regularly beaded appearance of hairs in monilethrix due to hair keratin defects. Of note, the intracellular domains of desmosomal cadherins are connected to keratin intermediate filaments via armadillo and plakin family proteins. It is therefore not surprising that inherited defects in members of these families can lead to other hair abnormalities, such as woolly hair due to mutations in plakoglobin (in Naxos disease) or desmoplakin (in Carvajal syndrome).

## Diagnostic Principles

Examination of hair shafts for the characteristic beaded appearance (regularly spaced elliptical nodes alternating with constricted internodes) is central to the diagnosis of monilethrix. This can be accomplished by light microscopy or dermoscopy. Additional findings include fractures and bending of the hair shaft at sites of constriction. In a newborn with alopecia, a glass slide can be scraped against the scalp to collect hair rudiments for evaluation. Genetic analysis may be helpful in establishing a precise molecular diagnosis.

### Therapeutic Principles

There is no effective treatment for monilethrix, although gentle handling of the hair can help to minimize breakage. Spontaneous improvement sometimes occurs after puberty. A beneficial effect of oral retinoid therapy has been described, but the hair abnormality recurs upon discontinuation of the medication. Treatment with vitamins, griseofulvin, topical and systemic corticosteroids and minoxidil has not been successful.

## Moniliform Hair

►Monilethrix

## Monocytopenia (in Adults)

Claudiu Plesa, Franck E. Nicolini
Hematology Department, Edouard Herriot Hospital, Lyon, France

### Synonyms

Neutropenia; Lymphocytopenia; Thrombocytopenia; Anemia (the latter will be excluded from this chapter)

### Definition and Characteristics

In the peripheral blood:

- Neutropenia: absolute neutrophil count (ANC) < 1.5 $10^9$/l
- Lymphopenia: lymphocyte count < 1 $10^9$/l
- Thrombocytopenia: platelet count < 150 $10^9$/l

### Prevalence

Highly variable along countries, patients, and causes. General prevalence increases with age.

### Genes

Some monocytopenias are the consequence of single hit genetic lesions (e.g., adenosine deaminase deficiency).

### Molecular and Systemic Pathophysiology

All monocytopenias are induced either through a decreased production, an increased destruction, or a variation in the distribution of the hematopoietic cells (Fig. 1).

They illustrate either a central defect in their production (located in the central hematopoietic organ in adults: bone marrow) or an abnormality residing in the periphery (by opposition to bone marrow: peripheral blood, secondary hematopoietic organs, non-hematopoietic organs).

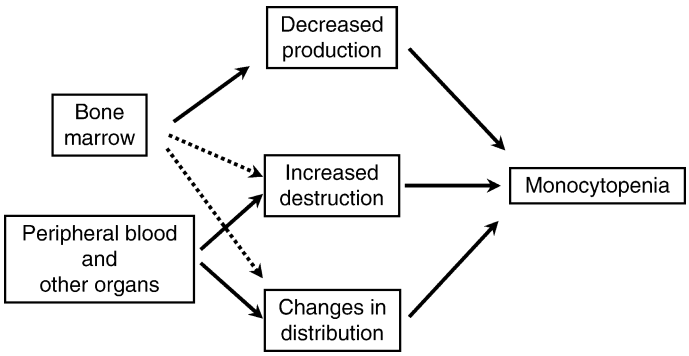
#### Neutropenias

Because of the particular physiology of neutrophils (nycthemeral cycle, genetic inheritance), only true neutropenias are discussed in this chapter.

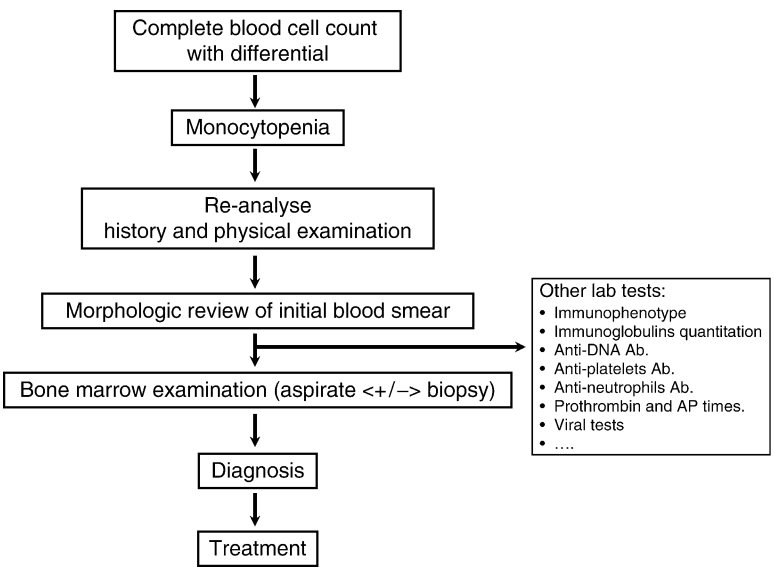
- *Decreased production*: Bone marrow damage or infiltration (Leukemias, solid tumor metastasis, megaloblastic anemia, myelodysplastic syndrome, primitive myelofibrosis, Gaucher's disease, aplastic anemia, Fanconi's syndrome, ongoing radiation or chemotherapy, idiosyncratic drug reaction (Noramidopyrine), constitutive neutropenic disorders (cycling neutropenia, Kostmann and Chédiak-Higashi syndromes)
- *Increased destruction*: Auto-immune disorders, severe infections (pneumococcae, meningococcae).
- *Redistribution*: The total body granulocyte pool is normal, but the number of circulating neutrophils is reduced (e.g., excessive margination), no severe bacterial infection occur. Splenic sequestration, restricted to neutrophils, and bone marrow release defect (rare) are possible.

##### *Lymphocytopenias*

- *Decreased production.* Autosomal recessive diseases as Severe Combined Immunodeficiency Diseases (SCIDs), Adenosine Deaminase deficiency, and protein-calorie malnutrition.
- *Increased destruction*: Acquired Immundeficiency Syndrome (AIDS) results in the selective loss of $CD4^+$ T lymphocytes. Radiotherapy induces lymphocytopenias by direct exposure. Cytotoxic agents can cause prolonged lymphocytopenias (e.g., glucocorticosteroids, anti-thymocyte globulins, alkylating



**Monocytopenia (in Adults). Figure 1** General pathophysiological mechanisms of monocytopenias.



**Monocytopenia (in Adults). Figure 2** General diagnostic principles of monocytopenias.

agents, ciclosporin A). In systemic lupus erythematosus lymphocytopenias are caused by cytotoxic autoantibodies against T- and B-cells. Abnormalities of lymphatic vessels can be responsible for direct abundant loss of lymphocytes (thoracic duct).

- *Redistribution*: During glucocorticoid treatment, lymphocyte redistribution appears as a primary mechanism for lymphocytopenia. Viral infections (influenza, rhinoviruses) and tuberculosis may induce lymphocytopenias. During sarcoidosis, extensive burns, anesthesia, and surgical stress, lymphocytopenia may also occur.

### *Thrombocytopenias*

- *Decreased production*: Bone marrow megakaryocytes are decreased, and the causative disorder is usually obvious (Leukemia, solid tumor metastasis, megaloblastic anemia, myelodysplastic syndrome, primitive myelofibrosis, Gaucher's disease, ongoing radiation or chemotherapy, Fanconi's syndrome, aplastic anemia).
- *Increased destruction*: Bone marrow megakaryocytes are increased, and platelets are destroyed by immune reactions (Idiopathic thrombocytopenic purpura [ITP], lymphoproliferative disorders [systemic lupus erythematosus]), by heparin or other drugs (e.g., diuretics, quinidine, sulfa-drugs) or mechanically (Disseminated Intra-vascular Coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), prosthetic materials).
- *Redistribution*: Splenic sequestration (with spleen enlargement) is the cause of platelet redistribution.

## Diagnostic Principles

There are common diagnostic principles for all monocytopenias. First, a detailed medical history (drug therapies) and second, a complete physical examination (spleen enlargement, occult neoplasm, immunologic disease) are

mandatory information to elucidate (a) the causes and (b) the consequences of the monocytopenias (Fig. 2).

## Therapeutic Principles

There are no general therapeutic principles for monocytopenias. The treatment required is the treatment (whenever possible) of the underlying disease responsible for the monocytopenia, and the immediate treatment of the consequences of the monocytopenia (e.g., septic shock, deep hemorrhage) before its final and definitive correction.

# Mononucleosis, Infectious

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Kissing disease; Pfeiffer´sches Drüsenfieber

## Definition and Characteristics

Prodromal symptoms, which may last for 1–2 weeks, include malaise, fatigue, headache, arthralgia, and myalgia. The classic symptoms of infectious mononucleosis are fever, sore throat, and lymphadenopathy [1]. The pharynx is usually diffusely inflamed. There is often marked tonsillar enlargement with thick tonsillar exudates. Palatal petechiae may be present [2]. Lymphadenopathy occurs most commonly in the anterior and posterior cervical lymph nodes, but generalized lymphadenopathy may be observed [1]. Splenomegaly and hepatomegaly occurs in approximately 50% and 10% of cases, respectively [3]. The rash is usually maculopapular and occurs in approximately in 10–15% of cases [1]. Between 80% and 90% of patients, who are treated with antibiotics containing ampicillin or amoxicillin experience a pruritic maculopapular rash [1].

## Prevalence

The disease most commonly affects young adults aged 15–35 years, with a peak at 15–19 years [1]. The overall incidence is approximately 12 per 1,000 university students per year [4].

## Molecular and Systemic Pathophysiology

Infectious mononucleosis is caused by the Epstein-Barr virus (EBV). The incubation period from the time of viral exposure to development of infectious mononucleosis is approximately 4–7 weeks [1]. The virus is transmitted primarily in saliva (hence its colloquial appellation, "the kissing disease"), and less commonly, by blood transfusion and sexual contact [4]. EBV infects B-lymphocytes binding to the cell surface protein CD21, the EBV receptor in B lymphocytes, resulting in a lymphoproliferative response and enlargement of lymphoid tissue. EBV-infected B lymphocytes trigger T-cell response which attempts to control the proliferation of infected B cells [1]. A higher concentration of EBV, which probably occurs in adolescents, increases the number of infected B cells. This magnifies the T-cell response and causes symptomatic infectious mononucleosis [1]. The disease course is associated with the presence of atypical lymphocytes in peripheral blood and internal lymphoid organs. The atypical lymphocytes seen in infectious mononucleosis are T lymphocytes of the CD8+subset, with a smaller contribution from CD4+cells [1]. The relative, as well as absolute, increase in CD8+lymphocytes results in a transient reversal of the normal 2:1 CD4+/CD8+(helper/suppressor) T-lymphocyte ratio [1] (Fig. 1).

## Diagnostic Principles

Peripheral blood leukocytosis is observed in most patients; lymphocytes make up at least 50% of the white

**Mononucleosis, Infectious. Figure 1** A 17-year-old girl with infectious mononucleosis. Note the whitish exudates in the tonsillar areas and the maculopapular rash on the face.

blood cell differential count. Atypical lymphocytes (also called Downey cells) are mature T lymphocytes that have been antigenically activated; they constitute at least 10% of the total leukocyte count. These atypical lymphocytes vary in size but tend to be larger overall and to have vacuolated basophilic cytoplasm; eccentrically placed, indented or folded nuclei; and an increased cytoplasmic/nuclear ratio. The classic test for infectious mononucleosis is the demonstration of heterophil antibodies (Paul-Bunnell test). These antibodies can agglutinate sheep and horse erythrocytes but not guinea pig kidney cells. This adsorption property distinguished this response from the heterophil response found in patients with serum sickness and rheumatic diseases and in some normal persons. A rapid slide (monospot) test, a qualitative test using the latex agglutination technique, is the most widely used method to detect the serum heterophil antibodies of infectious mononucleosis [1]. The test is unreliable in children younger than 4 years because of the incidence of false-negative results. When confirmation of the diagnosis is required in children younger than 4 years, serologic testing for antibodies to EBV is recommended [1]. Antibodies to viral capsid antigens (VCA-IgG and VCA-IgM) are useful in diagnosing patients who have highly suggestive clinical features but negative heterophil antibody test results [2].

## Therapeutic Principles

Treatment is mainly supportive. Patients should be advised to avoid contact sports or strenuous exercise for 2–3 weeks or while splenomegaly is still present [1].

# Monosaccharide (Glucose-Galactose and Fructose) Malabsorption

Eric Sibley
Division of Pediatric Gastroenterology, Stanford University School of Medicine, Stanford, CA, USA

## Synonyms

Monosaccharide transporter deficiency; Monosaccharide intolerance; Glucose-galactose intolerance; Fructose intolerance

## Definition and Characteristics

Glucose-galactose malabsorption is caused by an autosomal recessive intestinal transport defect that presents in the first weeks of life with symptoms of diarrhea, dehydration and failure to thrive while consuming breast milk or standard formulas. The clinical consequences are usually fatal unless glucose and galactose are removed from the diet.

Fructose malabsorption has been recognized as a less severe cause of gastrointestinal symptoms in children and adults. In children, drinking excessive amounts of juices high in fructose may result in nonspecific diarrhea and recurrent abdominal pain. In adults, fructose malabsorption has been associated with irritable bowel syndrome.

## Prevalence

Glucose-galactose malabsorption is an extremely rare clinical entity. Wright et al. reported knowledge of ~300 patients worldwide in 2003 [1].

While excessive consumption of fructose can result in symptoms of malabsorption, inherited disorders of fructose transport have not yet been reported.

## Genes

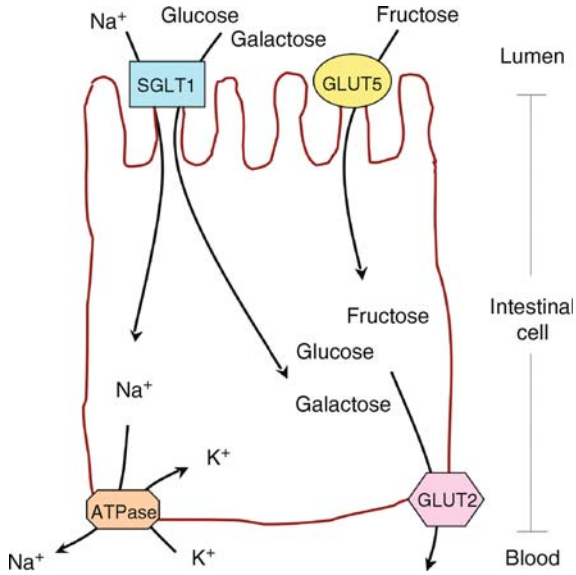
SLC5A1, solute carrier family 5 (sodium/glucose cotransporter), member 1, localized on chromosome 22q13.1 (also symbolized SGLT1).
SLC2A5, solute carrier family 2 (facilitated glucose/fructose transporter), member 5, localized on chromosome 1p36.2 (also symbolized GLUT5).

## Molecular and Systemic Pathophysiology

Monosaccharides (glucose, galactose and fructose) are the products of luminal and membrane-bound hydrolysis of starches and sugars in the small intestine. These monosaccharides are absorbed across the apical membrane of intestinal epithelial cells by facilitated transport mechanisms shown in Fig. 1.

The sodium/glucose cotransporter, SLC5A1 or SGLT1, is a 664 amino acid protein with twelve transmembrane spanning domains and is expressed on the apical surface of intestinal epithelial cells. The apical membrane absorption of glucose and galactose is carried out predominantly by a $Na^+$-dependent active transport mechanism in which each monosaccharide is transported along with two $Na^+$ molecules. Sodium molecules enter the enterocyte via an electrochemical gradient that is maintained by a $Na^+$, $K^+$-ATPase that pumps sodium molecules out the basolateral surface. By coupling transport to the sodium gradient, glucose and galactose molecules are able to be transported actively into the cell. Mutations of the SLC5A1 gene encoding a dysfunctional transporter result in malabsorption of glucose and galactose in the intestinal lumen

M



**Monosaccharide (Glucose-Galactose and Fructose) Malabsorption. Figure 1** Intestinal monosaccharide transport. Defects in the brush border apical membrane SGLT1 protein result in glucose-galactose malabsorption. Concentrations of luminal fructose exceeding the transport capacity of the GLUT5 protein can result in symptoms of fructose malabsorption.

and sequelae of osmotic diarrhea, hyperosmolar dehydration and metabolic acidosis [2,5].

Fructose is transported across the intestinal brush border membrane of intestinal epithelial cells via a $Na^+$-independent facilitated diffusion mechanism. SLC2A5 or GLUT5 is a 501 amino acid transmembrane protein that transports fructose and glucose molecules. Fructose is not as well absorbed as is glucose. Consequently, ingestion of high levels of fructose in the diet can lead to carbohydrate intolerance in the absence of a transporter defect [3,4].

### Diagnostic Principles

Diagnosis of glucose-galactose malabsorption relies on high clinical suspicion in infants with severe diarrhea in the neonatal period and resolution of symptoms upon removal of glucose and galactose from the diet. While DNA analysis has allowed for identification of multiple mutations of the SLC5A1 gene in patients with glucose–galactose malabsorption, genetic testing is not currently widely available or practical.

In patients with clinical suspicion of fructose malabsorption, symptoms resolve on a fructose free diet and return upon rechallenge. Breath hydrogen testing may aid in establishing a diagnosis of both glucose–galactose and fructose malabsorption.

### Therapeutic Principles

Treatment for glucose-galactose malabsorption consists of rehydration and initiation of a glucose- and galactose-free diet. Since fructose is tolerated, most of the carbohydrate initially can be given as fructose.

Treatment of fructose malabsorption consists of dietary restriction of fructose.

Department of Dermatology, University Hospital of Muenster, Muenster, Germany

M

### Synonyms

Reiter's syndrome; Reiter's triad; Reiter's disease; Maladie de Fissinger-Leroy-Reiter; Reactive arthritis; ReA

### Definition and Characteristics

Triad of acute nonpurulent seronegative arthritis, nongonococcal urethritis/cervicitis, and conjunctivitis/uveitis following enteric or urogenital infections. Cutaneous manifestations often resembling to those of psoriasis palmoplantaris are keratodermia blennorrhagica and circinate balanitis. Erythema or ulcers of oral mucosa can also be present. Reiter's disease represents one part of the clinical spectrum of reactive arthritis/ReA.

### Prevalence

Rare in patients <16 years, often men in their twenties or thirties, 60–85% of patients with ReA are positive for HLA-B27 [1]. The prevalence in different populations depends on genetic susceptibility factors, the rate of genitourinary or gastrointestinal infections and may reach 1:1,000 for ReA.

### Genes

Unknown. The role of HLA-B27 remains to be determined.

## Molecular and Systemic Pathophysiology

Several enteric pathogens, including Salmonella, Shigella, Yersinia, Campylobacter, Chlamydia species, and Clostridium difficile, are described as cause of initial intestinal infection. The process leading to a late synovial inflammation is still under investigation. Attempts to cultivate bacteria, such as yersiniae or salmonellae, from the affected joints usually failed. Although there are sequence similarities (molecular mimicry) between bacterial structures and the MHC class 1 allele HLA-B27, there is no direct proof that Reiter's disease is an autoimmune disease attributable to cross-reacting T-lymphocytes [2]. It is suggested that bacteria may invade joint tissue and that, after eradication of living bacteria, pathogenic components, such as LPS or certain protein antigens, may persist leading to induction of arthritis through a special cytotoxic T-cell response. The ability of different HLA-B27 subtypes to bind certain "arthritogenic" peptides and to present these antigens to CD8(+) T-cell is believed to play a pathological key role. Other studies suggest that HLA-B27 itself has an abnormal cell biology such as partial misfolding of its structure or unusual recognition by CD4(+) T-cell [3,4].

## Diagnostic Principles

The diagnosis is based on the special clinical findings and the evaluation of triggering events such as an episode of diarrhea or dysuria. Laboratory findings (HLA-B27, antibodies to Yersinia, Salmonella, or Chlamydia, seronegative-RF (rheumatic factors) and -ANA (antinuclear antibodies), urine analysis, and synovial fluid aspiration can be helpful. Radiographic changes of Reiter's arthritis are very similar to those of other spondyloarthropathies such as psoriatic arthritis. In early mild disease they may be absent.

## Therapeutic Principles

Currently, most patients with Reiter's disease are treated with nonsteroidal antiinflammatory drugs (NSAID), appropriate vocational counseling, and as the case may be physiotherapy. Those having an inadequate response to treatment with NSAID are treated with sulfasalazine, MTX, or other immunosuppressive agents such as azathioprine. Antibiotic therapy can be important for ReA with underlying urinary tract infection. Patients with ReA treated with infliximab – an anti-TNF-α agent – showed a good response in the acute phase of the disease [5].

### Synonyms

AMS; Puna soroche; Acosta's disease; Mareo

### Definition and Characteristics

AMS describes a collection of non-specific vegetative symptoms that include headache, anorexia, nausea, vomiting, fatigue, dizziness and insomnia experienced by non-acclimatized mountaineers within 6–12 h of arrival to altitudes above 2,500 m [1,2]. It is considered a primary disorder of the central nervous system since headache, indistinguishable from that encountered during migraine without aura, is the most common feature. AMS is generally benign though may progress to high-altitude cerebral edema (HACE) in more severe cases or during continued ascent when symptoms of AMS are present. HACE typically occurs above 4,000 m and leads, if left untreated, to death due to brain herniation [1]. Current opinion suggests that AMS is a self-limiting sub-clinical form of HACE and that both syndromes share a common pathophysiology [1].

### Prevalence

Complicated by differences in the clinical definition of AMS [2], individual susceptibility, rate of ascent and prior exposure have been identified as the major independent risk factors that determine prevalence [1–3]. In susceptible individuals exposed to 4,559 m, the prevalence of AMS was 7% assuming prior exposure and slow ascent, 29% with prior exposure only, 33% with slow ascent only and 58% following rapid ascent and no prior exposure. In non-susceptible individuals the corresponding prevalence was estimated at 4, 11, 16 and 31% respectively. The overall odds-risk-ratio for developing AMS in susceptible versus non-susceptible individuals was estimated to be 2.9 [3].

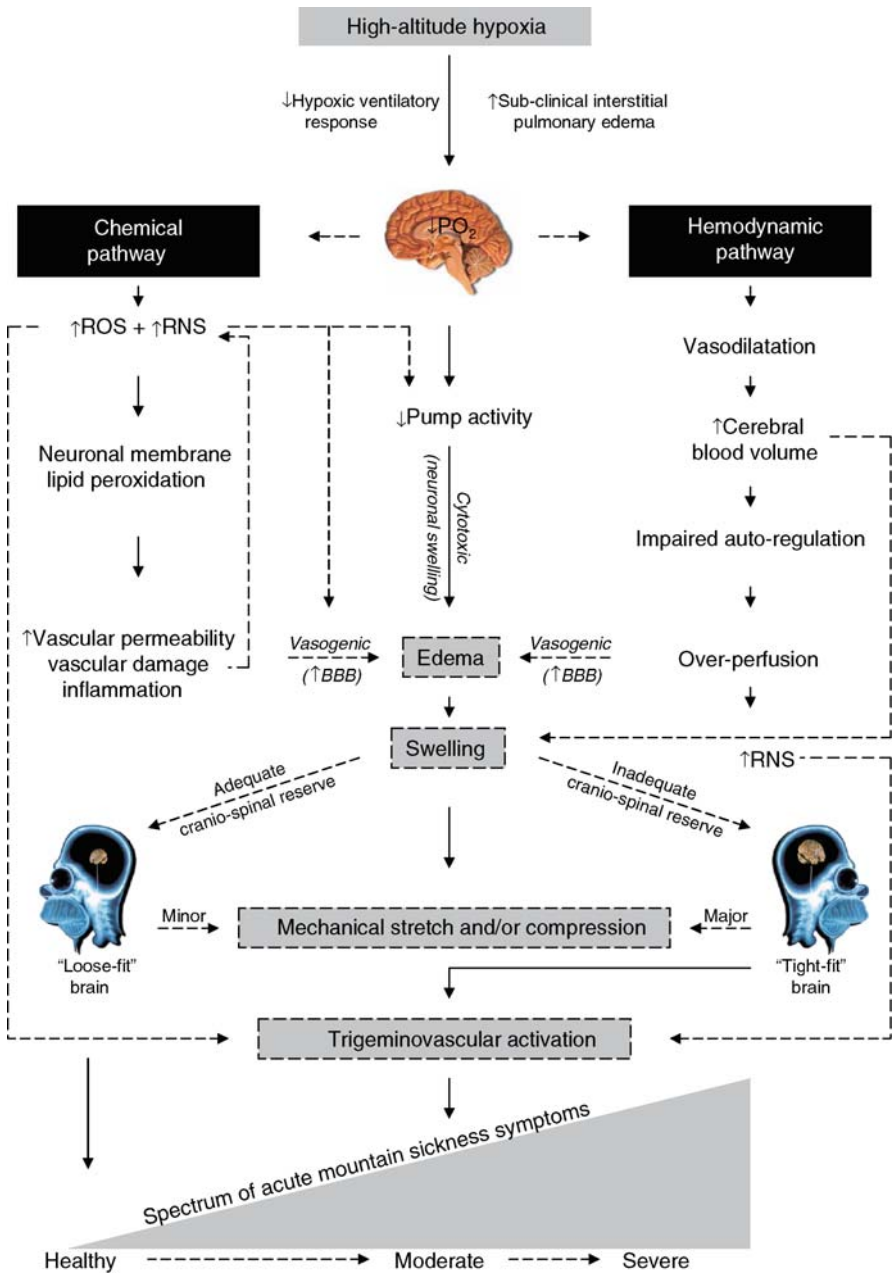
### Genes

Though a history of AMS correlates with the condition on subsequent ascents there is no clear evidence to date to suggest that the condition has a genetic basis. The three studies that have focused on two specific gene polymorphisms (ACE and HSP) have been largely inconclusive due to the limitations associated with small sample sizes. Gene identification that predicts AMS susceptibility, outcome or treatment response will no doubt prove complicated due to its high prevalence and phenotypic heterogeneity. Recent advances in the field of common migraine, especially the linkage reported on chromosome 5q21 associated with pulsating headache may provide some useful genetic molecular clues to AMS.

### Molecular and Systemic Pathophysiology

Figure 1 represents a hypothetical scheme describing how cerebral hypoxia activates the major pathways responsible for the development of AMS. The decrease in cerebral $PO_2$ can be further compounded by a blunted hypoxic ventilatory response and/or the presence of sub-clinical interstitial pulmonary edema. The scheme describes how chemical and hemodynamic stimuli act in concert to cause edema and brain swelling. The resultant mechanical perturbation to the brain ultimately leads to activation of the trigeminovascular system which is considered the primary trigger for headache and thus by consequence, AMS. Though these pathways are probably inter-linked, emerging evidence suggests that there may be subtle differences in the mechanisms that cause edema and brain swelling. The hemodynamic pathway favors the formation of extracellular vasogenic edema since hypoxia can result in cerebral over-perfusion subsequent to sustained vasodilatation and autoregulatory breakthrough to cause a transient opening of the blood-brain barrier [1]. However, barrier dysfunction could not be confirmed in a recent study [4] and, contrary to the vasogenic hypothesis, provided clear evidence for intracellular cytotoxic edema confined to the corpus callosum and basal ganglia [5], areas that are especially rich in redox-reactive catalytic iron. Since the human brain is so exquisitely sensitive to damaging redox reactions, the

chemical pathway was advanced to reconcile these findings [2]. It describes how a self-perpetuating cascade of iron-catalyzed reactive oxygen and nitrogen species (ROS/RNS) can result in membrane destabilization leading to increased permeability, vascular damage and inflammation. Pump failure subsequent to hypoxia and/or a free radical-mediated reduction in the expression and/or activity of Na/K-ATPase may prove the mechanism responsible for the neuronal cell swelling and cytotoxic edema recently observed [5]. The direct molecular detection of free radicals in AMS and protective benefits conferred by antioxidant prophylaxis add preliminary support for the chemical pathway [2]. Recent evidence identified that subjects with AMS were characterized by a "tight-fit" brain [1] since the ratio of brain volume to intracranial volume ratio was consistently higher than that observed in healthy controls [5]. This suggests that an individual's inability to compensate for brain swelling through displacement of cerebrospinal fluid (cranio-spinal capacitance or reserve volume) may



**Mountain Sickness, Acute. Figure 1** Schematic overview of the major hypothetical pathways implicated in the pathophysiology of AMS.

prove an additional risk factor. However, the morphological changes that occur in AMS are relatively minor thus questioning the functional significance of brain swelling and inadequate reserve volume [2]. Furthermore, since both pathways can independently generate nitric oxide which has been shown to stimulate the trigeminovascular system, it is equally conceivable that redox-priming of the meninges and pial vessels can occur independently of altered brain morphology.

## Diagnostic Principles

Headache is the cardinal symptom of AMS and is associated with, if not the primary trigger for anorexia, nausea, vomiting, fatigue, dizziness and insomnia. There are no diagnostic physical findings in benign AMS although the onset of ataxia and altered consciousness signal clinical progression to HACE [1]. The Lake Louise (LL) and Environmental Symptoms Questionnaire Cerebral (ESQ-C) scoring systems are the subjective tools most commonly employed to rate AMS. A LL score of ≥5 points and ESQ-C score of ≥0.7 points in the presence of headache and following a recent gain in altitude signals the presence of clinically significant AMS [2].

## Therapeutic Principles

AMS can be prevented by gradual ascent thus ensuring adequate time for acclimatization. Analgesics for the symptomatic relief of headache and day of rest are recommended for mild to moderate AMS. If no improvement is observed, the individual should descend. Severe AMS can be managed through immediate descent or the administration of low-flow oxygen (1–2 L/min). If descent and oxygen are unavailable, dexamethasone (4 mg every 6 h) is advised. Acetazolamide (250 mg twice daily) might be considered for mild to moderate AMS in a setting where further ascents must be made as a mixed therapeutic and prophylactic intervention. Prophylaxis is recommended in individuals with a history of AMS when slow ascent is not possible or for those with unknown susceptibility who plan to ascend above 3,000 m to 4,000 m (sleeping altitude) within 1–2 days.

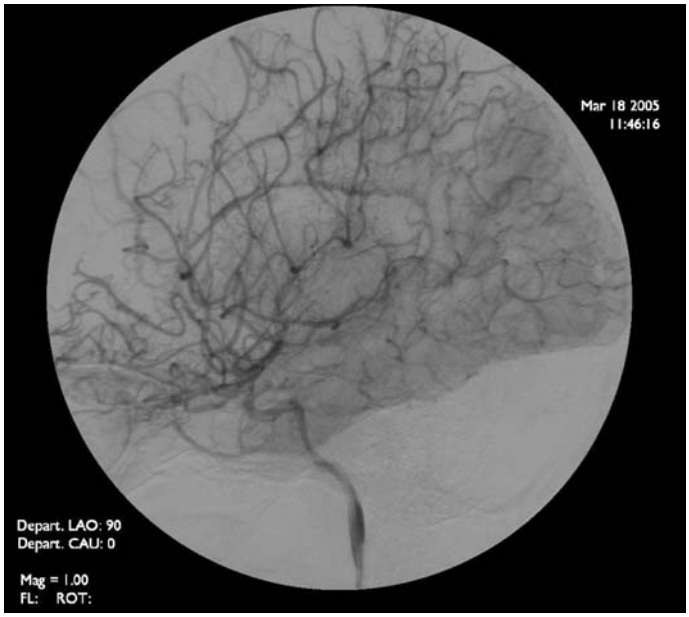
# Moyamoya Disease

Alexander K. C. Leung[1],
Alexander A. C. Leung[2], Justine H. S. Fong[3]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Department of Medicine, The University of Alberta, Edmonton, AB, Canada
[3]Asian Medical Centre, The University of Calgary Medical Clinic, Calgary, AB, Canada

## Definition and Characteristics

Moyamoya disease is a chronic, non-atherosclerotic, non-inflammatory, occlusive intracranial vasculopathy of unknown etiology. It is characterized by progressive stenosis or occlusion of the terminal portions of the internal carotid artery, often with involvement of the circle of Willis, accompanied by the formation of extensive collateral vessels ("moyamoya" vessels) at the base of the brain (Fig. 1) [1].

The disease is bilateral in 80% of cases. Moyamoya disease has a bimodal age distribution with a higher peak around the age of 5 years and a lower peak at 30–40 years of age. Children typically present with recurrent transient ischemic attacks or ischemic infarctions which are often precipitated by hyperventilation, crying or blowing. Clinical manifestations include headaches, monoparesis/hemiparesis, sensory deficit, or dysphasia [1]. Mental retardation and epileptic seizures may also occur [1]. Adults, on the other hand, typically present with intracranial hemorrhage, manifesting as disturbance of consciousness and/or hemiparesis. The bleeding is mostly intraventricular or intracerebral, and not subarachnoid [1]. Cerebral aneurysms are found in 10% of cases [1]. Moyamoya vasculopathy can be idiopathic or can be found in association with a variety of conditions such as neurocutaneous syndromes, Down syndrome, sickle cell anemia, and Graves' disease.



**Moyamoya Disease. Figure 1** Cerebral angiogram showing occlusion of the right middle cerebral artery and prominent collateral vessels giving rise to a "puff-of-smoke" appearance in the region of the right basal ganglia.

## Prevalence

The overall incidence in Japan is 0.35 per 100,000 population [2]. The male to female ratio is 1:1.8 [2]. Approximately 10% of cases are familial. In Europe, the incidence is one tenth of that in Japan.

## Genes

Linkage analyses show that the loci for familial moyamoya disease reside on 3p24.2–p26, 6q25, 8q23, 12p12 and 17q25 [3]. The concordance rate for monozygotic twins is 90%. Pedigree analysis of highly aggregated Japanese families with moyamoya disease indicates that the disease is inherited as an autosomal dominant trait with incomplete penetrance [3]. There is a possible association between mutations of the TIMP2, TIMP4 and TGIF genes in 17q25, 3p25 and 18p11.3, respectively and moyamoya disease [4].

## Molecular and Systemic Pathophysiology

Fibrocellular intimal thickening due to smooth muscle cell proliferation and migration as well as increased elastin accumulation result in stenosis of the cerebral arteries [1,5]. It has been suggested that nitric oxide, basic fibroblast growth factor, platelet-derived growth factor, vascular endothelial growth factor, transforming growth factor β-1, hepatocyte growth factor, $\alpha_1$-antitrypsin, cellular retinoic-acid binding protein-1, and elastase, either alone or combination, promote the proliferation of smooth muscle cells and their migration from the media to the intima [1,5].

## Diagnostic Principles

The diagnosis is based on the clinical presentation and the characteristic findings on angiography or magnetic resonance angiography. Characteristic angiographic findings include stenosis or occlusion of the terminal portion of the internal carotid artery and the smoky appearance of collateral vascularization. Magnetic resonance angiography is less invasive as it does not require intravenous contrast medium. It can also delineate the intracranial vasculature more precisely and is now the procedure of choice. Computed tomography may reveal cerebral cortical atrophy, infarcts and intracranial hemorrhage.

## Therapeutic Principles

Treatment is mainly symptomatic. Anti-platelet agents such as acetylsalicylic acid and vasodilators such as calcium channel blockers have been used with variable results. Good results have been reported with surgical revascularization of the brain.

### Definition and Characteristics

Mucopolysaccharidoses (MPS) are lysosomal storage disorders caused by deficiency of lysosomal enzymes that are responsible for the stepwise degradation of glycosaminoglycans. There are 11 known enzyme deficiencies that give rise to 7 distinct MPS types. Each of the types is characterized by a considerable clinical variability, regarding both the age of onset of symptoms and severity of organ manifestation [1].

The phenotypic spectrum of MPS I (deficiency of α-Iduronidase) ranges from the early-onset, severe form (Hurler syndrome) to the more attenuated (adult) form (Scheie syndrome). Hurler syndrome is often seen as the prototype of a mucopolysaccharidosis: The affected patients appear normal at birth, first clinical signs that include hernias, thoracic kyphosis and large head, are seen between 6 and 24 months of age. Subsequently, coarsening of the facial features, large tongue, recurrent infections, increased liver and spleen size and developmental delay are becoming noticed. Severe skeletal dysplasia, called dysostostis multiplex, leads to disproportionate dwarfism. Patients die before the age of 10 years from severe infections of the respiratory tract or from therapy-resistant cardiomyopathy. In patients with Scheie syndrome joint contractures, corneal clouding and carpal tunnel syndrome are the leading symptoms. In addition, affected individuals may suffer from heart failure due to insufficiency of heart valves. Compression of the spinal cord at the cranio-cervical region represents a complication very common in Scheie syndrome that needs neurosurgical intervention in order to prevent paraplegia. A condition that shows a clinical phenotype intermediate between Scheie and Hurler syndrome has been designated as Hurler/Scheie syndrome. Hunter syndrome (MPS II) has many features in common with MPS I such as hernia, recurrent infections, skeletal dysplasia, coarse face features and mental retardation. However, in contrast to all other mucopolysaccharidoses that follow the autosomal-recessive mode of heredity, MPS II is inherited in an X-linked recessive manner.

Further prominent signs in affected boys include joint contractures, hearing impairment and skin changes that are characterized by pale, pebbly nodules that extend to the shoulders, upper arms and thighs. Patients with the more attenuated (adult) form have a normal intelligence, but often get blind in their later life due to retinal degeneration. The genetic defects of four different enzymes that are required for the degradation of heparan sulfate, lead to the different forms of Sanfilippo syndrome (MPS III A,B,C,D). Sanfilippo syndrome is characterized by its major involvement of the central nervous system whereas there are only mild, if at all, somatic signs of a mucopolysaccharidosis. First symptoms in all forms of MPS III are recurrent middle ear infections, causing hearing impairment. Later on, the delay in speech development becomes evident. At the age of 6–8 years, affected children loose their ability to speak and become aggressive and hyperactive. Sleep disturbances are very common in MPS III. Severe neurological degeneration occurs in most patients by 8–10 years of age, accompanied by rapid deterioration of social and adaptive skills. In MPS IV (Morquio syndrome) skeletal changes are the most remarkable signs that lead to disproportionate dwarfism. In most cases, the height of adults does not exceed 110 cm. Mental development is always normal. Patients affected by MPS VI (Maroteaux-Lamy syndrome) resemble MPS I patients in many aspects, however, they are always of normal intelligence. MPS VII shows a very broad phenotypic spectrum, ranging from non-viable fetal hydrops to almost healthy patients

**Mucopolysaccharidoses. Table 1** Classification of the mucopolysaccharidoses

| Mucopolysaccharidosis | Enzyme-defect | Clinical signs | Gene | Prevalence[a] |
|---|---|---|---|---|
| MPS I (Hurler, Scheie) | α-Iduronidase | Disproportionate dwarfism, coarse facial features, hepatosplenomegaly, often mental deterioration | 4p16.3 | 0.71–1.6 |
| MPS II (Hunter) | Iduronate Sulfatase | Disproportionate dwarfism, coarse facial features, hepatosplenomegaly, joint contractures, often mental deterioration | Xq28 | 0.3 (0.6[a])–0.6 (1.3[b]) |
| MPS IIIA (Sanfilippo A) | Heparan N-Sulfatase | Profound mental deterioration, hyperactivity, relatively mild somatic manifestations | 17q25.3 | All types of MPS III:0.36–1.89 |
| MPS IIIB (Sanfilippo B) | N-Azetylglucosaminidase | Profound mental deterioration, hyperactivity, relatively mild somatic manifestations | 17q21 | |
| MPS IIIC (Sanfilippo C) | Acetyl-CoA Transferase | Profound mental deterioration, hyperactivity, relatively mild somatic manifestations | 8p11.1 | |
| MPS IIID (Sanfilippo D) | N-Acetylglucosamine-6-sulfatase | Profound mental deterioration, hyperactivity, relatively mild somatic manifestations | 12q14 | |
| MPS IVA (Morquio A) | N-Acetylgalactosamine-6-sulfatase | Severe skeletal deformities leading to disproportionate dwarfism, stenosis at the cranio-cervical junction, hearing impairrment, normal intelligence | 16q24.3 | 0.16–0.3 |
| MPS IVB (Morquio B) | β-Galactosidase | Skeletal deformities leading to disproportionate dwarfism, stenosis at the cranio-cervical junction, involvement of the heart valves, normal intelligence | 3p21.33 | Not known (very rare) |
| MPS VI (Maroteaux-Lamy) | N-Acetylgalactosamine-4-sulfatase (=Arylsulfatase B) | Disproportionate dwarfism, coarse facial features, hepatosplenomegaly, heart involvement, normal intelligence | 5q13 | 0.15–0.3 |
| MPS VII | β-Glucuronidase | Broad phenotypic spectrum, ranging from hydrops fetalis to almost healthy subjects | 7q21 | 0.05–0.24 |
| MPS IX | Hyaluronidase | Periarticular soft-tissue masses, short stature | 3p21.3 | Only one case described |

[a]Prevalence rate (given as cases per 100,000 births) is reviewed from the literature.
[b]Based on male live births.

subjects whose only complaint is hip pain. Only one case of MPS IX (hyluronidase deficiency) has been described, main clinical symptoms in the affected girl were multiple periarticular soft-tissue masses in ankle, finger and knee [2].

## Prevalence

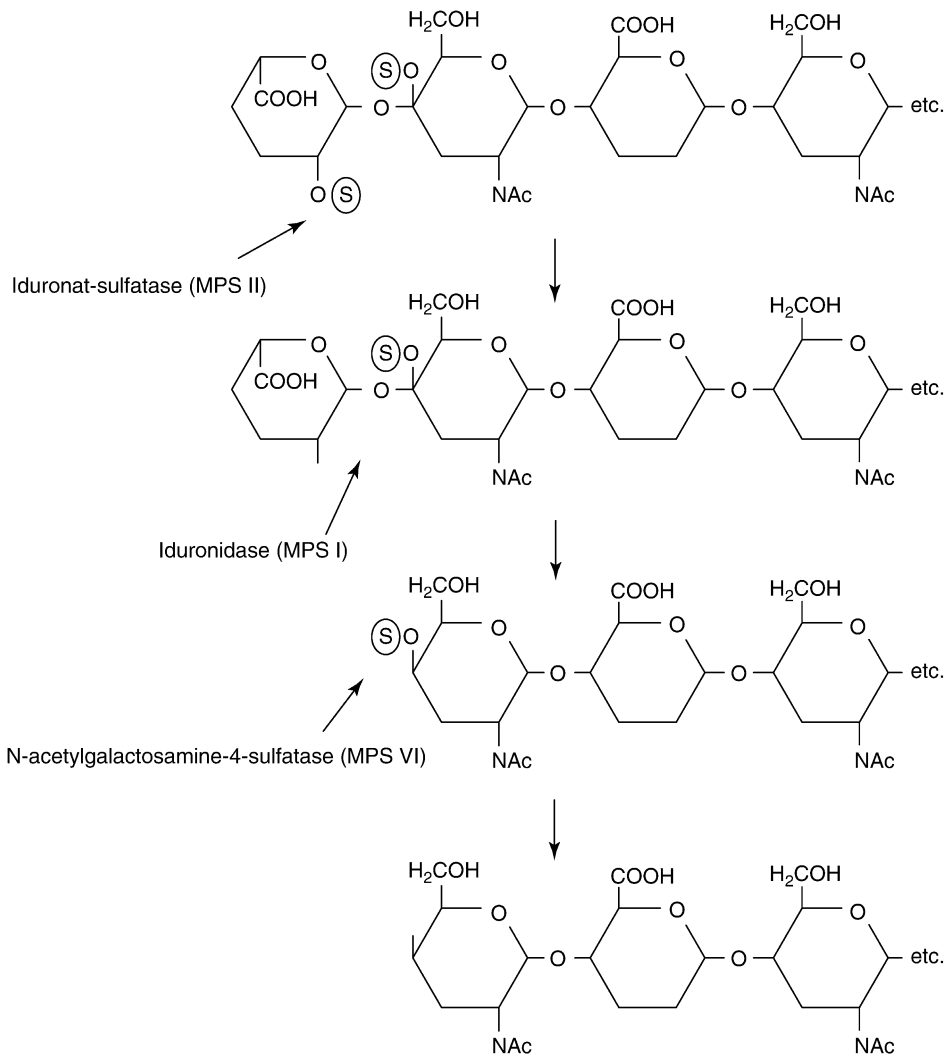
Mucopolysaccharidoses are found in all ethnic groups; however, there are population differences in the frequency of particular mucopolysaccharidoses. For instance, MPS II is more common in Israel, and MPS IV is often observed in Northern Ireland. MPS IIIB is the most prevalent MPS in Greece, and MPS IIIA in England. Table 1 shows the crude cumulative incidence rate (CIR) as reviewed from the literature [3].

## Genes

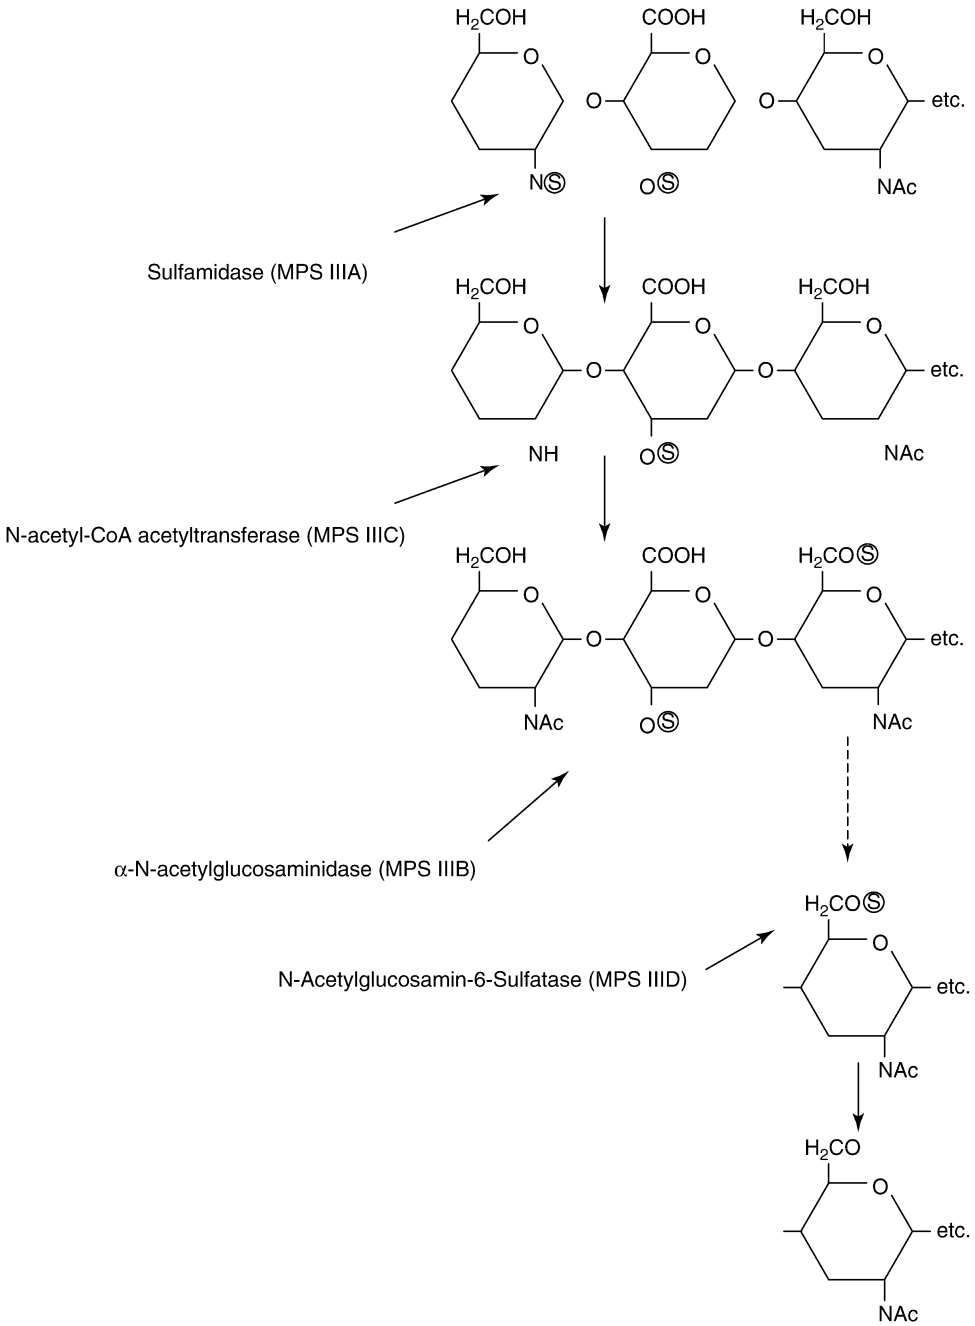
Mucopolysaccharidoses are inherited in an autosomal-recessive manner, except for MPS II (Hunter's syndrome), which is an X-linked disorder. The gene loci for all mucopolysaccharidoses have been identified (see Table 1). There are numerous mutations that have been detected in any one MPS, however, in specific populations a few mutant alleles may predominate. Whereas most are point mutations or small changes in the gene, major rearrangements and large deletions have been found in MPS II. There is some correlation of the phenotypic expression with genotype; however, it is difficult to predict disease severity in individual cases.

## Molecular and Systemic Pathophysiology

Glycosaminoglycans (GAGs) consist of repeating disaccharide units, which are composed of a hexuronic acid (iduronic or glucuronic acid) and an amino sugar (N-acetylglucosamine or N-acetylgalactosamine). In keratan sulfate, hexuronic acid is replaced by galactose. At different position, the GAGs contain sulfate groups (Figs. 1 and 2).



**Mucopolysaccharidoses. Figure 1** Stepwise degradation of dermatan sulfate.



**Mucopolysaccharidoses. Figure 2** Stepwise degradation of heparan sulfate.

For stepwise degradation there are required four exoglycosidases, five sulfatases and one transferase. If one of these lysosomal enzymes is deficient, GAGs remain undegraded resulting in cell, tissue and organ dysfunction. The clinical phenotype depends on the GAG that is accumulating: For instance, if heparan sulfate, an important component of nerve cells, is not catabolized, there will clinical manifestations predominantly of the central nervous system as in MPS III (Sanfilippo syndrome). Accumulation of keratan sulfate, an essential component of cartilage, leads to skeletal changes as in MPS IV (Morquio syndrome).

## Diagnostic Principles

MPS patients excrete undegraded GAGs. Therefore, as the first diagnostic procedure, the urine should be

analyzed for increased excretion of GAGs. For definitive diagnosis, enzyme assays have to be performed in serum, leukocytes or fibroblasts. In MPS II, mutation analysis is mandatory, in order to determine the carrier status of the mother and of further female relatives of the mother. Prenatal diagnosis is possible in all MPS by using biochemical or genetic techniques.

### Therapeutic Principles

The management of MPS is primarily palliative and directed at disease-specific complications. Although those supportive measures may lead to significant improvement in quality of life, the systemic disease course is progressive and in most cases leads to substantial shortening of lifespan. Bone marrow transplantation is generally recommended only for MPS I (Hurler disease) [4]. Enzyme replacement therapy is available now for MPS I, II and VI [5]. This therapeutic regimen can improve the clinical course, but cannot cure the disease.

## Mucosulfatidosis

►Multiple Sulfatase Deficiency

## Mucous Candidiasis

►Candidiasis, Mucous, Cutaneous and Systemic

## Mucous Membrane Pemphigoid

Silke Hofmann, Leena Bruckner-Tuderman
Department of Dermatology, University Medical Center, Freiburg, Germany

### Synonyms

Cicatricial pemphigoid; Ocular cicatricial pemphigoid; Scarring pemphigoid; Desquamative gingivitis; MMP

### Definition and Characteristics

Mucous membrane pemphigoid (MMP) is a chronic autoimmune subepithelial blistering disorder. Immunopathologic findings consist of tissue-bound and – to a lesser extent – circulating autoantibodies to a distinct basement membrane proteins, such as collagen XVII/BP180 or laminin-5. Clinical hallmarks are erosive or vesiculobullous lesions of mucous membranes often resulting in scarring and functional impairment [1].

### Prevalence

Not known. The annual incidence is estimated to be $1 \times 10^{-6}$.

### Genes

HLA class II alleles DQB1* 0301 have been reported to be overexpressed in MMP patients.

### Molecular and Systemic Pathophysiology

Autoantibodies of MMP patients recognize epitopes within the anchoring filament zone. Located extracellularly below the hemidesmosomal plaque, anchoring filaments (laminin-5 and the ectodomain of collagen XVII) maintain dermoepidermal adhesion (see Fig. 1, ►Bullous pemphigoid). The major antigenic regions in MMP are located on the C-terminus of collagen XVII [2]. Since the collagen XVII C-terminus extends into the lamina densa, antibodies against these regions may account for the scarring phenotype of this disease. In a subgroup of MMP patients' autoantibody reactivity against laminin-5 has been reported and in vivo studies provided convincing evidence that these antibodies induce blistering independent of complement activation [3]. Although the etiology has remained obscure, patients with anti-laminin-5 MMP appear to have an increased relative risk for malignancies. MMP patients with predominant ocular disease mostly have autoantibodies against the β4 subunit of the hemidesmosomal α6β4-integrin.

### Diagnostic Principles

Subepidermal blister formation in histology and linear IgG, IgA, and/or C3 deposits at the dermoepidermal junction in direct immunofluorescence are required for diagnosis. Circulating autoantibodies may bind to the epidermal or dermal side of saline-separated human skin. Immunoblotting with native proteins from keratinocyte extracts or ELISA using recombinant proteins allow to specify the target autoantigen.

### Therapeutic Principles

MMP is treated by topical and systemic corticosteroids in combination with dapsone, azathioprine, cyclophosphamide, intravenous immunoglobulins, immunoadsorption or rituximab. Surgery may be required for severe scarring in patients with well-controlled disease.

## Mucoviscidosis

►Cystic Fibrosis

## Muir-Torre Syndrome

Dieter Metze
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Cutaneous sebaceous neoplasms and keratoacanthomas; (multiple, with gastrointestinal and other carcinomas)

### Definition and Characteristics

Muir-Torre syndrome is an autosomal dominant disorder characterized by the association of sebaceous neoplasms of the skin, with or without keratoacanthomas, with one or more low-grade visceral malignancies in the absence of other predisposing factors [1].

Sebaceous neoplasms appear before the internal malignancy, concurrently, and after. Both sebaceous and visceral cancers are often multiple and usually indolent, less aggressive than their counterparts unassociated with this syndrome, and permit prolonged survival. Gastrointestinal cancers are the most common internal malignancies, followed by endometrial, ovarial, urologic, laryngeal, breast, and other carcinomas [1,2]. Sebaceous tumors are difficult to classify and include sebaceous adenoma, sebaceoma, sebaceous carcinoma, and superficial epithelioma with sebaceous differentiation.

### Prevalence

The disorder is rare.

### Genes

Muir-Torre syndrome is part of the hereditary nonpolyposis colorectal cancer (Lynch cancer family syndrome), which has been related to mutations in the MSH2 gene located on 2p22-p21. Mutations in the MLH1 gene, located on 3p21.3, also cause the syndrome [3].

### Molecular and Systemic Pathophysiology

In Muir-Torre syndrome, the majority of germ line mutations identified have been in DNA mismatch repair gene MSH2. Microsatellite instability in tumor tissue develops after somatic inactivation of the corresponding second mismatch repair allele (second hit) [4].

### Diagnostic Principles

Sebaceous neoplasms on the skin always should raise the suspicion of Muir-Torre syndrome, in particular when they develop in young patients, when they are multiple, or show kerathoacanthoma-like or cystic aspects by histology. Screening for microsatellite instability in sebaceous gland neoplasias can be of value in the detection of an inherited DNA mismatch repair defect [5].

### Therapeutic Principles

Pharmacological treatment includes retinoids and interferon, tumors are removed by surgery.

# Mulibrey Nanism

Riikka H. Hämäläinen[1], Anna-Elina Lehesjoki[1], Marita Lipsanen-Nyman[2]
[1]Folkhälsan Institute of Genetics and Neuroscience Center, University of Helsinki, Helsinki, Finland
[2]The Hospital for Children and Adolescents, University of Helsinki, Helsinki, Finland

## Synonyms

Muscle-liver-brain-eye nanism; Perheentupa syndrome

## Definition and Characteristics

Mulibrey nanism is a rare inherited growth disorder characterized by prenatal onset growth restriction, constitutional gracility and typical craniofacial features including high and broad forehead and low nasal bridge [1]. Other typical features include J-shaped sella turcica, yellowish dots in the ocular fundi, cutaneuos naevi flammei, fibrous dysplasia of long bones and hepatomegaly. A restrictive perimyocardial heart disease constituting of constrictive pericarditis and variable myocardial hypertrophy and fibrosis is the most serious element of mulibrey nanism [2]. The psychomotor development of the patients is mainly normal but mild hypotonicity is evident in half of the infants. Feeding difficulties, pneumonias and recurrent respiratory infections are the most common problems during infancy and the risk of Wilm's tumor is increased [1]. Female patients with mulibrey nanism are infertile and present failure of sexual maturation, premature ovarian failure and a very high risk of developing ovarian tumors of the fibroma-thecoma group. In addition, most patients develop severe insulin resistance and metabolic syndrome already at young age.

## Prevalence

Mulibrey nanism is an extremely rare disorder with only ~130 cases reported around the world. Most of the cases (90) are from Finland where mulibrey nanism is enriched due to a founder effect.

## Genes

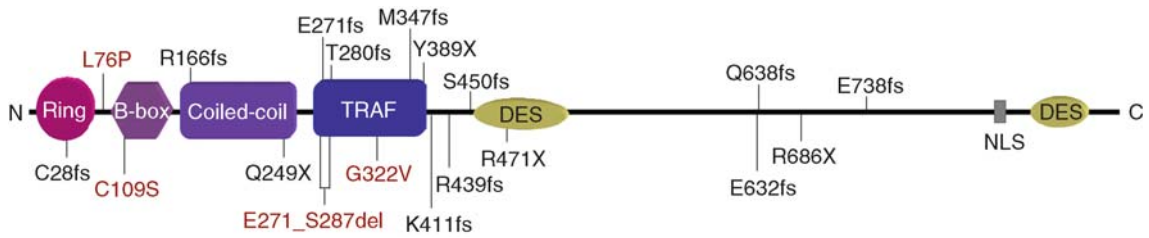
Mutations in the TRIM37 gene underlie mulibrey nanism [3]. To date 19 different mutations are known (Fig. 1). Fifteen mutations result in premature termination codons and most likely lead to degradation of mutated mRNA through nonsense-mediated decay. The four non-truncating mutations lead to either diminished ubiquitin ligase activity or incorrect subcellular localization of the mutant TRIM37 proteins. Thus, all known mutations seem to result in loss-of-function alleles. While the Finnish founder mutation is present in all Finnish patients and in 98% of all disease-associated chromosomes in Finland [3], the other mutations are present only in one or two families. No phenotype-genotype correlation can be seen in the patients.

## Molecular and Systemic Pathophysiology

The TRIM37 gene underlying mulibrey nanism encodes a member of the TRIpartite Motif (TRIM) protein family (Fig. 1). The normal physiological function of TRIM37, as well as the molecular pathways leading from TRIM37 dysfunction to the mulibrey nanism phenotype, are as yet unknown. However, like many other members of the TRIM protein family, also TRIM37 has RING domain dependent autoubiquitinating activity and seems to function as a ubiquitin E3 ligase, possibly mediating ubiquitin dependent proteasomal protein degradation [4]. Thus, accumulation of yet unknown substrate proteins may contribute to the pathogenesis of mulibrey nanism. Further, in some cell types the TRIM37 protein localizes at least partially into peroxisomes, classifying mulibrey nanism as a peroxisomal disorder [5]. Thus, impaired peroxisome metabolism may also play a role in the pathophysiology of mulibrey nanism. Interestingly, mulibrey nanism shares several features with other peroxisomal disorders, although the symptoms are much less severe in mulibrey nanism than in peroxisomal disorders in general.

## Diagnostic Principles

Diagnosis should be considered in infants born small for gestational age with progressive growth failure and poor weight gain through infancy and who present



**Mulibrey Nanism. Figure 1** A schematic presentation of the TRIM37 protein structure showing the positions of the 19 mulibrey nanism-associated mutations. The two zinc-binding domains, a RING-finger and a B-box, together with the coiled-coil domain form the TRIpartite Motif. In TRIM37, the N-terminal TRIM domain is followed by an internal TRAF (TNF-Receptor Associated Factor) domain. In addition two DES (aspartate-glutamate-serine) rich regions and a nuclear localization signal (NLS) are present. The mutations predicting premature termination codons are denoted with black and the non-truncating mutations with red letters.

hepatomegaly and characteristic craniofacial features. The major diagnostic signs are growth failure, characteristic radiological findings (slender long bones with thick cortex and narrow medullar channels or J-shaped sella turcica), characteristic craniofacial features (scaphocephaly, triangular face, high and broad forehead, low nasal bridge) and characteristic ocular findings (yellowish dots in retinal mid peripheral region). Minor diagnostic signs include peculiar high-pitched voice, hepatomegaly, cutaneous naevi flammei and fibrous dysplasia of long bones. For the diagnosis three major signs or two major signs with three minor signs are needed [1]. Detection of mutations in the TRIM37 gene confirms the diagnosis.

### Therapeutic Principles

During infancy, early recognition and management of feeding and respiratory problems or heart involvement are of major importance [1]. In most patients pericardiectomy relieves the symptoms and signs of congestive heart failure [2]. Growth hormone treatment induces a good short-term but only a modest long-term growth effect. From adolescence, the glucose metabolism should be observed and postpubertal females need a regular gynecological follow-up.

## Synonyms

Polyglandular failure; MEA; Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; APECED syndrome

## Definition and Characteristics

In the pediatric patient, polyglandular failure usually presents after the first 2 years of life along with other autoimmune diseases in the form of two polyglandular autoimmune syndromes: multiple endocrine abnormalities types-1 and -2 (MEA-1 and MEA-2) (Table 1) [1].

In the most comprehensive series of patients with autoimmune Addison disease ever published, 295 patients were analyzed [2]. Addison disease occurred in the context of MEA-1 in association with chronic mucocutaneous candidiasis and/or acquired hypoparathyroidism and the age of onset was predominantly in childhood or in the early adult years. MEA-1 was also frequently associated with chronic active hepatitis, malabsorption, juvenile onset pernicious anemia, alopecia and primary hypogonadism, whereas insulin-dependent diabetes and/or autoimmune thyroid disease were infrequent. Addison disease in the context of MEA-2 was associated with insulin-dependent diabetes and/or autoimmune thyroid disease, had a later but variable age of onset, and it occurred predominately in females. The association of HLA-B8, -DR3 and -DR4 with MEA-2, but not with MEA-1, further confirmed the different clinical and genetic nature of these two syndromes, which account for almost all pediatric and approximately 50% of adult cases of autoimmune Addison disease.

## Prevalence

MEA-1 (APECED) is a rare autosomal recessive disorder [2]. APECED is more common in certain genetically isolated populations. In Finland, the incidence has been estimated to be 1:25,000 and in Iranian Jews 1:9,000 [2]. APECED is also relatively common among Sardinians (1:14400) and in Northern Italy [2,3].

## Genes

Based on linkage analysis in Finnish APECED families, the locus for APECED gene was mapped to chromosome 21q22.3. Recently, the gene responsible for this disease was cloned [3]: it is a novel gene

**Multiple Endocrine Abnormalities. Table 1** Clinical manifestations of the MEA-1 and -2 syndromes (with prevalence in %)

| Disorder | MEA-1 | MEA-2 |
|---|---|---|
| Hypoparathyroidism | 89% | Not present |

| Hepatitis | 9% | Not present |
| Myasthenia gravis, thrombocytopenia | Not known | ~1% and other autoimmune disorders |

encoding a predicted 545 amino acid protein, which was named AIRE (autoimmune regulator). It contains two plant homeodomain (PHD)-type zinc finger motifs and a newly described putative DNA-binding domain SAND, a proline rich region, and three LXXLL motifs, all suggestive of a transcription regulator. To date, several mutations in the AIRE gene have been described in APECED patients. A common Finnish mutation, R257X, was shown to be responsible for 82% of Finnish APECED cases. R257X is also a predominant Northern Italian APECED mutation [3,4] and, in addition, has been detected in other patients of diverse origin, because it occurs on different haplotypes with closely linked markers suggesting several independent mutational events [4]. Another common mutation, a deletion of 13 nucleotides (1094–1106del), has been detected in several patients of different ethnic origin and on different haplotypes [3,4]. Finally, another nonsense mutation, R139X, is the major mutation among Sardinian APECED patients [4], whereas another five described mutations have been described in individual kindreds.

## Molecular and Systemic Pathophysiology

AIRE is expressed in thymus, lymph node and fetal liver, tissues that have an important role in the maturation of immune system and development of immune tolerance. These findings together with the immunologic deficiency in APECED patients suggest that AIRE may participate in the control of immune recognition and may function as a transcription factor or as transcriptional coactivator.

APECED was the first autoimmune disease that was molecularly characterized (the familial Mediterranean fever gene was cloned at about the same time) and was found to be caused by a defect in a single gene. The protein product of AIRE gene not only has the features of a potent transcriptional regulator but it has also, in the meantime, been localized to nuclear body-like structures of cell nuclei, which appear to be involved in the regulation of transcription, oncogenesis and differentiation of cells [5]. Recently the mouse Aire gene was cloned and fully characterized, a development, which has lead to the development of a mouse APECED model.

APECED patients usually have at least two out of three main symptoms: Addison's disease, hypoparathyreoidism and chronic mucocutaneous candidiasis. Patients may also develop other organ specific autoimmune disorders leading to gonadal failure, pancreatic (β-cell) deficiency, gastric (parietal cells) dysfunction, hepatitis and thyroiditis. Other, less common, clinical manifestations include ectodermal dystrophy, affecting the dental enamel and nails, alopecia, vitiligo and corneal disease (keratopathy) [1,2]. MEA-1 usually occurs in early childhood but new, tissue-specific symptoms may appear throughout lifetime. Immunologically, the main finding in APECED patients is the presence of autoantibodies against the affected organs, including those against steroidogenic enzymes (P450scc, P450c17 and P450c21) in patients with Addison's disease, glutamic acid decarboxylase in patients with diabetes and the enzymes aromatic L-amino acid decarboxylase and P4501A2 in patients with liver disease.

Muco-cutaneous candidiasis, hypoparathyroidism and Addison disease usually present in this order in pediatric patients with APECED. As with the other manifestations of the syndrome, there is a wide variability of age of onset, from 6 months to 41 years with a peak around 13 years of age.

## Diagnostic Principles

Addison disease usually leads to the diagnosis of MEA-I; it develops in 60–100% of patients with APECED and may be preceded by months or years of detectable adrenal cortex autoantibodies.

In both MEA-1 and MEA-2, autoimmune destruction of the affected glands causes permanent damage (although low-level hormone production may be present for several years after the onset of disease). The screening of first-degree relatives of patients with familial hypoparathyroidism, diabetes, or thyroid disease is essential; recommendations vary from annual surveys to every 2–3 years.

## Therapeutic Principles

Treatment for patients with established failures is directed towards appropriate replacement of the missing hormones.

# Multiple Endocrine Neoplasia Type 1

Francesca Marini, Alberto Falchetti, Maria Luisa Brandi
Regional Center for Hereditary Endocrine Tumors, Department of Internal Medicine, University of Florence, Florence, Italy

## Synonyms

Wermer syndrome; MEN 1

## Definition and Characteristics

Multiple endocrine neoplasia type 1 (MEN1) [OMIM 131100] is a rare inherited autosomal dominant cancer syndrome characterized by the occurrence of primary tumors involving two or more endocrine tissues within a single patient. The classical clinical manifestation is the triad of tumors of parathyroids (95% of cases), pancreatic islets, gastrinomas and insulinomas, (30–80% of cases), and anterior pituitary (15–90% of cases). Other endocrine and nonendocrine neoplasms, as adrenocortical and thyroid tumors, visceral and cutaneous lipomas, meningiomas, facial angiofibromas and collagenomas, and thymic and bronchial carcinoids may also occur. The onset of the MEN1-associated primary hyperparathyroidism and the onset of MEN1-associated gastrinoma and insulinoma anticipate the onset of the corresponding sporadic counterparts of three and one decades, respectively. Endocrine tumors cause symptoms either due to overproduction of hormones, local mass effects and/or malignant progression of the neoplasms. The main cause of mortality is the malignant progression of pancreatic neuroendocrine tumors, duodenal gastrinomas, and thymic or bronchial carcinoids.

## Prevalence

MEN1 occurs in approximately 1 in 30,000 individuals with an equal sex distribution and no ethnic groups or racial predilection. It affects all age groups (age range 8–81), but the onset of the disease is rare before age 10. More than 95% of patients develop clinical manifestations by the fifth decade of life.

## Genes

The responsible gene, the tumor suppressor gene MEN1 (11q13), spans 10 Kb and consists of 10 exons encoding a 610 amino acid nuclear protein, named menin (Fig. 1a).

More than 400 independent germline or somatic mutations, distributed over the entire coding region, have been described. The vast majority (75%) of the MEN1 mutations is inactivating, and approximately 70% of all mutations predict premature truncation of the menin protein. About 10–20% of MEN1 patients may not harbor mutations within MEN1 coding region. To date no genotype–phenotype correlation has been shown.

## Molecular and Systemic Pathophysiology

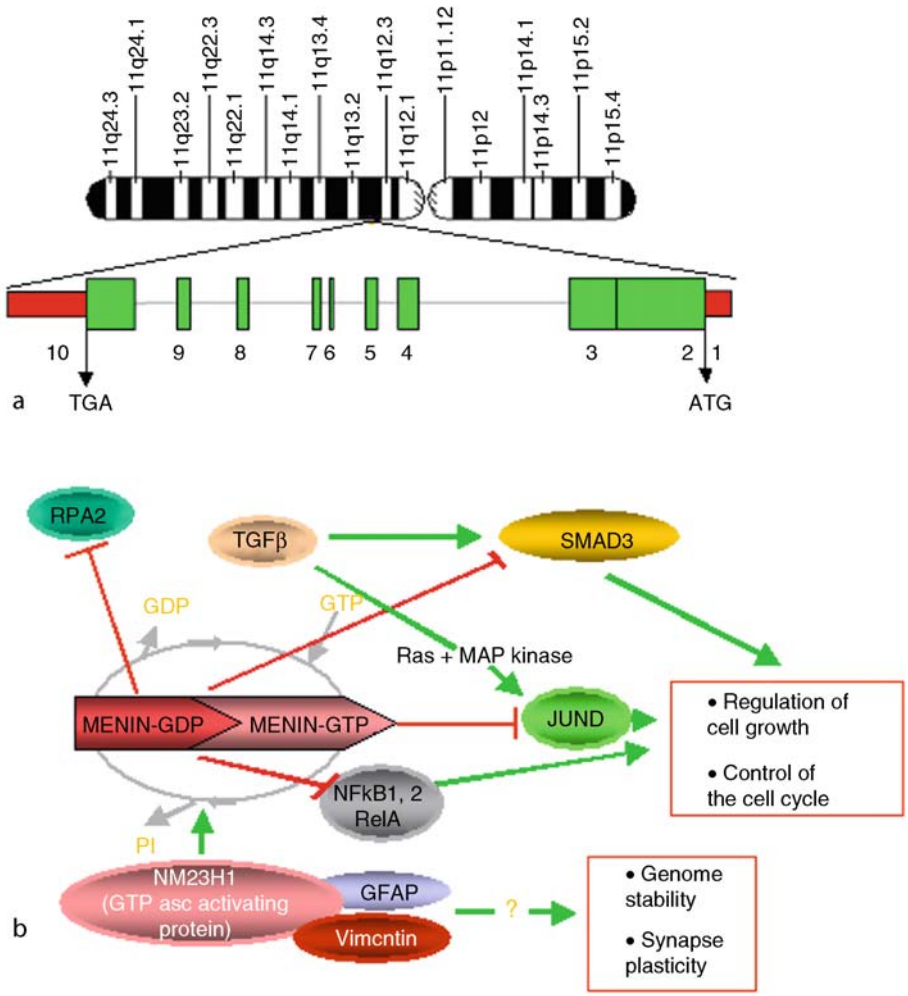
Menin is a 67-kD protein showing no homology to any other known protein, sequence motif, or signal peptide, thus its functions could not be deduced by its sequence. Menin has been shown to interact with several proteins of known function, as JunD, NFkB, Smad1, Smad3, Smad5, Pem, Nm23H1, GFAP, vimentin, Hsp70, FANCD2, RPA, NMMHC II-A, etc [1] (Fig. 1b).

It is expressed in all human tissues and located primarily in the nucleus via 2 C-terminal nuclear localization signals (NLSs). Its nuclear localization suggests its possible role in the regulation of transcription, DNA replication and/or repair, or cell cycle. Truncating mutations lead to loss of one or both NLSs, maybe leading to protein instability or loss of function by displacing menin out of the nucleus.

In constitutively activated Ras-transformed NIH3T3 murine tumor cells, menin overexpression reverts the transformed phenotype in vitro and reduces tumor growth after injection of cells in nude mice [2]. The molecular mechanisms for menin's growth suppression could in part be explained by its interaction with transcription factors or by its direct binding to the promoters of target genes. Moreover, menin has been shown to associate with histone methyltransferase complex proteins inducing methylation of histone 3 at lysine 4 and thus promoting transcription of target genes as HOXA9, HOXC6, HOXC8, $p18^{Ink4c}$, and $p27^{Kip1}$ [3–4]. In the pancreas, menin loss results in decreased expression of $p18^{Ink4c}$ and $p27^{Kip1}$ accelerating $G_0/G_1$ to S phase entry; complementation of menin-null cells with wild-type menin represses S phase entry [5].

## Diagnostic Principles

MEN1 diagnosis consists of clinical and genetic analysis. Clinical diagnosis is based on detection of MEN1-typical tumors and lesions and includes hormonal assessment, endoscopic, isotopic, or other imaging studies. Particularly, biochemical screenings permit to detect endocrine tumors 5–10 years before the development of clinical symptoms, allowing for early surgical intervention. These diagnostic tools generally do not allow to distinguish MEN1-associated tumors from sporadic disease. Anyway, MEN1-associated tumors typically arise at younger age than sporadic counterparts, thus clinical manifestations in individuals <40 years



**Multiple Endocrine Neoplasia Type 1. Figure 1** (a) Schematic representation of the MEN1 gene. Green boxes are the translated exons, red boxes indicate the untranslated regions). (b) Scheme of menin's interactions with its various partners; red lines indicate inhibitory effects.

of age can be suggestive of MEN1. In this context, a careful medical history and strong clinical evidence are essential for correct diagnosis. Cutaneous tumors (angiofibromas, collagenomas, lipomas) may be helpful in the presymptomatic diagnosis of MEN1 individuals before manifestations of hormone-secreting tumors appear.

Early recognition of affected and individuals at risk is facilitated by the availability of MEN1 gene mutation analysis. The DNA-testing is recommended for patients who meet clinical criteria for MEN1 and for those in whom a diagnosis of MEN1 is suspected. The lack of genotype–phenotype correlation does not allow to foresee the clinical phenotype. Anyway, identification of a mutation in a patient enables testing for relatives, allowing the early identification of asymptomatic mutant gene carriers to undergo periodic biochemical and radiological screenings for the early recognition of MEN1-associated tumors. This provides the opportunity to initiate treatment at earlier stages and thus reduce morbidity and mortality.

## Therapeutic Principles

There is currently no prevention or cure for MEN1 tumors, and cancer treatment options are generally limited to surgery that should be performed before malignant progression of the neoplasms.

# Multiple Endocrine Neoplasia Type 2

Christian A. Koch[1],
Constantine A. Stratakis[2]
[1]Division of Endocrinology, University of Mississippi, Jackson, MS, USA
[2]Program on Developmental Endocrinology & Genetics, National Institute of Child Health and Human Development, Bethesda, MD, USA

## Synonyms

Sipple syndrome; MEN 2

## Definition and Characteristics

Multiple endocrine neoplasia type 2 (MEN2) is an autosomal dominant tumor syndrome characterized by the presence of medullary thyroid carcinoma (MTC), pheochromocytoma, and parathyroid hyperplasia/adenoma. In 1886, it has been described by Felix Fraenkel and in 1959 by Sipple. In 1993, missense germline mutations in the RET proto-oncogene have been identified in patients with MEN2. Based on genotype–phenotype correlations, three different types of tumor syndromes exist: (1) familial MTC, (2) MEN2A, and (3) MEN2B. MEN2A consists of MTC, pheochromocytoma, and hyperparathyroidism. MEN2B is defined as MTC and pheochromocytoma [1,2].

## Prevalence

Approximately 1,000 kindreds have been identified worldwide; approximately 1 in 40,000 individuals are affected.

## Genes

RET (rearranged during transfection) has been discovered in 1985 during transfection assays and has been classified as a proto-oncogene located at chromosome 10q11.2 with activating mutations leading to MEN2. "Inactivating RET mutations" have been found in patients with Hirschsprung's disease, intestinal aganglionosis. RET is expressed in neural-crest-derived cells such as the parafollicular C-cells in the thyroid gland and the chromaffin cells in the adrenal medulla. RET consists of 21 exons and encodes a receptor tyrosine kinase. Six exons, exons 10, 11, 13, 14, 15, and 16 are called "hot spots," since germline mutations in these exons are found in approximately 97% of patients with MEN2. The most common affected exon is exon 11 including codon 634 which is mutated in about 80% of patients with MEN2A. More than 94% of patients with MEN2B have RET germline mutations in exon 16, most commonly in codon 918. There are strong genotype–phenotype correlations (see Fig. 1).

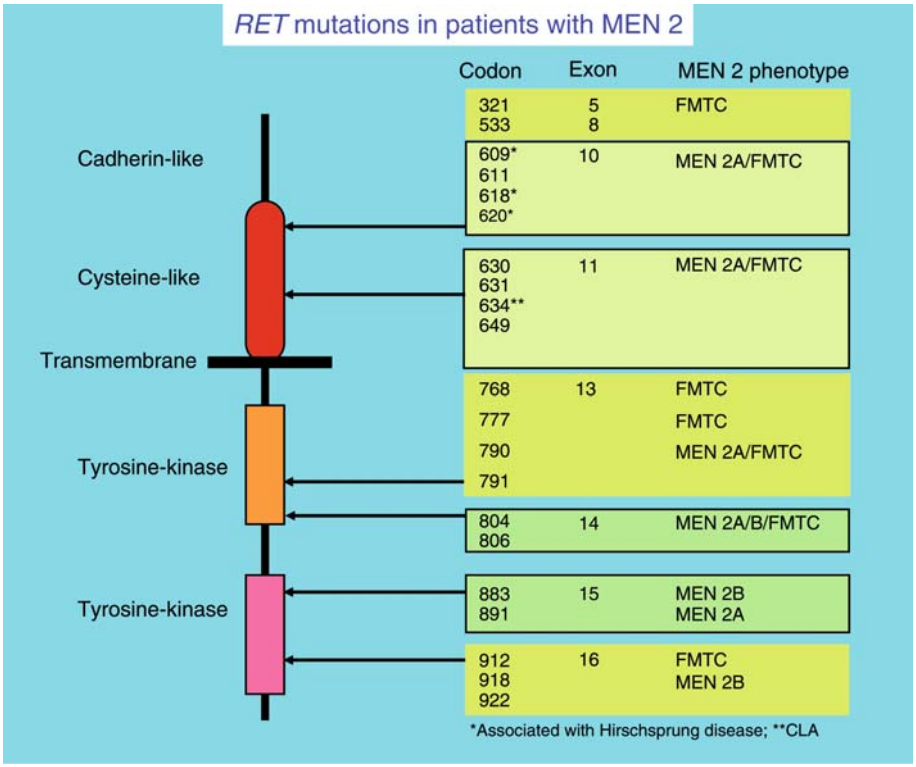
## Molecular and Systemic Pathophysiology

Ligands for the RET receptor include glial cell line derived neurotrophic factor (GDNF), neurturin, persephin, and artemin. In vitro studies indicate that certain RET germline mutations can lead to autophosphorylation and/or dimerization with constitutive activation of RET. The RET receptor consists of several domains: a cadherin-like, cysteine-rich, transmembrane, and intracellular tyrosine kinase domains (see Fig. 1).

A complex array of downstream interactions mediates RET's functions in normal and tumorigenic cells. For instance, RET stimulates the RAS pathway including activation of the mitogen (MAP) kinase pathway which is necessary for differentiation and neuronal survival. RET also can activate phosphoinositol 3 (P13) kinase which has been implicated in cell proliferation and motility. Transgenic mice heterozygous for the M918T RET mutation develop hyperplasia of C-cells and adrenomedullary hyperplasia without progression to medullary thyroid carcinoma or pheochromocytoma. On the other hand, mice homozygous for this RET mutation not only have an earlier onset of C-cell and adrenomedullary hyperplasias but also progression to medullary thyroid carcinoma and pheochromocytoma. It remains puzzling, why related and unrelated patients with the same heterozygous germline mutation in RET develop the respective tumor (MTC or pheochromocytoma) at widely different ages, i.e., at age 1 and at age 81, and why only a few cells in the target organs develop into tumors. Selected cells of the C-cells in the thyroid gland and of the chromaffin cells in the adrenal gland may undergo a "second hit" event, giving these cells a growth advantage and making them prone to more replication errors [1,2].

## Diagnostic Principles

The diagnosis is based on serum calcitonin measurements in patients with nodular thyroid disease. Usually, patients are routinely operated on when a basal calcitonin value is >30 pg/ml or a pentagastrin-stimulated



**Multiple Endocrine Neoplasia Type 2. Figure 1** Genotype-phenotype correlation in patients with MEN2.

M

calcitonin value is above 100 pg/ml. A basal calcitonin value of >30 pg/ml or a stimulated one >200 pg/ml is highly predictive of MTC (positive predictive value 93%, sensitivity 80%). Hypercalcitonemia also occurs in other disease states such as other neuroendocrine tumors, renal failure, chronic lymphocytic thyroiditis, follicular thyroid adenomas, and others. False positive tests for abnormal calcitonin values in individuals suspected to have MTC occur in 5–10%, as determined by retrospective testing for RET germline mutations. Fifty percent of patients with a negative pentagastrin test but a positive test for RET mutation had already developed MTC. Screening for pheochromocytoma in patients at risk for MEN2 should start around age 6, depending on the mutation type. Once the presence of a pheochromocytoma has been confirmed by a more than threefold elevation of metanephrines from baseline, an imaging study such as high-resolution (thin cuts, 1–2 mm) computed tomography or magnetic resonance imaging of the adrenal glands should be performed. Screening for primary HPT in MEN2A should include serum calcium and intact parathyroid hormone [3–5].

## Therapeutic Principles

Before performing thyroidectomy, one should always screen for pheochromocytoma. Prophylactic thyroidectomy with central lymph node dissection has been recommended for individuals with a RET germline mutation. This has lowered the mortality rate from hereditary MTC to <5%. Multifocal hyperplasia of parafollicular C-cells has been regarded as precursor lesion for hereditary MTC. Metastases usually develop in the cervical and mediastinal lymph nodes as well as in lung, liver, or bone. Calcitonin is an excellent tumor marker in postsurgical follow-up. In addition, carcinoembryonic antigen is helpful. Among different chemotherapeutic regimens, none has proven beneficial. Neither has radiation therapy to these relatively insensitive tumors. All individuals scheduled for adrenalectomy for a biochemically confirmed pheochromocytoma should be treated with an alpha-blocker such as phenoxybenzamine 7–10 days prior to surgery. The preferred surgical approach is laparoscopic adrenalectomy. Primary HPT in patients with MEN2A develops in about 25% and is usually mild. Surgical intervention should be based on the same criteria as for sporadic primary HPT, i.e., serum calcium elevation >0.25 mmol of upper limit of normal, 24 h urinary calcium >400 mg, creatinine clearance reduced by 30%, T score of bone mineral density (radius, femur, spine) −2.5 SD, and age below 50 years. Removal of 3.5 parathyroid glands should be performed.

# Multiple Epiphyseal Dysplasia

Michael Briggs
Wellcome Trust Centre for Cell Matrix Research, University of Manchester, Manchester, UK

## Synonyms

Epiphyseal dysplasia, Fairbank type; Epiphyseal dysplasia, Ribbing type

## Definition and Characteristics

A form of skeletal dysplasia characterized by varying degrees of disproportionate short stature, lower limb deformity, joint laxity and pain and stiffness of the large joints. Radiographic features include delayed and irregular ossification of multiple epiphyses. Usually diagnosed in childhood by clinical presentation and appropriate X-rays. Both autosomal dominant and recessive forms have been described.

## Prevalence

The prevalence of MED has not been accurately determined primarily due to differences in the age of onset between families and the variable clinical severity. A point prevalence of 1/10,000 has been suggested but it is likely that any prevalence is an underestimate.

## Genes

See Table 1.

## Molecular and Systemic Pathophysiology

*AD MED*: Cartilage oligomeric matrix protein (COMP), type IX collagen and matrilin-3 are all oligomeric structural proteins of the cartilage extracellular matrix (COMP is also found in tendon and ligament, hence the ligamentous laxity seen in patients with a COMP mutation). The mutations in these genes all reside within important structural and/or functional domains of the relevant gene products, including the type III and C-terminal domains of COMP, the COL3 domain of type IX collagen and the A-domain of matrilin-3. The mutations in the type III repeats of COMP and the A-domain of MATN3 are thought to cause protein misfolding and prevent or delay secretion of the protein from the rough endoplasmic reticulum (rER). The mechanism(s) of type IX collagen gene mutations have not been determined but may include reduced levels of protein (through mRNA degradation), retention of misfolded protein within the rER or dominant interference within the cartilage ECM [1,2].

*AR MED*: Homozygosity for specific mutations in the gene encoding the solute carrier family 26, member 2 (SLC26A2) can give rise to a distinctive form of MED. The SLC26A2 gene product is a sulfate–chloride transporter of the cell and inactivation of this protein leads to a reduction in intracellular sulfate levels, which ultimately results in the synthesis and secretion of undersulfated proteoglycans from chondrocytes [3].

## Diagnostic Principles

The diagnosis of MED is usually based upon the clinical and radiographic features of the proband. Molecular testing is usually helpful in confirming the

**Multiple Epiphyseal Dysplasia. Table 1** The genetic loci that have been shown to date to cause AD and AR forms of MED and their approximate contribution

| MED locus | Mode of inheritance | Gene | Protein | Location | Approx. contribution |
|---|---|---|---|---|---|
| EDM1 | AD | COMP | Cartilage oligomeric matrix protein | 19p13.1 | 30% |

| Not assigned | AD | COL9A1 | | 6q13 | |
| EDM4 | AR | SLC26A2 | Solute carrier family 26, member 2 | 5q32-33.1 | 10% |
| EDM5 | AD | MATN3 | Matrilin-3 | 2p24-23 | 5% |

diagnosis and may help in determining prognosis of the disease based on genotype–phenotype correlations [4].

## Therapeutic Principles

The aim of clinical management is to control pain and to limit joint destruction, which may in itself slow the development of osteoarthritis. Pain can be difficult to control but a combination of analgesics and physiotherapy including hydrotherapy is helpful in many cases. Referral to a rheumatologist or pain specialist may be required. Weight control and avoidance of exercise that causes repetitive strain on affected joints are beneficial. Consultation with an orthopedic surgeon can determine if realignment osteotomy and/or acetabular osteotomy may be helpful in slowing the progression of symptoms. In some cases, total joint arthroplasty may be required. Psychosocial support addressing issues of short stature, disability, employment, and risk to other family members is appropriate.

# Multiple Exostoses, Hereditary

Wim Wuyts, Filip Vanhoenacker, Wim Van Hul
Department of Medical Genetics, University of Antwerp, Antwerp, Belgium

## Synonyms

Multiple osteochondroma; Multiple cartilaginous exostoses; Diaphyseal aclasis

## Definition and Characteristics

Autosomal dominant bone disorder characterized by bony outgrowths (osteochondroma) mainly located at the juxtaepyphyseal parts of the long bones [1]. Number, size, site and shape of the osteochondroma can vary greatly between patients. Pressure of the osteochondromas on neighboring tissues and organs causes pain, reduced mobility and compression of nerves, muscles and blood vessels. Deformity of legs, forearms (resembling Madelung deformity) and shorter stature are frequently observed in osteochondroma patients. In 0.5–2% of these patients chondrosarcoma development is observed.

## Prevalence

The prevalence of hereditary multiple exostoses is estimated to be one in 50,000 world wide.

## Genes

EXT1 localized on chromosome 8q24 [2] and EXT2 localized on chromosome 11p11.2. [3,4].

## Molecular and Systemic Pathophysiology

EXT1 and EXT2 genes encode glycosyltransferases which form a functional complex involved in the polymerization of heparan sulfate (HS) [5]. The majority of mutations identified in EXT1 and EXT2 are inactivating mutations causing changes in heparan sulfate expression affecting the function of heparan sulfate proteoglycans (HSPG). These HSPG act as coreceptors for several growth factors and signaling molecules, including Indian Hedgehog (Ihh) which is known to play a role in chondrocyte differentiation. Chondrocytes in the growth plate committed to hypertrophy secrete Ihh, which binds to its receptor initiating a signaling pathway resulting in the release of PTHrP. Perturbing HS levels may therefore prevent Ihh signaling and thus PTHrP release. As PTHrP acts on proliferating and prehypertrophic chondrocytes to maintain their proliferative state this may disturb the negative feedback loop. The exact mechanism causing aberrant bony growths observed in multiple exostoses is, however, still unknown.

## Diagnostic Principles

Osteochondromas are recognized on X-rays as cartilage capped bony outgrowths, continuous with the underlying bone. Detection of a mutation in either the EXT1 or the EXT2 gene confirms the diagnosis.

## Therapeutic Principles

Currently, patients can only be helped by surgical removal of exostoses that cause secondary problems.

# Multiple Familial Trichoepithelioma

Dieter Metze
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Epithelioma adenoides cysticum of Brooke; Brooke-Fordyce trichoepitheliomas

## Definition and Characteristics

Multiple familial trichoepithelioma is a predisposition to multiple benign neoplasms with hair follicle differentiation. There is an autosomal dominant inheritance with a female preponderance [1].

At childhood or at time of puberty many papules arise with predilection for the central part of the face [1]. Multiple trichoepithelioma can be associated with cylindroma and spiradenoma (familial cylindromatosis) [2], and, rarely, with ungual fibromas, dystrophia ungius congenita, or the ROMBO syndrome. Malignant transformation of trichoepithelioma into basal cell carcinoma has been disputed, still, basal cell carcinoma may develop in trichoepithelioma.

## Prevalence

The disorder is rare.

## Genes

Harada et al. found linkage of a gene for multiple familial trichoepithelioma mapping to chromosome 9p21 [3] while solitary trichoepithelioma that are not inherited show deletions at 9q22.3 implicating a second locus [4]. In cases where trichoepithelioma are associated with cylindroma, mutations are identifiable in a gene (CYLD1) on 16q12-q13 [5].

## Molecular and Systemic Pathophysiology

The gene for multiple familial trichoepithelioma is discussed to have the genetic attributes of a tumor suppressor gene [3].

## Diagnostic Principles

Skin biopsies show nests of basaloid cells with abortive hair follicle differentiation. Trichoepithelioma are best regarded as a superficial variant of trichoblastoma.

## Therapeutic Principles

Treatments available are surgical excision or carbon dioxide laser vaporization.

### Synonyms

Encephalomyelitis disseminata (ED)

### Definition and Characteristics

Multiple sclerosis (MS) is one of the most common chronic and disabling disorders of the central nervous system (CNS). A chronic autoimmune-inflammatory process of multifactorial origin leads to demyelinating lesions in the brain and spinal cord which cause variable neurological symptoms. MS usually begins in young adults, and it affects women more frequently than men.

In 85–90% of cases, MS starts with a relapsing–remitting course (RR-MS). The first clinical manifestation usually consist of either visual disturbance, focal weakness or sensory deficits. The RR-MS form is characterized by repeated clinical relapses, defined by the appearance of neurological symptoms with variable remission. The number of relapses decreases during the course of the disease. Most patients convert to the so-called secondary progressive phase (SP-MS) in which they develop slowly progressive and irreversible neurological deficits that occur independently of relapses. In 10–15% of patients, MS begins with a primary progressive course (PP-MS) without any preceding acute relapse. MS can affect any area of the central nervous system (the brain and spinal cord), and as such, there are a wide variety of symptoms [1].

### Prevalence

The prevalence of MS varies significantly depending on the genetic background of the patient. MS is highly prevalent in Caucasians with a frequency of 0.05–0.15%. In Asians or Africans it is rarely observed [1,2].

### Genes

Family studies revealed that family members of MS patients were at a significantly higher risk of developing the disease. In identical twins this risk is 250-fold (lifetime prevalence 25%), in siblings 30-fold (2–5%) and in half-brothers and half-sisters 10-fold (1%) increased compared to the average population.

Because of the polygenetic and heterogeneous predisposition for the disease, efforts to define genes responsible for transition to MS have been unsuccessful or led to ambiguous results. Only the DR14/DQw6 alleles of the human class II leucocyte antigen showed a reproducible association with the disease in Caucasians [2].

### Molecular and Systemic Pathophysiology

Recent findings document that genetic and environmental factors substantially influence the course of MS as well as the chance of getting the disease.

The pathological correlate for the clinical relapse is an acute inflammation with demyelination and axonal loss in the central nervous system. One of the main findings in the early phase of the acute event is a disruption of the blood-brain-barrier.

The primary events leading to the immune response in the first place are still not known, but it seems likely that initialization as well as maintenance of the immune response takes place in the lymphatic system. Antigens from the CNS are drained into the periphery, end up in the lymphatic system and are processed by professional antigen-presenting cells (APCs). Dendritic cells play an outstanding role in this process, because they can tow in exogenous antigens via the HLA-class I as well as class II processing pathway and in this way can activate CD4 + as well as CD8 + T cells. In the same way, B-cell responses are initiated by soluble antigens. Verification of a continuous intrathecal IgG antibody synthesis (oligoclonal IgG bands) is compatible with a persistent immune response to proteins [2,3].

### Diagnostic Principles

MS is a disease that is disseminated over time and space. Thus, a definite diagnosis necessitates proof of more than one attack in different parts of the nervous system based on the clinical history, the neurologic exam, magnetic resonance imaging, evoked potentials and cerebrospinal fluid (CSF) analysis obtained by spinal tap. A CSF analysis needs to be done for two reasons: firstly to rule out other diseases that mimic MS (such as infectious nervous system disease) and secondly to detect oligoclonal bands, which help to support the diagnosis of MS.

Since all MS-related symptoms and paraclinical findings are not specific for MS, other causes of the clinical symptoms must be excluded.

## Therapeutic Principles

Although there is still no cure for MS, today it is a highly treatable condition. MS treatment consists of (i) reducing the length and frequency of acute relapses by corticosteroids, (ii) halting or slowing the natural course of MS by disease-modifying immune therapy, and (iii). controlling specific symptoms by symptomatic treatment.

*Treatment of Acute Relapses*: Intravenous corticosteroids are an established treatment of acute relapses. Corticosteroids have immunomodulatory and anti-inflammatory effects that restore the blood-brain-barrier, reduce edema, and may possibly improve axonal conduction. Corticosteroid therapy shortens the duration of the relapse and accelerates recovery, but an improvement of the overall degree of recovery or an effect on the long-term course has not been demonstrated.

*Immune Therapy*: Disease-modifying drugs (DMD) include beta-interferons, glatiramer acetate, immunoglobulins, natalizumab, mitoxantrone and other immune suppressants. These treatments manipulate the immune system in a variety of ways to decrease the frequency of attacks and to slow down the progression of the disease. The mechanism of action of most DMD's is not totally clear, but it is thought that they block the release of myelin-damaging substances that cause swelling and inflammation. They can also reduce the number of new lesions found on MRI scans. They also may prevent immune cells from crossing the protective blood-brain barrier to enter the central nervous system.

*Symptomatic Treatment*: There are many drugs that can be used to relieve the individual symptoms of MS such as spasticity, bladder dysfunction, fatique, etc. These treatments can help minimize symptoms, but do not change the course of the disease. In other words, these treatments will improve the discomfort and inconvenience associated with MS symptoms, but they do not influence the course of the disease.

# Multiple Sulfatase Deficiency

Kurt Von Figura[1], Thomas Dierks[2], Bernhard Schmidt[1]

[1]Department of Biochemistry, Georg-August-University Goettingen, Goettingen, Germany

[2]Department of Biochemistry, University of Bielefeld, Bielefeld, Germany

## Synonyms

Mucosulfatidosis; Austin disease; MIM 272200

## Definition and Characteristics

Autosomal recessive lysosomal storage disorder with storage of sulfated lipids and sulfated glycans and a profound deficiency of all lysosomal and nonlysosomal sulfatases.

## Prevalence

A rare disorder with a frequency of $1:10^6$ or less. No ethnic or regional prevalence known.

## Genes

SUMF1 coding for the Cα-formylglycine generating enzyme (FGE), localized on chromosome 3p26.

## Molecular and Systemic Pathophysiology

The profound deficiency but not complete absence of all known sulfatase activities in multiple sulfatase deficiency (MSD) is caused by mutations in the SUMF1 gene encoding FGE [1,2] (see [3] for review). FGE is highly conserved among eukaryotes and localized in the lumen of the endoplasmic reticulum. It posttranslationally converts a cysteine residue in newly synthesized sulfatase polypeptides into Cα-formylglycine (FGly). The cysteine is part of the 'Sulfatase signature', a short linear sequence motif that is conserved among all eukaryotic sulfatases and directs FGly formation. In native sulfatases the FGly residue is part of the active site. Its aldehyde group is hydrated and one of the two geminal hydroxyl groups is transiently sulfated during the catalytic cycle. MSD causing missense mutations affect either FGE activity, binding of sulfatase substrates or/and FGE folding and stability [3,4]. As a result, catalytically severely compromised sulfatases are synthesized, some of which in addition are unstable. It is characteristic for MSD that some residual sulfatase activity is found, usually less than 10% of control. However, sometimes considerly higher residual activities are measurable, in particular when determined from patient cells with milder FGE mutations and after longer cell cultivation. This residual activity is due to the hypomorphic nature of the MSD causing

mutations leading to low but measurable FGE activity (sometimes <1%) and in many cases severly reduced stability. Notably, among the MSD causing mutations (deletions, nonsense and missense mutations) only missense mutations have been found so far to occur in homozygous form. A paralog of FGE (pFGE), encoded by the SUMF2 gene, lacks FGly-generating activity and is not affected in MSD [3,4]. Its precise function is unknown so far.

The clinical symptoms of MSD represent a composite of the symptoms found in disorders caused by deficiency of single sulfatases. The leukodystrophy-like (deficiency of arylsulfatase A) and mucopolysaccharidosis-like (deficiency of glycosaminoglycan degrading sulfatases) features prevail.

## Diagnostic Principles

The diagnosis is based on the demonstration of deficiency of two or more sulfatase activities and supported by findings such as increased mucopolysaccharidurie, sulfatide excretion, and imaging parameters characteristic of leukodystrophy. Detection of mutations in the SUMF1 gene confirms the diagnosis.

## Therapeutic Principles

There is no therapy known. Presently the therapeutic capacity of sulfatase replacement therapy in several single sulfatase deficiencies is evaluated. The production of recombinant sulfatases for enzyme replacement therapy is much facilitated by coexpression of FGE, as the latter is rate-limiting the biosynthesis of catalytically active sulfatases in eukaryotic expression systems. An MSD mouse model has been developed recently [5].

# Multiple Symmetric Lipomatosis

Luca Busetto, Giuliano Enzi
Department of Medical and Surgical Sciences, University of Padova, Padova, Italy

## Synonyms

Launois-Bensaude syndrome; Madelung's disease; MSL

## Definition and Characteristics

Multiple symmetric lipomatosis (MSL) is a lipodistrophy characterized by the formation of multiple non-encapsulated lipomas with a symmetrical distribution and with sparing of distal arms and legs. The most frequent site of lipomas is the submental area (>90%), followed by nucal region, dorsal and deltoid areas, abdomen, breasts, upper segment of arms and legs. In type I MSL the lipomas are well circumscribed, protruding from the body surface of a lean body. In type II MSL, the lipomatous tissue involve extensively the subcutaneous layer, mimicking the appearance of simple obesity (Fig. 1) [1].

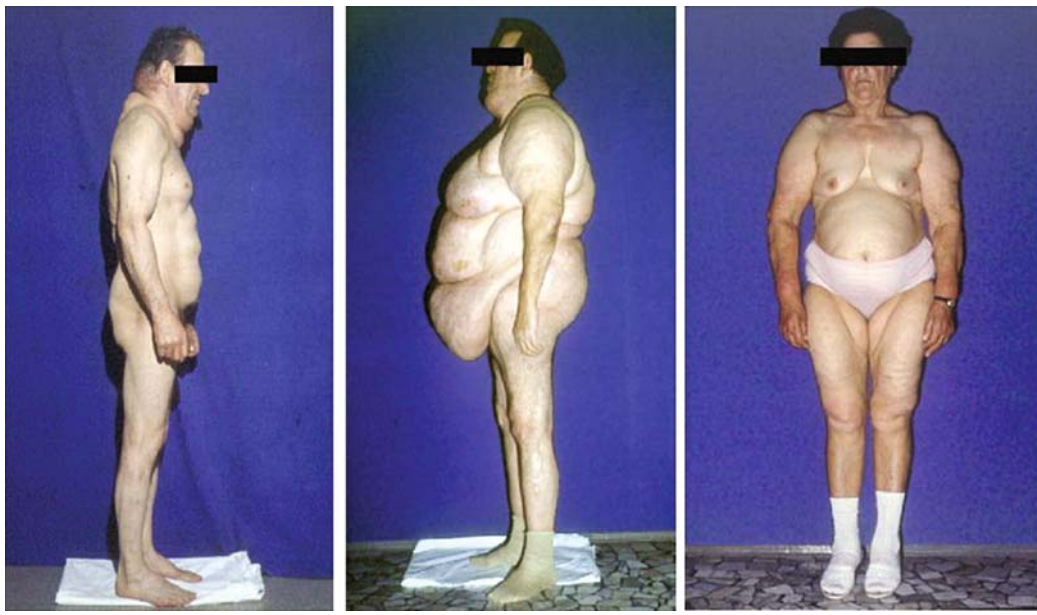
The disease is typically associated with high ethanol intake and with somatic and autonomic neuropathies. The growth of uncapsulated lipomas in the neck can be associated with compression, dislocation and infiltration of upper airways and the trachea. A high rate of sudden death has been reported [2].

## Prevalence

The prevalence of MSL is generally low, with an estimated rate of 1:25,000 in the Mediterranean population [1]. The onset of the disease is usually in the fourth or in the fifth decade of life. The disease is most prevalent in men, with a male-to-female ratio of 30:1 [2]. Familial cases have been reported [2] and an autosomic dominant inheritance has been proposed. However, non single gene defects have been identified so far.

## Molecular and Systemic Pathophysiology

MSL may be the consequence of defective noradrenergic modulation of proliferation and differentiation of brown adipose tissue (BAT) [3]. Cultured precursor adipocytes from the lipomatous tissue of MSL patients express



**Multiple Symmetric Lipomatosis. Figure 1** Three patients with MSL: Left side: Type I MSL man, showing circumscribed fatty tumours protruding from the body surface. Middle: Type II MSL, with a widespread deposition of lipomatous tissue mimicking the appearance of simple obesity. Right side: A MSL woman. Female patients usually belong to Type II MSL, with a low prevalence of the submental fat deposition and a high prevalence of fat deposition to the proximal arms and legs. From: Busetto L, et al. (2003) Differential clinical expression of multiple symmetric lipomatosis in men and women. Int J Obes 27:1419–1422.

specific molecular markers of brown adipocytes, including the mitochondrial inner membrane uncoupling protein-1 (UCP-1). However, unlike in normal BAT, the expression of those markers in MSL cells is not stimulated by noradrenaline (NA). The failure of NA to enhance the expression of UCP-1 in MSL cells is not related to changes in the levels and structure of the beta-adrenoceptors, but it is probably due to abnormal amount or defective function of G-proteins or other proteins downstream. The defective noradrenergic modulation has a profound influence in MSL cells function. First, MSL cells have normal lipolytic response to cAMP, but a defective lipolytic response to catecholamine, leading to increased intracellular lipid accumulation [4]. Second, unlike in normal BAT, NA do not stimulate the expression of inducible nitric oxide synthase (iNOS) in MSL cells, leading to defective NO production [3]. In BAT, NO markedly inhibits proliferation and triggers the differentiation program by modulating the expression of peroxisome proliferation-activated receptor gamma (PPARgamma). Therefore, NO deficiency in MSL cells could translate in a state of dysregulated proliferation and defective differentiation. In particular, the transcriptional peroxisome proliferators-activated receptor gamma co-activator-1 (PGC-1), which plays a key role in the NA-stimulated mitochondrial biogenesis of brown adipocytes, is expressed but not induced by NA in MSL cells. Lipid storage may be therefore secondary to defective oxidative mitochondrial activity. Several authors report mitochondrial dysfunction and multiple deletions of mitochondrial DNA in MSL and some patients with the myoclonic epilepsy ragged red fibers (MERRF) syndrome caused by a point mutation in the tRNA-lysine gene of mitochondrial DNA (A8344G) have MSL [5]. However, abnormalities of mitochondrial DNA can be identified only in a minority of patients with MSL [2].

## Diagnostic Principles

The diagnosis is based on the phenotypical appearance of the patient and the history of alcohol abuse. Electromyography and evaluation of cardiovascular autonomic reflexes usually confirm the presence of associated neuropathies. The metabolic profile is characterized by very high HDL-cholesterol concentrations caused by a markedly increased lipoprotein lipase activity in the lipomatous tissue [2]. A CT study of the neck is warranted in patients with neck enlargement to evaluate the extension of deeply localized lipomatous tissue. Compression of the oro-pharyngeal tract and infiltration of oro-pharyngeal mucosa may be evaluated with video-laryngoscopy.

## Therapeutic Principles

No pharmacologic treatments have shown to be effective to date and surgical excision of the lipomatous

masses remains the only therapeutic option. Giving the absence of net borders between the lipomatous tissue and the surrounding structures and the rich vascular bed of the lipomas, surgery is frequently complicated. In a longitudinal study, alcohol discontinuation is associated with a slight regression of lipomatous tissue and an increase in ethanol consumption seems to accelerate the lipomatous growth [2]. Abstinence from alcohol should be therefore recommended.

# Multiple System Atrophy

Thomas Klockgether
Department of Neurology, University Hospital Bonn, Bonn, Germany

## Synonyms

MSA

## Definition and Characteristics

Multiple system atrophy (MSA) is a sporadic, adult-onset disease encompassing the former disease categories striatonigral degeneration, sporadic olivopontocerebellar atrophy and Shy-Drager syndrome. Clinically, MSA is characterized by poorly levodopa-responsive Parkinsonism and/or cerebellar ataxia in combination with severe autonomic failure. Mean age at disease onset is 55 years. MSA takes a relentlessly progressive course. After a median latency of 6 years, MSA patients become wheelchair-bound. The median life expectancy after disease onset is 9 years. At autopsy, MSA brains show neurodegeneration mainly in the striatum, substantia nigra, pons, inferior olives and cerebellum. In addition, there is a loss of preganglionic sympathetic neurons in the intermediolateral cell columns of the spinal cord and loss of motoneurons in Onuf´s nucleus.

## Prevalence

The prevalence of MSA is 4.4:100,000.

## Genes

MSA is a sporadic, non-hereditary disease. There are no known genetic alterations causing or predisposing for MSA.

## Molecular and Systemic Pathophysiology

In MSA, glial cytoplasmic inclusions (GCI) that stain positively for α-synuclein are abundant in oligodendroglial cells and distributed throughout the brain beyond the areas of overt neuronal loss. α-Synuclein is also the major constituent of the intraneuronal Lewy bodies characteristic for idiopathic Parkinson's disease. Mice overexpressing α-synuclein in oligodendroglia develop MSA-like neurodegeneration, suggesting that neurodegeneration is secondary to oligodendroglial α-synuclein accumulation. An autopsy study using antibodies that specifically recognize an epitope of myelin basic protein that is exposed in areas of myelin degeneration detected widespread immunoreactivity in oligodendrocytic processes indicating significant myelin degeneration in MSA.

## Diagnostic Principles

Clinical diagnostic criteria that allow a clinically probable diagnosis of MSA have been proposed by Quinn (1989) and recently refined by an international consensus conference. An essential diagnostic criterion is the demonstration of severe autonomic failure defined by urinary incontinence or orthostatic hypotension with a drop of systolic blood pressure of more than 30 mmHg after rising from a supine position. Formal autonomic testing may aid the diagnosis. Magnetic resonance imaging (MRI) of the brain typically shows cerebellar and brainstem atrophy as well as signal abnormalities in the putamen, pons and middle cerebellar atrophy. Positron emission tomography (PET) provides evidence of pre- and post-synaptic degeneration of the nigrostriatal system.

## Therapeutic Principles

There is no curative or preventive treatment for MSA. Parkinsonian symptoms respond to dopaminergic medication although the response is less robust than in idiopathic Parkinson's disease. Autonomic symptoms are treated in a standard manner. There is no effective symptomatic treatment for ataxia.

►Catecholamine Deficiency

## Synonyms

Glycogenosis type IX; PGK deficiency

## Definition and Characteristics

Phosphoglycerate kinase (PGK) deficiency (glycogenosis type IX) is an inborn error of the glycogen metabolism located in the terminal anaerobic glycolysis and inherited in an x-linked recessive modus [1]. Clinical presentation includes nonspherocytic hemolytic anemia, myopathy, and central nervous system dysfunction (seizures, mental retardation, or late language acquisition). Affected patients express one, two, or all three clinical phenotypes. Only a few cases with isolated myopathy have been described, nevertheless hereditary PGK deficiency is classified to the group of glycogenoses that affect skeletal muscle. Myopathy does not present as fixed muscle weakness but as exercise intolerance, myalgia, muscle cramps, myoglobinuria, and rhabdomyolysis. No cardiac involvement has been reported. One patient developed retinitis pigmentosa.

## Prevalence

The exact prevalence rate is unknown and more than 30 families with inherited PGK1 deficiency have been identified so far. More than 15 patients with isolated or predominant myopathy have been reported.

## Genes

Human PGK (EC 2.7.2.3) is a monomeric glycolytic enzyme which consists of 416 amino acid residues. It plays a key role in ATP generation during terminal glycolysis and catalyzes the reversible conversion of 1,3-bisphosphoglycerate to 3-phosphoglycerate generating one molecule of ATP.

There are two isoforms of the enzyme: PGK1 and PGK2. PGK1 is encoded by a single gene and is expressed in all tissues except the testis. The full-length cDNA of PGK1 was cloned and the gene consisting of 11 exons and 10 introns, encompassing a region of about 23 kb, has been isolated [2] and assigned to chromosome Xq13 [3]. PGK2, the testicular isoform, is encoded by a gene on chromosome 19 and is expressed only in germ cells [3].

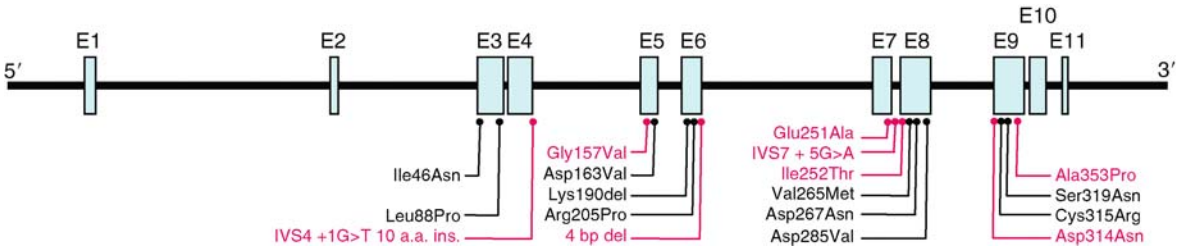
At the present time, the structural aberrations of 18 PGK1 gene mutants, all characterized by reduced catalytic activity or loss of structural stability of the enzyme, have been elucidated in families with PGK deficiency. These mutations include 13 missense point mutations with a single amino acid substitution, 2 deletion mutations (1 of 3 bp with 1 amino acid deletion and one of 4 bp with frameshift and the emergence of an abnormal stop codon) and 3 splice-junction mutations. Their position on the PGK1 gene and their special characteristics are schematically shown in Fig. 1.

## Molecular and Systemic Pathophysiology

All glycogenoses that cause exercise intolerance and myoglobinuria are due to muscle-specific enzyme defects. In contrast, PGK1 is expressed ubiquitously in all somatic cells, except for the germ cells of the testis, and there is no muscle-specific isoform of the enzyme. In addition, no clear genotype/phenotype association has been identified [4]. Therefore, the biochemical and molecular bases for the variable involvement of hematopoietic, muscle and nervous tissue in PGK deficiency is difficult to understand.

Lack of myoglobinuria, in patients with severe hemolytic anemia and brain dysfunction, may be attributed to their inability to exercise. However, there is still no explanation for the converse situation, i.e., the lack of blood dyscrasia or brain disease in individual patients with myopathy [1].

There are no organ-specific isoenzymes, with the exception of the nonallelic testicular form of PGK. In addition, no tissue-specific posttranslational modifications were accessed as PGK derived from different tissues in the same individual does not differ in physical and biochemical properties. Nevertheless, the variable clinical features of the disease are thought to be the consequence of the unique biochemical properties of the individual PGK mutants. Theoretically these



**Muscle Phosphoglycerate Kinase Deficiency. Figure 1** Schematic representation of the mutations in the human gene encoding phosphoglycerate kinase 1 (PGK1) reported so far. Mutations previously shown to induce myopathy (i.e., exercise intolerance) are shown in red.

properties might affect the amount of residual PGK1 activity in various tissues and be thus related to the degree of clinical symptoms.

## Diagnostic Principles

In patients with myopathy, the resting serum creatine kinase (CK) level is usually elevated. During myopathy attacks the levels of CK or other muscle specific enzymes are enhanced and myoglobinuria can be detected in urine. Histochemistry and electron microscopy of muscle biopsy reveals mild to moderate increase of glycogen storage. In individual cases, electron microscopy revealed increased number of mitochondria (in one) and the existence of large matrix granules in several mitochondria (in another) [5]. Biochemistry of muscle biopsy reveals a very low residual PGK activity, which varies from 2.0 to 11.5% of normal. Due to residual PGK activity, the forearm ischemic exercise test can cause an increase of venous lactate to some degree (less than twofold) which may lead to misdiagnosis. Electromyography and nerve conduct studies were normal in all examined patients.

## Therapeutic Principles

Currently, there is no effective treatment available for patients with PGK1 deficiency. Avoidance of intensive exercise is advised and may prevent myoglobinuria.

# Muscle Phosphoglycerate Mutase Deficiency

Georgios M. Hadjigeorgiou
Department of Neurology, School of Medicine, University of Thessaly, Larissa, Greece

## Synonyms

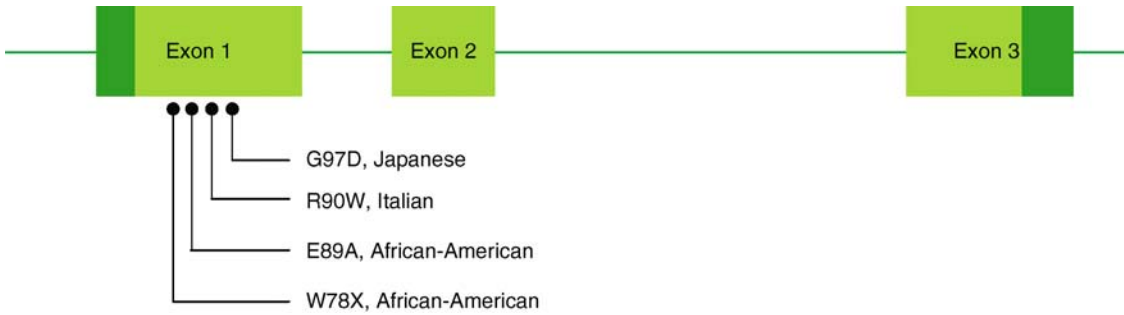
Glycogenosis type X

## Definition and Characteristics

Muscle phosphoglycerate mutase (PGAM-M) deficiency is an autosomal recessive disease due to a genetic defect in terminal anaerobic glycolysis [1]. It belongs to the group of glycogenoses that affect preferentially skeletal muscles but without fixed muscle weakness [2]. Clinical presentation includes intolerance to extensive exercise, myalgia, muscle cramps, and recurrent myoglobinuria. No cardiac involvement has been reported. In a Japanese patient diabetic polyneuropathy has been reported [3].

## Prevalence

The exact prevalence rate is unknown. PGAM-M deficiency has been reported in few (<15) patients of both genders from United States with African American genetic background, Italy, and Japan.



**Muscle Phosphoglycerate Mutase Deficiency. Figure 1** Schematic representation of the so far reported mutations in the human gene encoding the muscle specific subunit of phosphoglycerate mutase (PGAM-M).

## Genes

PGAM (EC 2.7.5.3) is a dimeric glycolytic enzyme that catalyzes the interconversion of 2-phosphoglycerate and 3-phosphoglycerate using 2,3-bisphosphoglycerate as a cofactor. There are two subunits of mammalian PGAM, a muscle-specific subunit (PGAM-M) expressed in skeletal muscle, heart, and sperm and a nonmuscle-specific, or brain, subunit (PGAM-B) expressed in most other tissues, including brain, liver, erythrocytes, leukocytes, and fetal skeletal muscle. The cDNA encoding PGAM-M has been cloned, and the gene with three exons has been isolated, and assigned to chromosome 7p12-7p13 [4]. Four point mutations have been reported in families with PGAM-M deficiency (Fig. 1) [3,5].

A stop-codon mutation (W78X) was predominant among African Americans; a missense mutation (Q89A) was also found in one African American family; a missense mutation (R90W) was reported in an Italian family; and a missense mutation (G97D) has been detected in a Japanese family with two heterozygous patients presenting muscle symptoms. The phenomenon of manifesting heterozygous has also been reported in other PGAM-M families as well as in other families with a defect in anaerobic glycolysis (glycogenosis V, McArdle's disease).

## Molecular and Systemic Pathophysiology

Three types of PGAM dimers (MM, BB, and MB) are present in mammalian tissues. Although early in development, fetal human skeletal muscle contains almost exclusively the BB homodimer, mature human skeletal muscle contains all three dimers in different percentage. In particular, PGAM-MM homodimer accounts for 80–90% of the total isoform pool and with the remaining made up of PGAM-MB and PGAM-BB homodimers in different percentage in different tissues. In vitro anaerobic glycolysis showed reduced, though not absent, lactate production (the terminal product of glycolysis). This is in accordance with the residual PGAM activity found in biochemical analysis attributed to the presence of PGAM-MB and PGAM-BB homodimers in skeletal muscles. The different proportions of these homodimers in different tissues probably explain why clinical manifestations are confined to skeletal muscle. The tissue-specific expression of PGAM-M has been attributed to a single myocyte-specific enhancer-binding factor (MEF-2) in the 50-untranslated region of the PGAM-M gene. All the so far reported mutations are located within PGAM-M gene coding region (exon 1).

## Diagnostic Principles

Resting creatine kinase has been reported elevated in most patients even in manifesting heterozygous. During attacks of pigmenturia, myoglobinuria can be detected in urine. Histochemistry and electron microscopy of muscle biopsy reveals mild glycogen storage, while biochemistry analysis shows very low residual activity of PGAM, which varies from 2.1 to 6.0% of normal. Due to residual PGAM activity the forearm ischemic exercise test cause some increase (less than twofold) of venous lactate that may cause misdiagnosis. Electromyography and nerve conduct studies were normal in all examined patients except the one who was suffering from diabetic polyneuropathy.

## Therapeutic Principles

Currently, there is no effective treatment available for patients with PGAM-M deficiency. Avoidance of intensive exercise may prevent myoglobinuria.

## Muscle-Liver-Brain-Eye Nanism

►Mulibrey Nanism

## Muscular Atrophy, Spinal I–III

Klaus Zerres, Sabine Rudnik-Schöneborn
Institute of Human Genetics, Aachen University of Technology, Aachen, Germany

### Synonyms

SMA type Werdnig-Hoffmann (type I); Intermediate SMA (type II); SMA type Kugelberg-Welander (type III); SMA

### Definition and Characteristics

Degeneration and loss of the anterior horn cells in the spinal cord, and – depending on type and severity – sometimes also of the brainstem nuclei, resulting in muscle weakness and atrophy. The sensory neurons are clinically spared, and there are no signs of upper motor neuron (pyramidal tract) involvement. Types defined according to achieved motor milestones: I: ability to sit not achieved; II: ability to sit but not to walk; III: ability to walk [1].

### Prevalence

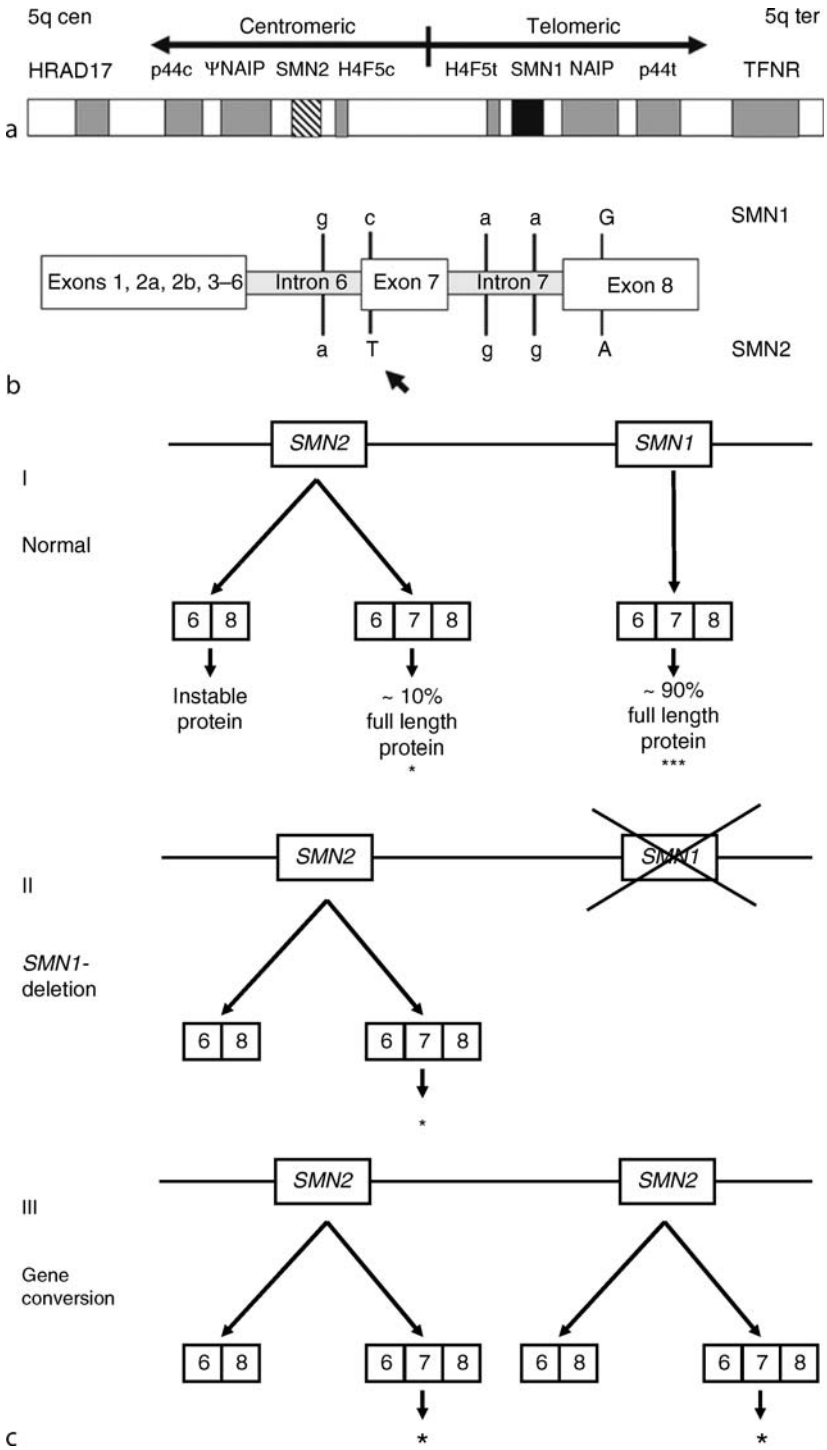
Considering the incidence of at least 1:10.000 for acute and chronic autosomal recessive proximal SMA, the estimated heterozygosity frequency is about 1:50 in the general population. Autosomal dominantly inherited SMA is extremely rare in infancy and youth.

### Genes

Homozygous deletions of the SMN1 gene (5q11.2–q13.3) [2] are detected in more than 90% of SMA type I–III patients. Moreover, isolated deletion of exon 8 has been detected in rare instances of mild SMA. The centromeric copy of the SMN gene (SMN2) is nearly identical with the SMN1 gene except for single nucleotide differences in exon 7 and 8, yet their transcriptional products are not the same. Although SMN1 produces full-length transcripts (90%), the SMN2 primarily gives rise to truncated transcripts lacking exon 7 and only minor amounts of full-length transcripts (∼10%) [3]. The critical difference between SMN1 and SMN2 is a C→T base change in exon 7 that causes alternative splicing of SMN2 exon 7. Homozygous deletions of SMN2 genes can be detected in about 5–10% of the normal population but are not associated with a disease phenotype if at least one SMN1 copy is retained. Only in a small number of patients (approximately 5–10%), subtle mutations in the SMN gene have been identified that mostly occur as compound heterozygosity in conjunction with a deletion.

### Molecular and Systematic Pathophysiology

The SMN protein is involved in RNA processing and acts in concert with several other proteins in the regeneration of the snRNPs, acting as an assemblyosome in the formation of diverse RNP particles [3]. There are currently two prevailing views that provide different explanations as to the mechanism by which the single nucleotide change between the SMN genes alters the splicing of exon 7 in the SMN2 gene. The difference might disrupt an exonic splicing enhancer (ESE) in exon 7 to which the splicing factor ASF/SF2 binds. The efficient binding of ASF/SF2 to SMN1 exon 7 but not SMN2 exon 7 causes the latter to be skipped, resulting in ∼10% of the transcript from the SMN2 gene to be full length. The alternative explanation is that the C/T transition acts to create an exonic splicing enhancer (ESS) to which a splicing repressor hnRNP A1 binds. Binding of the repressor to SMN2 exon 7 but not SMN1 exon 7 induces skipping of this exon from the majority of the transcripts from the former gene. Although the mechanisms differ, the result is the same, i.e., vastly reduced levels of the FL-SMN transcript from the SMN2 gene. It is still unclear why SMN protein deficiency results in selective motor neuron loss because the gene is ubiquitously expressed (see Figure 1).



**Muscular Atrophy, Spinal I–III. Figure 1** (a) Schematic representation of the inverted and duplicated SMA region (5q13), including four duplicated genes: *H4F5, SMN, NAIP*, and *BTFp44*. (b) Localization of the nucleotides by which *SMN1* can be distinguished from *SMN2*. The arrow indicates the C→T base exchange in exon 7 of *SMN2* that disrupts a putative exonic splice enhancer and causes alternative splicing. (c) SMN protein synthesis depending on the number of SMN1- and SMN2-copies. Representation of only one allele, different compound situations possible. *Small amount of full-length protein; ***high amount of full-length protein: (I) wild type allele. (II) SMA-allele with SMN1-deletion (characteristic of SMA I); (III) SMA-allele with gene conversion (characteristic of SMA III).

## Diagnostic Principles

The detection of homozygous deletions of SMN1 confirms the diagnosis and establishes autosomal recessive inheritance in SMA. In clinically typical patients without homozygous, quantitative analysis of SMN1 gene copies is recommended to identify a heterozygous SMN1 gene deletion, which is likely to act with a subtle mutation on the other chromosome. SMN1 mutation screening is not offered on a routine basis because of the complex inverted region on 5q13. The genetic basis of patients who are unlinked to chromosome 5q remains to be identified; especially for the mild SMA type III phenocopies of SMA have to be considered. Heterozygosity testing of relatives or spouses is meanwhile an integral part of genetic counseling. The SMN1 copy number can be measured by quantitative methods (e.g. MLPA) and can reliably identify heterozygous carriers of SMN1 gene deletions. The test sensitivity does not exceed 95%, because two or more SMN1 copies are present on 3–4% of normal chromosomes, thus leading to false negative results carriers with a heterozygous SMN1 deletion. In addition, new SMN1 deletions occur in about 1% of SMA chromosomes, and subtle mutations cannot be identified by the quantitative test.

## Therapeutic Principles

A curative treatment of SMA is not yet available, but the knowledge of the genetic defect in SMA 5q currently has major impact on therapeutic strategies. As an increased number of SMN2 copies might partly compensate for or prevent the motor neuron loss, agents that enhance the production of the SMN protein might be a means of therapy. Compounds have been detected that can up-regulate SMN2 gene expression, by preventing exon 7 skipping, or stabilize truncated SMN transcripts. Clinical trials have been initiated but thus far no medication is known to have a significant positive influence on the disease course. The main therapeutic elements in SMA are physical and orthopedic therapy and ventilatory support [4].

# Muscular Atrophy, Spinobulbar (Kennedy Syndrome)

Hans-Jürgen Gdynia, Anne-Dorte Sperfeld
Department of Neurology, University of Ulm, Ulm, Germany

## Synonyms

Kennedy's disease; Bulbospinal muscular atrophy

## Definition and Characteristics

X-linked spinal and bulbar muscular atrophy (XSBMA) is a chronic, slowly progressive adult onset motor neuron disease [1]. Affected persons suffer from progressive, usually proximal and bulbar muscular weakness and atrophy, generalized fasciculations with predominance of facial muscles and additional symptoms including gynecomastia and postural tremor. Facultative neuromuscular symptoms are therapy-resistant muscle cramps, premature exhaustion and rarely a myasthenic syndrome. During the course of the disease, various symptoms occur due to a partial androgen insensitivity and more than half of the patients develop mild afferent ataxia due to a central-distal axonopathy. Muscular weakness and progressive gait disturbance usually require adjuvant therapy after 15–20 years of disease progress. Bulbar paralysis with consecutive dysarthria and dysphagia can develop in every stage of the disease, usually simultaneously with the limb weakness. Rarely, dysphagia necessitates adjuvant nutrition or gastrostoma. Clinical pyramidal signs are not observed, but electrophysiological abnormalities in motor evoked potentials have been described [2]. Due to the genetic defect, affected males often show signs of partial androgen insensitivity long before distinct neurological symptoms occur. About 50% of patients develop gynecomastia at puberty and facultative infertility, erectile dysfunction and testicular atrophy in their fourth or fifth decades [3,4]. Further concomitant conditions are mild cognitive impairment, hypercholesterinemia, hyperlipidemia, elevated creatine kinase, diabetes mellitus and impaired glucose tolerance.

## Prevalence

The worldwide prevalence is estimated to be 1:40,000. Since clinical symptoms overlap with other neuromuscular disorders, for example amyotrophic lateral sclerosis or spinal muscular atrophies, and clinical signs are often unspecific in early stages of the disease, XSBMA is possibly under diagnosed.

### Genes

Gene map locus Xq11–q12, gene SMAX1 (OMIM 313200).

### Molecular and Systemic Pathophysiology

The underlying genetic defect in XSBMA is an expansion of a CAG trinucleotide repeat in the first exon of the androgen receptor gene (SMAX1). Only males are affected, reportedly homozygous women can show mild muscle cramps. The CAG repeat encodes a polyglutamine expansion in the amino-terminal domain of the protein. In normal individuals, the gene has 5–36 repeats. In patients with XSBMA, more than 40 repeats have been reported. The molecular mechanisms of XSBMA are not completely understood. The mutation leads to both a toxic gain of function in affected cells and a loss of normal androgen receptor function. The androgen receptor is ubiquitously expressed in the brain and spinal cord, including both sexually dimorphic and non-dimorphic neurons. Neuropathological investigations of XSBMA patients showed degeneration of androgen receptor-containing brainstem and spinal motor neurons as well as sensory neurons in the dorsal root ganglia. It is known that androgens exert a trophic response on neurons, which is probably disturbed in XSBMA. In peripheral nerves, androgens are linked to an increase in mRNA expression of structural proteins such as neuritin, connexins, and beta-tubulin.

### Diagnostic Principles

Beside a detailed medical history and neurological examination, serum glucose, lipids and liver enzymes should be determined. If Kennedy's syndrome is suspected, a molecular analysis of the androgen receptor gene can confirm the diagnosis.

### Therapeutic Principles

Up to now, a causal therapy has not been established. In current studies, the chemical blockade of dihydrotestosterone is being evaluated. Application of testosterone and creatine has no positive effects. The treatment focuses on symptomatic and supportive strategies. Physical therapy, logopedia and other adjuvant therapies are the most important issues. Few patients become wheel chair bound or need noninvasive ventilation.

## Muscular Dystrophy Type Landouzy-Dejerine

►Facioscapulohumeral Muscular Dystrophy

## Muscular Dystrophy, Duchenne and Becker

Eric P. Hoffman
Research Center for Genetic Medicine, Children's National Medical Center, George Washington University, Washington, DC, USA

### Synonyms

Duchenne muscular dystrophy; Becker muscular dystrophy; DMD

### Definition and Characteristics

Common genetic disorders of muscle and heart tissue caused by abnormalities of the large cytoskeletal protein "dystrophin" [1]. Both disorders show degeneration and regeneration of muscle fibers, and progressive muscle weakness and loss.

### Prevalence

1/3,500 males in most world populations. Implementation of molecular diagnostics, carrier detection and prenatal diagnosis has reduced incidence by ~30% in some countries.

### Genes

Duchenne and Becker are caused by mutations in the 2.5 million base pair dystrophin gene at Xp21 on the short arm of the X chromosome [2]. Duchenne muscular dystrophy (DMD) is caused by loss of function (absence) of dystrophin, while Becker dystrophy shows residual but abnormal dystrophin (partial loss of function). The gene has 79 exons, and is the largest gene identified to date. Both Duchenne and Becker muscular dystrophy patients often show deletions of one or more exons of the dystrophin gene. Duchenne patients often show out-of-frame (nonsense) mutations where the remaining exons do not maintain the translational reading frame of the dystrophin protein. Becker patients typically

show in-frame deletions, where a partially functional dystrophin protein is produced lacking amino acids corresponding to the deleted exons.

## Molecular and Systemic Pathophysiology

Dystrophin (427 kDa) is a component of the plasma membrane cytoskeleton of myofibers, cardiocytes, smooth muscle cells, and some neurons. The biochemical role of dystrophin is to provide structural stability to the plasma membrane by linking a series of other intracellular and transmembrane proteins, including actin, dystroglycans and others. The dystrophin-associated glycoprotein complex anchors the cells within the surrounding basal lamina, and prevents contraction-induced injury to the cells. When dystrophin is defective, membrane instability occurs, with contraction induced damage and cell death. Some cells are more susceptible to membrane damage, and the pathophysiology of specific skeletal muscle, cardiac muscle, smooth muscle, and neuronal tissues varies. Bouts of degeneration of skeletal muscle are followed by regeneration, but with time, regeneration progressively fails, leading to muscle weakness and an early death [3]. Duchenne dystrophy patients become wheelchair bound between 7–15 years of age, while Becker patients show a milder but variable clinical course.

## Diagnostic Principles

Duchenne dystrophy presents in young males (2–5 years old) with proximal muscle weakness, associated with very high serum creatine kinase levels. Molecular confirmation of Duchenne is done either by detection of gene mutation (70% patients show deletion mutations), or by demonstration of dystrophin deficiency on muscle biopsy. Becker muscular dystrophy patients are males that show proximal weakness at an older age, also associated with high serum creatine kinase and gene deletions. Protein studies of muscle biopsy show dystrophin of abnormal size and/or amount. Genetic counseling is often offered to the families of a patient with Duchenne or Becker dystrophy. The disease is X-linked recessive with the mother and sisters of a male proband at high risk for being a carrier. However, many mothers of DMD patients are not carriers, due to the high mutation rate of the gene (1/10,000 sperm and eggs).

## Therapeutic Principles

Supportive therapy such as physical therapy, prevention of contractures, respiratory therapy, and assistance with activities of daily living are important. Chronic glucocorticoids (prednisone or deflazacort) are prescribed in many patients, and this provides a rapid increase in strength and slower progression in many patients. Experimental therapeutics is a very active area of research, with many avenues holding considerable promise.

## Synonyms

Hauptmann-Thannhauser muscular dystrophy; AD-EDMD

## Definition and Characteristics

EDMD is a skeletal and cardiac muscles disease characterized by the coexistence of the clinical triad of: early childhood onset joint contractures mainly involving elbows, Achilles' tendons, neck and spine, slowly progressive muscle weakness and wasting of humero-peroneal predominance in the early stages, and cardiac disease with conduction defects, arrhythmias and dilated cardiomyopathy [1]. Onset usually occurs in the first decade by joint Achilles' tendons and elbow contractures. Cardiac disease often occurs by the end of the second decade by asymptomatic atrioventricular conduction defects and atrioventricular extrasystoles. Normal or moderately elevated CPK, myopathic electromyographic pattern and dystrophic abnormalities on muscle biopsy are classical findings. Historically known as an X-linked trait, the autosomal dominant form have been progressively individualised during the last three decades [1]. The X-linked and AD forms had grossly the same clinical characteristics. However, a wider clinical variability has been

observed in AD-EDMD patients in terms of age of onset, symptoms and severity.

## Prevalence

The exact prevalence of AD-EDMD is unknown, but AD-EDMD is extremely rare, as for example in France only 70 cases were genetically identified since 1999.

## Genes

Heterozygous mutations in the LMNA gene encoding lamins A/C are responsible for the AD-EDMD [2]. Lamins A/C are type V intermediate filament and component of the nuclear lamina underlying the inner nuclear membrane. EDMD belongs therefore to the group of laminopathies. All mutation types and localisations along the LMNA gene have been observed, although a majority of cases is due to missense mutations (for details see http://www.umd.be:2000/).

## Molecular and Systemic Pathophysiology

On the basis of the different roles assigned to lamins A/C, two main models are proposed to explain the pathogenesis of lamins A/C related diseases involving striated muscles [3]. The structural model is based on the fact that mutated lamins A/C lead to defects in maintaining the structural integrity of the nucleus of the skeletal and cardiac muscle fibres, as they are particularly subjected to mechanical load leading to structural damage and cell death. The cell proliferation model postulates that muscle satellite cell differentiation is disturbed in lamins A/C mutated cells thus leading to perturbation of muscle regeneration in patients showing striated muscle disease such as EDMD. Those two hypotheses are not mutually exclusive and may both participate to the pathomechanisms of the LMNA mutations.

## Diagnostic Principles

See chapter on ►Limb Girdle Muscular Dystrophy, Autosomal Dominant Type 1B.

As for other muscular dystrophies, EDMD diagnosis is mainly based on:

- The presence of the clinical triad of early and extensive joint contractures, muscle atrophy and weakness of typical topography and dilated cardiomyopathy with conduction defects and arrhythmias.
- Because of the high clinical variability of AD-EDMD patients, the exclusion of similar muscular conditions presenting with joint contractures, a scapulo-peroneal muscle atrophy, and those showing concomitant cardiac and skeletal muscle involvement may be required. These diseases include several forms of congenital muscular dystrophies, several scapulo-peroneal syndromes with or without contractures or cardiac disease, Bethlem myopathy, rigid spine syndrome especially those due to SEPN1 gene mutations, and other myopathies with cardiac involvements (myotonic dystrophies, dystrophinopathies, desmin related myopathies, FKRP related myopathies).
- The autosomal dominant pattern of inheritance may be obvious from the familial history. However, the high frequency of de novo LMNA mutations and the high intrafamilial phenotypical variability rate may lead to the absence of this typical pattern of inheritance and the presence of other laminopathic traits within the same family. On the other side, the possibility of an X-linked form of EDMD might be taken into account especially for isolated male cases.

The formal genetic AD-EDMD diagnosis is based on the identification of LMNA gene mutations as protein analysis of lamins A/C on several tissues (muscle, fibroblasts) shows normal protein amounts in the majority of cases.

## Therapeutic Principles

See chapter on ►Limb Girdle Muscular Dystrophy, Autosomal Dominant Type 1B.

Evaluations at initial diagnosis and follow up are based on routine procedures mainly including neurological evaluation, cardiological investigations (ECG, Holter-ECG monitoring, echocardiography). Electrophysiological testing may be required in a selected set of patients. Cardiologic assessment once a year is highly recommended to detect patients, free of cardiac symptoms. Evaluation of respiratory function is also advisable (vital capacity and other pulmonary volume) as respiratory insufficiency has been reported in some patients. A regular follow up of respiratory function may be required is some patients showing vital capacity impairment. Prevention of orthopaedic complications (promoting mobility and preventing joints contractures by physiotherapy and stretching exercises) and systemic thromboembolisms (antithromboembolic drugs such as vitamin K antagonists, warfarin, heparin) prevention may be required. Treatment of manifestations may include surgery (for releasing of Achilles tendons and other contractures, scoliosis if indicated), use of mechanical aids (canes, walkers, orthoses, wheel chairs) as needed to help ambulation, treatment of cardiac features may require specific treatments including antiarrhythmic drugs, cardiac devices (pacemaker, implantable cardioverter defibrillator) for primary or secondary prevention of sudden death [4], and both pharmacological and non-pharmacological therapy for heart failure. Heart transplantation is often required at the end stages of heart failure. Use of respiratory aids (respiratory muscle training and assisted coughing techniques, mechanical ventilation) may be required if indicated in late stages.

# Muscular Dystrophy, Emery-Dreifuss, X-linked

Dominique Récan-Budiartha
Laboratoire de Biochimie et Génétique Moléculaire, Hôpital Cochin AP-HP, Paris, France

## Synonyms

XL-EDMD; Emerinopathy; Muscular dystrophy, tardive, with contractures, formerly; Scapuloperoneal syndrome, x-linked, formerly

## Definition and Characteristics

X-linked recessive degenerative myopathy characterized by the clinical triad of (i) slowly progressive muscle wasting and weakness with humeroperoneal distribution in the early stages; (ii) early contractures of the elbows, Achilles tendons, and postcervical muscles; and (iii) cardiomyopathy with conduction defects [1].

Most of carrier females are asymptomatic, but a cardiomyopathy with conduction defects may be observed.

## Prevalence

The prevalence of the X-linked EDMD was estimated at 1/100,000, but has not been studied since the genetic diagnosis has been available. The disease has a worldwide distribution mostly in large families. Neomutations are rare. The autosomal dominant EDMD (heterozygous mutations in LMNA gene coding for lamins A and C) is more frequent.

## Genes

EMD gene coding for emerin, localized on chromosome X q28 [2].

## Molecular and Systemic Pathophysiology

Emerin is an ubiquitous integral membrane protein of the inner nuclear membrane and interacts with several nuclear proteins as lamins A and C, components of the nuclear lamina, actin and muscle specific nesprin, thus participating to the structural stability of the nucleoplasm-nuclear envelope skeleton. Emerin also interacts with some DNA bridging proteins as BAF, and is involved in the reorganization of the nuclear envelope and of the chromatin after mitosis. The hundred EMD mutations identified in XL-EDMD patients are spread all along the gene, and most of them (90%) are nul mutations, leading to the absence of emerin in nuclei. Few EMD missense mutations/ in frame deletions result in mislocalization of emerin to the cytoplasm, defective interaction with lamins A/C and alteration of the cell cycle (Fig. 1) [3]. Analyses of muscle cells and skin fibroblasts of XL-EDMD patients show focal loss of the nuclear membrane and chromatin extrusion into the cytoplasm. The involvement of lamins A/C mutations in AD-EDMD suggests that the interaction emerin–lamins A/C is one of the keys of these diseases. Two main pathophysiological mechanism models are proposed: (i) the "mechanical/structural model" in which the absence of emerin at the nuclear rim might weaken the structural integrity of the lamina-nuclear membrane network and induce alterations in muscular cells permanently submitted to mechanical stress, and (ii) the "gene expression model" in which the absence of emerin might compromise the chromatin organization, leading to changes in the pattern of gene expression [4,5]. However, the exact pathophysiological mechanisms remain to be elucidated, especially in cardiac and skeletal muscular tissues specifically damaged in EDMD.

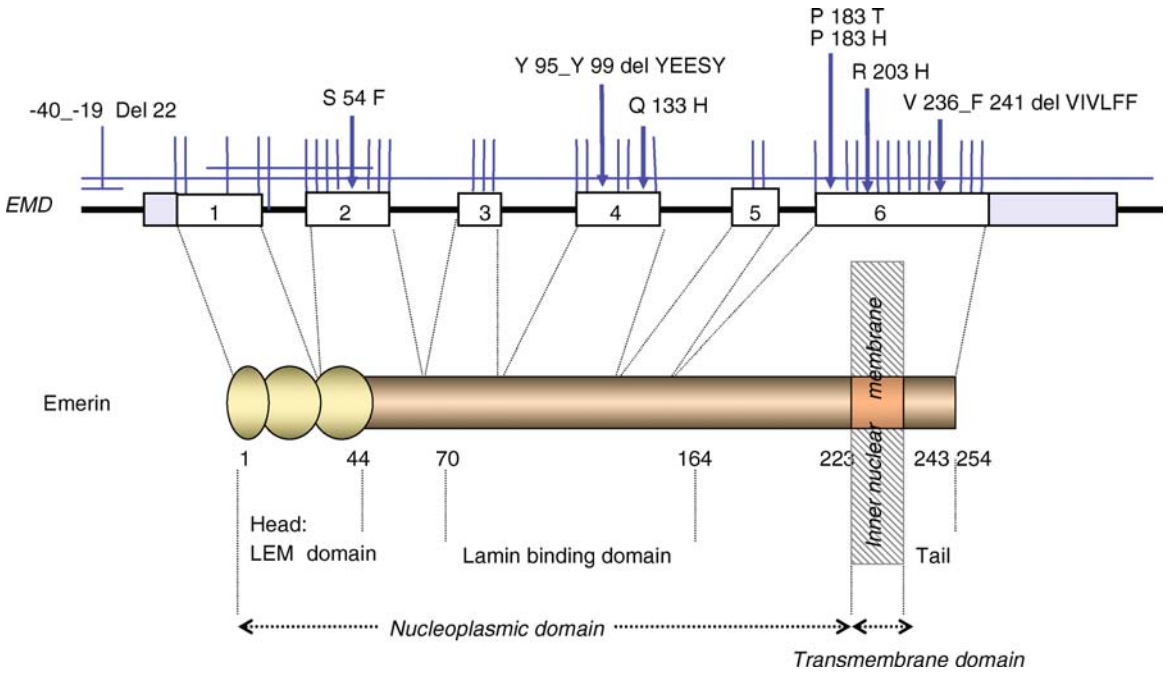
## Diagnostic Principles

*Clinical Diagnosis*: Based on the typical triad: humeroperoneal muscular dystrophy, early joint contractures (elbows, Achilles tendons, neck and spine) and cardiomyopathy with conduction defects: AV block, atrial fibrillation/ flutter/ paralysis, bradyarythmia etc.).

*Protein Diagnosis*: The absence of emerin in muscle biopsy, skin biopsy, lymphocytes or lymphoblasts, analyzed by immunohistochemistry or immunoblotting, confirms the diagnosis.

In carrier females, the diagnosis is confirmed by immunohistochemistry: emerin is absent in various proportions of nuclei, but the western-blot is not reliable since it may show a normal or reduced amount of emerin.

*Genetic Diagnosis*: EMD gene mutation screening.



**Muscular Dystrophy, Emery-Dreifuss, X-linked. Figure 1** *EMD* gene and emerin with position of mutations identified in XL-EDMD patients (indicated by blue lines). Vertical lines indicate nonsense mutations, horizontal lines: large out of frame deletions, vertical arrowheads: missense mutations and in frame deletions. LEM: BAF-binding domain.

## Therapeutic Principles

*Pharmacological therapy*: Cardiac disease: anti-arrhythmic drugs (beta blockers, amiodarone, etc.), anticoagulant drugs (vitamin K antagonists, heparin) to prevent thromboembolic complications, CEI for heart failure [5].
*Dietary therapy*: Dietary specific of cardiac disease (low salt, etc.).
*Other treatments available*: Physiotherapy to prevent increasing of joint contractures, orthopaedic surgery: tenostomy; Cardiac disease: pacemaker implantation [5].

## Definition and Characteristics

Autosomal dominant mutations in the c-terminus of the gigantic sarcomeric titin causing late onset distal myopathy most prominently in the anterior compartment muscles of the lower legs.

## Prevalence

The prevalence of >8/100,000, according to incomplete ascertainment, has been reported for the Finnish population where the founder mutation on chromosome 2q31 has an approximated frequency of 1/2,000 (Fig. 1).

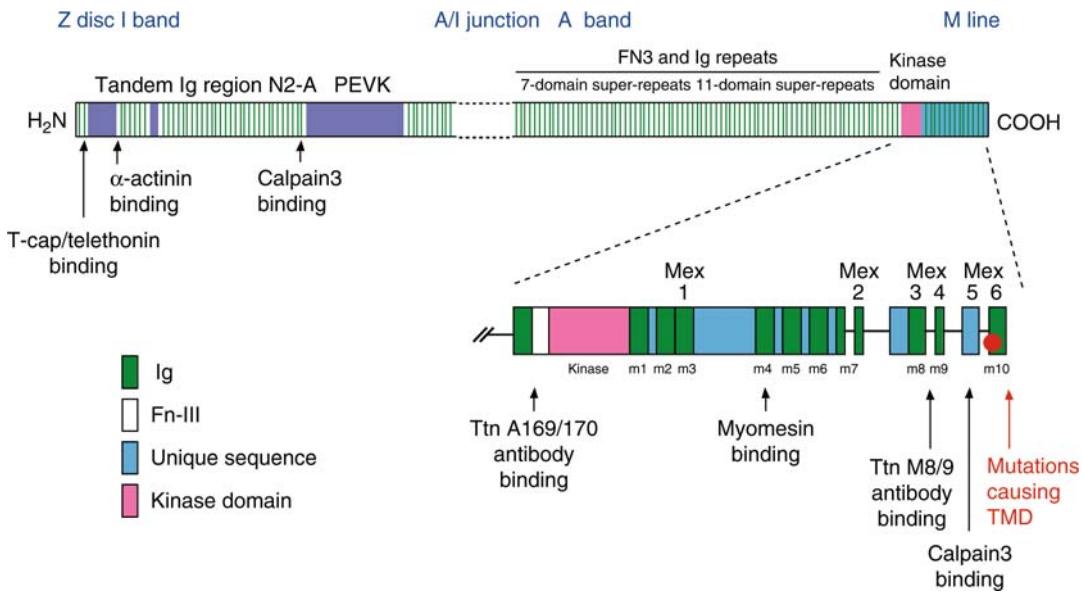
## Molecular and Systemic Pathophysiology

Titin is a major third filament structural protein of the sarcomere with a huge size; the largest isoforms of the 100 kb cDNA gene have >38,000 amino acids giving rise to the molecules of >4,000 kDa. Titin has a multitude of functions shown by binding to many of the other sarcomeric proteins, such as: calpain3, MURF-1, α-actinin, myosin, myomesin, telethonin, etc. It has mechanical, developmental, and regulatory roles in striated muscles, and stretches over the length of one half sarcomere, from the Z-disc to the M-band. The exact role of the c-terminal M-line titin is unknown and it contains a kinase domain with unknown substrate(s). A function as a sensor organ for the muscle cell has been proposed.

The Finnish TMD mutation has been proven to cause a completely different, severe early onset limb-girdle muscular dystrophy (LGMD2J) in some rare homozygote individuals. The phenotypic difference is underscored by the occurrence of rimmed vacuolated fibers in TMD, whereas this feature is lacking in the homozygote LGMD2J state. Heart muscle is not affected by the TMD mutations. The reason is not determined, but one of the ligands of M-line titin, muscle specific calpain3, is secondarily reduced. Findings of apoptosis have also been confirmed in accordance with studies on primary calpain3 defects (LGMD2A). Calpain3 has no major role in adult heart muscle and could thus explain the lack of cardiomyopathy in TMD. Variable proportions of different titin isoforms in different muscles may constitute another background for the selective involvement of muscles.

## Diagnostic Principles

The main founder mutation in the Finnish population is determined by SSCP-analysis and shown to be present also in descendants of Finnish immigrants in Sweden, Germany, Canada. A second titin exon Mex6 mutation has been identified in two unrelated TMD families in northern France and a third Mex6 mutation was identified in a Belgian TMD family. Sequencing of the c-terminal gene is currently undertaken for eventual new mutations. The c-terminal defect is possible to detect with corresponding antibodies on immunohistochemistry in the recessive LGMD2J state.



**Muscular Dystrophy, Tibial, Udd Myopathy. Figure 1** Schematic structure of the titin molecule. Blow-up of the c-terminal M-line region showing the location of TMD mutations in the last exon, Mex 6, and functional domains of the protein.

## Therapeutic Principles

No curative therapy is available and many TMD patients manage relatively well. The walking ability is impaired but preserved even late in life. Patients with severe foot drop are offered tibialis posterior tendon transposition surgery. Ankle orthoses are commonly used.

# Mutations at 10q11.2

Wolfgang Dietmaier, Arndt Hartmann
Institute of Pathology, University of Regensburg, Regensburg, Germany

## Synonyms

MEN-2A: Sipple syndrome; MEN-2B: Wagemann-Froboese syndrome, MEN-3 multiple endocrine neoplasia type II; MEN-2

## Definition and Characteristics

The chromosome 10q11.2 locus contains the RET proto-oncogene which encodes for a receptor tyrosine kinase. Germline mutations in the RET oncogene cause the autosomal dominant inherited cancer syndrome Multiple Endocrine Neoplasia type II (MEN-2). In the MEN-2 syndromes, medullary thyroid carcinoma is the key malignoma and represents the first manifestation of MEN-2 [1,2]. Depending on the involvement of other tissues MEN is grouped as MEN-2A, MEN-2B, and familial medullary thyroid carcinoma (FMTC).

Over 90% of cases are classified as MEN-2A which involves pheochromocytomas and parathyroid hyperplasia/adenomas as secondary and third tumor manifestations, respectively. Other MEN-2A manifestations comprise Hirschsprung's disease (agangliosis of submucosal and myenteric colonic plexus), lichen amyloidis, and adrenal ganglioneuroma. Familial cases of MEN-2A are diagnosed clinically at the age of 30–40 years, sporadic cases in the sixth decade [3]. Of note, medullary thyroid carcinoma has been found in children aged 10 years and below, in MEN-2B even at the age of 6 months.

MEN-2B, also termed Wagenmann-Froboese syndrome, accounts for approximately 5% of all MEN-2. Besides medullary thyroid carcinoma and pheochromocytoma, additional manifestations of the disease are ganglioneuromatosis, myelinated corneal nerves, as well as "marfanoid" skeletal abnormalities and sometimes café-au-lait spots. MEN-2B occurs on average 10 years earlier than MEN-2A.

The third form of MEN-2 is FMTC where medullary thyroid carcinoma is the only clinical feature (Fig. 1).

## Prevalence

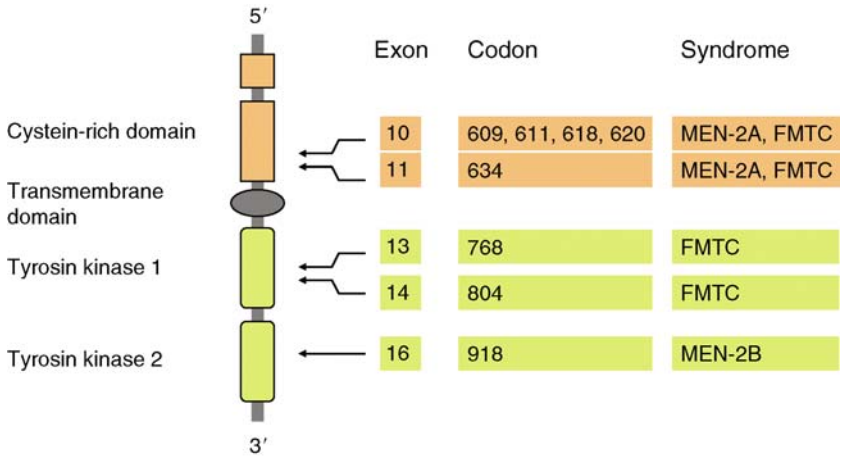
1:35,000

## Genes

MEN-2A: RET oncogene, Exon 10 and 11 (codon 609, 611, 618, 620, and frequently 634 within the extracellular cystein-rich domain)
MEN-2B: RET oncogene, Exon 16. A germline mutation in codon 918 is found in 95% of MEN-2B individuals.
FMTC: RET oncogene, Exon 10, 11, and 13 (codon 609, 611, 618, 620, and 634 within the extracellular cystein-rich domain or codon 768, 790–791, 804, 844, and 891 within the intracellular residues).

## Molecular and Systemic Pathophysiology

RET (rearranged during transfection) proto-oncogene encodes a receptor tyrosine kinase that is expressed in derivatives of neural-crest cells, including neural-crest-derived tumors such as medullary thyroid carcinoma



**Mutations at 10q11.2. Figure 1** Scheme of RET proto-oncogene showing mutations associated with MEN-2.

and pheochromocytoma. Germline point mutations in the RET gene has emerged as a molecular basis for FMTC, MEN-2, as well as Hirschsprung's disease (aganglionosis of the submucosal and myenteric plexus of the colon) by affecting substantially four types of tissues originating from neural crest cells: thyroid C cells, parathyroid cells, chromaffin cells of the adrenal medulla and enteric autonomic plexus.

Point mutations involving the extracellular codons 609, 618, and 620 can cause (i) a gain of function in FMTC and MEN-2 by impaired disulfide bonding of two adjacent RET molecules owing to steric hindrance or (ii) a loss of function (Hirschsprung's disease) due to decreased RET protein levels at the cell surface. Mutations affecting the extracellular domain codons 609, 611, 318, 620, 630, and 634 lead to RET activation by ligand-independent dimerization and cross-phosphorylation. Mutations involving the intracellular domain codons 768, 790, 791, 804, and 891 lead to interference with intracellular ATP binding of the tyrosine kinase receptor.

## Diagnostic Principles

Suggestive evidence: medullary thyroid carcinoma, elevated serum calcitonin concentration, family history, multifocal tumors, testing for germline mutation in the RET proto-oncogene.

Genetic screening should be performed in all patients with medullary thyroid cancer.

## Therapeutic Principles

A total thyroidectomy is recommended as prophylactic treatment at around the age of 6 years in children carrying MEN-2A mutations and shortly after birth in children with the MEN-2B mutation [4]. However, the age at which surgery is recommended may depend primarily on the individual mutation that is present as well as on other manifestations [5]. Livelong clinical surveillance to detect tumors of the adrenal and tumors or hyperfunction of parathyroid is warranted. A yearly biochemical screening in individuals with germline mutations (calcitonin, metanephrines, vanillyl mandelic acid, calcium, parathyroid hormone) should be done [1].

# Mutations in the Type 2a Sodium-Phosphate Transporter

Dominique Prié[1], Caroline Silve[1], Bernard Grandchamp[2], Gérard Friedlander[1]
[1]INSERM, University of Paris, Paris, France
[2]Service de Biochimie B, Hôpital Bichat, Paris, France

## Synonyms

Hypophosphatemia with renal phosphate loss; Hypophosphatemia associated with nephrolithiasis or bone demineralization; Nephrolithiasis and osteoporosis associated with hypophosphatemia caused by mutations in the type 2a sodium-phosphate cotransporter (NPT2a)

## Definition and Characteristics

Hypophosphatemia and increased urinary phosphate excretion due to mutations in the renal sodium-phosphate cotransporter NPT2a.

## Prevalence

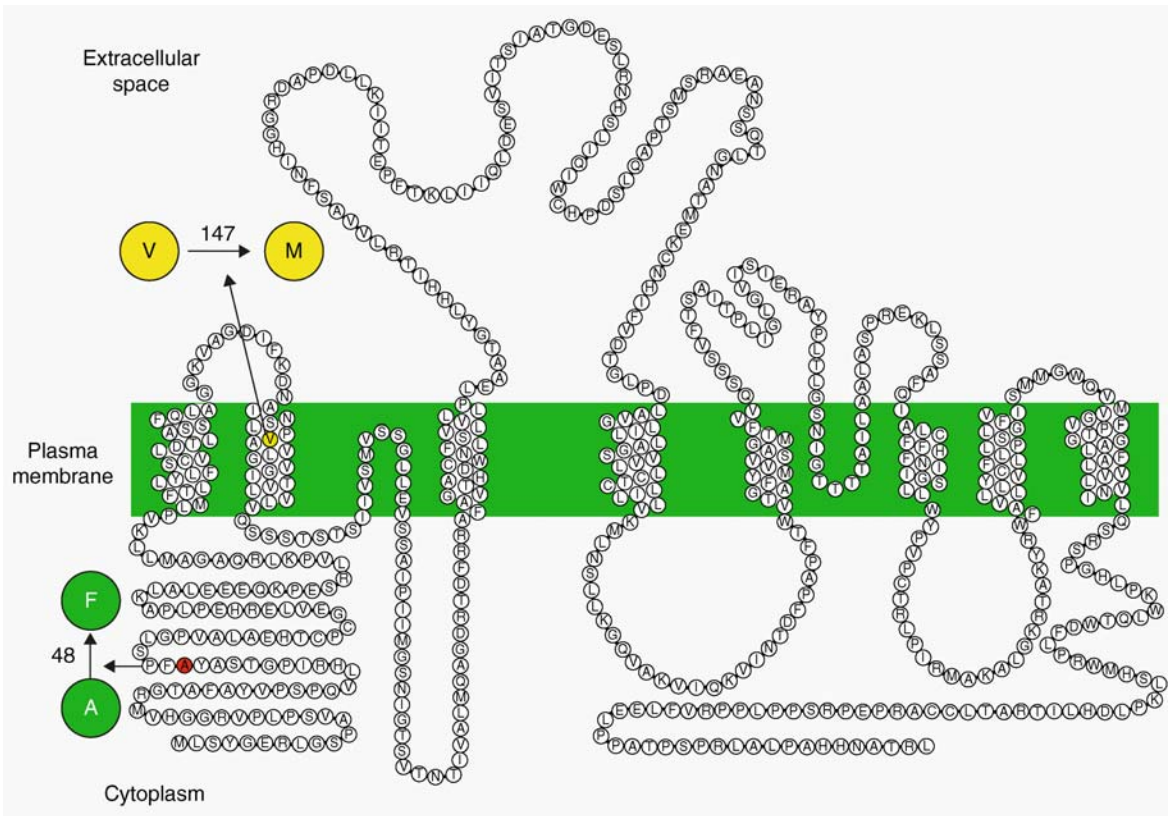
Unknown. Two family cases reported.

## Genes

NPT2a, SLC17A2, solute carrier family 34 (sodium phosphate) member 1, solute carrier family 17 (sodium phosphate) member 2. Chromosomal location: 5q35.

## Molecular and Systemic Pathophysiology

Kidney plays a major role in phosphate homeostasis by adapting urinary phosphate excretion to phosphate intake. Phosphate is freely filtered at the glomerulus and is then almost exclusively reabsorbed in the proximal tubule. Phosphate reabsorption is a sodium-dependent process that involves several sodium phosphate cotransporters expressed at the apical domain of proximal tubular cells. Phosphate uptake at the apical domain is the rate-limiting step of renal phosphate reabsorption. The data obtained in knock out mice indicate that the type 2a sodium phosphate cotransporter NPT2a is the main carrier involved in renal phosphate transport [1]. NPT2a is almost exclusively expressed in the renal proximal tubule [2]. In the kidney, NPT2a expression



**Mutations in the Type 2a Sodium-Phosphate Transporter. Figure 1** Location of mutations in human NPT2a protein.

**Mutations in the Type 2a Sodium-Phosphate Transporter. Table 1** Main biologic findings observed in patients with heterozygous NPT2a mutations

| | |
|---|---|
| Fasting serum phosphate concentration | Low |
| Serum PTH concentration | Normal |
| Serum ionized calcium concentration | Normal |
| Maximal capacity of kidney to reabsorb phosphate (TmPi/GFR) | Decreased |
| Fractional excretion of phosphate in urine (FEPi) | Increased |
| Serum calcitriol concentration | Increased or upper normal range |
| Excretion of calcium in urine | Increased or upper normal range |

is inhibited by parathyroid hormone and high phosphate diet [2].

To date, two distinct heterozygous mutations in the NPT2a gene have been identified in two unrelated families [3]. The localization of these mutations in the NPT2a protein is presented in Fig. 1. The identified mutations modify amino acids that are conserved among species.

Both mutations decrease renal phosphate reabsorption leading to low serum phosphate concentration that, in turn, increases serum calcitriol concentration. Calcitriol stimulates intestinal absorption of phosphate and calcium leading to high urinary excretion of phosphate and calcium.

Low serum phosphate concentration is associated with low bone mineralization. High calcium and phosphate excretions increase urine saturation and may contribute to urolithiasis formation [4,5].

### Diagnostic Principles

The diagnosis of mutations in NPT2a gene is suspected in patients with urolithiasis or bone demineralization associated with low fasting serum phosphate concentration. The main biologic findings observed in patients with heterozygous NPT2a mutations are presented in table 1.

### Therapeutic Principles

No specific treatment has been tested.

## MVP

►Mitral Valve Prolapse

## Myalgic Encephalomyelitis

►Chronic Fatigue Syndrome

## Myasthenia Gravis

Andrew G. Engel
Department of Neurology, UCLA School of Medicine, Reed Neurologic Research Center, Mayo Clinic, Rochester, MN, USA

### Synonyms

Autoimmune myasthenia gravis

### Definition and Characteristics

A defect of neuromuscular transmission caused by autoimmune-mediated endplate acetylcholine receptor (AChR) deficiency.

## Prevalence

Estimates of prevalence range from 118 to 150 per million.

## Molecular and Systemic Pathophysiology

In the vast majority of MG patients the disease stems from an autoimmune response against AChR. Consistent with this, 80–90% of MG patients have circulating antibodies against AChR. About 30% of myasthenic patients seronegative for anti-AChR antibodies carry antibodies against MuSK, a muscle specific tyrosine kinase that plays a role in the aggregation of AChR at the endplate (EP). This implies that MG can also arise from an autoimmune response against MuSK.

The basic event that breaks tolerance to self-AChR or -MuSK remains unknown. Three predisposing conditions have been recognized for AChR-seropositive MG, treatment with penicillamine, treatment with α- or β-interferon and bone marrow transplantation. As in other autoimmune diseases, the afferent limb of the immune response involves presentation of processed antigen (peptide fragments of AChR) by HLA class II positive antigen-presenting cells to specific autoreactive $CD4^+$ T helper cells which, in turn, stimulate production by B cells and plasma cells of antibodies that recognize specific epitopes of AChR and presumably MuSK. The thymus gland is probably involved in autoimmunity to AChR-seropositive MG since it contains epithelial cells (known as myoid cells) that express AchR, the myasthenic thymus harbors lymph nodes with germinal centers that contain AChR specific B cells that secrete anti-AChR antibodies and the gland is hyperplastic in ∼70% of patients and harbors epithelial tumors in ∼15% of patients. These findings suggest that a thymic abnormality could result in recognition of self-AChR components as nonself and thereby trigger the afferent limb of the immune response.

In AChR seropositive MG, the efferent limb of the autoimmune response is mediated by anti-AChR antibodies that reduce the number of EP AChRs by antibody-dependent complement-mediated lysis of the junctional folds, accelerated internalization and destruction of AChRs (antigenic modulation) and blocking the binding of acetylcholine (ACh) to AChR. The AChR deficiency decreases the amplitude of the miniature EP potential (MEPP) and hence that of the EP potential (EPP) which, in turn, reduces the safety margin of neuromuscular transmission.

The pathological mechanisms that impair neuromuscular transmission in MuSK-seropositive MG are not fully understood. The basic event that breaks tolerance to self-MuSK is not known. Anti-MuSK antibodies inhibit agrin-induced clustering of extrajunctional AChR expressed by myotubes; this suggests that they also decrease the density of AChR at the EP. Studies of MuSK-antibody-positive MG, however, are still incomplete; the number of AChRs is normal or only mildly diminished, substantive immune deposits have not been demonstrated at the EP, EP fine structure has not been analyzed and electrophysiological studies of patient EPs have not been performed. Thus, the pathogenesis of MuSK-antibody-positive MG is less well understood than that of AChR-antibody-positive MG.

The pathogenesis of MG in patients who carry neither anti-AChR nor anti-MuSK antibodies remains unclear. Some seronegative patients with ocular MG test positively for AChR antibodies when their disease becomes generalized; other seronegative patients may have a genetically determined congenital myasthenic syndrome.

## Diagnostic Principles

The diagnosis of myasthenia gravis is based on the clinical history, the physical findings, pharmacological tests, electromyography (EMG) investigations (conventional needle EMG, study of the decremental response and in some cases single fiber recordings) and tests for anti-AChR antibodies that bind, modulate or block AChR. Tests for modulating and blocking antibodies are needed only when the test for binding antibodies is negative. A history of acquired weakness increased by exertion, involvement of the external ocular muscles, a positive anticholinesterase drug test and a decremental EMG response are usually sufficient to confirm the diagnosis. A positive test for AChR or MuSK antibodies supports the diagnosis but a negative test does not exclude it. The AChR tests are positive in 100% of adults with moderately severe or severe MG, in 80% with mild generalized MG, in 50% with ocular MG and in 25% of those in remission.

Striated muscle antibodies recognizing myosin, actin, titin and the calcium release channel of the sarcoplasmic reticulum also occur in MG patients. Their role in the disease remains unknown, but they are sensitive markers for associated thymoma in younger patients. These antibodies are present in 84% of patients with thymoma. In patients without thymoma, they are present in 5% when the onset is before age 40 and in 47% when the onset is after age 40. Once the diagnosis of MG is established, all patients should have a CT scan of the chest for detection of thymoma or to document thymic enlargement.

## Therapeutic Principles

Anticholinesterase drugs, which increase the synaptic response to ACh, and manipulation of the immune response by alternate-day prednisone therapy, immunosuppressants other than prednisone, plasmapheresis and

intravenous immunoglobulin (IVIG) are currently acceptable forms of therapy for MG. There is general agreement on four principles of therapy for AChR seropositive MG [1]. Anti-AChE drugs are first line agents in treating all forms of MG, [2] anti-AChE drugs are the mainstay of therapy in ocular MG, [3] plasmapheresis and IVIG have only transient effects and do not confer greater long-term protection than immunosuppressants alone and [4] thymoma is an absolute indication for thymectomy. Patients with MuSK seropositive MG respond to anti-AChE drugs inconsistently, but usually respond to a form of immunosuppression and have not been shown to be improved by thymectomy.

# Myasthenic Syndrome

►Lambert Eaton Myasthenic Syndrome

# Myasthenic Syndrome, Slow-Channel Congenital

Andrew G. Engel
Department of Neurology, UCLA School of Medicine, Reed Neurologic Research Center, Mayo Clinic, Rochester, MN, USA

## Synonyms

Slow-channel syndrome

## Definition and Characteristics

An autosomal dominant disorder caused by abnormally prolonged openings of the acetylcholine receptor (AChR) channel.

## Prevalence

Not determined.

## Genes

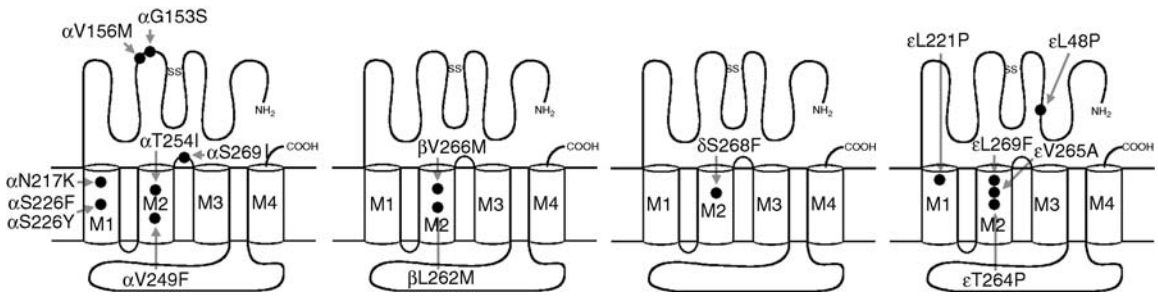
CHRNA – encodes α subunit of muscle AChR
CHRNB – encodes β subunit of muscle AChR
CHRND – encodes δ subunit of muscle AChR
CHRNE – encodes ε subunit of muscle AChR

## Molecular and Systemic Pathophysiology

The slow-channel syndrome is caused by gain-of-function mutations in the extracellular domain or the transmembrane domains (TMDs) in the α, β, δ, and ε subunits of AChR. The reported sites of mutations are shown in Fig. 1.

The prolonged opening episodes of the AChR channel prolong the endplate potentials and currents beyond the refractory period of the muscle fiber; thus single nerve stimuli elicit one or more repetitive compound muscle action potentials (CMAPs). In addition, the mutant AChR channels open even in the absence of ACh, resulting in a continuous cation leak into the postsynaptic region. The cation leak and the prolonged opening episodes of the AChR channel cause cationic overloading of the postsynaptic region with excessive accumulation of $Ca^{2+}$, an endplate myopathy with destruction of the junctional folds and loss of AChR, widening of the synaptic space, degeneration of membranous organelles in the junctional sarcoplasm and apoptosis of nearby nuclei. The safety margin of neuromuscular transmission is compromised by the altered endplate geometry, loss of AChR from degenerating junctional folds and a depolarization block during physiological activity owing to staircase summation of the markedly prolonged endplate potentials.

Patch-clamp studies at the endplate, mutation analysis and expression studies in human embryonic kidney (HEK) cells indicate that mutations near the extracellular ACh binding site (for example αG153S) and the αN217K mutation in the N-terminal part of TMD1 act mainly by enhancing affinity for ACh. This slows dissociation of ACh from the binding site and results in repeated channel reopenings during receptor occupancy by agonist, which prolong the activation episode. The αS226Y as well as the αS226F mutation in TMD1 enhance both affinity and gating efficiency. Mutations in TMD2 that lines the channel pore, such as βV266M, εL269F, εT264P and αV249F, as well as



**Myasthenic Syndrome, Slow-Channel Congenital. Figure 1** Slow-channel syndrome mutations reported to date. The mutations occur in different domains of the AChR subunits. M, transmembrane domain. The recently observed alpha-subunit M4 domain mutation, C48W is not indicated in the figure.

αS269I in the extracellular TMD2/TMD3 linker, act mainly by enhancing gating efficiency (channel opening rate β/channel closing rate α). Variable increases in steady-state affinity for ACh and concomitant increases in extent of desensitization are also observed with αV249F, εL269F, and εT264P. The δS268F mutation in TMD2 affects mainly gating.

## Diagnostic Principles

Clinical clues consist of dominant inheritance, fatigable weakness with selectively severe involvement of the forearm extensor muscles, a decremental response of the CMAP on nerve stimulation at low (2 Hz) as well as higher (40 Hz) frequencies, and repetitive CMAPs. A repetitive CMAP also occurs in endplate acetyl cholinesterase (AChE) deficiency or after exposure to anticholinesterase agents. Normal reactivity for AChE at the endplate excludes the diagnosis of endplate AChE. In vitro electrophysiological studies confirm the diagnosis by demonstrating abnormally slowly and biexponentially decaying miniature endplate currents and abnormally prolonged opening events of single AChR channels.

## Therapeutic Principles

Quinidine and fluoxetine are used in the treatment of the slow-channel syndrome. Both drugs act as long-lived open-channel blockers of AChR and normalize the prolonged opening episodes of mutant slow-channels at clinically attainable levels. AChE inhibitors are contraindicated because they enhance cationic overloading of the endplate by increasing the number of normal and abnormal receptors activated by acetylcholine.

# Mycosis Fungoides

Werner Kempf, Reinhard Dummer, Günter Burg
Department of Dermatology, University Hospital Zurich, Zurich, Switzerland

## Definition and Characteristics

Mycosis fungoides (MF) is a cutaneous T-cell lymphoma (CTCL) with distinct clinicopathologic features and a slowly progressive course in most patients.

## Prevalence

MF is the most common form of primary cutaneous lymphomas with an incidence of approximately 5 cases per 1,000,000 inhabitants per year in Western countries.

## Genes

Many structural and numerical chromosomal abnormalities on several chromosomes such as chromosomes 1, 6, 8, 9, 11, 13, 15, and 17 were identified [1,2]. Most of those alterations are more common in advanced stage. Chromosomal loss at 10q and abnormalities in p15, p16, and p53 tumor suppressor genes are commonly found in patients with MF. Previous CGH studies on MF have demonstrated gains in chromosomes 2q and 4q. Tumor suppressor gene NAV3 (neuron navigator 3), located in the chromosomal area 12q21, was shown to be deleted or translocated in all stages of MF [3]. Loss of 17p and gain of chromosome 7 do not influence the prognosis of patients with MF or Sézary syndrome. MF-specific chromosomal translocations have so far not been identified. Similar to other CTCL, clonal rearrangement of T-cell receptor genes are detected in most MF cases in plaque and tumor stage.

## Molecular and Systemic Pathophysiology

Mycosis fungoides is a neoplasm derived from T-cells exhibiting a CD3+, CD4+, CD45RO+, CD8− phenotype in most cases. Some experts consider MF starting initially as a reactive process which progresses to a true neoplasm by persisting antigenic stimulation, ongoing autocrine and paracrine growth stimulation, and acquisition of genetic alterations.

Functionally, the neoplastic cells express a TH2 phenotype, which accounts for many systemic changes associated with MF due to the production of a TH2-specific cytokine pattern (IL-4, IL-5, IL-10, and others) leading to eosinophilia, pruritus, increase of IgE or IgA, and impaired delayed type hypersensitivity. Tumor cells express bcl-2 indicating that reduced apoptosis rate with prolonged survival is more essential than proliferative activity for disease progression [4]. Increased expression of c-myc, often coexpressed with bcl-2, and p53 proteins has been found in MF and correlates with aggressiveness of the disease.

Growth maintenance is mediated by an autocrine growth stimulation including IL-7 and IL-15 acting on STAT factors and c-myb [5]. In addition, reduced apoptosis is due to aberrant splice variants with functional loss of Fas protein as well as increased telomerase activity. Increased expression of HLA-G, downregulation of MHC class II on tumor cells, and resistance to interferon allow tumor cells to escape the antitumoral host immune response.

The etiology of MF remains to be elucidated. Current data do not support evidence for an etiologic role of human T-cell lymphotropic viruses (HTLV-1 or 2) or oncogenic human herpesviruses (e.g., Epstein Barr virus) in MF. Recently, higher seropositivity for cytomegalovirus was detected in MF patients. No association between exposure to chemical agents or other mutagenic substances could be identified.

## Diagnostic Principles

Diagnosis is based on clinicopathologic features with development of patches, plaques, and tumors (Fig. 1), and histologically an epidermotropic lymphocytic infiltrate composed of CD4+ (and rarely CD8+) T helper cells with clonal rearrangement of T-cell receptor genes.

## Therapeutic Principles

Treatment of MF depends on disease stage and activity. In early stages, topical and systemic nonaggressive modalities such as psoralen-UVA, steroids and retinoids (acitretin, bexarotene), interferon-α, as well as topical chemotherapy (nitrogen mustard) are employed. Treatment for advanced stages usually consists of combination of multiagent chemotherapy and radiotherapy. Experimental therapeutic strategies include targated theropies, dendritic cell vaccination or gene transfer mediated by viral vectors (e.g., adenovirus, IFN-γ).

**Mycosis Fungoides. Figure 1** Characteristic clinical presentation with patches, plaques and tumors.

# Myelocele

►Spina Bifida

# Myelodysplastic Syndromes

Daniela Cilloni, Giuseppe Saglio
Department of Clinical and Biological Sciences, University of Turin, S. Luigi Hospital, Turin, Italy

## Synonyms

Dysmyelopoietic syndromes; Hemopoietic dysplasia

## Definition and Characteristics

Clonal hematopoietic disorders resulting in ineffective hematopoiesis and increased risk of transformation to acute myeloid leukemia.

## Prevalence

0.01%

## Molecular and Systemic Pathophysiology

The myelodysplastic syndromes originate from a multistep process with many genetic derangements within a pluripotent stem cell, accumulating during the disease evolution. The mutated clone undergoes accelerated proliferation but shows defective maturation and differentiation. The majority of the cells remain in the bone marrow and the patient suffers from peripheral cytopenia. The increased rate of apoptosis contributes to ineffective hematopoiesis. The natural history is highly variable and ranges from an indolent chronic course to rapid leukemic progression. The heterogeneity of these diseases is reflected also at the molecular and cytogenetic level [1]. The presence of cytogenetic abnormalities is detectable in about 40–60% of de novo MDS, whereas more than 80% of patients affected by secondary MDS occurring after exposure to cytotoxic agents are characterized by abnormal karyotypes [2]. Single or complex chromosomal abnormalities may be present initially and evolutionary changes may occur during the course of the disorders.

Chromosomal aberrations vary from single numerical or structural changes to complex genomic lesions involving three or more different chromosomes [3–5].

The loss of gene function may occur in a number of ways, including chromosomal loss or deletion, balanced translocations, point mutations, or by transcriptional silencing via methylation of the control elements of the gene. This results into the loss of genes, mainly of tumor suppressor genes. Inactivation of p15 INK4B and p53 contribute to clonal expansion followed by disease progression and transformation to acute leukemia.

The chromosomal deletions involve principally chromosomes 5 [del(5q),-5], 7 [del(7q),-7], 20 [del(20q)], 11 [del(11q)], and 17 [del(17p)]. Other chromosomal changes that are frequently observed in MDS are additional chromosomes like trisomy 8, and occasionally reciprocal translocations [1].

Since partial or complete deletions of chromosome 5 are the most common cytogenetic abnormalities in MDS (10–15% of primitive MDS, 50% of therapy-related MDS), the most commonly interstitially deleted region to 5q31-5q33 includes several cytokine genes (GM-CSF, IL-3, IL-4, IL-5, IL-9), the FMS gene encoding the M-CSF receptor, and two genes (IRF1, EGR1) involved in signal transduction and transcriptional regulation. Chromosome 7 deletions are invariably associated with an unfavorable prognosis, and the critically deleted region at 7q22 probably includes genes involved in DNA repair. Other genes involved in leukemic transformation include the MLL gene on 11q23,31, the nucleoporin 98 kDa (NUP98) on 11p15,(32), and the AML-1 gene on 21q22,(33) and are mostly limited to therapy-related MDS. The paracentric inversion inv(3)(q21q26) and a reciprocal translocation t(3;3)(q21;q26) involve the EVI1 protooncogene, which has been demonstrated to be involved in the pathogenesis of MDS.

## Diagnostic Principles

Peripheral blood cytopenia involving one or more lineages. Morphological analysis on bone marrow biopsy confirms the presence of displasy according to standardized criteria. Cytogenetic and molecular analysis on BM aspirate may reveal the presence of clonal abnormalities. Immunophenotypical analysis may show a maturation defect.

## Therapeutic Principles

Bone marrow transplantation, standard chemotherapy, differentiating agents, HDAC inhibitors (valproic acid, SAHA, etc.), demethylating agents (5-azacytidine, decytabine), new drugs; (Thalidomide, arsenix trioxide).

# Myelofibrosis

Ulrich S. Schuler
Medical Clinic I, University Hospital Dresden, Dresden, Germany

## Synonyms

Osteomyelofibrosis; OMF; Chronic idiopathic myelofibrosis; CIMF; Myelofibrosis with myeloid metaplasia; MMM; Agnogenic myeloid metaplasia

## Definition and Characteristics

CIMF is an acquired stem-cell disorder, characterized by a secondary, reactive stromal reaction in the bone marrow microenvironment, which is responsible for impaired hematopoesis. In an early hyperproliferative phase proliferative features (thrombocytosis) may be dominant. Later hepatosplenomegaly, cytopenias and extramedullary hematopoesis are prominent features. A small proportion of patients progress to a leukemic transformation [1,2].

Bone marrow fibrosis may be an end-stage feature of another hematological disease (e.g. post-polycythemic (PPMM) or post-thrombocythemic (PTMM) myelofibrosis), sometimes difficult to differentiate from primary IMF.

## Prevalence

Estimates of IMF incidence range from 0.5–1.5 new cases/100,000. Given the long survival, prevalence estimates are about 5–10-fold higher.

## Molecular and Systemic Pathophysiology

Although the clonal nature of the disease was established in the 1960s and several genetic markers have been described, the definitive description of IMF pathophysiology still remains elusive. Interestingly, clonality has been demonstrated in various progenitors (erythroid, granulocyte–monocyte, and granulocyte–monocyte–erythroid progenitors) sometimes B and T lymphocytes, but not in fibroblasts. Using classical cytogenetic methods, about half of untreated IMF patients show  Among the most frequently observed are del(20q11;q13), del(13q12;q22), trisomy 8, trisomy 9, t(1;7), del(12p11;p13), monosomy, or long-arm deletions involving chromosome 7, and trisomy 1q. None of these is specific for IMF, and most of the individual lesions described occur in less than 5% of patients.

Recently, mutations in the Janus Kinase-2 (JAK2 kinase) have been described (JAK2V617F), which are observed in the majority of patients with polycythemia vera (PCV) [3]. In smaller percentages, this mutation is also observed in other myeloproliferative disorders and seems to occur in about half of the patients both with IMF and essential thromcythemia (ET). The presence of JAK-2 mutations may be used as a new classification criterion of myeloproliferative disorders in the future.

It has been hypothesized that clonal proliferation, e.g., in the megakaryocyte compartment, leads to abnormal cytokine release, which results in a stromal reaction characterized by collagen fibrosis and new bone formation (osteogenesis or osteosclerosis). The exact sequence of events and the cytokines involved are only poorly defined. Possible roles are attributed to PDGF, basic fibroblast growth factor (bFGF), and transforming growth factor beta 1 (TGF-b1). Plasma levels of the latter have been shown to be increased in IMF patients. In the experimental setting, TGF-b1 induces fibroblasts to proliferate and secrete extracellular matrix and cell adhesion proteins.

Another cytokine possibly involved in IMF is osteoprotegerin (OPG), which inhibits RANK-L binding to its receptor RANK, thus inhibiting osteoclastogenesis. In animal experiments, increased secretion of osteoprotegerin (OPG) by stromal cells results in osteosclerosis through inhibition of osteoclastogenesis.

## Diagnostic Principles

Currently, the hallmark of diagnosis is the histological demonstration of bone-marrow-fibrosis with a striking bone marrow megakaryocyte hyperproliferation exhibiting abnormal morphology [1]. This has to be supplemented by the exclusion of CML, MDS, and other disorders, hematologic or otherwise, which might be associated with bone marrow fibrosis. Clinical symptoms that may initiate the diagnostic procedures may range from thrombotic events in the early hyperproliferative phase, perception of the hepatosplenomegaly, or symptoms resulting from cytopenia (anemia, thrombocytopenic bleeding, infection). In later stages, there is a myriad of possible symptoms resulting from extramedullary hematopoesis, which may grow in a tumor-like fashion, resulting in enigmatic clinical presentations. Microscopic examination of the blood may reveal a leukerythroblastic blood picture (circulating immature granulocytes and erythroblasts), and anemia with the presence of teardrop-shaped red cells. {Barosi} In advanced stages, a hypercatabolic state with weight loss, fatigue, night sweats, low-grade fever, and cachexia may be present.

## Therapeutic Principles

Currently, the only curative therapy in IMF is allogeneic hematopoetic stem cell transplantation (AHSCT). This is only feasible in a minority of patients, given the high prevalence of the disease in the age group >60 years. In early stages, median survival without AHSCT may be >10 years, which makes an early decision for this treatment modality, which is associated with a relatively high risk of transplant-related mortality, difficult [4].

A number of modalities have been described, which may ameliorate cytopenias in a proportion of patients (e.g., thalidomide, prednisolone, erythropoietin, interferon alpha), however, there are no randomized trials, which would allow one to estimate the impact on survival of these treatments. Cytostatic drugs (such as hydroxyurea, 2CDA, and melphalan) have been used to treat hyperproliferative phases and problems associated with extramedullary hematopoesis.

In patients with significant problems from massive splenomegaly, spelenectomy may be considered, but is associated with a high mortality. The procedure may result in only temporary relief, as hepatomegaly may ensue.

Clinical problems from extramedullary hematopoesis (e.g., spinal cord compression) may respond in the majority of patients to radiotherapy.

Current research focuses on the role of JAK2 mutations, the resulting alterations in signal transduction and their modification through therapeutic drugs.

Treatment of leukemic transformation is similar to the treatment of acute myelogenous leukemia, but much less successful.

## Synonyms

Chronic idiopathic osteomyelofibrosis; Primary myelofibrosis; Myelofibrosis with myeloid metaplasia; Agnogenic myeloid metaplasia; PMF

## Definition and Characteristics

Primary myelofibrosis (PMF) is part of the heterogeneous complex of BCR-ABL negative chronic myeloproliferative disorders (CMPD) which further include polycythemia vera (PV) and essential thrombocytosis (ET) [1]. The disease is characterized by increased granulopoiesis and megakaryopoiesis in the bone marrow in association with reactive deposition of bone marrow connective tissue. The initial, prefibrotic stage is typically followed by a fibrotic stage characterized by collagen fibrosis and osteomyelosclerosis. Extramedullary hematopoiesis (EMH) involves the spleen and the liver and, less frequently, other organs such as lymph nodes or the gastrointestinal tract. Clinical symptoms include organomegaly, anemia, B-symptoms, bleeding and dyspnea. 30% of patients are asymptomatic at the time of diagnosis.

The clinical course is heterogeneous with survival ranging from months to decades. Median survival is four years, which is less than in all other chronic myeloproliferative disorders. The major causes of morbidity and mortality are infections and hemorrhagia due to bone marrow failure, thromboembolic events, portal hypertension, cardiac failure, and transformation to acute myeloid leukemia (AML). Leukemic transformation during the first ten years after the onset of disease was reported in 5–30% of all cases.

A small number of cases can be linked to radiation or exposure to toxins such as benzene and toluene, but in the majority of cases the cause of the disease remains unknown.

## Prevalence

With an incidence of 0.5–1.5/100,000 individuals per year, PMF is the least common of all chronic myeloproliferative syndromes. There is a slight male preponderance with a male to female ratio of 1.3:1. The incidence is highest in Ashkenazi Jews in Israel. Median age at diagnosis is 65 years. The proportion of patients <30 years of age is extremely low.

## Molecular and Systemic Pathophysiology

*Clonality and Growth Factors:* Like all other chronic myeloproliferative disorders PMF represents a disorder of the pluripotent stem cell resulting in clonal myeloproliferation. This was demonstrated by studies of X-chromosome inactivation patterns and isoenzyme analyses, e.g., glucose-6-phosphate-dehydrogenase. Recent studies focused on X-linked DNA polymorphisms. Extramedullary hematopoiesis in PMF participates in the clonal changes which are detected with cytogenetic techniques in the bone marrow. In contrast, fibroblast proliferation in the bone marrow is a reactive or secondary phenomenon and was not found to be part of the malignant clone due to X-inactivation studies and

also proven by cytogenetic findings. Fibrosis in PMF is supposedly associated with an inappropriate release of growth factors, such as PDGF and the transforming growth factor-β (TGF-$\beta$). TGF-$\beta$ is released by megakaryocytes and by thrombocytes. The TGF-$\beta$ signaling pathway is centrally involved in the regulation of proliferation, differentiation, migration and cell survival and also has a tumor suppressor function in human malignancies. In hematopoiesis TGF-$\beta$ has an antiproliferative effect and mediates differentiation. In PMF TGF-$\beta$ is supposed to mediate at least some of the bone marrow stromal reactions such as collagen synthesis, osteosclerosis and angiogenesis [2].

However, fibrosis in PMF is probably a multifactorial process, as gene expression profiling revealed also the upregulation of other transcription factors such as N-myc and other growth factors such as granulocyte-macrophage colony stimulating factor (GM-CSF) in patients with PMF.

*Cytogenetics:* Cytogenetics are hampered in many cases due to the low quality of metaphases as a consequence of myelofibrosis. Chromosomal abnormalities were reported in approximately 30% of patients with PMF on the basis of conventional chromosome banding analysis. An abnormal karyotype is significantly associated with an inferior prognosis. The progress towards secondary acute myeloid leukemia (s-AML) is often accompanied by a clonal evolution to more complex karyotypes and results in a chromosomal aberration rate of around 90%. This suggests a multistep process of leukemogenesis.

Comparative genomic hybridization (CGH) suggests that chromosomal abnormalities are more common than indicated by standard cytogenetic analysis. Partial gains of chromosome 9p could be demonstrated in around 50% of all cases by CGH.

There are no disease specific chromosomal abnormalities in PMF. The most frequent recurrent clonal abnormalities include deletions of the long arms of the chromosomes 13 (del13(q12q14)), and 20 (del(20)(q11q13)), or of the short arms of 12p (del12(12)). The breakpoint 13(q12q14) was also found to be involved in unbalanced translocations. The microdeletions, which were reported in the del(13q)(q12q14) cases do not involve the *RB1* tumor suppressor gene locus, which is located in this region. Frequent chromosomal changes are in addition represented by numerical gain of the chromosomes 8 or 9 and numerical or partial loss of chromosome 7.

Partial gains of 1q occur often associated with certain derivative chromosomes, e.g., der(6)t(1;6)(q21–23; p21–23) representing the only chromosomal abnormality with high specificity for PMF. The respective region 6p21 houses the FK-506 binding protein 5 (FKBP51) gene. The FKBP51 gene was found to be overexpressed in CD34+ cell derived megakaryocytes in PMF and might contribute an antiapoptotic effect through inhibition of calcineurin.

Deletions of 13q and 20q were not found to influence survival negatively. All other chromosomal abnormalities seem to have a negative impact on survival and are associated with higher rates of disease progression and leukemic transformation [3].

*Mutations:* The V617F mutation of the JAK2 kinase gene was found in 35–55% of patients with PMF. Thus, the incidence is lower than in polycythemia vera (PV) (>90% of all cases) and comparable to essential thrombocytemia (ET) (40% of all cases).

Long term follow-up studies with respect to the prognostic influence of the JAK2 mutation in CIMF are missing as the association of this mutation with the CMPD was published as recently as 2005. The value of the JAK2 mutation for the monitoring of response to treatment also remains still to be established. However, according to preliminary reports on the prognostic impact of JAK2 mutations in PMF survival is negatively influenced by a positive mutation status. The transformation rate to acute myeloid leukemia so far does not seem to be influenced by the occurrence of JAK2 mutations in PMF.

A positive JAK2 mutation status in PMF is significantly correlated with higher peripheral leukocytes. The need for blood transfusions is lower in PMF patients with a positive JAK2 mutation status when compared with patients who show JAK2 wildtype. This is in accordance with previous findings in the animal model suggesting an association of the mutation with erythrocytosis. Most PMF patients suffering from pruritus or thrombosis are positive for the mutation. This observation suggests a biological link between JAK2 associated CMPD and certain features, which are characteristic for polycythemia vera.

Other parameters such as spleen size, platelet count, CD34+ counts, and hemoglobin levels did not depend on the occurrence of the V617F mutation. This suggests that the clinical phenotype of PMF is influenced by many factors which are not associated with the V617F mutation. Further the high frequency of abnormal cytogenetics in PMF also in patients with a positive mutation status implies that other acquired abnormalities contribute to the phenotype in PMF [4].

Most patients with PMF show a heterozygous JAK2 mutation status. Homozygosity of the JAK2 mutation, which seems to correlate with a more aggressive course of the disease or with a tendency to disease progression occurs in PMF in 10–30% which is less than in PV or ET.

Additional molecular markers were discussed to play a causative role in the disease. Loss of heterozygosity studies (LOH) revealed frequent allelic loss involving the chromosomal regions 1q, 3p, and 3q. Based on this observation, the expression of the retinoid acid receptor

RAR-β2 gene, a tumor suppressor gene located on chromosome 3p24, was found to be decreased in CD34+ stem cell samples in PMF. This seems to be the result of an epigenetic mechanism mediated by abnormal methylation of the RAR-β2 gene promoter.

Oncogene mutations including point mutations in N-RAS, c-KIT, and TP53 are rare in PMF.

*Immunophenotyping:* PMF is characterized by increased numbers of circulating hematopoietic precursors and lineage restricted progenitor cells. Flow cytometry reveals an increased CD34+ stem cell count in the peripheral blood. Circulating endothelial progenitor cells are also increased. This might be explained by the increased revascularization characterizing the disease.

## Diagnostic Principles

In many cases, differential diagnosis in PMF provides difficulties with respect to the overlapping stages of the disease during progress and with respect to the overlap with secondary fibrosis in other chronical myeloproliferative syndromes. Further bone marrow aspiration is technically difficult due to myelofibrosis or -sclerosis (with the result of a dry tap).

Cytomorphology of the peripheral blood has a role for diagnosis. The classical picture shows leukoerythroblastosis and abnormal red cell morphology with poikilocytosis, and the characteristical dakryocytes, meaning tear-shaped erythrocytes. Granulopoiesis is left-shifted. The cytomorphologic aspect of the bone marrow in PMF is variable in accordance to the different stages during progress of the disease. In most cases megakaryocytes show marked dysplasia. An increased percentage of bone marrow blasts indicates progress to the accelerated phase or to secondary acute myeloid leukemia (s-AML). Bone marrow histology is characterized by marked fibrosis, dysplastic megakaryocytes, and osteosclerosis. Marrow sinusoids are dilatated accompanied by intravascular hematopoiesis.

Bone marrow analysis should be completed by cytogenetic examination, even if a sufficient number of metaphases may be missing. Screening for the JAK2V617F mutation should be performed in all cases. A diagnosis of CML should be excluded by interphase fluorescence in situ hybridization (FISH) or by PCR for BCR-ABL fusion gene.

Diagnostics may further include tissue biopsies and cytologic examinations of serosal implants demonstrating extramedullary hematopoiesis. Magnetic resonance imaging is useful for detection of a soft tissue mass indicating extramedullary hematopoiesis [5].

## Therapeutic Principles

Drug therapy is largely supportive and is not able to alter the natural course of the disease. Androgens, steroids, and thalidomide are effective for the treatment of anemia. Recombinant erythropoietin was found to be effective in patients with low levels of erythropoietin. Chemotherapy with hydroxyurea remains the treatment of choice for control of leukocytosis, thrombocytosis, and organomegaly. Splenectomy or splenic irradiation can be performed in case of severe splenomegaly. However, splenectomy is accompanied by a high mortality and morbidity rate and should be limited to cases with severe complications of splenomegaly such as severe portal hypertension or refractory hemolysis. Splenic irradiation results in relief of symptoms but is accompanied by severe cytopenias.

In recent years allogeneic stem cell transplantation has become a potentially curative approach for a smaller subset of patients. However, for the majority of patients this approach is not suitable due to advanced age or comorbidity. Anemia with a hemoglobin level <10 g/dl and age >60 years are independent parameters for an inferior prognosis. Additional parameters of an adverse prognosis include B-symptoms, leukocytosis >30 G/l, leukocytopenia <4 G/l, >10% immature circulating granulocytes or circulating myeloblasts, thrombocytopenia <100 G/l, and clonal cytogenetic abnormalities. Treatment may not be necessary for low-risk patients whereas it is reasonable to consider either experimental drug therapy or allogenic stem cell transplantation for intermediate-risk or high-risk patients.

## Synonyms

Meningomyelocele; Spina bifida; Spina bifida cystica; Spinal dysraphism

## Definition and Characteristics

Myelomeningocele is characterized by herniation of the meninges and spinal cord at the site of a defect of bony fusion of vertebral arches. Most often, it presents as a sac-like protrusion in the thoracolumbar, lumbar, lumbosacral, sacral, or rarely, cervical area, with no dura, bone, muscle, or skin covering (Fig. 1) [1].

The lesion is usually symmetrical, contains a neural placode bathed in cerebrospinal fluid, and affects several segments of the spinal cord and vertebrae. Varying degrees of flaccid paralysis below the lesion are common. Almost all patients have paralyzed urethral and rectal sphincters. Approximately 95% of patients have Arnold Chiari II malformation. Other associated anomalies include hydrocephalus, syringomyelia, kyphoscoliosis, club foot, and rocker bottom foot.

**Myelomeningocele. Figure 1** A newborn infant with a myelomeningocele.

## Prevalence

The incidence in the United States is about 0.4–1.4 per 1,000 live births and is lower among African-Americans than Caucasians [2]. In Africa, the incidence is 0.1/1,000 live births [2].

## Molecular and Systemic Pathophysiology

Myelomeningocele may result from a primary failure of neural tube closure, overdistension and rupture of a previously closed neural tube, or development of paired instead of one notochordal anlage from the Hensen node during gastrulation [3]. Failed expression of one or more organizer genes during the primitive streak and neural placode stages of early ontogenesis might be responsible. The cause is multifactorial. A genetic component is suggested by the higher familial incidence, the variation of incidences between different ethnic groups, and its association with known genetic syndromes and chromosomal anomalies [3]. Environmental factors such as folic acid deficiency and maternal use of carbamazepine and valproic acid may also be responsible. Myelomeningocele may also result from allelic variants of the gene encoding the folate dependent enzyme 5,10-methylentetrahydrofolate reductase [4]. Regardless of the cause, without protective tissue coverage, secondary destruction of the exposed neural tissue by trauma may occur in utero [5].

## Diagnostic Principles

The diagnosis is mainly clinical. Radiography of the spine will reveal the extent of non-fused vertebrae and associated kyphoscoliosis. Prenatal diagnosis is possible by maternal blood screening which shows elevation of α-fetoprotein, amniocentesis which shows elevated α-fetoprotein and acetylcholinesterase, or ultrasonography which demonstrates the spinal defect.

## Therapeutic Principles

Management must be individualized. At present, aggressive surgical therapy with systemic antibiotic coverage is advocated for most infants. Ideally, surgical repair of the lesion should be performed within 24 h of life so as to prevent local infection and trauma to the exposed neural tissue, and to avoid further stretching of nerve roots. Detethering and insertion of a ventriculoperitoneal shunt are often required. Further management requires a multidisciplinary team including a general surgeon, neurosurgeon, orthopedic surgeon, neurologist, pediatrician, urologist, gastroenterologist, physiotherapist, occupational therapist, educator, and social service. As folic acid supplementation before

conception and within the first month of pregnancy can decrease the rate of myelomeningocele by 70%, women of childbearing age should receive 0.4 mg folate per day before conception and during pregnancy. Women who are in the high risk group should receive 4 mg folate per day. Preliminary data suggest that intrauterine repair of the myelomeningocele may reduce the severity of hindbrain herniation and decrease the incidence of hydrocephalus, the procedure may also lead to an increased risk of oligohydramnios and premature labor.

# Myelophthisic Anemia

Stephen N. Makoni
Trinity Cancer Care, Minot, ND, USA

## Synonyms

Myelophthisis; Leukoerythroblastic anemia; Leukoerythroblastosis; Bone marrow infiltration; Infiltrative myelopathy; Extramedullary hematopoiesis; Myeloid metaplasia

## Definition and Characteristics

Myelophthisis is a form of bone marrow failure that results from bone marrow infiltration or marrow fibrosis. Infiltrative myelophthisis most commonly occurs during the advanced stages of cancer [1]. Nonmalignant causes of myelophthisis include myeloproliferative conditions such as myelofibrosis with myeloid metaplasia (MMM), also known as agnogenic myeloid metaplasia, or idiopathic myelofibrosis; myelodysplastic syndrome, infiltration by inflammatory cells, miliary tuberculosis, fungal infections, sarcoidosis, necrosis in sickle cell disease and septicemia; bone disease in congenital osteopetrosis and macrophage proliferation in storage diseases such as Gaucher disease [2]. The clinical manifestations of myelophthisic anemia depend on the underlying disease and the severity of the peripheral blood cytopenias. Patients may present with fatigue, dyspnea or signs of heart failure due to anemia. Neutropenic patients may present with infection and sepsis. These are typically bacterial, including pneumonia and urinary tract infections. Invasive fungal infection is a common cause of death, especially in subjects with prolonged and severe neutropenia. Severe thrombocytopenia may produce petechiae or ecchymoses. Bleeding is usually the most alarming presentation. Physical findings usually reflect the underlying medical condition, such as metastatic carcinoma, lymphoma, or tuberculosis.

## Prevalence

Myelophthisis occurs in less than 10% of cancer patients with metastatic disease. The prevalence in non malignant myelophthisis is uncertain.

## Genes

Genetic lesions responsible for myelophthisic anemia have not been worked out. Given the clinical hetrogeneity of cases, great complexities can be expected. Occasional mutations of RAS gene family or p53 gene have been observed. Recurrent karyotypic abnormalities in MMM include del (13q), del (20q) and trisomy 9 all of which have been found in other chronic myeloid disorders and have no specificity. Other gene lesions reflect the underlying medical condition.

## Molecular and Systemic Pathophysiology

Myelophthisis results from the destruction of bone marrow precursor cells and their stroma, which nurture these cells to maturation and differentiation [1]. Infiltration of the marrow by cancerous cells causes release of suppressive and destructive cytokines and fibroblastic growth factors leading to the reduction in the available bone marrow space. This will cause pluripotent stem cells to migrate to the liver, spleen and other organs in the body resulting in extramedullary hematopoiesis. The stromal support system outside the bone marrow is not optimal for hematopoiesis resulting in the premature release of hematopoietic cells into the circulation (leukoerythroblastosis) [1]. In chronic leukemias, the invading cells will not cause structural damage. The expansion volume of the pathologic cells and their release of suppressor cytokines will eventually lead to cytopenias without the morphologic features of myelophthisis [3]. In MMM, fibrogenic and angiogenic cytokines, including transforming growth factor-*B*, basic fibroblast growth factor and platelet-derived growth factors are associated with excess collagen fibrosis, new bone formation (osteosclerosis) and angiogenesis [2]. Macrophage proliferation in lipid storage disorders such as Gaucher disease can also lead to myelophthisis [4].

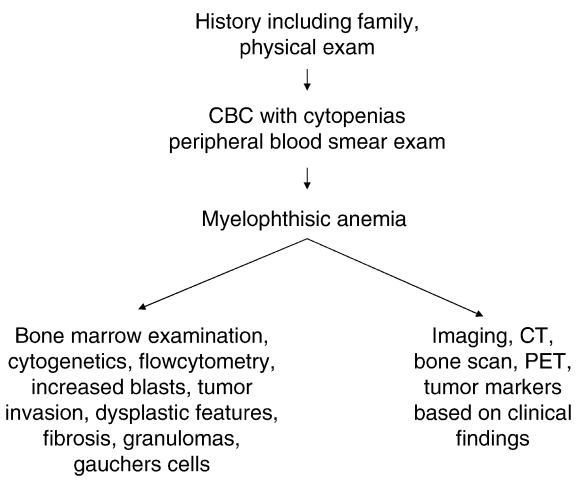
## Diagnostic Principles

In most cases the diagnosis will be made based on the clinical presentation, physical examination, complete blood counts and a peripheral blood film examination.

A peripheral blood smear may show a Leukoerythroblastic picture (tear drop forms and nucleated red cells, immature myeloid precursors, giant platelets and thrombocytopenia) characteristic of marrow infiltration. Carcinocythemia (cancer cells on the blood film) always indicates marrow invasion. Imaging such as chest x-rays, CT scans, MRI, bone scans can be ordered based on the clinical presentation. A bone marrow aspirate and biopsy should be performed if other less invasive procedures are non-revealing. The core biopsy specimen should be at least 1 cm long. Inability to aspirate the marrow (dry tap) may suggest infiltration, fibrosis or marrow replacement. Infiltration by cancer cells may show a packed marrow and tumor clumps or nests. Infiltration by Gaucher cells causes an "onion-peel" appearance of the cytoplasm [4]. In some cases, cytogenetics may be helpful in the diagnosis of hematological malignancies. The BCR ABL and Jak 2 V617F mutations may be useful for the diagnosis of myeloproliferative disorders. Figure 1 illustrates an approach to diagnosis as outlined in the preceding section.

## Therapeutic Principles

The treatment if possible should be directed at the underlying condition. Supportive measures should be provided for symptomatic patients. Transfusions of red blood cells are given for maintenance of oxygen delivery to tissues and hemodynamic homeostasis in patients with symptomatic anemia [3]. Erythropoietic growth factors may be helpful in those patients with low serum erythropoietin or cancer related anemia. Platelet transfusion can be administered to reduce the risk of hemorrhage when the platelet count falls below a predefined threshold level. This threshold level for transfusion varies according to the patient's diagnosis, clinical condition, and treatment modality. Splenectomy is indicated in myelofibrosis for the treatment of resistant anemia with heavy transfusion requirements. Low dose radiation therapy may be effective in the treatment of nonhepatosplenic extramedullary hematopoiesis [2].



**Myelophthisic Anemia. Figure 1** Summary of Skeletal Muscle Energy Metabolism. Energy demand (muscle contraction) can exceed energy supply (glycolysis and osidative phosphorylation) during vigorous exercise. The accumulation of ADP disrupts myokinase and AMP. Myoadenylate deaminase (mAMPD) and AMP-preferring cytosolic 5′nucleotidase (cN-I) compete for available AMP. These two enzymes function, in part to maintain myokinase dysequilibrium during periods of energy imbalance by removing AMP from the adenine nucleotide pool, thus promoting the production of additional ATP.

## Synonyms

mAMPD deficiency; MADD deficiency; MDD deficiency

## Definition and Characteristics

Autosomal recessive deficiency involving the skeletal muscle (primarily) isoform of a purine nucleotide catabolic enzyme. mAMPD deficiency is a common disorder with heterogeneous clinical consequences that can be subdivided into: asymptomatic inherited (complete genetic deficiency with no apparent clinical symptoms); symptomatic inherited (complete genetic deficiency with exertional myalgia); coincidental inherited (complete genetic deficiency associated with a wide array of other defined neuromuscular and rheumatological disorders) and acquired (partial genetic deficiency that is further reduced into the deficient range secondary to other pathological disorders of skeletal muscle) [1].

## Prevalence

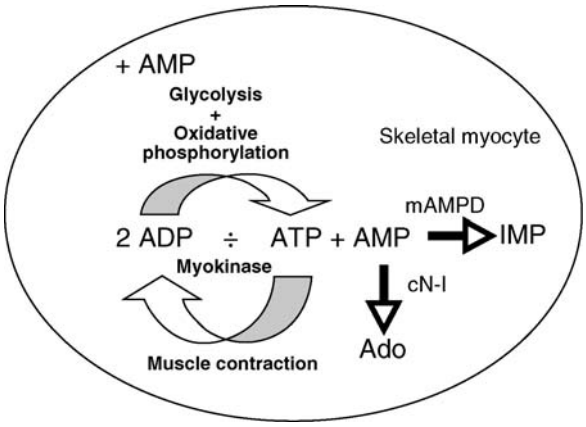
The incidence of a complete genetic deficiency in the Caucasian population is ≈2% with a heterozygote frequency of nearly 1 in 4 individuals [1]. There are substantially lower incidences in the African-American [2] and Japanese populations [1].

## Genes

AMPD1 codes for mAMPD (the skeletal muscle isoform of AMP deaminase) and is located on chromosome 1p13–p21 [1].

## Molecular and Systemic Pathophysiology

A multigene family encodes AMP deaminase (AMPD) and one member (AMPD1) is expressed predominantly in adult skeletal muscle [1]. AMPD (EC 3.5.4.6) catalyzes a branch point reaction in the purine nucleotide catabolic pathway and competes for available AMP with the adenosine-producing enzyme, AMP-preferring cytosolic 5′nucleotidase (Fig. 1).



**Myoadenylate Deaminase Deficiency.**
**Figure 1** AMP-preferring cytosolic 5′nucleotidase.

The AMP deaminase reaction is a key component of skeletal muscle adenine nucleotide catabolism. Energy demand (muscle contraction) can exceed energy supply (glycolysis and oxidative phosphorylation) during vigorous exercise. The accumulation of ADP disrupts myokinase reaction equilibrium and produces molar equivalents of ATP and AMP. Myoadenylate deaminase (mAMPD) and AMP-preferring cytosolic 5′nucleotidase (cN-I) compete for available AMP. These two enzymes function in part to maintain myokinase disequilibrium during periods of energy imbalance by removing AMP from the adenine nucleotide pool, thus promoting the production of additional ATP.

AMPD1 gene mutations are solely (all inherited deficiencies) or partially (acquired deficiency) responsible for mAMPD deficiency. Most individuals with inherited forms of the disorder are homozygous for a common mutant allele characterized by double transitions at nucleotides +34 in exon 2 and +143 in exon 3 [1]. The upstream transition is the dysfunctional mutation and introduces a premature stop codon (Q12X) into the AMPD1 mRNA. The functional significance of the downstream mutation is unknown, but a P48L substitution would be introduced into the mAMPD polypeptide during translation of approximately 0.6–2% of total AMPD1 mRNAs that lack C34T-containing exon 2 due to a cassette-type alternative splicing event [1]. Rare AMPD1 mutations have been identified and typically exist in the compound heterozygous state together with the common mutant allele. The low incidence of mAMPD deficiency in the Japanese population is due to an apparent absence of the common AMPD1 mutant allele [1].

The asymptomatic group is the largest subdivision of mAMPD deficiency, suggesting that this purine nucleotide metabolic disorder may simply be a harmless genetic variation. However, a causal relationship between exertional myalgia and symptomatic inherited deficiency in the absence of other identifiable abnormalities argues against this conclusion. Moreover, there is evidence that AMPD1 mutant alleles contribute to myopathic symptoms when inherited together with defects in other energy-related pathways, either in homozygous or heterozygous register [3].

Comparative muscle function studies are conflicting, although the most comprehensive among these found diminished exercise capacity and cardiorespiratory responses to exercise in the sedentary state in individuals with asymptomatic inherited deficiency compared to controls and heterozygotes [2].

A genetic reduction in mAMPD expression owing to inheritance of the common AMPD1 mutant allele may be beneficial in heart disease, but studies are also conflicting [4]. The basis for an apparent cardiac effect of reduced mAMPD expression has not been established, but could be due to enhanced production of

adenosine (see Fig. 1). A multifactoral correlative analysis has demonstrated that the AMPD1 genotype exerts the greatest effect on AMPD enzyme activities in healthy adult skeletal muscle, which in turn are related directly to the accumulation of IMP and indirectly to adenosine production during exercise [5].

## Diagnostic Principles

A flat plasma ammonia response in association with a normal rise in lactate during ischemic exercise testing is highly suggestive of mAMPD deficiency [1]. This diagnosis can be confirmed by enzyme assay using biopsy material or by a number of available PCR-based AMPD1 genotyping assays using genomic DNA isolated from whole blood [1].

## Therapeutic Principles

There are no reliable therapies to treat the symptomatic inherited disorder. Oral administration of pentose sugars, such as ribose or xylitol, reportedly improves stamina and exertional myalgia in some individuals, but has had no effects in others [1]. Management of coincidental inherited and acquired deficiencies is typically dictated by the associated disorder.

Division of Cardiology, Walter Mackenzie Center, University of Alberta, Edmonton, AB, Canada

## Synonyms

Acute coronary syndrome

## Definition and Characteristics

A myocardial infarction (MI) can be pathologically defined as myocardial cell death due to prolonged ischemia [1]. MIs are further categorized by amount of damage to the left ventricle (small [<10%], medium [10–30%] and large [>30%]), location (anterior, septal, lateral, inferior, posterior), time (acute [<7 days], healing [7–28 days] and healed [>28 days], and by a combination of clinical symptoms, biochemical markers and the electrocardiogram (unstable angina, non-ST-elevation MI, ST-elevation MI).

A myocardial infarction is a clinical syndrome that results from sub-total or total occlusion of an epicardial coronary artery.

## Prevalence

Coronary heart disease is the leading cause of death in Europe and North America, and is a leading and rapidly increasing cause in developing nations [2,3]. Nearly 3.5% of individuals in North America will have a MI in any given year, and one third of the population has some degree of cardiovascular disease. Of the 7% who have coronary heart disease, MI and unstable angina have an equal split.

M

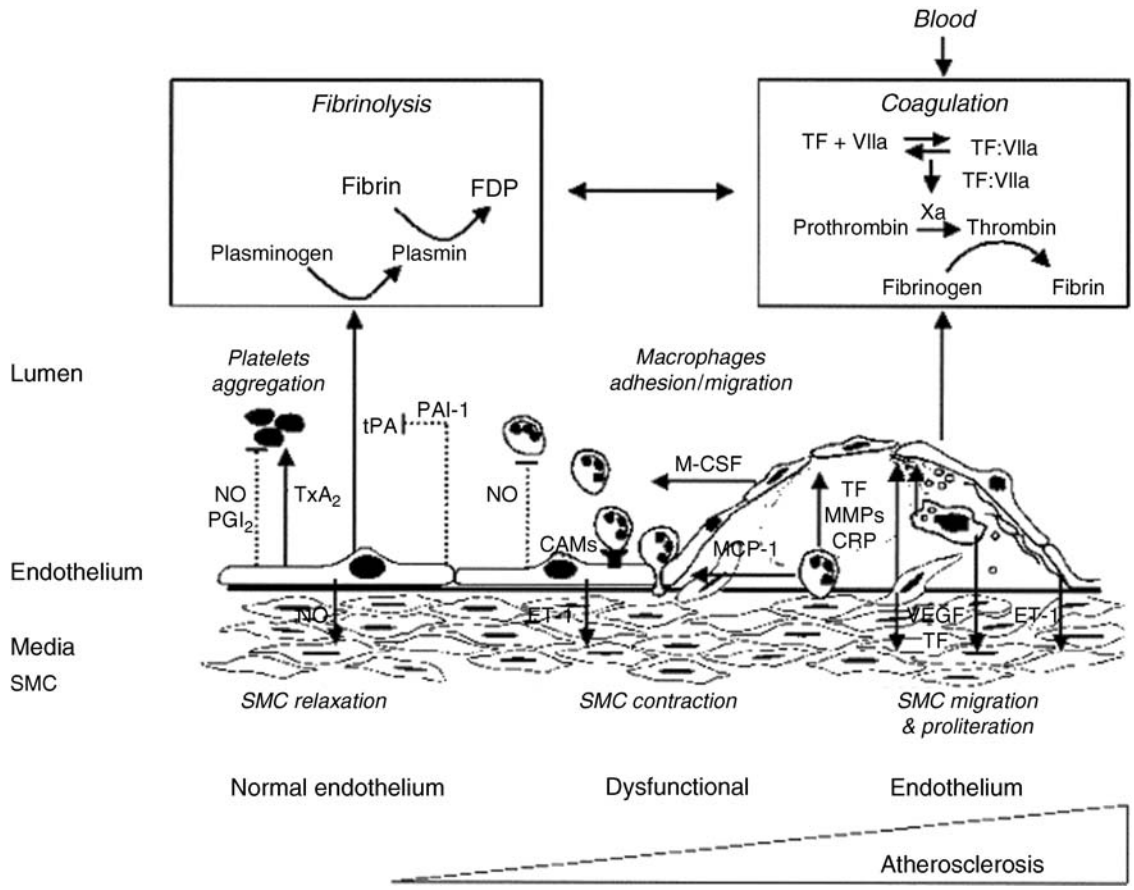
## Molecular and Systemic Pathophysiology

Knowledge of the events occurring at the cellular level is critical for understanding both diagnostic and therapeutic strategies. Plaque disruption is the primary mechanical event that triggers the clinical syndrome, and plaque composition rather than actual degree of baseline stenosis is critical. The plaque is composed of a lipid-rich core, a fibrous cap and a base made of the endothelium and extracellular matrix. Endothelial dysfunction is found in and around the area of a plaque, and as depicted in Fig. 1, has multiple factors that are either up or down regulated including vascular cell adhesion molecule-1, intercellular adhesion molecule-1, E-selectin, and P-selectin [4].

## Diagnostic Principles

MI's are diagnosed using clinical symptoms and signs, the ECG and biochemical markers. The ECG may show a range of abnormal findings that are acute including ST-segment elevation or depression, T-wave inversion or flattening, or arrhythmias associated with an MI (e.g. accelerated idioventricular rhythm). The currently used blood markers are creatine kinase (CK) and its mycardial specific subtype CK-MB; and troponin I or T, both of which are specific to the myocardium.

Early diagnosis, triage and treatment are emphasized since there is a time-dependent process of cell injury that can be mitigated with treatment.



**Myocardial Infarction. Figure 1** MI occurs when the plaque ruptures or fissures with exposure of the thrombogenic substrates found in the extracellular matrix and lipid core. Rupture of the cap occurs in the thinnest region. The risk of rupture of a fibrous cap is enhanced by activation of cellular material within the lipid-core which contains matrix metalloproteinases produced by macrophages and activated by lymphocytes. Platelet activation and thrombus formation ensues via activation of the coagulation cascade. Within the disrupted arterial segment, vasoconstriction occurs as an adaptive mechanism, which can produce further hemodynamic alterations leading to local shear stress.

## Therapeutic Principles

Treatment of MI's is broken down into the acute, subacute and recovery phases, and emphasis is placed on normalization of myocardial and vascular function as well as identification of modifiable risk factors for secondary prevention. This includes pharmaceutical agents directed at interrupting platelet function (aspirin, clopidogrel, glycoprotein 2b/3a inhibitors), the coagulation cascade (fibrinolytics, heparin), and lipid metabolism (HMG-CoA reductase inhibitors). In addition, modulation of the renin-angiotensin-aldosterone axis (angiotensin-converting enzyme inhibitors, aldosterone blockade) and beta-blockade are important. Post-MI risk stratification may include intervention on the coronary artery with percutaneous stenting, or referral for coronary artery bypass surgery.

## Definition and Characteristics

The critical phase of coronary heart disease becomes clinically evident as an acute coronary syndrome (ACS) and is mostly associated with acute severe chest pain. This clinical entity is differentiated by use of ECG and biochemical markers between ST elevation myocardial infarction (STEMI), non-ST elevation myocardial infarction (NSTEMI), and unstable angina. In contrast to unstable angina, myocardial infarction is associated with cell necrosis as a result of ischemia and, by definition, is accompanied by release of sensitive serum markers (e.g., troponins) [1].

## Prevalence

The American Heart Association estimates that 1.1 million myocardial infarctions occur in the United States per year and that 40% of these patients will die. Based on registry data, the incidence of all ACS is approximately threefold the incidence of STEMI. Thus, the annual incidence of ACS in Europe is estimated at between 1 per 80 and 1 per 170 of the population per year. However, the incidence of chest pain leading to hospital assessment, of suspected ACS, is substantially higher and varies regionally. The combined data from prevalence studies suggest that ~4% of men and 2% of women have sustained a myocardial infarction in the UK [1].

## Genes

Gene variants associated with ACS are identical with candidate genes for coronary heart disease (specified in chapter "Angina pectoris"). More recently, a region on chromosome 9 was suggested to account for 20% of the incidence of myocardial infarction in populations of European origin and a third of cases of early-onset infarction. People who possess two copies of that particular allele are at double risk of an early-onset heart attack compared with those who do not carry it at all [2].

## Molecular and Systemic Pathophysiology

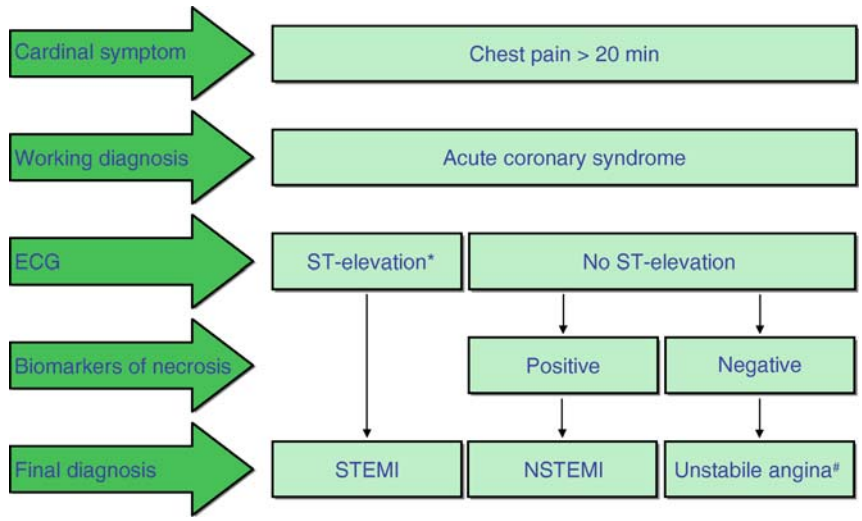
Physical disruption of atherosclerotic plaque in the coronary artery and thrombus formation at this site cause a sudden and critical reduction in blood flow and account for almost all myocardial infarctions. Plaque rupture can occur as through-and-through rupture of the plaque's protective fibrous cap or as superficial erosions, intraplaque hemorrhage, and the erosion of a calcified nodule. Thrombosis develops following activation of platelets by contact with the plaque's extracellular matrix and of the coagulation cascade by smooth muscle cells and tissue factor.

Beside the disrupted plaque presenting the "solid state" for thrombus formation, blood presenting the "fluid phase" can promote coronary thrombosis. Circulating plasminogen activator inhibitor-1 (PAI-1) which is increased in diabetes, obesity, and hypertension extinguishes the naturally occurring fibrinolytic activity of blood by inhibiting urokinase-like and tissue-type plasminogen activators. Moreover, particulate tissue factor increase the thrombogenicity of blood and may also account for the "no-reflow" phenomenon observed in percutaneous coronary intervention because of distal thrombosis in the microcirculation [3].

## Diagnostic Principles

An accurate history is essential in patients with chest pain that is typically described as burning, tightness, or heaviness. Of patients with STEMI two-thirds have prodromal symptoms in the preceding weeks. Physical examination is not diagnostic for ACS but is necessary for exclusion of differential diagnoses and for recognition of complications like acute heart failure.

The resting 12-lead ECG plays a central role in the early assessment of patients with suspected ACS and should be evaluated within 10 min by an experienced physician. Repeated recordings over an observation period of up to 12 h may be necessary. ST-segment elevations and depression and T-wave changes are the most reliable ECG indicators of ACS. The terminology used in ACS is based on ECG criteria and biochemical markers and is specified in Fig. 1. Routine laboratory measurements and special markers reflecting distinct pathophysiological processes like troponins, creatine kinase MB must be obtained in all patients presenting with chest pain. Echocardiography can show regional wall-motion abnormalities which occur within seconds after coronary occlusion, but may also be the result of old infarctions. A normal ECG and normal biochemical markers on repeated examinations does not definitely rule out an ACS, but should direct to other possible causes for the patients chest pain. Coronary angiography is the gold standard to prove or exclude coronary artery disease. The culprit lesions usually show filling defects, indicating intracoronary thrombus [1].



**Myocardial Infarction, Acute. Figure 1** Terminology used in acute coronary syndrome. *Measurement of biomarkers should not delay immediate revascularization when ST-elevation is present, but usually show increased values. #Differential diagnoses must also be considered.

## Therapeutic Principles

When the diagnosis is established, patient management includes antiplatelet therapy, antithrombin therapy, fibrinolytic therapy coronary angioplasty or cardiac surgery.

In patients presenting without ST-segment elevation, treatment with acetyl salicylic acid or heparin reduces the incidence of death or non-fatal myocardial infarction by 53 and 34%, respectively. Glycoprotein IIb/IIIa inhibitors reduce the risk of thrombotic complications by 41% in patients undergoing early percutaneous coronary intervention.

In patients presenting with ST-segment elevation reperfusion therapy is crucial and should be initiated as early as possible from symptom onset. Fibrinolytic therapy is associated with an 18% mortality reduction. Moreover, if applied within 1 h of symptom onset, a 48% event reduction is obtained. A primary percutaneous coronary intervention results in an additional 30% mortality reduction.

## Synonyms

Autoimmune cardiomyopathy

## Definition and Characteristics

Myocarditis is an inflammatory heart disease characterized by myocyte destruction and mononuclear cell infiltration with or without fibrosis. It may be caused by a variety of infectious and noninfectious agents including viruses, bacteria, protozoans, fungi,

drugs, and heavy metals. Worldwide the most common cause of myocarditis is the protozoan parasite trypanosoma cruzi, the causative agent of Chagas disease, which currently infects approximately 18 million people and results in 50,000 deaths each year. Clinical and experimental evidence indicates that, in some individuals, myocarditis is mediated by autoimmunity toward various cardiac autoantigens exposed to the immune system following cardiomyocyte injury [1]. Although myocarditis is often asymptomatic, clinical features may include dysrhythmia, angina, fever, malaise, and as it progresses, varying degrees of heart failure.

## Prevalence

Because the pathogenesis of autoimmune myocarditis involves a myriad of genetic and environmental factors and the autoimmune component of the disease is not routinely examined, no precise estimate of prevalence is available. Myocarditis resulting from all causes has been linked to approximately 20% of all cases of unexpected death in adults less than 40 years of age. Myocarditis is also a significant cause of childhood mortality, with an estimated 2,500 children developing myocarditis each year.

## Genes

Genetic linkage among several genes and autoimmune myocarditis has been suggested by limited studies in humans and animal models. Polymorphisms in the major histocompatibility complex (MHC) are often associated with predisposition to autoimmune disease. Studies in humans suggest that HLA-DQ5 and HLA-DQ8 may be risk factors for development of autoimmune myocarditis. Non-MHC genes appear to be more important in autoimmune myocarditis than in other autoimmune diseases. In mice, two loci, Eam1 on proximal chromosome 1 and Eam2 and distal chromosome 6 have been identified as likely contributors to autoimmune myocarditis. The human counterparts of these loci have already been linked to several autoimmune diseases in humans. Observed mutations and experimental manipulation of other genes such as CD45, CTLA-4, ICOS, and PD-1 also suggest links to development of autoimmune myocarditis [2].

## Molecular and Systemic Pathophysiology

Non-infectious agents such as heavy metals and drugs may lead to non-autoimmune myocarditis through (i) direct toxic effects on cardiomyocytes, (ii) immune-mediated mechanisms, or (iii) drug-induced allergic reactions. Following this damage, autoimmune myocarditis may develop via (i) bystander activation whereby damaged myocytes release copious amounts of self-antigen in an environment rich in inflammatory cytokines resulting in the ablation of self-tolerance and subsequent activation of autoreactive T cells and/or B cells, or via (ii) release of cryptic epitopes previously sequestered from the immune system that will quickly activate autoreactive lymphocytes. Although pathogenic microorganisms may also cause myocarditis lacking an autoimmune component, cardiotropic infections are much more likely to result in autoimmunity. In addition to bystander activation and release of cryptic epitopes, autoimmunity induced by pathogens such as coxsackievirus, group A streptoccous, and T. cruzi can involve other mechanisms such as molecular mimicry and epitope spreading. Molecular mimicry occurs when antigenic determinants of a microorganism that evoke an immune response are so immunologically similar, via structural or secondary sequence similarity, to a host antigen that the response is "cross-reactive" with self-antigen and autoimmunity develops. Epitope spreading occurs following bystander activation, when autoimmunity that develops against one epitope causes tissue damage resulting in the release of additional self antigens, the processing and presentation of which induces the stimulation of non-cross-reactive autoimmunity against additional epitopes. Several animal models have been developed to study autoimmune myocarditis, including those that induce experimental autoimmune myocarditis in rats and mice by immunization of susceptible strains with purified cardiac myosin or immunogenic myosin peptides as well as experimental models of infections that result in cardiac autoimmunity (e.g. T. cruzi, coxsackievirus B3, streptococcus pyogenes) [3]. These models have allowed for the characterization of cardiac pathophysiology involving both humoral and cellular immune components. Autoantibodies can alter contraction and cell signaling of cardiomyocytes and disrupt cardiac microvasculature and extracellular matrix formation. Myocyte damage can also be initiated via an antibody-dependent cytotoxicity mechanism. Direct recognition of autoreactive epitopes present on myocytes by cytotoxic lymphocytes (CTLs) and non-specific damage initiated by release of cytotoxic molecules from CTLs or granulocytes that have been recruited to the myocardium by the presence of inflammatory chemokines secreted by autoreactive lymphocytes can lead to myocytolysis. As a consequence of myocyte destruction, mononuclear cell infiltration, and production of inflammatory cytokines and chemokines, fibrosis and interstitial edema develop. This reduces cardiac function. If myocarditis is persistent, as in some cases of chronic disease, it may lead to dilated cardiomyopathy.

## Diagnostic Principles

Clinical features of myocarditis vary widely from asymptomatic to exhibiting fulminant heart

failure. Myocarditis may be indicated by an abnormal electrocardiogram, elevated erthyrocyte sedimentation rate, leukocytosis, eosinophilia, and other markers of myocardial damage and inflammation, such as elevated serum levels of C-reactive protein, troponin I, and creatine kinase [4]. When the etiology involves infection, increased pathogen-specific IgG and IgM may be detected. Evidence of autoimmunity includes presence of autoantibodies and autoreactive T cells specific for abundant cardiac proteins such as cardiac myosin heavy chain, β1-adrenergic receptor, laminin, or muscarinic receptor [5]. These may be detected by serology or analysis of peripheral blood mononuclear cells. Formal diagnosis of myocarditis occurs post mortem or following cardiac biopsy by the observation of myocyte necrosis and degeneration, with adjacent mononuclear cell infiltration, in the presence or absence of fibrosis and interstitial edema.

### Therapeutic Principles

For infection-induced autoimmune myocarditis, appropriate antibiotics, antiviral or antiparasite therapies are the first line of treatment. For treatment of heart failure, appropriate measures must be taken depending on the specific clinical indications. Heart transplantation may be necessary in some severe cases. Clinical trials investigating the efficacy of various immunosuppressive therapies have yielded few advancements but, in several small studies, novel agents such as rapamycin and interferon-β directed to attenuating myocyte injury and apoptosis seem promising [6].

## Myoclonus Epilepsy with Ragged Red Fibers

THOMAS KLOPSTOCK
Friedrich-Baur-Institute, Department of Neurology, Ludwig-Maximilians-University Munich, Munich, Germany

### Synonyms

MERRF

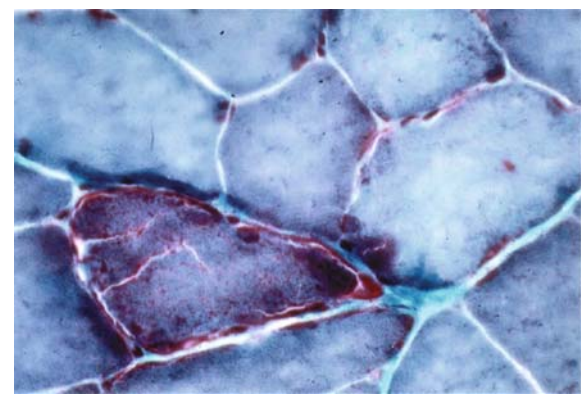
### Definition and Characteristics

Maternally inherited defect of mitochondrial energy metabolism leading to a chronic neurodegenerative disease that is characterized by myoclonus, generalized epilepsy, and ataxia, as well as ragged red fibers (RRF, see Fig. 1) in muscle biopsies [1].

Other clinical manifestations include hearing loss, optic atrophy, peripheral neuropathy, exercise intolerance, dementia, short stature, and multiple lipomas.

### Prevalence

The prevalence of the MERRF mutation is reported to be approximately 0.25/100,000 in the North East of England and in Western Sweden.



**Myoclonus Epilepsy with Ragged Red Fibers. Figure 1** A typical "ragged red fiber" in the muscle biopsy of a MERRF patient.

## Genes

The responsible mutations are located in the gene for the transfer-RNA for lysine ($tRNA^{Lys}$) of the mitochondrial DNA (mtDNA). The most frequent mutation (80–90% of patients) is at nucleotide position 8344 [2]. Less frequent mutations are at positions 8356, 8361, and 8363.

## Molecular and Systemic Pathophysiology

The mtDNA is a small circular double-stranded DNA molecule of 16,569 basepairs that encodes 13 polypeptides of the respiratory chain as well as 22 tRNAs and two ribosomal RNAs for an own mitochondrial translation machinery. All of the other factors that are necessary for mtDNA transcription, translation, and replication, as well as the remaining enzymes of the mitochondrial metabolism are encoded by the nuclear genome, translated in the cytoplasm and then imported into the mitochondria.

All MERRF mutations affect highly conserved base pairs in the $tRNA^{Lys}$ gene of the mtDNA, either in the TψC stem or in the aminoacyl acceptor stem [1]. For the 8344 mutation, it was shown that the mutant $tRNA^{Lys}$ is normally processed and aminoacylated, but it lacks the modification of the wobble base, leading to an impaired codon-anticodon interaction and concomitantly reduced mitochondrial translation [3].

On the cellular level, impaired mitochondrial protein synthesis corresponds to cytochrome c oxidase deficiency, decreased oxygen consumption and decreased ATP synthesis. In the case of the 8356 mutation, the respiratory chain defect leads to a derangement of mitochondrial calcium homeostasis, which impairs the calcium-mediated stimulation of ATP production [4]. If ATP levels are not sufficient to maintain the membrane potential of neurons, epileptic activity may result.

Clinical expression of mtDNA mutations depends on the degree of heteroplasmy (mutation load). Despite clear evidence of a direct relationship between mutation load and respiratory chain function in vitro, it has been more difficult to demonstrate a clear correlation with the clinical phenotype. For example, the selective vulnerability of CNS neurons does not correlate with the level of 8344 mutation in individual neuronal isolates [5]. Other factors that may have an impact on the clinical manifestation are the tissue distribution of the mutation and the specific vulnerability of a tissue to an energetic deficit.

## Diagnostic Principles

The combination of myoclonus, generalized epilepsy, and ataxia points to the disease group of progressive myoclonic epilepsies. Additional clinical manifestations as described above and maternal inheritance narrows the differential diagnosis down to MERRF. Blood lactate is often elevated. Brain imaging may show global atrophy and basal ganglia calcifications. The diagnosis is confirmed by finding RRF in a muscle biopsy or by detection of mutations in the mitochondrial $tRNA^{Lys}$.

## Therapeutic Principles

There is no specific therapy. Many patients are treated "empirically" with vitamins and cofactors, including coenzyme Q 10, l-carnitine or creatine, but there are no controlled trials. Symptomatic management includes antiepileptic therapy (cave valproate!) and control of myoclonus with levetiracetam or clonazepam. Gene therapy is not available.

# Myoclonus-Dystonia

Friedrich Asmus, Thomas Gasser
Department of Neurodegenerative Diseases, Hertie-Institute for Clinical Brain Research, Center of Neurology, Tuebingen, Germany

## Synonyms

Myoclonus-dystonia-syndrome; Alcohol-responsive myoclonus; Essential myoclonus; Essential hereditary myoclonus; Paramyoclonus multiplex Friedreich; DYT11; DYT15; Myoclonic dystonia

## Definition and Characteristics

Myoclonus-Dystonia (M-D) is a rare, early-onset movement disorder characterized by "lightning-like," non-epileptic myoclonus and focal or segmental dystonia presenting mainly as cervical dystonia or writer's cramp [1]. Many patients respond dramatically to alcohol ingestion. Psychiatric comorbidity with alcohol and substance abuse or anxiety disorders and

phobias is common [2]. The use of the term myoclonic dystonia (MIM #159900) should be limited to idiopathic dystonias with jerky movements only in the body parts displaying dystonic posturing.

Following an autosomal-dominant (AD) inheritance pattern with reduced penetrance after maternal inheritance, heterozygous epsilon-sarcoglycan (SGCE) [3,4] mutations cause M-D. This transmission-specific reduction of penetrance in M-D can be explained by maternal imprinting of the 7q21.3 region harboring the *SGCE* gene.

## Prevalence

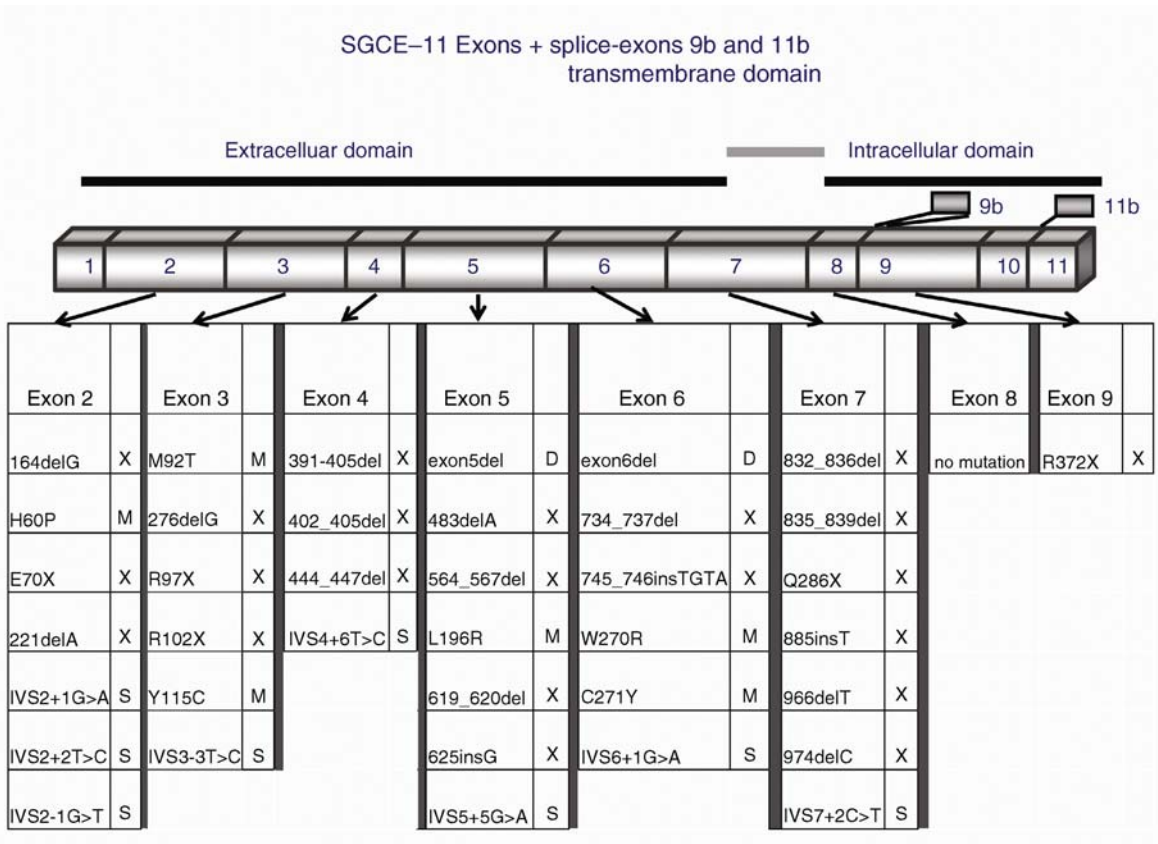
Although the prevalence of M-D has not been studied systematically, it appears to be the second most common dystonia plus syndrome. About 80 M-D families have been published worldwide since the cloning of the gene in 2001 [3]. In contrast, jerky, "myoclonic" movements can be detected in idiopathic cervical dystonia in up to 20% of cases, but are not related to SGCE mutations.

## Genes

The SGCE gene consists of 13 exons. Major splice variants with yet unknown functional significance originate from the alternative use of exon 2, 8 and 11b. Skipping of exon 2 truncates the N-terminus of the epsilon-sarcoglycan (ε-SG) protein in frame by 44 amino acids. The use of exon 11b leads to a brain-specific SGCE splice variant with an expanded C-terminus.

A genetic hallmark of M-D is maternal genomic imprinting of SGCE: by promoter methylation, the maternal allele is constitutively inactivated. Therefore heterozygous SGCE mutations can cause M-D by a presumed loss-of-function mechanism. Thirty-eight different heterozygous SGCE mutations have been reported (Fig. 1).

All mutations except one (R372X) are located before the transmembrane domain of ε-SG. Nonsense mutations in exon 3 (R97X and R102X) have been reported in several families and appear to have originated independently. In M-D caused by SGCE mutations no genotype-phenotype correlations can be observed.



**Myoclonus-Dystonia. Figure 1** The epsilon-sarcoglycan gene encompasses 13 exons including the splice exons 9b and 11b. The majority of heterozygous SGCE mutations known to date are nonsense (X) and splicing (S) mutations. In addition exon deletions (D) and missense (M) mutations have been reported. All except one mutation are located in extracellular domain of the gene.

Lack of SGCE mutations in up to 90% of sporadic patients referred as M-D for mutational screening, might be explained by the fact, that these patients actually suffer from idiopathic cervical or segmental dystonia with jerky movements (myoclonic dystonia).

A missense change (Val154Ile) in the gene for the dopamine D2-receptor and a 18bp deletion in exon 5 of the TOR1A gene have been found in one M-D pedigree each. However, the significance of these findings remains to be determined, since in both families heterozygous SGCE mutations were detected too. In one family with a typical M-D phenotype but no evidence for maternal imprinting, a second M-D locus (DYT15) maps to chromosome 18p. Occasionally, other conditions like dopa-responsive dystonia or Vitamin E deficiency may mimic M-D.

### Molecular and Systemic Pathophysiology

The pathophysiology of M-D caused by SGCE mutations is poorly understood, since the physiological role of ε-SG in the CNS remains to be elucidated. ε-SG is a ubiquitously expressed 438-amino acid protein, which has a single transmembrane domain and shows 68% homologous to α-sarcoglycan. The sarcoglycan gene family itself has been studied extensively in autosomal recessive muscular dystrophies. However, M-D patients show no muscle or peripheral nerve pathology on biochemical and ultrastructural examination.

A role of ε-SG in synaptic neurotransmission is suggested by the synaptic localization of ε-SG in neurons and by the deficit in GABAergic neurotransmission in M-D patients suggested by the therapeutic benefit of alcohol ingestion.

### Diagnostic Principles

The diagnosis of M-D is based on a careful clinical examination [1]. Indicative clinical features are onset during childhood or early adolescence with no continuous progression of symptoms as well as brief, lightning-like myoclonic jerks typically precipitated by intentional movements. Electrophysiological and neuroimaging studies are unremarkable and do not allow to differentiate M-D from myoclonic dystonia. Epileptic seizures are exceptional in M-D. Additional neurological manifestations, such as (cerebellar) ataxia, spasticity or dementia so far have not been found in M-D patients, unless explained by additional pathology.

### Therapeutic Principles

Most patients with SGCE mutations experience symptomatic relief by alcohol or benzodiazepines. Effective doses may vary considerably and patients can experience a rebound of motor symptoms after single doses. GABAergic drugs like clonazepam or GHB (gamma-hydroxybutyrate) induce marked but often time-limited effects. With these drugs M-D patients are at special risk of getting addicted.

For cervical dystonia or writer's cramp, focal botulinum toxin injections can be effective. Valproic acid, piracetam or levetiracetam provide no significant improvement of motor symptoms.

In severe cases of M-D bilateral deep brain stimulation to the thalamic VIM nucleus or to the internal pallidum (Gpi) confers substantial and lasting symptomatic relief [5]. In M-D patients with marked dystonia Gpi stimulation might be preferred.

Psychiatric comorbidity should be treated according to psychiatric guidelines. Selective serotonin reuptake inhibitors (SSRI) have been shown to control depression, panic attacks and agoraphobia in M-D patients. In some patients myoclonus might worsen with SSRI.

## Definition and Characteristics

Infantile myofibromatosis (IM) is one of the most commonly diagnosed fibromatoses of infancy and childhood [1]. Subclassifcation into solitary, multiple and generalized IM is used to describe both the location and extent of tumor involvement. Solitary tumors are solely located in areas of soft tissue. Multiple IM includes both soft tissue and bone, with tendency for metaphyseal involvement. Patients with generalized IM also have visceral involvement in addition to soft tissue tumors [2].

Tumors have been identified prenatally via ultrasonography and fetal MR imaging. Although the tumor is most commonly identified in infants and children, adults can also be affected. The reported incidence seems to decrease with age. However, those adults with a history of generalized IM can demonstrate new tumors throughout life. Most complications arise from the location of a tumor: for example, tumors involving the meninges present with the expected symptoms of increased intracranial pressure, and those involving GI viscera can present with bowel obstruction. Patients with Generalized IM often have more complications due to the presence of a higher number of tumors.

## Prevalence

Unknown and probably under-reported.

## Genes

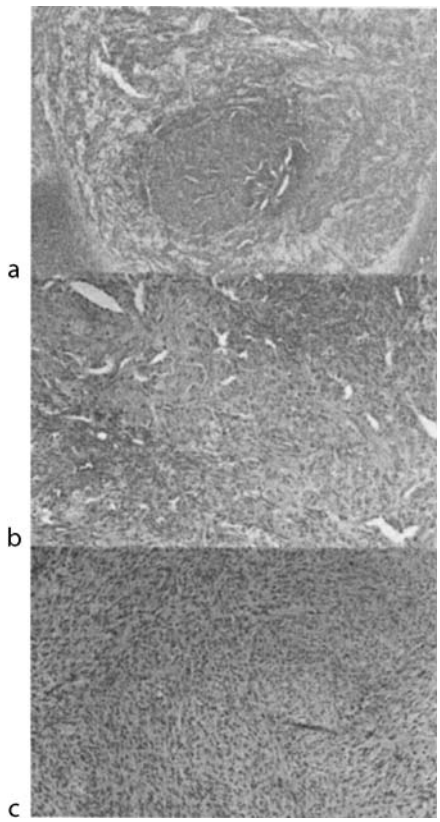
Despite one report of an interstitial deletion in chromosome 6q detected in tumor cells, no gene has been identified.

## Molecular and Systemic Pathophysiology

This tumor appears to be multifocal in its pathogenesis and no evidence for metastasis has been reported. The literature has debated inheritance patterns from autosomal recessive to autosomal dominant with variable expressivity, as the natural history of most tumors is to regress without intervention (Fig. 1) [3,4]. Variability of severity among affected family members has been reported in cases of familial IM. Increased growth potential in response to estrogen has been postulated though not substantiated.

## Diagnostic Principles

Diagnosis is primarily based upon histopathologic evaluation. Histopathology is characterized by cells which grow in a zonal pattern, where more primitive appearing cells tend to be located centrally and spindle type cells are located on the periphery. The spindle cells appear similar to both differentiated fibroblasts and smooth muscle. (myofibromas). After staining with hematoxylin and eosin (H & E), the highly eosinophilic spindle cells are often arranged in fascicles resembling smooth muscle. The more primitive cells are often visualized in a "hemangiopericytoma-like" vascular pattern. Necrosis and calcification are common in the central zone of the tumor.



**Myofibromatosis, Infantile. Figure 1** Hematoxylin and eosin (H&E) staining of infantile myofibromatosis (IM) biopsies. (a) Zonal pattern of spindle shaped cells with central necrosis and calcification. (b and c) These photos demonstrate the prominent vascularity often seen in IM.

Immunohistochemistry has demonstrated staining for both vimentin and smooth muscle actin. However, these findings by themselves are not diagnostic and only complement routine histopathology evaluation.

## Therapeutic Principles

Treatment is directed toward individual symptoms or complications. Screening via imaging is presumed to be of low yield; except for those individuals with generalized IM who have had multiple complications. Presently, there is no specific chemotherapeutic or radiation based regimen reported which has demonstrated consistent success with any form of IM. Only surgical excision is most successful for IM nodules causing life threatening complications. Presumably, with identification of the causal genetic mechanism, specific therapies may be created.

# Myogastrointestinal Encephalomyopathy

►Mitochondrial Disorders

# Myo-Neuro-Gastro-Intestinal Encephalopathy

Thomas Klopstock
Friedrich-Baur-Institute, Department of Neurology, Ludwig-Maximilians-University Munich, Munich, Germany

## Synonyms

MNGIE

## Definition and Characteristics

Autosomal recessive mitochondrial disorder caused by mutations in the thymidine phosphorylase gene, which is clinically characterized by progressive external ophthalmoplegia, severe gastrointestinal dysmotility, cachexia, peripheral neuropathy, diffuse leukoencephalopathy on brain magnetic resonance imaging, and evidence of mitochondrial dysfunction (histologic, biochemical, or genetic abnormalities of the mitochondria).

## Prevalence

Uncommon.

## Genes

Thymidine phosphorylase (TP) gene on chromosome 22q [1].

## Molecular and Systemic Pathophysiology

TP catalyzes the first step in the degradation of the pyrimidine nucleosides thymidine and uridine. Homozygous or compound heterozygous mutations in TP are present in all MNGIE patients tested. TP activity in patient's leukocytes is <5% of controls, indicating that loss-of-function mutations in TP cause the disease [1]. The consequence is a much higher plasma level of thymidine and uridine. This causes imbalances of mitochondrial nucleotide pools that, in turn, cause somatic alterations of mitochondrial DNA (mtDNA), including depletion, multiple deletions, and site-specific point mutations [2]. Three factors may contribute to the predominant damage to mitochondria as compared to nuclei: (i) mitochondrial nucleotide pools are physically separate and regulated independently; (ii) they are probably more vulnerable to the toxic effects of excessive thymidine because mtDNA is more dependent on thymidine salvage than is nuclear DNA, which relies upon the de novo synthesis of thymidine; (iii) human mitochondria may lack an effective mismatch repair system. The mtDNA alterations in MNGIE are likely to contribute to the disease pathogenesis by causing respiratory chain enzyme deficiencies.

## Diagnostic Principles

The unique combination of central nervous and gastrointestinal symptoms renders MNGIE a recognizable entity. However, diagnosis may be much more difficult in the early oligosymptomatic course of the disease. Cerebral leukodystrophy is a characteristic finding in brain imaging. Secondary abnormalities such as multiple deletions and depletion of the mtDNA in muscle hint to the diagnosis. Measurement of either plasma thymidine and uridine or TP activity in buffy coat provides sufficient evidence to make a definitive diagnosis. The TP gene may be sequenced to identify specific mutations.

## Therapeutic Principles

The poor quality of life and early death in patients with MNGIE call for treatment, but so far, therapy has largely been supportive, including total parenteral nutrition, pain relief, and treatment of infections. Hemodialysis to remove excess thymidine and deoxyuridine from the extracellular space has been tried in single patients, but the predialysis concentrations were restored <3 h after the end of the treatment, indicating that the rate of production of thymidine in MNGIE patients exceeds the ability of the dialysis to eliminate the molecule from the blood. In one patient, there was sustained clinical benefit from continuous ambulatory peritoneal dialysis although nucleoside levels remained unchanged [3]. Two recent studies have shown partial correction of the excessive nucleoside levels in the plasma of patients with MNGIE by either infusing platelets from healthy donors [4] or by performing allogenic bone marrow transplantation [5]. These treatments provide "proof of

principle" that toxic nucleosides can be removed in vivo, but the clinical effect of the treatments has not been studied so far.

# Myophosphorylase Deficiency

►McArdle Disease

# Myopia: Molecular Targets and Gene Mapping Attempts

Frank Schaeffel
Section Neurobiology of the Eye, University Eye Hospital, Tuebingen, Germany

## Definition and Characteristics

Myopia is characterized by exaggerated axial eye growth placing the focused image in front of the retina for vision at far distances, and without optical correction. Myopia develops typically between 8 and 15 years of age and tends to stabilize after puberty, although higher degrees of myopia can continue to progress. Higher myopia (>5 D) carries increased risk of ocular complications like retinal detachment, glaucoma, premature cataract, and macular degeneration. In most cases, myopia occurs isolated but it may also occur as part of genetic syndromes. Myopia is both environmentally and genetically controlled – genetics shows up most clearly in population with similar visual exposure whereas the effect of environment becomes obvious if populations are compared with similar genotype but different ways of living, e.g., urban versus rural [1]. The mechanisms of myopia development have been studied for long – animal studies have clearly shown that the fine tuning of axial eye growth is under visual control. Major results were also that the feedback mechanism resides within the eye and achieves a point by point match of image plane and photoreceptor plane: the retina controls the growth of the underlying sclera, even when the optic nerve has been cut. A satisfactory therapy is still not available and most money is currently spent on optical correction of myopia.

## Prevalence

Myopia is the most common human ocular disorder. According to a recent survey it affects 32% of the 12–19-year old population in the USA, with similar prevalence in Europe, but sometimes more than 90% in the cities in the Far East [1]. In the USA, about 6% are more myopic than 5 D. Low myopias are often acquired, triggered by visual experiences which include short viewing distances and tense education, but high myopias may be entirely predetermined by genetics.

## Genes

Some known syndromes are associated with myopia, e.g., Stickler syndrome (autosomal dominant connective tissue disorder with ocular, orofacial, and skeletal abnormalities – ocular: high myopia, glaucoma, cataract, retinal detachment – candidate genes are collagen 2A1 (12q13.1-q13.3 type1) or collagen 11A1 (6p21.3 type2). Marfan syndrome (autosomal dominant with myopia, lens dislocation, tall body habitus, and increased aortic wall distensibility – candidate gene: fibrillin (15q15-q21.1). Knobloch autosomal recessive high myopia, vitreous degeneration – candidate gene: collagen 18A1 (21q22.3). However, the vast majority of individuals with myopia have no associated defects.

Twin studies have demonstrated a surprisingly high level of control of eye growth by genes: Hammond et al. [2] in the UK found that the heritability was 90% for myopia and 89% for hyperopia. A recent Australian twin study (2006) found a heritability of spherical equivalent refractive errors of 88% in men and 75% in women, and of 94 and 92% in axial length, with significantly higher correlations in monozygotic twins. Axial length, anterior chamber depth, and corneal curvature were found to be predominantly genetically determined. Familial factors (genetic + shared environments) were found to account for 63–100% of the refraction variability in Singapore [3].

There are four major approaches to investigate the genetical basis of myopia: (i) inducing myopia in animal models by experimental manipulations of visual

experience and using pharmacology at the same time – if modulation of certain receptor pathways can block myopia, the involved genes may be important, (ii) using gene microarrays or proteomic mapping to screen for transcriptional or translational changes in retinal, choroidal, or scleral genes under visual conditions that cause myopia development, and using knock-out models for further verification, (iii) using known genetic markers to map loci in human family studies which are transmitted together with high myopia, (iv) to select and sequence potential candidate genes within such loci and try to correlate polymorphisms (SNPs) in the genes with the refractive errors of the subjects. These studies are mostly performed in highly myopic pedigrees (Table 1) to reduce the impact of uncontrollable environmental factors.

## Molecular and Systemic Pathophysiology

Approach (1) has identified (for instance) dopamine (chick, monkey), glucagon (chick), and ZENK(chick)/Egr1 (monkey/mouse), muscarinic (human, monkey, chick), and nicotinic (human, chick) antagonists as potential growth inhibitors, VIP (chick, monkey) and insulin (chick) as growth stimulators. It was found that Egr1 knock-out mice have longer eyes and more myopia. Synthesis and accumulation of scleral proteoglycans decorin, biglycan, and aggrecan, matrix metalloproteinases MT1-MMP, MMP2, MMP3 and their inhibitors TIMP-1, TIMP-2, and TIMP-3, and collagen change during induction of experimental myopia and return to normal, following recovery. The complete cascades of biochemical events, leading to axial elongation of the eye, have not been uncovered [4].

**Myopia: Molecular Targets and Gene Mapping Attempts. Table 1** Mapped myopia loci in human studies, as of June 2007

| Symbol | Cytogenetic localization | Mode of inheritance | Description; tested candidate genes | Typical reference (not complete) |
|---|---|---|---|---|
| MYP1 | Xq28 | X-linked recessive | Bornholm eye disease; deuteranopia in males | Schwartz et al. (1990), Young et al. (2004) |
| MYP2 | 18p11.31 | Autosomal dominant | High myopia; TGIF; CLUL1, EMLIN-2, Lipin 2, LAMA (all excluded) | Young et al. (2001), Lam et al. (2003), Zhou and Young (2005) |
| MYP3 | 12q21-q23 | Autosomal dominant | High myopia; decorin, lumican, DSPG3 (all later excluded, no mutations) | Young et al. (1998) |
| MYP4 | 7q36 | Autosomal dominant | High myopia; ? | Naiglin et al. (2002) |
| MYP5 | 17q21-q22 | Autosomal dominant | High myopia; CHAD, COL1A1 (no disease causing mutations found) | Paluru et al. (2003), Inamori et al. (2007) |
| MYP6 | 22q12 | ? | Mild/moderate myopia; ? | Stambolian et al. (2004), Klein et al. (2007) |
| MYP7 | 11p13 | Twin study | Moderate myopia; PAX6 (later not confirmed) | Hammond et al. (2004) |
| MYP8 | 3q26 | Twin study | Moderate myopia; ? | Hammond et al. (2004) |
| MYP9 | 4q12 | Twin study | Moderate myopia; ? | Hammond et al. (2004) |
| MYP10 | 8p23 | Twin study | Moderate myopia; ? | Hammond et al. (2004) |
| MYP11 | 4q22-q27 | Autosomal dominant | High myopia; RRH tested, no causative mutation | Zhang et al. (2005) |
| MYP12 | 2q37.1 | Autosomal dominant | High myopia; SAG, DGKD no causative mutations | Paluru et al. (2005) |
| MYP13 | Xq23-q25 | X-linked recessive | High myopia; ? | Zhang et al. (2006) |
| None | 10q21.1 | Autosomal dominant | High myopia; ? | Nallasamy et al. (2007) |
| None | Xq25-q27.2 | X-linked, outside MYP1 | High myopia; ? | Zhang et al. (2007) |

TGIF, transforming growth factor induced factor; CLUL1, transcription genes clusterin-like 1; EMLIN-2, elastin-microfibril located interface-protein; LAMA, subunit of laminin; decorin, lumican are members of the small interstitial proteoglycan family of proteins expressed in the etxracellular matrix of various tissues, interacting with collagen and controlling the growth of fibril diameter; CHAD, proteoglycan chondroadherin; COL1A, collagen type alpha Iota encodes collagen; DSPG3, dermatan sulfate proteoglycan-3 – a small interestitial proteoglycan expressed in cartilage; RRH, rhodopsin homolog; SAG, S-antigen; DGKD, diacylglycerol kinase delta.

Approach (2) has provided a list of up- or down-regulated genes which were partially confirmed by PCR. The transcripts or proteins require histological localization by in situ hybridization or immunohistochemistry, and subsequent pharmacological studies for verification of their effects on myopia.

Approach (3) has created a list of at least 15 genomic loci (2007) that are associated with development of high myopia (Table 1). Descriptions of these loci are available at http://www.ncbi.hlm.nih.gov/omin ("Online Mendelian Inheritance in Man"). Furthermore, mapping loci for eye size in mice has uncovered two loci, EYE1 on chromosome 5 and EYE2 on chromosome 17. It is clear that myopia is genetically heterogenous.

Approach (4) proved to be demanding. Many of the selected candidate genes had to be excluded because the tested polymorphisms had no association with myopia [5]. Examples were: sequence variants of the TGF-beta1 (SNPs) – not associated with high myopia, and also no associations with myopia for SNPs in lumican, decorin, or DSPG (Table 1). Evaluation of MMP3 and TIMP1 as candidate genes for high myopia also showed no association with high myopia in young Taiwanese men. Lipin 2, a candidate gene for lipid dystrophy, as a candidate for autosomal dominant 1 high-grade myopia had to be excluded. A recent mouse knock-out study implicated lumican and fibromodulin as functional candidate genes for high myopia (lumican in the MYP3 locus, fibromodulin maps to 1q32) – but both had to be excluded. There was also no significant linkage of high myopia to the MYP2 locus, or to COL2A1, COL11A1, and FBN1 genes in UK families. PAX6 was first proposed to play a role in myopia development based on a classical twin study in the UK [2] but both PAX6 and SOX2 were later considered unlikely to be significant modifiers of refraction. Sequence variants in the TGIF gene were not associated with high myopia in the USA and Japan although a study in China (2003) had found an association of SNPs in the TGIF gene with high myopia.

On the other hand, some associations were significant: myocilin polymorphisms were linked to high myopia in Hong Kong (2007). It was found that the NYX (nyctalopin) gene can account independently for congenital stationary night blindness (CSNB1) and myopia, which often occur together. The collagen COL1A1 gene diplotype was found to be associated with high myopia (candidate gene for MYP5). One SNP (rs3759223, C→T) in the promoter region of the lumican gene was also associated with high myopia. It was concluded that MYP3 could be responsible for high myopia with autosomal dominant transmission in up to 25% of the cases in the UK. A hepatocyte growth factor (HGF) gene polymorphism was found associated with high myopia in China. Also, sequence variations in SLRP (small leucine-rich repeat proteoglycans, regulating collagen fibril diameter and spacing) expressed in the eye may be among the genetic risk factors underlying the pathogenesis of high myopia [5].

## Diagnostic Principles

Myopia is realized by the patient because clear vision for distant targets is lost. The existence of refractive errors is confirmed by optical measurements (classically, by streak retinsocopy under cycloplegia, but today often by measurements with a commercial autorefractor). In addition, it may be confirmed that the eyes are longer than normal, using A-scan ultrasonography, or low coherence interferometry, like the Zeiss IOL Master. Sometimes, people are myopic without that a conspicious axial eye elongation can be measured – but who knows how long the particular eye should have been if it were emmetropic (normal-sighted). Eye sizes also vary among people even if they all are emmetropic.

## Therapeutic Principles

A potential treatment would involve the application of drugs to inhibit or stimulate gene products that are involved in the signaling cascade which links visual processing in the retina to growth of the sclera – although most studies screen only for scleral targets (see Table 1). Muscarinic antagonists were effective as eye drops, but none went into phase III studies, probably because they were effective only for a limited period of time (<3 years) and the underlying mechanisms remained diffuse. In the case of animal studies, microarray analyses provide currently a large number of new candidates for potential pharmacological intervention. In the case of human mapping studies, identification of candidate genes can also lead to new pharmacological targets. Given the risks, gene therapeutic approaches in the eye appear unrealistic at present.

[1]Department of Pathology, Sahlgrenska University Hospital, Goeteborg, Sweden
[2]Department of Pediatrics, Sahlgrenska University Hospital, Goeteborg, Sweden
[3]Department of Clinical Genetics, Sahlgrenska University Hospital, Goeteborg, Sweden

## Synonyms

Hereditary inclusion body myopathy 3; IBM3; Autosomal dominant myopathy with congenital joint contractures, ophthalmoplegia and rimmed vacuoles

## Definition and Characteristics

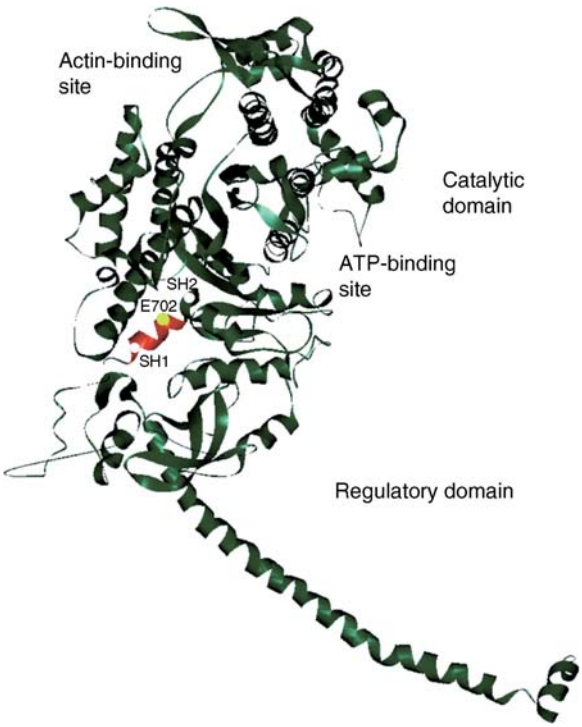
This is an autosomal dominant myopathy with full penetrance. The onset of muscle weakness varies from birth to adulthood. Clinical characteristics are congenital joint contractures, which normalize during early childhood, external ophthalmoplegia and predominantly proximal muscle weakness and atrophy [1]. The course is frequently progressive in adulthood. Muscle biopsies show marked inter-individual variability [1–3]. Young individuals show minor changes including reduced number and hypotrophy/atrophy of type 2A fibers. Adults with a clinically progressive course show severe myopathy with increased interstitial connective tissue, marked variability in fiber size and centrally located nuclei. Some cases show vacuoles in muscle fibers and inclusions of 15–18 nm tubulofilaments.

## Prevalence

This MYH2 mutation has so far only been described in one Swedish family. Other recently described mutations in MYH2 are associated with other phenotypes [4].

## Molecular and Systemic Pathophysiology

Myosin heavy chain (MyHC) IIa myopathy is associated with a mutation of the myosin heavy chain type IIa gene (HMG locus MYH2) on chromosome 17 p13 [2]. Myosin is a molecular motor protein that converts the chemical energy of ATP hydrolysis into mechanical force. There are three major MyHC isoforms in human skeletal muscle. Slow/beta MyHC (MYH7) is expressed in the heart and in type 1 muscle fibers in skeletal muscle. Type IIa MyHC (MYH2) is mainly expressed in type 2A muscle fibers while MyHC IIx (MYH1) is the major isoform in type 2B muscle fibers of skeletal muscle. Myosin heavy chain IIa myopathy (E706K) is caused by a mutation (nt2116G>A) in exon 17 of MYH2. The sequence alteration leads to a missense mutation, Glu706Lys, in the highly conserved region of the motor domain, the so-called SH1 helix region (Fig. 1).



**Myosin Heavy Chain IIa Myopathy, Autosomal Dominant. Figure 1** Ribbon model of MyHC subfragment 1 of chicken skeletal muscle. The ATP- and actin-binding sites are indicated. The site of the mutation (Glu-706⇒Lys) (E107 in chicken) in the SH1 helix (red) is indicated by a yellow sphere. Conformational charges upon binding and hydrolysis of ATP in the catalytic region are transmitted via the SH-1 helix region, to the regulatory domain, which acts as a lever arm. Reproduced from [2], with permission, Copyright (2000) National Academy of Sciences, USA.

By conformational changes this region communicates activity at the nucleotide-binding site to the neck region, which causes myosin to move along actin filaments during muscle contraction. An experimental model of the disease demonstrates impaired function in spite of normal sarcomeric thick filament formation [5].

## Diagnostic Principles

The diagnosis may be suspected when there is early onset muscle weakness with autosomal dominant inheritance, combined with structural changes mainly affecting type 2A muscle fibers. The diagnosis is based on genetic analysis of MYH2.

## Therapeutic Principles

There is no specific therapy. Endurance training seems to be beneficial.

# Myositis, Sporadic Inclusion Body

Ursula Knirsch[1],
Gisela Stoltenburg-Didinger[2]
[1]ALS-Clinic, Kantonsspital St. Gallen, St. Gallen, Switzerland
[2]Institute of Neuropathology, Campus Charité, Berlin, Germany

## Synonyms

SIBM

## Definition and Characteristics

Sporadic inclusion body myositis (SIBM) is the most common disabling muscle disease in persons older than 50 years. Clinical characteristics are painless, slowly progressive, proximal, and/or distal limb weakness (with prominent involvement of quadriceps and deep finger flexors), often dysphagia, and mildly elevated serum creatine kinase levels. Electromyography shows increased spontaneous activity and myopathic voluntary motor units. Pathomorphologically, SIBM is defined by the trias of inflammatory lymphomononuclear T-cell infiltration, rimmed vacuoles (RVs), and sarcoplasmic and/or nuclear aggregates of 15–21 nm filaments in skeletal muscle. Additionally, myofibers with subsarcolemmal accumulation of mitochondria (ragged red fibers, RRF) and fibers with deficient enzyme histochemical cytochrome c oxidase (COX) activity are often found [1]. Cytotoxic T-cells often invade intact, nonvacuolated myofibers whereas vacuolated fibers lack invasion but show strong upregulation of major histocompatibility complex class I antigens [2]. The RVs and the filamentous inclusions are associated with different types of proteins such as ubiquitin, β-amyloid, β-amyloid precursor protein, apolipoprotein E, and further pathological proteins, which were initially described in brains of patients suffering from Alzheimer's disease (AD) [3].

SIBM shares immunopathological similarities with polymyositis. Therefore, it is often subsumed under the idiopathic inflammatory myopathies [2]. By the "pathological protein" viewpoint, it is accounted to the myodegenerative disorders [3]. SIBM is distinct from the group of the hereditary forms of inclusion body myopathies (HIBM), which share the SIBM pattern but show the absence of a significant inflammatory infiltration. Few reports of familiary disorders, which meet the clinical and morphological criteria of SIBM, do exist [4].

## Prevalence

The prevalence of SIBM has been estimated to be 4.3–9.3 per 1,000,000 and arises 10–35.3 per 1,000,000 for people over the age of 50 years. There is a gender discrepancy toward males [2].

## Genes

No candidate gene for the diagnosis of SIBM is known.

## Molecular and Systemic Pathophysiology

The molecular mechanisms and the pathophysiological cascade resulting in SIBM are poorly understood and mainly hypothetical.

Three attempts have been made:

First, the finding of proteins in SIBM muscles, initially described in brains of AD patients, indicate that the pathophysiological cascade shares similarities to that in AD [3].

Second, the aetiology of the high frequency of multiple mitochondrial DNA mutations (namely the 4977 bp "common deletion") and COX deficient muscle fibers is not yet clarified, but the impaired mitochondrial function possibly contributes to muscle weakness and wasting [1].

Third, the autoimmune features of SIBM are underlined by the association of the disease with HLA I and II antigens, other autoimmune disorders, HIV and HTLV-I infection, and clonally expanded CD8 positive autoinvasive T cells, driven by specific but still unidentified antigens [2].

These inflammatory, degenerating, and aging features coexist and progress either parallel or independently.

## Diagnostic Principles

The diagnosis of SIBM is defined by the clinical course, the pathomorphological trias, and the "AD typical proteins" within skeletal muscle biopsy specimens.

### Therapeutic Principles

Different therapeutic approaches with common immunotherapeutic agents such as corticosteroids, intravenous immunoglobulins (IVIG), azathioprine, methotrexate, cyclophosphamide, cyclosporine, and total lymphoid irradiation showed no remarkable sustained beneficial effects. Only the response of dysphagia to IVIG was demonstrated to be significant. More specific or potent agents, for example, monoclonal antibodies interfering with the T cell regulatory pathways (CD56), costimulatory molecules (CD 28/CTLA-4), adhesion molecules (integrins/LFA-1/ICAM), and cytokines (TNF-alpha) or anti-T-lymphocyte globulin may be more promising [2].

## Myotilinopathy

►Limb Girdle Muscular Dystrophy, Autosomal Dominant (1A) (Myotilin)

## Myotonia and Paramyotonia

Karin Jurkat-Rott, Frank Lehmann-Horn
Applied Physiology, Ulm University, Ulm, Germany

### Synonyms

Dominant congenital myotonias; Chloride channel myotonia (Thomsen, DMC); Sodium channel myotonia (Potassium-aggravated myotonia, PAM; subtypes Myotonia fluctuans and Myotonia permanens); Paramyotonia congenita (Eulenburg, PC); Recessive myotonia: Recessive generalized myotonia (RGM, Becker)

### Definition and Characteristics

Myotonia is characterized by muscle stiffness due to involuntary electrical after-activity following voluntary strong muscle activity. If the myotonia is severe, transient weakness can occur. The myotonia decreases with continued activity, a phenomenon called warm-up. Also the weakness, if present at all, resolves. On the contrary, paradoxical myotonia as seen in paramyotonia worsens with exercise in the cold. Paradoxical myotonia of the eyelid muscles may also occur in the warmth; it is indicative of sodium channel myotonia. This type of myotonia can be aggravated by ingestion of potassium (potassium-aggravated myotonia). On electromyographic (EMG) examination, myotonic muscles exhibit myotonic runs, i.e. action potentials characterized by a modulation of frequency and amplitude. In mild cases, myotonia may not be evident on clinical examination, yet EMG may reveal the typical myotonic bursts. This is termed latent myotonia. In general, myotonia and corresponding muscle hypertrophy are more prominent in Becker than in Thomsen's disease and myotonia fluctuans.

### Prevalence

Heterozygous carrier of a recessive CLCN1 mutation: 1:200; Becker myotonia: 1:25,000; PC: 1:150,000; PAM: 1:300,000; Thomsen myotonia: 1:400,000 [1].

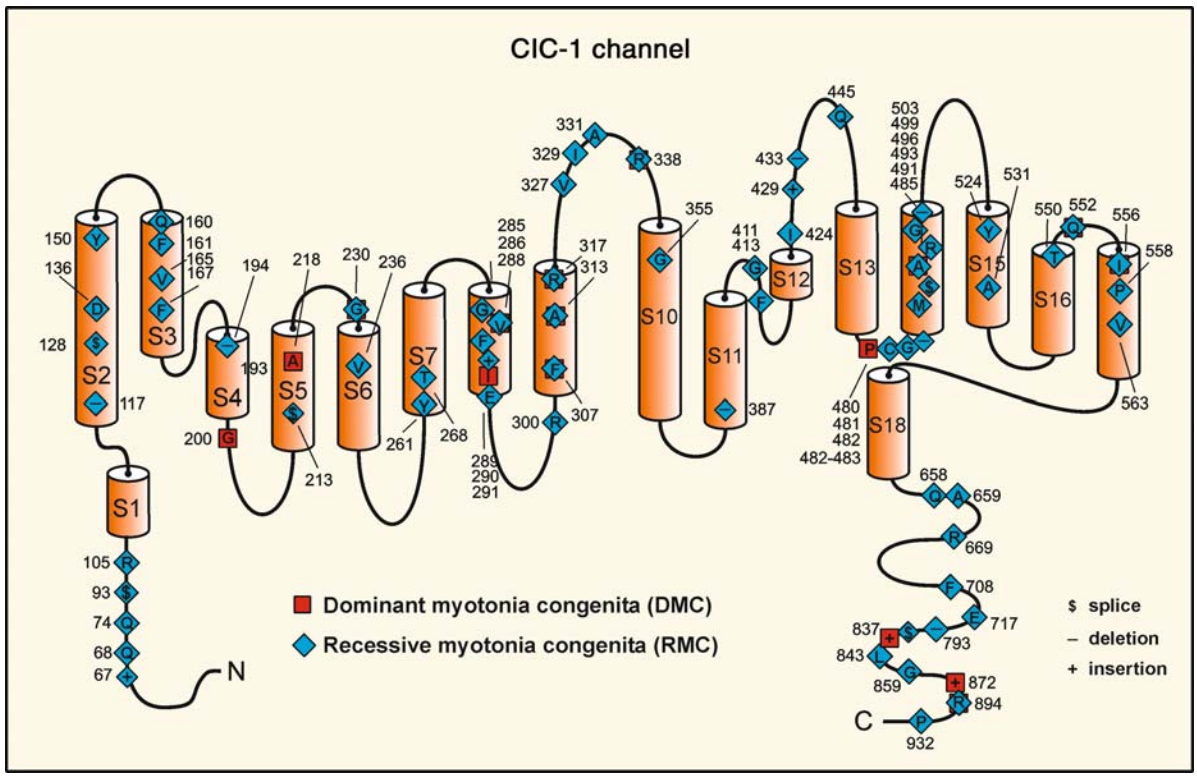
### Genes

Missense and nonsense mutations of CLCN1 (7q35) encoding the skeletal muscle ClC-1 chloride channel [2], point mutations in SCNA4 (17q23) encoding Nav1.4, the voltage-gated sodium channel of skeletal muscle [3].

### Molecular and Systemic Pathophysiology

During electrical activity of skeletal muscle, $K^+$ accumulates in the T-tubules. The expected after-depolarization of the action potential is prevented by $Cl^-$ conducted through tubular $Cl^-$ channel complexes, which are formed by homodimeric ClC-1 channels (Fig. 1).

If this muscle-specific high $Cl^-$ conductance is decreased by 75% or more, after-depolarizations are large and cause bursts of action potentials. These so-called myotonic runs result in involuntary after-contractions [4]. In Thomsen's disease, only one allele is mutated and a typical mutation affects the channel complexes (50% WT/mutant, 25% WT/WT, 25% mutant/mutant) so that their activation threshold is shifted towards more positive membrane potentials out of the physiological range. As a consequence of this, the $Cl^-$ conductance is drastically reduced in the vicinity of the resting membrane potential. This means that Thomsen mutations exert a dominant-negative effect on the channel complex. In contrast, Becker mutations result in simple loss of function of the mutant/mutant complex only. Therefore both alleles must be mutated for the $Cl^-$ conductance to fall below 25% of its normal value.



**Myotonia and Paramyotonia. Figure 1** Membrane topology of the skeletal muscle Cl– channel. The model shows the skeletal muscle chloride channel monomer, ClC-1, encoded by CLCN1. The functional channel complex is a homodimer with anti-parallel orientation of the two proteins. The different symbols used for the known mutations leading to either dominant or recessive myotonia are explained on the bottom. Conventional 1-letter abbreviations are used for replaced amino acids.

In PAM and PC, the $Cl^-$ conductance is normal. However, gain-of-function mutations are situated in the Nav1.4 sodium channel, which is essential for the generation of the muscle action potential (see Fig. 1 in the chapter on ►Familial periodic paralyses). The mutations cause a pathologically increased inward sodium current, which generates action potential bursts [3,4]. This repetitive activity reflects a dominant-positive effect of the SCN4A mutations, which is pronounced at a pre-existing membrane depolarization. This depolarization results from elevated serum potassium in PAM or cold environment in PC and facilitates activation of the mutant channels. The activation leads to involuntary action potentials and, thus, myotonia.

## Diagnostic Principles

Given a clinical diagnosis of myotonia by electromyographic examination, muscle atrophy, cataracts and tri-and tetra-nucleotide repeat expansions as in myotonic dystrophies types 1 and 2 must be excluded. The presence of paradoxical myotonia, most pronounced during repetitive strong eyelid contractions and eye openings, points to sodium channel myotonia whereas the warm-up phenomenon of limb muscles may occur in all types of myotonia regardless of the underlying mutated gene. Provocative tests using exercise and local cooling are helpful for the diagnosis of PAM and PC [4,5]; molecular genetics can then confirm the diagnosis. Sodium channel myotonia can easily be proven by identification of one of the ~30 known SCN4A mutations. Since CLCN1 mutations are distributed over the entire gene, mutational screening, requires complete sequencing.

## Therapeutic Principles

Chloride channel myotonia can be partially managed by keeping the muscles in the "warmed-up" state by continuous slight movements. However, Becker myotonia patients in particular require long-term medication. The myotonic stiffness responds to class 1 anti-arrhythmic drugs, which show use-dependence and block the repetitive activity. Of the many drugs tested that can be administered orally, mexiletine is the drug of choice. Mexiletine preferentially blocks the non-inactivating mutant sodium channels that reopen abnormally frequently. Thus, mexiletine has a much

greater beneficial effect in sodium channel myotonias than in chloride channel myotonia. Patients with myotonia permanens need long-term continuous therapy. The drug is also very effective in preventing and reducing the degree of cold-induced stiffness and weakness in PC. Carbonic anhydrase inhibitors are an alternative treatment for patients with sodium channel myotonias but may induce weakness in PC patients and exacerbate chloride channel myotonia [4].

## Synonyms

Myotonic dystrophy type 1 [OMIM #160900]; Dystrophia myotonica 1; DM1; Steinert's disease; Myotonic dystrophy type 2 [OMIM #602668]; Dystrophia myotonica 2; DM2; Proximal myotonic myopathy; PROMM

## Definition and Characteristics

Myotonic dystrophy (dystrophia myotonica, DM) is the most common inherited muscular dystrophy in adults. DM1 and DM2 show similarities in their clinical features including progressive myopathy, myotonia and multiorgan involvement. Both myotonic dystrophies are dominantly inherited disorders caused by repeat expansion mutations.

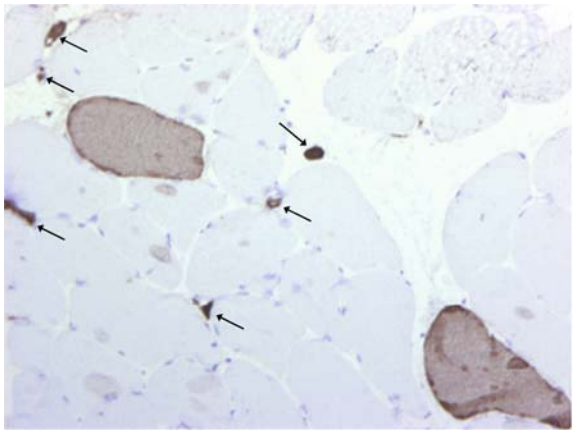
Clinical symptoms and signs in DM1 comprise three different phenotypes: (i) the most common adult onset DM1 with clinical myotonia, distal and facial weakness and atrophies, cataracts, cardiac conduction defects, frontal baldness, endocrinological, liver and skeletal abnormalities and CNS involvement with sleepiness, personality and cognitive changes. Later patients develop incapacity, dysphagia, respiratory failure and have a shortened lifespan (ii) childhood onset DM1 with predominant brain symptoms showing up as school difficulties and only later developing neuromuscular phenotype, and (iii) congenital DM1 with floppiness, poor feeding, respiratory failure, and retardation.

The core symptoms of DM2 include late onset proximal muscle weakness, muscle pain and/or stiffness, cataracts, myotonia, tremor, cardiac conduction defects and endocrinological abnormalities. However symptoms and signs in DM2 are much more variable and usually milder than in DM1, in any individual DM2 patient any of these symptoms may be absent, and even EMG myotonia may be variable over time. A number of less consistent findings are occasionally associated with this disorder, which makes clinical diagnosis a challenge. Rare juvenile onset patients have been reported but a congenital form of the disease is lacking in DM2.

Histological features in both DM1 and DM2 include increased variation in fiber size, rare fiber necrosis and high number of internal nuclei. In DM1 ring fibers and sarcoplasmic masses are characteristics usually absent in DM2, which instead may show numerous scattered nuclear clump fibers early and even before definite clinical muscle weakness. Type 1 fiber atrophy may be seen as an early change in DM1, whereas in DM2 type 2 nuclear clump fibers and other extremely small atrophic type 2 fibers, many of which are not detected by conventional ATPase staining, are regular and characteristic (Fig. 1) together with internal nuclei in large type 2 fibers.

## Prevalence

The estimated prevalence of DM1 is 1/8,000 while in DM2 the prevalence has not been established, but



**Myotonic Dystrophy Type 1 and Type 2.**
**Figure 1** Immunohistochemical myosin fast staining showing extremely small atrophic type 2 fibers indicated by arrows.

it might even be more common than DM1 in certain countries.

## Genes

DM1 is caused by a (CTG)n trinucleotide repeat expansion mutation in the 3′ untranslated region (UTR) of the dystrophia myotonica protein kinase (DMPK) gene located in chromosome 19q13.3 [1,2,3]. The mutation underlying DM2 disease is a (CCTG)n tetranucleotide expansion located in the first intron of zinc finger protein 9 (ZNF9) gene on chromosome 3q21 [4]. Repeat expansion size in DM1 may vary from 80 to more than 3,000 repeats and correlation is seen between repeat length and disease severity. Repeat size tends to increase and the disease is more severe in subsequent generations. In contrast, this anticipation is not seen in DM2. The number of repeats in the expansion mutation causing DM2 varies from 75 to 11,000. No correlation in disease severity and the size of the expansion mutation has been shown in DM2.

## Molecular and Systemic Pathophysiology

In both DM1 and DM2 the molecular pathomechanism is based on RNA gain-of-function. RNA transcripts of mutated expansions are accumulated in nuclei, where they interfere with the normal RNA metabolism of the cell. Mutant RNA transcripts sequester CUG-binding protein 1 (CUG-BP1) and muscleblind-like proteins (MBNL) which normally regulate alternative splicing. Several genes including CLCN1 (chloride channel-1), INSR (insulin receptor), TNNT2 (cardiac troponin T), TNNT3 (skeletal fast troponin T), LDB3 (ZASγ), ATP2A1 (SERCA1) and MAPT (microtubule-associated protein tau) show aberrant splicing patterns in DM1. Of these genes CLCN1, INSR and MAPT have also been confirmed to be abnormally spliced in DM2.

## Diagnostic Principles

In DM1 direct DNA analysis and mutation identification by Southern technique is the most convenient diagnostic procedure when clinical indications exist. In DM2 the diagnostic procedure is more complex due to the fact that DNA analysis is less straight forward and that the clinical phenotype may be difficult to identify, especially if EMG myotonia is lacking. If clinical indications exist, DNA analytics with DM2 locus allele sizing and mutation verification (modified Southerns or RP-PCR) can be applied for definite diagnosis. Less clinical indications usually lead to a diagnostic muscle biopsy. With compatible histopathology findings the sample can be used for further *in situ* hybridization (FISH or CISH) for mutation detection of both the mutation on the DNA strand and the accumulated mutant RNA transcript [5].

## Therapeutic Principles

Only symptomatic treatment is available. In DM1 this means monitoring of complications such as cardiac arrhythmia, dysphagia, respiratory failure, GI-problems and consecutive therapy including cataract surgery, pace makers, ventilation support etc. Myotonia and sleepiness are difficult to treat but mexiletine and modafiline have been used. In DM2 disability is much less a problem and in many adults pain may be the most prominent clinical problem, where no good treatment is available. Regular non-strenuous physiotherapy and balneology has been used. In some families cardiac arrhythmia is a major problem which may include early cardiac deaths and need for monitoring.

## Nail-Patella-Syndrome

Stephan J. Froehlich, Carlo A. Lackerbauer, Guenter Rudolph
Eye Clinic, Ludwig-Maximilians-University Munich, Munich, Germany

### Synonyms

NPS; Hereditary onychoosteodysplasia; Turner-Kieser-syndrome; Fong disease

### Definition and Characteristics

NPS is an autosomal dominant hereditary systemic disease characterized by dysplastic nails (onychodysplasia), absent or hypoplastic patellae, nephropathy and open-angle glaucoma.

### Prevalence

The incidence is estimated to be about 1:50,000.

### Genes

In patients affected by NPS, heterozygous mutations are found in the LIM-homeodomain gene, LMX1B, which is localised on chromosome 9q34. LMX1B is a transcription factor required for the normal development of dorsal limb structures, the glomerular basement membrane, the anterior segment of the eye as well as dopaminergic and serotonergic neurons. Although interfamilial variability is common in this disorder, there are comparable phenotypes for specific gene defects in the homeodomain, such as the presence and severity of skeletal abnormalities, nephropathy and ocular anomalies. Phenotypic variability could depend on interactions of the LMX1B causative gene with other genes during the development of limbs, kidney and eye, thereby acting as modifier genes.

### Molecular and Systemic Pathophysiology

In 80–100% of the affected patients, dysplasia or aplasia of fingernails can be detected, decreasing in degree of severity from thumb towards the little finger (Fig. 1).

In 60–100% of cases there is evidence of hypoplasia or, more rarely, aplasia of patellae, which can cause

**Nail-Patella-Syndrome. Figure 1** Dysplasia of fingernails in nail-patella syndrome: thumbs of affected mother (*left*) and son (*right*).

recurrent dislocations combined with an extension deficit of the knee-joint. Another cardinal symptom is iliac horns, which do occur in about 80% of cases. These are bilateral hyperostoses of the iliac bone and are pathognomonic for NPS. They can easily be seen with the use of radiology, but do not have any negative effect on movement. Alongside these typical symptoms, other skeletal malformations are reported, e.g. hypoplasia of humeroradial joints with deformation or luxation of the capitulum radii affecting the mobility of the elbow joint. Furthermore, underdevelopment of the muscular system at the extremities, dislocation of the hip and clubfoot can be associated with NPS. The mutation of LMX1B influences the expression of protein-type IV-collagen, which is an important component of the renal basement membrane. The resulting elevated permeability of the basement membrane causes proteinuria and microhematuria and is indicative of NPS-associated glomerulonephritis. It is evident in 30% of affected patients, leading to renal failure in 10% of cases. The occurrence of familial colon carcinoma was also reported in NPS-patients. Based on animal models, conclusions can be drawn regarding ocular involvement in NPS. Experiments on mice have shown mutations of the LMX1B gene result in the alteration of several structures of the anterior segments of the eye. These alterations include hypoplasia of the iris and ciliary body as well as defects in the development of corneal collagen, causing glaucoma or structural changes, at the corneal level. The incidence of open-angle glaucoma in NPS-patients is about 30%; refraction abnormalities such as excessive astigmatism are also reported, but rare.

## Diagnostic Principles

The diagnosis is made according to signs and symptoms (finger nails, hyperostoses of the iliac bone, other skeletal malformations) and confirmed by genetic analysis (mutations in the LIM-homeodomain gene LMX1B).

## Therapeutic Principles

Because of the link between the syndrome and open-angle glaucoma, NPS patients should undergo regular ophthalmological tests including measurements of intra-ocular pressure. In cases of refractive errors, visual acuity can be improved by wearing spectacles or contact lenses. Physiotherapeutic treatment, such as functional and cosmetic corrections to joints and nails can be carried out and controlling renal function is essential. In the early stages of renal disease with proteinuria ACE-inhibitors can be used to slow progression of the disease.

# NAME

►Carney Complex

# Narcolepsy

Jan Rémi, Soheyl Noachtar
Section of Sleep, Department of Neurology, University of Munich, Munich, Germany

## Definition and Characteristics

The syndrome is defined by excessive daytime sleepiness and pathological manifestations of REM-sleep episodes.

The latter are characterized as episodes of cataplexy (sudden loss of muscle tone), as sleep paralysis (inability to move upon waking up), and hypnagogic hallucinations (occurring in the process of falling asleep or waking up). EEG or polysomnography typically reveal sleep-onset REM, a further symptom of REM dissociation [1].

## Prevalence

Figures range between 0.03 and 0.16% of the general population. The age of onset has a peak in the second decade and a smaller peak in the fourth decade, here mostly in women. Overall, both sexes are affected equally.

## Genes

Narcolepsy is associated with the HLA loci DR2 and DQ1 (DR15 and DQ6 in newer nomenclature). The most specific HLA marker associated with narcolepsy is HLA DQB1*0602 (a subspecification of DQ6). However, they are neither sufficient nor necessary for developing the disease, and so the presence of the alleles is not required for the diagnosis of narcolepsy. The two alleles have an incidence of 10–35% in the general population [2].

## Molecular and Systemic Pathophysiology

Narcolepsy is thought to have an autoimmune background, with the above-mentioned HLA types predisposing to the disease. Affected are cholinergic (muscarinic receptors are upregulated in brainstem structures) and monoamine (alpha adrenergic and dopamine) transmitter systems, most likely involved in the arousal systems and REM-control systems of the brain [3]. Newer research has shown the involvement of the hypocretin transmitter system, with hypocretin receptor mutations and prehypocretin mutations resulting in animal models of narcolepsy [4]. In humans, hypocretin levels are lowest in narcolepsy with cataplexy. In narcolepsy without cataplexy, hypocretin levels are lower than those in the normal population, but levels are also lowered in other neurological disorders like Parkinson's disease [5].

## Diagnostic Principles

According to the international classification of sleep disorders, the diagnosis of narcolepsy requires either (i) daytime sleep attacks and cataplectic attacks or (ii) the tetrade of (a) excessive daytime sleepiness, (b) REM-dissociation symptoms like sleep paralysis, hypnagogic hallucinations, automatisms, and fragmented night sleep, (c) a sleep latency of <5 min and sleep-onset REM (<20 min after sleep onset) in polysomnography and sleep latency testing and (d) no other medical reasons for the symptoms [1]. Neither the HLA types nor the hypocretin levels are included in the diagnostic criteria because of their low specificity.

## Therapeutic Principles

Two therapeutic principles are effective: behavioral adaptation and pharmacological intervention.

Many patients attain excellent quality of life by scheduling short naps before important events and by informing their social environment about their medical condition.

Pharmacological treatment has to be tailored to the patient's symptoms: if daytime sleepiness is most pressing; amphetamines and their derivatives, especially methylphenidate and modafinil, have shown to be efficacious, and are also effective against the other symptoms. REM-dissociative symptoms are well treated with REM suppressants like tricyclic antidepressive drugs. Benzodiazepines and their derivatives are helpful in treating fragmented night sleep. A new medication to treat narcolepsy is sodiumoxybate, which is applied in two charges at night and improves night time sleep, daytime sleepiness, and symptoms of REM dissociation.

# NARES

Werner J. Heppt, Annette Cryer
Department of Otorhinolaryngology, Klinikum Karlsruhe gGmbh, Karlsruhe, Germany

## Synonyms

NARES; Non-allergic rhinitis with eosinophilic syndrome

### Definition and Characteristics

The non-allergic rhinitis with eosinophilic syndrome (NARES) is defined by a perennial rhinitis, the absence of allergy, and an eosinophil count higher than 20% of total leucocytes in nasal secretions [1]. Frequently associated with nasal polyps and olfactoric disorders.

### Prevalence

NARES is more frequent in females in mean age, and family history is positive in part of cases.

### Genes

No correlation known.

### Molecular and Systemic Pathophysiology

Eosinophils not only migrate from the vessels to the nasal secretions but also retain in the mucosa where they might be activated. The pathophysiological mechanism is yet unknown though weather changes, odors, and noxious or irritating substances are supposed to be triggers [2]. The patients experience perennial symptoms of sneezing paroxysms, profuse watery rhinorrhea, nasal pruritus, and occasional loss of smell. The cause for the frequently associated nasal polyps could be neurogenic inflammation. It is not sure whether NARES is a form of vasomotor rhinitis or the first stage of aspirin triad [3]. In aspirin sensitivity, nonsteroidal anti-inflammatory drugs block cyclooxygenase activity, increasing the production of the potent proinflammatory cysteinyl leukotrienes ($LTC_4$, $LTD_4$, and $LTE_4$) [4].

### Diagnostic Principles

Nasal symptoms include profuse watery rhinorrhea, nasal obstruction, sneezing paroxysms, and nasal itching. The precipitating factors are often non-specific irritants, weather changes, or strong odors. All immunological tests are negative. The serum IgE-level is normal. The eosinophil count in nasal secretion must be over 20% of total leucocytes [5].

A nasal biopsy from the middle turbinate reveals eosinophilic infiltration. Endoscopy and CT can rule out chronic sinusitis. Bronchial hyperreactivity is detected in part of patients.

### Therapeutic Principles

Topical steroids are highly effective, if not, then systemic corticoids are needed. On the contrary anti-H1 drugs usually fail to relieve symptoms. The appropriate management of a complicating chronic polypoid sinusitis has found to be functional sinus surgery combined with antiinflammatory drugs postoperatively. In the case of aspirin sensitivity, a desensitization might be advisable.

## Narrow Complex Tachycardias

►Arrhythmias, Supraventricular

## Nasal Hyper-Reactivity

Hans-Peter Zenner
Department of Otolaryngology and Head and Neck Surgery, University of Tuebingen, Tuebingen, Germany

### Definition and Characteristics

The nasal mucosa reacts more or less to any irritation with obstruction, secretion, sneezing, or combinations of these. If everyday physical, chemical or pharmacological irritations lead to an excessive reaction however, this is referred to as nasal hyper-reactivity [1,2]. Specific hyper-reactivity, especially to allergens is distinguished from non-specific reactivity towards environmental irritants cigarette smoke, dust clouds, cold air, changes in position or physical effort [2].

### Prevalence

Epidemiological studies on representative population samples in several European countries have been carried out regarding specific hyper-reactivity towards allergens. The prevalence data varies between 5 and 27%. Regarding the non-allergic forms of

hyper-reactivity there is far less reliable data. The prevalence of these hyper-reactivity forms together can be estimated to be about 15% [2].

## Molecular and Systemic Pathophysiology

Nasal hyper-reactivity is a clinical phenomenon, which is based on different and sometimes overlapping pathological mechanisms and which is determined by various etiological factors. In specific hyper-reactivity towards allergens [1,2], specific IgE antibody formation occurs upon first contact with the allergen due to a genetic predisposition of the patient. The antibodies bind locally in the nasal mucosa to mast cells, basophils and eosinophilic granulocytes. Upon further allergen exposure degranulation of the mast cells occurs and various mediators such as histamine, leukotrienes, prostaglandins, tryptase and kinins are released. At the same time cytokines are also released, which stimulate T lymphocytes and endothelial cells. During the late stage, a $TH_2$ cell controlled infiltration of various inflammatory cells occurs in the mucosa. The cellular reaction can lead to hyper-reactivity of the mucosa.

With neural dysregulation of the nose, the sensory nerve endings of the autonomous nervous system (irritant receptors) in the nasal mucosa react to various stimuli such as histamine and/or temperature changes. They induce a reflex loop, which is primarily transmitted via the trigeminal nerve to the brain stem where it is switched. The autonomic nervous system regulates the filling status of the blood vessels of the nasal mucosa, whereby a dominance of the parasympathetic system leads to mucosal swelling and hypersecretion.

By changing the osmolarity of the nerve secretion, cold dry air [1–3] can lead to a mast cell activation with subsequent histamine release. Non-steroidal anti-inflammatory agents [4] induce an inhibition of cyclooxygenase, which lowers the production of prostaglandins and increases the synthesis of leukotrienes. This leads to effects on glands and blood vessels of the mucosa. Cyclooxygenase inhibition serves as a model to explain aspirin sensitive rhinitis.

Trivial inflammatory processes [1–3] or even the local actions of various inhaled noxious influences such as chemical substances or heat [1–3] can lead to epithelial damage. As a result of this, a direct irritation of the free intraepithelial nerve endings can directly mediate symptoms of a nasal hyper-reactivity.

## Diagnostic Principles

1. Anamnesis
2. Anterior and posterior rhinoscopy
3. Endoscopy
4. Cutaneous allergy tests
5. In vitro allergy tests
6. Provocation tests
7. Rhinomanometry
8. Acoustic rhinometry
9. Imaging procedures

## Therapeutic Principles

*Preliminary Note*: The therapy of hyper-reactivity depends not just on its etiology and pathogenesis, but also on the symptoms that prevail.
*Elimination*: If the etiology is known, elimination of the irritative stimulus is the basic therapeutic principle.
*Immunotherapy*: With some forms of allergic hyper-reactivity immune therapy plays an important role.
*Drug Therapy*: For all forms of hyper-reactivity a pharmaceutical therapy may be a major therapeutic component. This may take the form of mast cell stabilizers, topical glucocorticosteroids or systemic antihistamines.
*Surgical Therapy*: For a marked nasal mucosa hyperplasia, a surgical reduction of the nasal sinus can also be helpful as an addition to pharmaceutical therapy and elimination.

# Nasal Pharyngeal Carcinoma

Hans Helmut Niller, Fritz Schwarzmann, Hans Wolf
Institute of Medical Microbiology, University of Regensburg, Regensburg, Germany

## Synonyms

Nasopharyngeal carcinoma; Nasopharynx carcinoma; NPC

## Definition and Characteristics

A tumor derived from the epithelium of the nasopharyngeal surface, in particular the Fossa Rosenmülleri [1]. Since 1991, the WHO classified two groups, keratinizing (I) and non-keratinizing (II) squamous cell carcinomas. Class II (undifferentiated carcinoma of the nasopharyngeal type, UCNT) comprises non-keratinizing epidermoid carcinomas and undifferentiated carcinomas, also called lymphoepitheliomas or Schminke tumors [2]. Class I tumors may be Epstein–Barr virus (EBV) infected in dependence of geographical origin, class II tumor cells are virtually always EBV infected [3], with each tumor carrying a single clone of EBV. The Schminke tumor with a strong T-lympocytic infiltration is the most common form [1,2].

## Prevalence

Class I tumors occur sporadically in all parts of the world, with a low incidence of 0.3–2/$10^5$. Class II tumors are endemic in South Eastern China (mostly Cantonese of the Guangzhou area) with a high incidence of up to 80/$10^5$, and in Inuit of Greenland and Alaska and in The Mediterranean (mostly Tunisians) with an intermediate incidence of 8–12/$10^5$. The male-to-female ratio is about 2–3:1 and the age peak is between 40 and 50 years; the North African NPC has an additional age peak between 10 and 20 years [4].

## Genes

HLA haplotypes A2Bw46 and A19B17 carried a twofold increased risk in Singapore Chinese, and A11 and B13 carried reduced risk. Chinese migration effects sort out genetic and environmental effects. In tumors, loss of heterozygosity (LOH) is frequent for chromosomal loci 3p25 and 3p14, and for 9p21–22 that carries the p16 tumor suppressor gene [1]. The expression of the p53 tumor suppressor gene is usually not reduced.

## Molecular and Systemic Pathophysiology

The etiology is multifactorial including genetic and environmental factors and an association with EBV. Consumption, especially in childhood, of salted fish containing volatile nitrosamines, teas containing phorbolesters, smoke, dust, and certain lignins promote tumorigenesis. Viral latency proteins EBNA1, LMP1, and LMP2 and viral EBER- and BART-RNAs are usually expressed in tumor cells. They may participate in the molecular mechanisms of viral pathogenesis. For the EBV negative class I tumors, the tumor promoting function normally provided by EBV may be replaced by other pathogenic factors, like papilloma virus infection, smoking, and others that remain unknown so far.

## Diagnostic Principles

Usually, the tumors are discovered when they cause clinical symptoms, already at stages III and IV, mostly without overt metastases. Local infiltration, lymph node metastasis, and systemic dissemination occur readily. EBV serology is very useful as a screening method in high-incidence areas and for tumor monitoring, but does not have prognostic value. IgG anti-VCA, anti-EA-D, anti-EBNA, IgA anti-VCA, and anti-EA-D rise with tumor progression and metastasis and well before clinical recurrence, fall with reduced tumor burden after therapy. Especially IgA anti-VCA and IgG anti-BZLF1 are markers of elevated tumor risk. Radiography, magnetic resonance imaging (MRI), and endoscopic biopsy is used for diagnosis of suspected cases and together with serology for monitoring residual or recurrent disease.

## Therapeutic Principles

The tumors are highly radio- and chemosensitive in general. Since the complex anatomical location does not allow resection, radical radiotherapy is the first choice; however, patients with locally advanced tumors seem to benefit from a combination treatment of radio- and chemotherapy [2]. Chemotherapy options are currently being further developed (Cisplatin + 5-fluorouracil or bleomycin + anthracycline, also gemcitabine, ifosfamid, epirubicin, taxanes). Adoptive immunotherapy, vaccination trials [5], and gene therapy are at the experimental stage.

## Nausea and Vomiting

Thomas Frieling
Medical Clinic II, Helios Klinikum Krefeld, Krefeld, Germany

### Synonyms

Postchemotherapy nausea and vomiting; PCNV; Postoperative nausea and vomiting; PONV; Chronic idiopathic nausea; CIN; Functional vomiting; Cyclic vomiting syndrome; CVS; Morning sickness; Hyperemesis gravidarum

### Definition and Characteristics

Nausea is an entirely subjective symptom and can be defined as an unpleasant sensation of the imminent need to vomit typically experienced in the epigastrium or throat. Nausea may present a basic, physiologic homeostatic response to an ingested exogenous toxin, or may indicate a disease process of the gastrointestinal tract, adjacent organs, or central nervous system (CNS). Chronic nausea often presents a greater clinical challenge because of failure to characterize the basic cause and the inability to satisfactorily suppress symptoms. In addition, it overlaps with functional dyspepsia.

Functional nausea and vomiting is the term used to describe chronic unexplained symptoms. Vomiting refers to the forceful oral expulsion of gastric or intestinal content associated with contraction of the abdominal and chest wall muscles. The Rom III Consensus Conference classified chronic nausea and vomiting among the symptoms attributable to the gastroduodenal region. These are epigastric complaints, excess belching, or recurrent unexplained nausea or vomiting that were grouped into Functional Gastroduodenal Disorders [1]. According to this classification, chronic idiopathic nausea (CIN), functional vomiting, cyclic vomiting syndrome (CVS) are subgrouped into Nausea and Vomiting Disorders. CIN comprises bothersome nausea, not usually associated with vomiting, occurring at least several times per week, and absence of abnormalities at upper endoscopy or metabolic disease that explains the nausea. The criteria should be fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis. CIN was differentiated from functional dyspepsia because of its often central or psychological origin, and the lack of responsiveness to empiric therapy for dyspepsia. Functional vomiting refers to chronic vomiting at least once a week. CVS is characterized by episodes of vomiting with a stereotypical onset and duration and varying intervals of absence of vomiting in between episodes. CVS has a strong family history of migraine headaches (80% of cases), and may be linked to the menstrual cycle or precipitated by pregnancy.

### Prevalence

Nausea and vomiting from all causes involve significant social and economic burden to the community. It has been estimated that acute enteric infectious illnesses increase medical expenses by $1.25 billion and lead to $21.8 billion in lost productivity in the USA each year. Likewise, nausea and vomiting of pregnancy may cause a lost of 8.5 million working days each year and postoperative nausea and vomiting incur additional costs of $415 per patient. Because the Rom III classification is somewhat arbitrarily, epidemiologic data on CIN are sparse. CIN is reported in 8% of otherwise normal subjects [2]. Functional vomiting at least once a month is reported in about 5%. CVS may affect over 1% of school age children. CVS in adults is rare, mean age was reported to be 35 years with a range of 14–73 years.

### Molecular and Systemic Pathophysiology

Because of anatomic localization and receptor mediation, central or peripheral mechanisms, and the combination of both may be differentiated. The pathophysiology of nausea and vomiting is complex and variable and not fully understood. For example, serotonin metabolism plays an important role in mediating acute nausea and vomiting from highly emetogenic agents and can be relieved by 5-$HT_3$-receptor antagonists. In contrast, delayed and anticipatory nausea and vomiting after chemotherapy are mediated by

serotonin-independent other neuroendocrine pathways (e.g., norepinephrine). Bacterial and viral infections may cause acute nausea and vomiting via direct action on the brainstem (Hawaii agent, rotaviruses, reoviruses, adenoviruses, Snow Mountain and Norwalk agents, Staphylococcus aureus, Salmonella, Bacillus cereus, Clostridium perfringens), in many cases via toxins. Labyrinthine disorders (motion sickness) are associated with activation of the brainstem nuclei mediated primarily via histamine $H_1$ and muscarinic cholinergic rather than dopaminergic or serotonergic pathways. Postoperative nausea and vomiting (PONV) is more prevalent in women and in younger patients, is associated with general anesthesia, the use of certain inhalation agents, the concomitant use of opiate medications, longer duration of surgery and anesthesia, and is more frequent after gynecologic and middle ear, abdominal and orthopedic surgery, and in those with a history of motion sickness. In other cases, the documentation of a disturbed function such as gastroparesis must not lead the clinician to assume that it is the fundamental cause of nausea and vomiting.

Among the various central causes are adverse medication that are among the most common causes of nausea and vomiting. They usually cause acute rather than chronic symptoms. Medications that evoke nausea and vomiting by an action on the area postrema include dopaminergic agonists (L-dopa, bromocriptine), nicotine (CNS active narcotics, antiparkinsonian drugs, anticonvulsants), digoxin, cytotoxics, and opiate analgesics. Medications that induce nausea and vomiting by activation of peripheral pathways, most likely vagal, which then stimulate the brainstem nuclei that coordinate the act of vomiting, are nonsteroidal anti-inflammatory drugs (NSAID) and erythromycin. Other medications that may cause nausea and vomiting include analgesics (auranofin, antigout drugs), cardiovascular medications (antiarrhythmics, antihypertensives, β-blockers, calcium channel antagonists), diuretics, hormonal preparations (oral contraceptives, oral antidiabetics), antibiotics and antivirals (tetracycline, sulfonamide, antituberculous drugs, acyclovir), antiasthmatics (theophylline), and gastrointestinal medications (sulfasalazine, azathioprine) hypervitaminosis. Nausea and vomiting resulting from chemotherapy (PCNV severe: cisplatinum, dacarbazine, nitrogen mustard, moderate: etoposide, methotrexate cytarabine, mild: fluouracil, vinblastine, tamoxifen) are classified as acute (within 24 h), delayed (≥1 day later), and anticipatory [3].

Diseases with central effects are CNS disorders (migraine, increased intracranial pressure, seizure disorders, demyelinating disorders, emotional responses, psychiatric diseases, labyrinthine disorders such as motion sickness, labyrinthitis, tumors, Meniere's disease), endocrinologic and metabolic disorders (pregnancy, hyperparathyroidism, hypoparathyroidism, Addison's disease, acute intermittent porphyria, uremia, diabetic ketoacidosis, hypoxemia, hypercalcemia), bacterial toxins, radiation therapy, or infections, ethanol abuse, otitis media. Causes mediating nausea and vomiting via peripheral afferents are gastric irritants (copper sulfate, Staphylococcus enterotoxin, salicylate, antral distension, gastric outlet obstruction, gastroparesis, peptic ulcer disease) and nongastric stimuli (colonic, biliary, or intestinal distension, inflammatory intraperitoneal disease, viral and bacterial gastroenteritis, mesenteric occlusion, abdominal radiation, chronic intestinal pseudo-obstruction, nonulcer dyspepsia, irritable bowel syndrome, pharyngeal stimulation, organic gastrointestinal disorders such as gastrointestinal carcinoma, cholecystitis, pancreatitis, hepatitis, Crohn's disease, retroperitoneal fibrosis, mucosal metastases). Nausea and vomiting can also be caused by cardiac diseases (myocardial infarction, congestive heart failure, radiofrequency ablation) and starvation.

## Diagnostic Principles

Given the vast number and diversity of potential causes of nausea and vomiting, a carefully considered and orderly approach to the evaluation is needed. A comprehensive history and physical examination is essential, because the differential diagnoses of nausea and vomiting are extensive. The acuteness of the symptomatology should be determined at the initial encounter. The nature of an acute illness can usually be detected on the basis of history and physical examination, supplemented where indicated by plain abdominal ultrasonography, radiographs, computed tomographic scanning, and appropriate blood tests. Several issues need to be addressed in acute nausea and vomiting (acute emergency because of mechanical obstruction/perforation/peritonitis, dehydration, and/or electrolyte abnormalities, likelihood of self-limitation such as it would be expected with viral gastroenteritis, potentially offending medication, initiation of empiric therapy with antiemetics, acid suppressives, or prokinetics). The broad categories of clinical conditions that may cause these symptoms should be considered in chronic nausea and vomiting. Rumination and eating disorders need to be excluded. Medication-related toxicity and other iatrogenic causes can usually identified by history alone. If symptoms suggest obstruction, radiographic studies should first be performed to exclude a mechanical cause. Mucosal disorders of the stomach and/or duodenum including malignancies are most accurately diagnosed by endoscopy. If neither obstruction nor mucosal disease is evident, systemic illness, CNS lesions, psychologic factors, and underlying motility disorders (gastroparesis, small bowel dysmotility) should be considered. Vomiting can be an atypical manifestation of ►gastroesophageal reflux disease (GERD). If endoscopy is negative, esophageal pH testing and PPI therapy should be considered. In addition, gastric emptying studies (scintigraphy, breath

tests, ultrasonography), electrogastrography (EGG), and antroduodenal manometry may be helpful. The evaluation of central disorders comprises neurological investigation, the search for papilledema. Central imaging includes computed tomography and magnetic resonance imaging, by virtue of superior visualization of the posterior fossa.

## Therapeutic Principles

Treatment of nausea and vomiting must include correction of any fluid, electrolyte, or nutritional deficiency, identification and elimination of the underlying cause of the symptoms, and suppression or elimination of the symptoms themselves if the primary cause cannot be identified easily and promptly eliminated. Fluid replacement should be based on the administration of normal saline solutions with appropriate potassium supplementation. A nasogastric tube may be helpful to relieve gastric distension. In nausea and vomiting related to gastroparesis, dietary measures may be of considerable importance (consumption of frequent small meals, reduction of the fat content of meals, avoidance of indigestible or partially digestible material, elimination of carbonated beverages). Medical therapy include antiemetic (phenothiazines, antihistamines, anticholinergics, dopamine antagonists, serotonin antagonists, butyrophenones, cannabinoids, steroids, benzodiazepines) and prokinetic agents. The clinical utility of anticholinergic agents has been limited to scopolamine as a transdermal patch for prophylaxis and treatment of motion thickness. Antihistamine drugs with histamine $H_1$-receptor antagonistic properties (meclizine, diphenhydramine) have central antiemetic effects and are used for the therapy of motion sickness, vertigo, and migraine. Phenothiazine compounds (prochlorperazine, promethazine, chlorpromazine, thietylperazine, perphenazine) act primarily through a central antidopaminergic mechanism in the area postrema and are commonly used for more severe episodes of nausea and vomiting. The butyrophenones, haloperidol and droperidol, also probably act via a central antidopaminergic effect. Droperidol, in particular, has been shown to be useful in the treatment of anticipatory and acute chemotherapy-related nausea and vomiting, and also in the therapy of PONV. Serotonin antagonists, particular the 5-$HT_3$ antagonists (ondansetron, granisetron, tropisetron, dolasetron), are remarkably successful in controlling nausea of various origins by acting in the area postrema, and/or vagal afferent fibers in the stomach and duodenum. In combination with dexamethason, they are potent agents for the treatment of severe PCNV. Corticosteroids, especially dexamethasone, have been used primarily in the treatment of PCNV, acting by reducing prostaglandin formation. Combination of dexamethason and metoclopramide, benzodiazepines, and substituted benzamides as well as a neurokinin-1 antagonists may be effective in both acute and delayed PONV. Among the prokinetic agents are the substituted benzamides domperidone and metoclopramide that act primarily as dopamine antagonists and appear to have both central and peripheral actions. They also have some direct and indirect cholinergic effects. In contrast to metoclopramide, domperidone is free of centrally mediated extrapyramidal side effects. Because of their dual action as prokinetics and antiemetics, they may be particularly useful in nausea and vomiting related to gastroparesis and PONV. Although surgical treatment of gastroparesis and motility disorders cannot be recommended, endoscopic placement of percutaneous endoscopic gastrostomy (PEG) may decompress prominent distension and relief symptoms. Gastric pacing may be an alternative treatment in gastroparesis; however, further studies are needed to prove this concept. In morning sickness and hyperemesis gravidarum, fluid and electrolyte replacement, thiamine supplementation, antiemetics (antihistamines, phenothiazines, promethazine), metoclopramide, and acupressure may be helpful. For those with hyperemesis gravidarum resistant to those interventions, total parenteral or enteral nutrition may be necessary. In CVS patients may require hospital admission and supportive care. Antimigraine medication (triptanes, β-blocker, tricyclic antidepressants, SSRI) may be helpful even if there is no such history.

## Synonyms

NLD

## Definition and Characteristics

Necrobiosis lipoidica diabeticorum (NLD) is characterized by ovoid plaques with an irregular, elevated periphery and an atrophic center [1]. NLD usually begins as painless erythematous papules. These gradually enlarge, then develop irregular margins, and can coalesce into irregular waxy plaques (Fig. 1).

The plaques often display a yellowish or reddish brown hue and tend to be sharply demarcated, with raised and sometimes indurated borders [1]. Some of the lesions may show central atrophy, telangiectasia, and yellow pigmentation. In 85% of cases, the lesion is confined to the pretibial area. Most NLD lesions are asymptomatic. Ulceration develops in one third of cases and is typically caused by minor trauma.

## Prevalence

NLD occurs in 0.3% in diabetic adults and 0.06% in diabetic children. The female to male ratio is approximately 4:1. Smoking increases the risk of NLD. The condition is more prevalent among those with thyroid disease, ►Crohn's disease, and ►ulcerative colitis.

## Molecular and Systemic Pathophysiology

Although the exact etiology and mechanism of development remain unknown, diabetic microangiopathy might be a major underlying cause. In this regard, persistent microalbuminuria and retinopathy are more common among patients with diabetes in whom NLD develops than among control patients with diabetes who do not have NLD [2]. Immunoglobulins have been found around blood vessels in affected areas. This could suggest an immune complex vasculitis. Focal degeneration of collagen could also be an initiating event. Histologically, the characteristic features include a brightly eosinophilic degeneration of collagen and infiltration of collagen bundles by pallisading histiocytes [3].

**Necrobiosis Lipoidica Diabeticorum.**
**Figure 1** Necrobiosis lipoidica diabeticorum. Note the well circumscribed, brownish plaques in the pretibial areas.

## Diagnostic Principles

Differential diagnosis includes pyoderma gangrenosum, granuloma annulare, diabetic dermopathy, xanthogranuloma. Pyoderma gangrenosum tends to be both more violaceous and more purulent-looking. Granuloma annulare presents as asymptomatic erythematous, dome-shaped papules arranged in a circle around a central depression. The sites most commonly affected are the dorsa of hands and feet, ankles, and elbows. Diabetic dermopathy (spotted leg syndrome or shin spots) is the most common cutaneous manifestation of diabetes. Diabetic dermopathy presents as multiple atrophic brown macules in the pretibial areas. Necrobiotic xanthogranuloma typically presents as multiple asymptomatic indurated papulonodules or plaques with a yellow xanthomatous hue. The periorbital area is selectively involved.

### Therapeutic Principles

NLD lesions are usually self-limited. However, they may recur. Because of the unsightliness of NLD lesions and concerns about potential infection or neoplasia, diverse treatments have been tried, without consistent benefit. These include topical, intralesional or systemic corticosteroids and topical retinoids, cryotherapy, and psoralen plus ultraviolet A light (PUUA), and topical photodynamic therapy with methyl aminolevulinate [4].

## Nemaline Myopathies

Carina Wallgren-Pettersson[1],
Hans H. Goebel[2]
[1]Departments of Medical Genetics, University of Helsinki and Folkhälsan, Helsinki, Finland
[2]Department of Neuropathology, Johannes Gutenberg University Medical Center, Mainz, Germany

### Synonyms

Rod myopathies

### Definition and Characteristics

Autosomal-recessive or autosomal-dominant congenital myopathies marked by generalized muscle weakness and the formation of nemaline bodies/rods in muscle fibers caused by mutations in at least six different genes [1].

### Prevalence

No prevalence figures have been published. An estimated incidence is 0.02 per 1,000 live births [2].

### Genes

So far, five different genes have been identified as being responsible for nemaline myopathies, NEM 1–6, (Table 1). In addition, two loci have been identified for the rare core-rod myopathies, where both cores and rods can be found in the muscle fibers.

### Molecular and Systemic Pathophysiology

Nemaline myopathies are considered a heterogeneous group of disorders which may be classified according to clinical features as encompassing six different types. Nemaline myopathies have been linked to at least six different loci, NEM 1–6, each of them coding for a separate sarcomeric protein component of the thin filament and therefore also of the Z disk. The two main causative genes, together responsible for the majority of cases, are nebulin and actin. The mutational spectrum of the nebulin gene includes frameshift, splice-site and nonsense mutations, while missense mutations are rare. Nebulin plays a role in determining sarcomere length, and the distribution of the numerous nebulin isoforms in different muscles, together with the localization and the nature of the mutation are likely to influence the extent and severity of muscle involvement. In the actin gene, mutations are commonly missense, with a dominant-negative effect, and in both genes, mutations are spread all along the length of the gene. Immunohistochemistry has not revealed complete protein deficiencies, but some cases of nemaline myopathy caused by mutations

**Nemaline Myopathies. Table 1** Gene loci and modes of inheritance in nemaline myopathies

| Type | Gene locus | Inheritance | Gene symbol | Gene product |
|---|---|---|---|---|
| NEM1 | 1q21-q23 | a.d. *and* a.r. | *ACTA1* | Skeletal α-actin |
| NEM2 | 2q21.2-q22 | a.r. | *NEM2* | Nebulin |
| NEM3 | 1q42.1 | a.d. *and* a.r. | *TPM3* | α-Tropomyosin |
| NEM4 | 9p13.2-p13.1 | a.d. | *TPM2* | β-Tropomyosin |
| NEM5 | 19q13.4 | a.r. | *TNNT1* | Slow troposin T |

Abbreviation: *ad* autosomal-dominant; *ar* autosomal-recessive.

in the nebulin gene have shown defective labeling with a carboxy-terminal antibody. Some patients with actin mutations have aggregation of sarcomeric actin filaments (see chapter on ►Actinopathies). Occasionally, intranuclear rods have been identified, sometimes with and sometimes without concomitant sarcoplasmic rods, perhaps a variant among the nemaline myopathies. Mutations in the α-actinin genes encoding the major proteins of the Z bands, have so far not been identified. How mutant proteins involved in molecularly defined nemaline myopathies influence formation of nemaline bodies/rods and derangements of the sarcomeres and how they cause muscle weakness in patients has not been clearly elucidated. Neither does molecular analysis precisely predict clinical or morphological features, nor do clinical and morphological features relate consistently to specific gene defects in nemaline myopathies. However, some genotype-phenotype correlation is discernible at this time. The clinically typical form is often associated with mutations in the nebulin gene, while the severe form is more commonly caused by mutations in the actin gene. Autosomal recessive cases are often caused by nebulin mutations, while mutations in the actin gene are most often *de novo* dominant, or sometimes dominantly recessively inherited. Finding the causative mutation determines the mode of inheritance but will largely not permit clinical prognostication.

## Diagnostic Principles

Any child showing muscle weakness and hypotonia in early life and delayed motor milestones, in whom a central or metabolic cause is not suspected, requires a muscle biopsy to ascertain presence or absence of nemaline bodies/rods to establish the diagnosis. Further molecular analysis to determine the precise causative gene and the mode of inheritance is currently available as a service regarding the actin gene, but not for the nebulin gene, due to its enormous size. An exception may be screening for the deletion in exon 55 of the nebulin gene in Ashkenazi Jewish patients, because of a reported carrier frequency in an Ashkenazi population of about 1:100 [3]. Families have been identified who do not show linkage to any of the so far known gene loci for nemaline myopathies, suggesting an even larger molecular spectrum.

## Therapeutic Principles

While there is no specific treatment preventing or eliminating the formation of rods and associated muscle weakness, management and therapy should include regular monitoring of respiratory capacity with vigorous treatment of infections and early ventilatory support when indicated, early surgery for scoliosis when necessary, and regular physiotherapy by a therapist familiar with the treatment of congenital neuromuscular disorders.

### Synonyms

Nephrolithiasis 1 (NPHL1 locus); Dent disease 1 (OMIM #300009); X-linked recessive hypophosphataemic rickets (OMIM #300554); Low-molecular-weight proteinuria with hypercalciuria and nephrocalcinosis (OMIM #308990); XRN

### Definition and Characteristics

X-linked recessive nephrolithiasis (XRN) (OMIM #310468) belongs to a heterogeneous group of X-linked disorders that is referred to as "Dent's disease". XRN is characterized by proximal tubule (PT) dysfunction associated with hypercalciuria, nephrolithiasis, nephrocalcinosis, and progressive renal failure [1]. The low-molecular-weight (LMW) proteinuria represents the most consistent manifestation of XRN, and is found in almost all affected males and obligate female carriers. There is considerable inter- and intra-familial variability in the other manifestations of PT dysfunction, which may cause a renal Fanconi syndrome with hypophosphataemic rickets, as well as in the extent of nephrocalcinosis/nephrolithiasis. Progression to end-stage renal failure occurs between the third and the fifth decades of life in 30–80% of affected males.

### Prevalence

XRN is a rare disorder, with around 100 families identified so far (2006) in Western Europe, North America, and Japan.

### Genes

XRN is caused by mutations in the CLCN5 gene (OMIM #300008) that is located on chromosome Xp11.22. CLCN5 encodes the electrogenic $Cl^-/H^+$ exchanger ClC-5, which belongs to the CLC family of $Cl^-$ channels/transporters [2]. The 746 amino acid ClC-5 protein contains 18 α helices, with two phosphorylation and one N-glycosylation sites. The protein forms diamond-shaped homodimers composed of two repeated halves that span the membrane in opposite orientation. Each subunit has its own pore responsible for the selective coupling of the $Cl^-$ flux to $H^+$ countertransport. Mutations in CLCN5 gene consist of nonsense, missense, donor splice site mutations, and intragenic deletions that compromise the function of ClC-5, as well as microdeletions that lead to a total loss of ClC-5. Most missense mutations are clustered at the interface between the two subunits, emphasizing the functional importance of ClC-5 homodimerization. No evidence for a genotype-phenotype correlation has been reported so far for mutations in CLCN5. Recent investigations demonstrated genetic heterogeneity in Dent's disease, with mutations in the OCRL1 gene (OMIM #300535) encoding a phosphatidylinositol [3,4] bisphosphate ($PIP_2$) 5-phosphatase being responsible for Dent disease 2 (OMIM #300555). Mutations in OCRL1 have been previously associated with the oculo-cerebro-renal syndrome of Lowe (OCRL) (OMIM #309000), an X-linked disorder characterized by bilateral congenital cataract, severe mental retardation, and renal Fanconi syndrome. Of note, some typical patients with Dent's disease do not harbor mutations in CLCN5 and OCRL1, pointing to the involvement of at least a third gene.

## Molecular and Systemic Pathophysiology

The complex phenotype of XRN/Dent disease 1 is probably explained by the expression of ClC-5 in multiple tubular segments, including the PT, the thick ascending limb (TAL) of Henle's loop, and the α-type intercalated cells [5]. Particularly, ClC-5 co-distributes with the vacuolar $H^+$-ATPase (V-ATPase) in the early endosomes of PT cells, which are responsible for the reabsorption and processing of albumin and LMW proteins that are filtered by the glomerulus. This endocytic process involves the multiligand tandem receptors, megalin and cubilin, located at the apical brush border [3]. Progression of ligand-receptor complexes along the endocytic pathway depends on the endosomal acidification driven by the V-ATPase. Since a parallel $Cl^-$ conductance is required to shunt the electrical potential generated by the V-ATPase, the defect in PT endocytosis observed in patients with XRN and mice lacking ClC-5 has been firstly attributed to impaired endosomal acidification secondary to the loss of the $Cl^-$ permeability. However, drugs abrogating vesicular acidification do not affect the rate of endocytic uptake, but inhibit recycling or arrest transfer to lysosomes. Furthermore, recent studies have demonstrated that the defective protein endocytosis linked to ClC-5 inactivation is due to a severe trafficking defect in PT cells, with loss of megalin and cubilin at the brush border and subsequent loss of their ligands in the urine [4]. The hypercalciuria observed in patients with Dent's disease and some ClC-5-deficient mice may be secondary to such PT dysfunction (urinary loss of vitamin D-binding protein and reduced phosphate absorption, leading to increased calcitriol synthesis) or caused by the functional loss of ClC-5 in the TAL. The role of the ($PIP_2$) 5-phosphatase OCRL1 along the endocytic apparatus in PT cells, as well as the functional link between PIP/$PIP_2$ levels and ClC-5 activity, remain unknown.

## Diagnostic Principles

The diagnosis of XRN is based on the presence of all three of the following criteria: (i) LMW proteinuria (elevation of urinary excretion of β2-microglobulin and/or retinol-binding protein by at least five-fold above the upper limit of normality); (ii) hypercalciuria (>4 mg/kg in a 24-h collection or >0.25 mg $Ca^{2+}$ per mg creatinine on a spot sample); and (iii) at least one of the following: nephrocalcinosis, kidney stones, hematuria, hypophosphataemia, or renal insufficiency. The clinical diagnosis is supported by a history of X-linked inheritance of renal Fanconi syndrome and/or nephrolithiasis. The identification of mutation in either CLCN5 or OCRL1 genes confirms the diagnosis.

## Therapeutic Principles

In the absence of a causal therapy targeting the molecular defect, the current care of patients with XRN is supportive, focusing on the prevention and treatment of hypercalciuria and nephrolithiasis. The hypocalciuric effect of thiazide diuretics, which is preserved in these patients, might be useful to prevent $Ca^{2+}$ stone recurrence. Treatment of rickets with vitamin D must be cautious since it may increase hypercalciuria. Studies performed on ClC-5-deficient mice suggest that long-term control of hypercalciuria by a high citrate diet delays progression of renal disease even in the apparent absence of stone formation.

# Nephropathic Cystinosis

►Cystinosis, Nephropathic

# Nephronophthisis

Massimo Attanasio, Friedhelm Hildebrandt
Department of Pediatrics, University of Michigan, Ann Arbor, MI, USA

## Synonyms

Autosomal recessive medullary cystic disease; Senior-Løken syndrome; Cogan syndrome; Joubert syndrome; NPHP

## Definition and Characteristics

Nephronophthisis (NPHP) is an autosomal recessive cystic disease of the kidney that represents the most

common genetic cause of end-stage renal failure in children and adolescents. Nine different genes have been identified by positional cloning as mutated in nephronophthisis. All known variants have in common a characteristic renal histology of tubular basement membrane disintegration, diffuse interstitial infiltration/fibrosis and tubular atrophy that progressively lead to end stage renal failure (ESRF) within the first three decades of life.

About 15% of juvenile forms are associated with extra-renal symptoms: retinal degeneration/retinitis pigmentosa (Senior-Løken syndrome), oculomotor apraxia (Cogan syndrome), mental retardation with cone shaped epiphysis (Mainzer-Saldino syndrome), coloboma of the eye, aplasia of cerebella vermis, ataxia and mental retardation (Joubert syndrome), liver fibrosis, and situs inversus.

## Prevalence

Pooled data indicate a prevalence of less than 5% in the North American pediatric end-stage renal disease population.

## Genes

Nine genes have been identified: NPHP1 (chromosome 2q13), INVS/NPHP2 (chromosome 9q31), NPHP3 (chromosome 3q22.1), NPHP4 (chromosome 1p36), NPHP5 (chromosome 3q13.33), CEP290/NPHP6 (chromosome 12q21.32), GLIS2/NPHP7 (chromosome 16p13.3), RPGRIP1L/NPHP8 (chromosome 16p12.2), NEK8/NPHP9 (chromosome 17q11.2). The proteins are called nephrocystin-1, inversin/nephrocystin-2, nephrocystin-3, nephroretinin/nephrocystin-4, nephrocystin-5, Cep290/nephrocystin-6, glis2/nephrocystin-7, rpgrip1l/nephrocystin-8, nek8/nephrocystin-9.

## Molecular and Systemic Pathophysiology

Nephrocystin-1 interacts with inversin, nephrocystin-3 and nephroretinin. All nephrocystins are expressed in the primary cilium, an organelle present at the apical side of the tubular epithelial cells. They localize to either the axonema or the anchoring structures to the cell surface (basal bodies) [1].

This subcellular localization is shared with other proteins that, if defective, result in the development of renal cysts (such as PKD1 and PKD2). This led to the hypothesis that primary cilia could serve as sensors able to react to mechanic stimuli and evocate multiple secondary intracellular responses via an increment in intracellular calcium concentration. The possible involvement of the nephrocystins in Wnt and Hedgehog pathways further substantiate the receptorial role of cilia [2–3]. These mechanisms would be important in the maintenance of the integrity of ciliated cells of different epithelia. Additional localization of NPHP proteins at the centrosome and mitotic spindle and at the adherens junctions and focal adhesion complexes of renal tubular epithelia, points to a role of these molecules in the cell-cell and cell-matrix signaling, with the possibility of their involvement in the regulation of the cell cycle.

## Diagnostic Principles

Nephronophthisis types 1–9 can now unequivocally be diagnosed by genetic analysis (www.renalgenes.org). However, since the presence of additional genes is expected, a negative result does not exclude the diagnosis of NPHP.

## Therapeutic Principles

Therapy of NPHP is aimed at the symptomatic control of the disturbances of electrolytes, acid-base and water balance or hypertension, if present. Dialysis and renal transplantation are the treatments of choice when ESRF is established.

Recently, the use of vasopressin in the pcy murine model of cystic disease (equivalent to NPHP3) resulted in inhibition of cysts development, opening the possibility of a future pharmacological therapy [4].

# Nephropathies, Toxic

Vivekanand Jha, Kirpal S. Chugh
Department of Nephrology, Postgraduate Institute of Medical Education and Research, Chandigarh, India

## Definition and Characteristics

Toxic nephropathies are a group of disorders that result from the human exposure to drugs, chemical, and biological products. The most important characteristic is a temporal relationship between exposure and development of renal injury [1].

## Prevalence

The true incidence and prevalence is unknown because of lack of awareness among physicians, the nonspecific

nature of presentation, and the pitfalls encountered in making a laboratory diagnosis. A good and accurate history is of paramount importance. The prevalence and spectrum of causes varies substantially in different geographic regions of the world. In certain parts of Africa, over 35–50% of renal diseases are secondary to toxin exposure [2]. The presentation can be with asymptomatic urinary abnormalities, acute reversible kidney injury, or slowly progressive irreversible renal failure.

## Genes

Environmental exposure to nephrotoxins is an essential prerequisite, but the role of genetic makeup in modulating response to toxic insult cannot be ruled out. This is illustrated by the varied response to ingestion of the Chinese herbs containing aristolochic acid (AA). Exposure to AA produces a progressive chronic interstitial nephritis with urothelial malignancies in European Caucasians (aristolochic acid nephropathy, AAN) whereas in Japan, it presents as adult-onset Fanconi's syndrome. Finally, very few cases of AAN have been reported from China despite extensive use of this herb for decades suggesting a genetic resistance.

## Molecular and Systemic Pathophysiology

The pathophysiology of kidney involvement in poisoning is variable and in many cases, unknown. Given below are the known molecular mechanisms in some conditions.

In Callilepis laureola (impila) poisoning, the nephrotoxic principle atractyloside inhibits ADP transport across mitochondrial membranes, preventing ATP synthesis and leading to cell death from energy starvation. s-quinone, the active metabolite of Larrea tridentate, increases the fragility of lysosomal membranes, causing autolysis and desquamation of proximal tubular epithelial cells leading to tubular obstruction. The mushroom Amanita phalloides produces ARF through amatoxin-induced inhibition of RNA polymerases causing fragmentation of nuclear components of renal tubular cells. Pithecolobium lobatum (djenkol) poisoning produces oliguric ARF as a result of precipitation of needle-like crystals of djenkolic acid in tubules [3].

Perturbation in the balance between the endothelium-derived vasoactive substances, e.g., endothelin (ET)-1 and adenosine on one side and nitric oxide (NO) on the other produces acute kidney injury following exposure to several nephrotoxins. Plasma ET levels go up within minutes of infusion of nephrotoxic contrast media. Selective ET-A receptor blockade could prove to be effective in prevention. The vasoactive effects of adenosine depend on the ratio of adenosine A1 and A2 receptors in the vascular bed. ATP depletion leads to adenosine accumulation, resulting in prolonged vasoconstriction. NO levels are decreased following contrast injection in experimental animals, and pre-treatment with L-NAME, an NO- synthesis inhibitor, accentuates the injury. The reduction is proportional to the osmolarity of the solution. Iron plays a role in the oxidative injury via generation of hydroxyl radical.

Snake venom contains a variety of enzymes, polypeptide toxins and cytokines. Renal injury can occur through direct nephrotoxic effect or via release of endogenous mediators, e.g. histamine, kinins, eicosanoids, platelet activating factor, catecholamines, and endothelin [4]. Zinc metalloprotease can cleave glutathione-S-transferase-TNFα fusion protein substrate to generate biologically active TNFα. Plasma concentrations of IL-1, IL-6, IL-10, IFN-γ, norepinephrine, epinephrine, dopamine, thromboxane-B2, endothelins, and 6-keto-PGF are elevated. Venom can bind with integrins, disrupting the integrity of cellular junctions and actin cytoskeleton, resulting in a loss of cell polarity. Phospholipase-A2 causes membrane injury through binding via basic hydrophobic amino acid residues near the C-terminal of the protein.

The exact pathogenesis of AAN is not understood. AA induces renal tubular epithelial cell apoptosis, inhibits regeneration, downregulates growth factor expression, induces epithelial transdifferentiation into a myofibroblastic phenotype, and induces production of extracellular matrix through increased transforming growth factor-β and connective tissue growth factor expression. AA-ANA adducts have been demonstrated in the affected kidneys of experimental animals and humans with AAN. AA binds to DNA sites in exons 3 through 8 of the gene encoding tumor suppressor protein, p53.

## Diagnostic Principles

A high index of suspicion and good history taking is critical to the diagnosis. Causative molecules can be identified using thin-layer or high performance liquid chromatography, immunoassay, or mass spectroscopy in body fluids or tissue. AA-DNA adducts have been detected using $^{32}$P-labeling. Urine examination, serologies and ultrasound examination are important in excluding other causes.

## Therapeutic Principles

Therapy is centered on immediate withdrawal of the offending agent(s). No specific treatment is available for most causes except snake bites, where use of monovalent or polyvalent antivenom can help in attenuation of injury. Patients with established renal injury may need supportive measures including dialysis depending upon the type and severity of the insult.

[2]Purine Research Unit, Guy's Hospital, London, UK

## Synonyms

Familial juvenile gout; Hereditary nephropathy with hyperuricemia and gout; FJHN

## Definition and Characteristics

Autosomal dominant renal transport defect leading to hyperuricemia associated with a grossly reduced fractional uric acid clearance ($FE_{ur}$ = uric acid clearance factored by creatinine clearance ×100) of 5.1 ± 1.6% irrespective of age or sex, which precedes deterioration in renal function (Fig. 1).

## Prevalence

Rare, but an EU database records 113 patients found mainly in two countries (GB 90, CZ 19), indicating poor clinical awareness. Reported in Japanese and Polynesians as well as in Caucasian kindreds.

## Genes

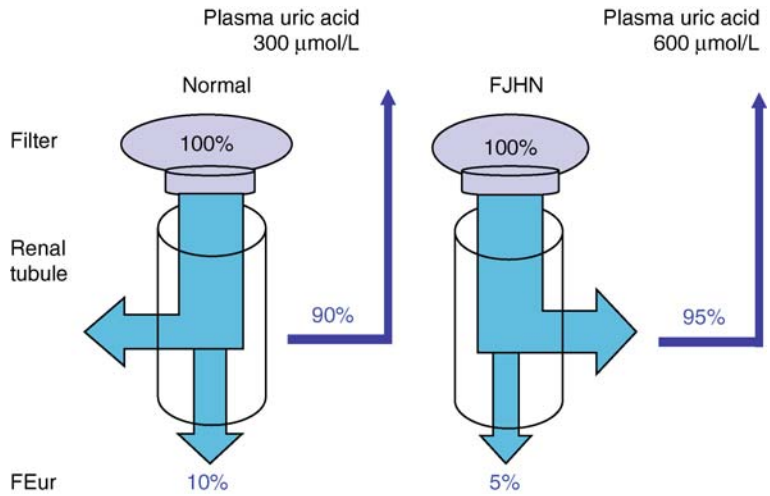
Heterogeneous genetic basis. Approximately 25% of cases of have a defect in the UMOD gene encoding uromodulin (Tamm-Horsfall glycoprotein) located on Chr16p12.3 [1] A mutation in the hepatocyte nuclear factor-1ß gene (HNF1-ß) on Chr 17q12 has been found in FJHN families with the additional clinical sign of diabetes [2]. Linkage to an unknown gene on Chr1q41 has been reported in a single family [3]. In the majority of families, the defect remains unknown (Fig. 1).

## Molecular and Systemic Pathophysiology

FJHN families have a strong history of renal disease and death in the thirties. A reduced $FE_{ur}$ is however apparent before renal function is impaired. There is evidence of abnormal uromodulin glycosylation, decreased intracellular trafficking and decreased transport to the exoplasmic face of the plasma membrame [4]. Long-term studies confirm that starting allopurinol when renal function is normal or mildly reduced can result in stable function, even improvement [5]. Allopurinol treatment started later when renal function is half normal or less is accompanied by rapid progression to dialysis and transplantation. The reason for the low $FE_{ur}$ in patients with defective urmodulin is unclear. The nephroprotective effect of allopurinol, implies that some aspect of the concentration or traffic of uric acid in the tubular cells plays a role in renal damage. Deposits of interstitial urate are rare in (mainly cortical) renal biopsies, however, crystal absence need not exclude a crystal nephropathy as the original cause of the lesion. $FE_{ur}$ is not altered by allopurinol, but the absolute amount of uric acid transiting the proximal tubular cells will be reduced as plasma and filtered urate fall. Thus agents that increase $FE_{ur}$, such as benzbromarone, will also help normalise the $FE_{ur}$ by blunting urate reabsorption.

## Diagnostic Principles

Plasma uric acid is markedly elevated for age and sex; urine uric acid is low relative to creatinine (which



**Nephropathy, Familial Juvenile Hyperuricemic. Figure 1** Reduced fractional excretion of uric acid is the biochemical hallmark of FJHN. In the normal kidney, approximately 90% of uric acid is reabsorbed leaving a fraction of 10% excreted. In FJHN, the fraction of uric acid excreted is reduced to 5%, setting plasma uric acid levels abnormally high.

excludes other genetic disorders presenting with hyperuricemia/gout). Early recognition is vital and all children in FJHN families must have biochemical screening. Confirmation of the genetic defect is possible only in the few families where the gene defect is known.

## Therapeutic Principles

A high fluid intake and low purine diet is advised, in addition to allopurinol. Allopurinol plus benzbromarone has been effective in some patients where hyperuricemia has proved intractable. Others allergic to allopurinol have sustained stable renal function on benzbromarone alone. Antenatal diagnosis is not yet available.

# Nephrosclerosis Arteriolar

Xiaoyan Zhou, Edward D. Frohlich
Ochsner Clinic Foundation, New Orleans, LA, USA

## Synonyms

Nephrosclerotic renal disease

## Definition and Characteristics

A slowly progressive disease manifested by: hyalinosis and sclerosis; wall thickening and lumen narrowing of the renal arterioles; with resultant ischemic alterations of the renal parenchyma.

## Prevalence

Arteriolar nephrosclerosis is highly prevalent in patients with hypertension, diabetes mellitus, and in the elderly. Aging is a particularly significant disease-accelerating factor in the presence of hypertension and/or diabetes.

## Molecular and Systemic Pathophysiology

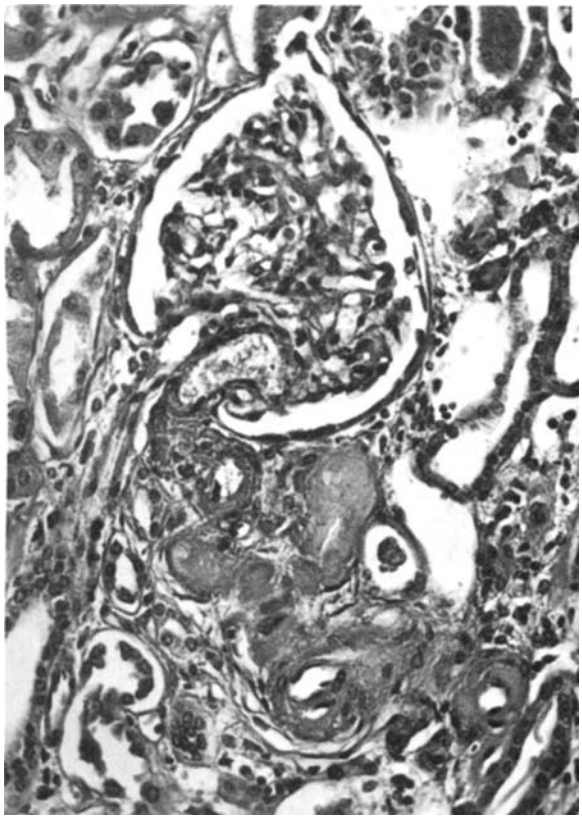
In hypertension, all arterioles are extremely vulnerable to arterial pressure elevation; particularly the renal afferent glomerular arterioles are more prominently affected than the efferent. Typical pathologic changes include hyaline degeneration, sclerosis, arteriolar wall thickening, and lumen narrowing. These lesions result from leakage of plasma components across vascular endothelium and excessive extracellular matrix

production by vascular smooth muscle cells. Fibrinoid necrosis of arterioles, presenting an onionskin appearance, occurs in malignant hypertension. As hypertension progresses, afferent arteriolar sclerosis is exacerbated; the glomeruli reveal ischemic wrinkling of the glomerular tuft, thickening of Bowman's capsule, periglomerular fibrosis, and glomerular sclerosis; and tubular atrophy and interstitial fibrosis also occur. Hemodynamically, total renal vascular and glomerular arteriolar resistances increase in the earlier stage while glomerular filtration rate may remain normal; often serum uric acid concentration increases in proportion to the hemodynamic changes [1]. Later, in essential hypertension or in malignant hypertension, total renal vascular and the glomerular arteriolar resistances increase further and are associated with increased glomerular hydrostatic pressure as well as reduced total renal and single nephron plasma flow with associated renal ischemia and dysfunction [2]. In diabetes mellitus, renal vascular lesions (e.g., arteriolosclerosis) are closely associated with glomerular lesions, affecting not only the afferent but also the efferent arterioles. The glomerular lesions include capillary basement membrane thickening, mesangial matrix expansion with focal segmental and diffuse glomerulosclerosis. Renal hemodynamics in the early stages is characterized by glomerular hyperfiltration resulting from elevated glomerular hydrostatic pressure, mediated by a greater relaxation of the afferent arteriole than the efferent arteriole [3]. Later, total renal and single nephron glomerular filtration rate decrease as glomerular blood flow is reduced [3].

The molecular mechanisms are complex, involving many cytokines, growth factors, and pathways. Activation of the intrarenal renin-angiotensin-aldosterone system contributes primarily to the progression of arteriolar nephrosclerosis [4]. Angiotensin II is a major pathogenetic factor that promotes arteriolar nephrosclerosis through hemodynamic and non-hemodynamic mechanisms; it involves progressive vasoconstriction as well as mitogenic and profibrogenic actions, resulting in production of extracellular matrix components that are importantly linked to stimulation of fibrogenic cytokines (e.g., TGF-). Additionally, reduced nitric oxide availability, owing to downregulation of endothelial nitric-oxide synthase activity, and increased oxidative stress further induce more severe vasoconstriction and renal ischemia [4] (see Fig. 1).

## Diagnostic Principles

Clinical presentations and laboratory findings are not usually evident early with arteriolar nephrosclerosis and microalbuminuria and proteinuria are not common. However, persistent microalbuminuria in diabetes may be the earliest reliable predictor and marker of renal involvement. Elevation of serum creatinine concentration occurs later when the blood flow and glomerular filtration rate become impaired. It is important that abnormal renal function caused by other systemic or renal diseases should be excluded. Definitive diagnosis relies a renal biopsy, a procedure not without some risk in hypertension. Vascular morphologic changes are not pathogenetically specific, however, hyalinization of both afferent and efferent arterioles is highly suggestive of diabetic arteriolosclerosis.



**Nephrosclerosis Arteriolar. Figure 1** Renal arterioles with hyalinosis, marked thickening of the walls, and narrowed lumina.

## Therapeutic Principles

Antihypertensive therapy with lower goal blood pressures (<130/<80 mmHg) and adequate glycemic control significantly delay the development and ameliorate the progression of arteriolar nephrosclerosis. Angiotensin-converting enzyme inhibitors or angiotensin II type 1 receptor blockers have demonstrated renal protection by effects over and beyond arterial pressure reduction [5].

# Nephrosclerotic Renal Disease

►Nephrosclerosis, Arteriolar

# Nephrotic Syndrome

Vladimir Tesar
Department of Nephrology, 1st School of Medicine and University Hospital, Charles University, Prague, Czech Republic

## Synonyms

Hereditary proteinuria syndromes

## Definition and Characteristics

Nephrotic syndrome (heavy proteinuria accompanied by hypoproteinemia, hypalbuminemia, hypercholesterolemia, and edema) is a clinical presentation of various primary (minimal change disease, focal segmental glomerulosclerosis, membranoproliferative glomerulonephritis) and secondary (diabetic nephropathy, lupus nephritis, amyloidosis) glomerulopathies.

The glomerular capillary wall is composed of fenestrated glomerular endothelial cells, glomerular basement membrane (GBM), and visceral epithelial cells (podocytes) with octopus-like appearance. Podocyte foot processes cover the outer layer of the GBM, and the slit diaphragm between the foot processes is considered to be the ultimate and the most important barrier preventing the passage of proteins into the glomerular filtrate.

Hereditary forms of nephrotic syndrome (NS) are caused either by the mutations of different podocyte genes (transcription factors, enzymes, slit diaphragm proteins, adapter protein) or (less frequently) by the mutation of glomerular basement membrane protein laminin.

Hereditary proteinuria diseases can be subdivided into groups with early (congenital nephrotic syndrome of the Finnish type, Denys-Drash syndrome, Pierson syndrome, and steroid-resistant NS caused by the podocin mutation) and late (familial FSGS caused by the mutation of ACTN4, MYH9, TRPC6, Frasier syndrome, and nail-patella syndrome) onset [1].

## Prevalence

Two thirds of cases of NS presenting in the first year of life and more than 80% of congenital NS are caused by mutations in four genes (NPHS1, NPHS2, WT1 and LAMB2). NPHS1 and NPHS2 represent together more than 90% of identified mutations [2]. Hereditary forms of FSGS may be responsible for up to 18% of all cases of FSGS [3].

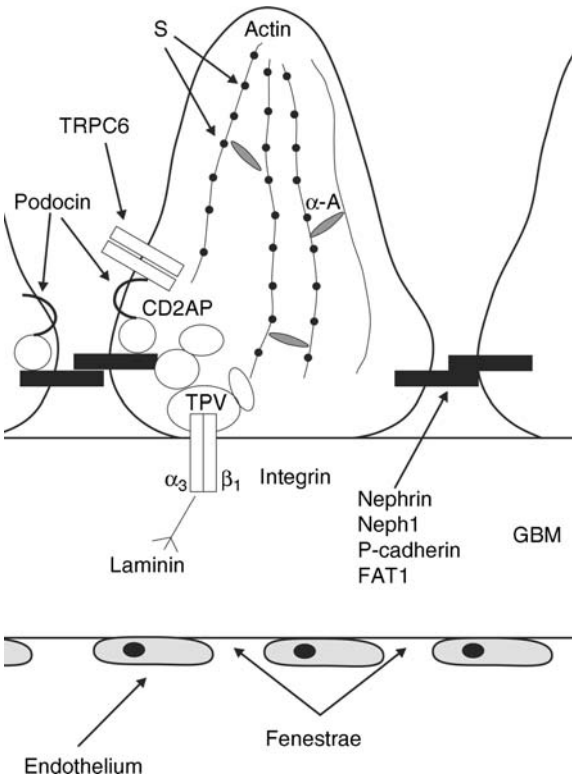
## Genes

*Congenital NS of the Finnish type*: autosomal recessive, mutation in NPHS1 (19q13.1) encoding protein of the podocyte slit diaphragm nephrin.
*Steroid-resistant NS*: autosomal recessive, mutation in NPHS2 (1q25–31) encoding the slit diaphragm-associated protein podocin.
*FSGS1*: autosomal dominant, mutation in ACTN4 (19q13) encoding α-actinin-4, the adapter protein connecting slit diaphragm proteins with the actin cytoskeleton.
*FSGS2*: autosomal dominant, mutation in TRPC6 (11q21–22) encoding transient receptor potential channel 6, cation channel participating in $Ca^{2+}$ signaling in the podocyte.
*Denys-Drash and Frasier syndrome*: autosomal dominant, mutation in WT1 (11p13) encoding WT1, the podocyte transcription factor.
*Pierson syndrome*: autosomal recessive, mutation in LAMB2 (3p21), encoding the laminin β2 chain, one of the main protein of the glomerular basement membrane.
*Nail-patella syndrome*: autosomal dominant, mutation in LMX1B (9q34.1), encoding Lmx1b, the podocyte transcription factor.
*Diffuse mesangial sclerosis*: autosomal recessive, mutation in NPHS3 (10q23–24), encoding phospholipase C epsilon (PLCε1), the enzyme expressed also in podocytes.

## Molecular and Systemic Pathophysiology

GBM is believed to restrict the passage of the large (>60 kDa) electronegative protein molecules. Out of GBM proteins (collagen IV, agrin, perlecan, etc.), only mutation of the β2 chain of the adult form of laminin (laminin 521) was shown to cause either Pierson syndrome (early, lethal form of congenital nephrotic syndrome with ocular – microcoria – and neuromuscular – severe muscular hypotonia, psychomotor retardation, blindness – abnormalities) or familial NS with isolated renal involvement.

Nephrin is a major structural protein of the slit diaphragm between the podocyte foot processes (Fig. 1).



**Nephrotic Syndrome. Figure 1** Schematic view of the glomerular capillary wall with the podocyte foot processes interconnected with the slit diaphragms. GBM: glomerular basement membrane; TPV: talin, paxilin, vinculin; S: synaptopodin; α-A: α-actinin-4; Nephrin, Neph1, P-cadherin, FAT1: proteins of the slit diaphragm.

Podocin interacts with nephrin and recruits nephrin to the specialized lipid rafts. α-Actinin-4 binds actin to other proteins (e.g., vinculin, synaptopodin, and β1-integrins) and mediates the connection between podocyte plasma membrane, including the slit diaphragm, and the actin cytoskeleton. TRPC6 is a cation channel associated with nephrin and podocin. Its gain-of-function mutation with increased TRPC6-dependent calcium currents results probably in deranged actin dynamics. PLCε1 possibly functions as an upstream regulator of the activation state of Ras GTPases and actin dynamics and is also indispensable for the normal glomerular development. WT1 transcription factor is of utmost importance for the normal development of glomeruli. Glomeruli in patients with mutated WT1 have small, immature glomeruli with reduced number of the capillary loops (histologic appearance of diffuse mesangial sclerosis similar to PLCε1 mutation). Expression of the Lmx1b transcription factor is necessary for the normal development of the GBM.

Congenital NS of the Finnish type is caused by the mutation of nephrin. Absence of nephrin results in the disappearance of the slit diaphragm and the fusion of foot processes. Mutation of podocin results in the NS that usually develops by 5 years of age, although patients with late-onset NS (in adolescence) were also described. Podocin mutations are responsible for about 50% of all familial NS. Cardiac abnormalities (left ventricle hypertrophy and/or pulmonary stenosis) are frequent in children homozygous for R138X podocyte gene mutation.

FSGS caused by both α-actinin-4 and TRPC6 mutation typically presents with the adult onset, non-nephrotic proteinuria, and slowly progressive chronic renal failure. Absence of podocyte expression of PLCε1 due to the truncating mutation of its gene results in the disordered glomerular development and in NS in early childhood (by 4 years) with rapid progression to the terminal renal failure. Mutations of WT1 result in a complex familial syndrome: Denys-Drash syndrome, which includes FSGS, or diffuse mesangial sclerosis (DMS), Wilms tumor and male pseudohermaphroditism, or Frasier syndrome (female gonadal dysgenesis with NS), but also in isolated NS. Renal involvement in all syndromes caused by the WT1 mutation may slowly progress to the end-stage renal failure.

Nail-patella syndrome, caused by the LMX1B mutation, is characterized by abnormalities of nails, skeleton, eyes, and kidney (which may ultimately result in end-stage renal failure).

## Diagnostic Principles

Diagnosis of the familial NS should be considered in any patient with early (childhood or adolescence) onset of steroid-resistant NS. Diagnosis depends on the combination of the histologic examination (e.g., DMS is strongly indicative of the genetic cause of NS) and genetic testing, including mutation analysis of the putative responsible genes. Conceivably, other mutations of podocyte proteins may yet be disclosed as causes of NS.

## Therapeutic Principles

Therapy of familial NS is currently only symptomatic and its effect on proteinuria and the progression of renal insufficiency is usually limited (blood pressure control, administration of the angiotensin converting enzyme inhibitors, and/or angiotensin antagonists). Patients with end-stage renal failure have to be treated by renal replacement therapy. Compared with acquired idiopathic FSGS recurrence of NS after renal transplantation is uncommon in patients with FSGS caused by the mutations of the podocyte proteins.

Recently, positive effect of corticosteroids on proteinuria and the progression of renal disease in patient with PLCE1 mutation have been reported.

# Nephrotic Syndrome, Steroid Resistant

Hannu Jalanko
Hospital for Children and Adolescents, University of Helsinki, Helsinki, Finland

## Synonyms

SRNS

## Definition and Characteristics

SRNS is a kidney disease characterized by proteinuria often leading to nephrotic syndrome (NS) with hypoalbuminemia, edema, and hypercholesterolemia. Typically SRNS progresses to renal failure within months or years.

## Prevalence

SRNS is the most common form of NS in adults and accounts for 20% of NS in children. SRNS causes 20% of end-stage renal failure in children and 5–10% in adults.

## Genes

Most cases of SRNS are non-genetic. So far, mutations in four genes (NPHS2, WT1, ACTN4, and TRPC6) have been identified in familial and sporadic cases.

## Molecular and Systemic Pathophysiology

SRNS is caused by the defective function of the filtration barrier in the kidney glomerulus. This filter is composed of three layers: fenestrated endothelium, basement membrane, and epithelial cell (podocyte) foot processes connected by the slit diaphragm. So far, most cases of SRNS are regarded as "acquired." In these cases, the pathophysiology remains unknown. It has been postulated that a circulating proteinuric factor, possibly secreted by lymphocytes, might impair the glomerular filter function and cause proteinuria. This hypothesis has not been verified.

A considerable amount of SRNS patients show mutations in genes encoding podocyte structural proteins. The most important is NPHS2 encoding a podocyte slit diaphragm protein podocin. In SNRS patients, about 50 different mutations in NPHS2 have been identified. These account for 40–50% of familial cases of SRNS (autosomal recessive form) and 10–30% of sporadic cases. Most mutations cause a severe disease with an onset in early childhood and development of terminal kidney failure within a few years. NPHS2 mutations have also been described in familial cases of SRNS with adolescent or adult onset. Many of these are compound heterozygotes, with one allele harboring a R229Q mutation. This mutation encodes a defective podocin protein with low affinity for binding to the major slit diaphragm protein, nephrin.

Besides NPHS2, other podocyte genes are associated with SRNS. Wilms' tumor suppressor gene (WT1) encodes for a transcription factor of the zinc finger family highly expressed in podocytes. Mutations in WT1 can cause SRNS usually discovered at the age of a few months. Mutations in exons 6–9 of WT1 account for 3–10% of pediatric SRNS cases. Mutations in the ACTN4 gene encoding an actin filament cross-linking protein α-actinin-4 cause an autosomal-dominant form of SRNS. The mutant α-actinin-4 binds actin filaments more strongly than the normal protein. This leads to formation of aggregates that gradually damage the podocyte. Affected individuals typically develop disease in adulthood. Transient receptor potential 6 ion channel (TRPC6) is expressed in podocytes and is a component of the glomerular slit diaphragm. Mutations in this gene have been identified in families with autosomal-dominant SRNS.

## Diagnostic Principles

The cardinal sign of SRNS is nephrotic range proteinuria (urinary protein >3.5 g/day) not responsive to corticosteroid therapy. The diagnosis is verified by a kidney biopsy. Over 80% of the biopsies exhibit histological features of focal segmental glomerular sclerosis (FSGS), and the rest demonstrate minimal glomerular changes (MCNS) or diffuse mesangial sclerosis (DMS). Genetic analysis of NPHS2 is warranted in all cases with SRNS.

## Therapeutic Principles

Non-genetic form of SRNS may respond to immunosuppressive medication, such as cyclosporin A and cyclophosphamide. SRNS caused by the gene mutations is not responsive to medical treatment. Kidney transplantation is the only curative treatment for most SRNS patients. An important issue here is the recurrence of NS in the graft, which is commonly seen in SRNS patients. The risk for recurrence is high in the non-genetic (30%) form of SRNS but may also occur in patients with NPHS2 mutations.

# Nervous Bowel

►Irritable Bowel Syndrome

# Nesidioblastosis

►Hyperinsulinism of Infancy

# Netherton Syndrome

Vinzenz Oji, Heiko Traupe
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Comèl-Netherton syndrome

## Definition and Characteristics

Netherton syndrome (NTS, MIM *256500) is a rare autosomal recessive disorder characterized by the triad of congenital ichthyosis with inflammatory skin, hair shaft anomalies, and severe atopic diathesis. At birth, patients often display congenital ichthyosiform erythroderma (CIE), which in approximately 90% gradually evolves into a milder phenotype with polycyclic migrating plaques known as ichthyosis linearis circumflexa (ILC). The disease features associated symptoms such as life-threatening neonatal dehydration, failure to thrive, and recurrent infections [1].

## Prevalence

Worldwide occurrence. Estimated at 1 in 50,000–200,000.

## Genes

SPINK5 (serine protease inhibitor Kazal-type 5/ chromosome 5q32).

## Molecular and Systemic Pathophysiology

SPINK5 encodes the putative multi-domain serine protease inhibitor LEKTI (lympho-epithelial Kazal-type related inhibitor) expressed in the epidermis, thymus, oral, and vaginal mucosa [2]. More than 37 SPINK5 mutations have been reported in patients, all of which cause premature termination codons of translation [3]. The protein consists of 1,064 amino acids and is organized into 15 potential inhibitory domains with a 4-/6-cysteine residue pattern (Kazal-type like/Kazal-type). Recent studies suggest that SPCs (subtilisin-like proprotein convertases) like Furin proteolytically cleave LEKTI full-length protein. Subsequent processing by carboxypeptidases creates several biologically active forms with different target specificities. For example, domains 5 and 6 exhibit trypsin-inhibiting activity supporting a key role for LEKTI in the regulation and control of trypsin- or chymotrypsin-like proteases in the stratum corneum. Reduction of inhibitory activity due to truncated or absent LEKTI can lead to over-desquamation of corneocytes explaining the scaling type of ichthyosis. There are other putative targets such as mast cell tryptase, which induces inflammatory response via PAR-2 (protease-activated receptor-2), kallikrein-6 (KLK6), or many allergens like house dust-mite and pollen [4]. Like other serine protease inhibitors, LEKTI or certain LEKTI products could be involved in the innate immune response.

## Diagnostic Principles

NTS may account for up to 18% of all cases of infantile erythroderma, however diagnosis is often delayed. Clinical diagnosis is based on the combination of inflammatory ichthyosis with atopic features such as type-I allergies, high IgE blood levels, and hypereosinophilia, as well as on typical hair shaft anomalies such as trichorrhexis invaginata (bamboo hairs) or pili torti. In up to 90%, diagnosis can be established by SPINK5 sequence analysis. Moreover, recent studies demonstrate that loss of detection of LEKTI antigen in the epidermis or in immunoblot analysis of lysated hair follicles are useful diagnostic features. At the

ultrastructural level, NTS epidermis displays characteristic features the most prominent being altered lamellar body secretion.

### Therapeutic Principles

So far no effective therapy is available. The impaired epidermal barrier is a major clinical problem causing severe fluid loss with neonatal hypernatremic dehydration, bacterial infections, and growth retardation. Symptomatic treatment is based on regular moistening, fluid substitution, high caloric nutrition, and prevention of allergies. Recurrent infections require antibiotic treatment; long-term application of corticosteroids should be avoided. Recent case reports propose topical anti-inflammatory immunomodulators such as tacrolimus or pimecrolimus, but as has been shown for tacrolimus significant absorption due to the impaired epidermal barrier prevents widespread application of this drug in NTS [5].

## Neuroacanthocytosis Syndromes

Adrian Danek
Department of Neurology, Ludwigs-Maximilians-University, Munich, Germany

### Definition and Characteristics

Syndromes in which nervous system abnormalities occur together with acanthocytosis, i.e. deformed erythrocytes that show spike-like protrusions that show spike-like protrusions [1].

McLeod syndrome (MLS) and chorea-acanthocytosis (ChAc) are the core neuroacanthocytosis syndromes. MLS and ChAc are both characterized by the presence of movement disorders, seizures, cognitive and behavioral impairment, as well as neuromuscular involvement. Initially, these disorders may resemble Huntington's disease or Tourette's syndrome.

MLS as an X-linked disorder affects males, usually with an onset of neurological signs and symptoms in the fourth decade. It is often associated with cardiomyopathy that may end fatally (arrhythmia, heart failure). Rarely, female mutation carriers may be clinically affected.

ChAc is transmitted as an autosomal recessive trait and affects males and females evenly. Neurological symptom onset is usually in the twenties. In contrast to MLS, cardiomyopathy is not observed but morbidity may be due to pronounced swallowing problems.

Acanthocytes may also occur in pantothenate kinase-associated neurodegeneration, Huntington´s disease-like 2, FAPED (familial acanthocytosis with paroxysmal exertion-induced dyskinesias and epilepsy), abetalipoproteinemia, hypobetalipoproteinemia, mitochondrial disorders and other conditions.

### Prevalence

Probably a few hundred (MLS) to around one thousand (ChAc) cases worldwide.

### Genes

MLS: XK gene, X-chromosome [2]; ChAc: VPS13A gene, chromosome 9 [3].

## Molecular and Systemic Pathophysiology

Details of the pathophysiology are not known in either MLS or ChAc.

The McLeod protein, XK, is located in the cell membrane and probably has transport functions. In erythrocytes it is linked to the Kell protein via disulfide bonds. This complex carries the antigens of the Kell blood group, the third most important blood group system in humans. The Kx antigen (on XK) is absent in McLeod syndrome and expression of other Kell system antigens (on the Kell protein) is severely depressed. Since Kell protein is involved in enzymatic cleavage of endothelins, it is conceivable that these molecules are transported by XK.

Chorein, the ChAc protein, is very large and has been identified as a member of the VPS13 family involved in *V*acuolar *P*rotein *S*orting. VPS13B mutations cause Cohen syndrome; however this is characterized by a static encephalopathy and is clinically completely different from ChAc.

## Diagnostic Principles

A standard procedure for acanthocyte determination has recently been developed [4]. A negative screen, however, does not exclude a neuroacanthocytosis syndrome. In both MLS and ChAc, muscle creatine phosphokinase and liver enzymes are elevated in serum.

The diagnostic procedure of choice in MLS is phenotyping of Kell blood group antigens. This is usually available in regional blood centers [5]. The typical finding is depression of Kell antigen expression. This must not be confused with a finding of "Kell negative," which does not rule out the diagnosis of MLS. Molecular genetic diagnosis is available.

In contrast, analysis of the large VPS13A gene is difficult and currently unavailable. An indirect method is based on protein expression: ChAc patients show a lack of erythrocyte chorein on Western blot [6].

## Therapeutic Principles

So far no curative treatment is known. In both MLS and ChAc, seizures and psychiatric manifestations should be managed according to established principles.

In MLS, blood transfusion problems need to be anticipated and banking of the patient's own blood is recommended. Cardiac complications need to be particularly considered and heart function should be monitored regularly.

The dysphagia in ChAc may respond to local botulinum toxin injections in some patients. Basal ganglia neurofunctional surgery (ablation, stimulation) is experimental but may be considered in individual cases.

# Neurodegenerative Disorders

Corrado Angelini
Department of Neurosciences, University of Padova, Padova, Italy

N

## Synonyms

Central nervous system; Neurogenetics

## Definition and Characteristics

Frontiers in clinical neurosciences are the developments in studies on pathophysiological mechanisms and research findings about mutations in genes that lead to neurological defects and neurodegenerative disorders. For example there are reports that mutations in the genes responsible for lissencephaly of the brain or "cobble-stone" brain, cause a complex malformation of the cerebral cortex due to alpha 2 laminin mutation or to proteins that control the cellular migration or alpha-dystroglican glycosilation.

## Prevalence

The prevalence of neurodegenerative disorders in the population is growing due both to the ageing effect and to the life style in western population.

## Genes

The cerebral alterations in CMD in the western type of congenital muscular dystrophy with alpha 2 laminin deficiency is localized on chromosome 6, and in the Japanese form (Fukuyama muscular dystrophy) due to a fukutin defect which is located in locus 9q,

31q33 [1]. A gene known to cause familial amyotrophic lateral sclerosis (f-ALS) is located in chromosome 21q22 (CuZn-SOD), while in other inherited neurodegenerative syndromes with fronto temporal dementia, features of amyotrophy, Parkinsonism the tau gene is implicated.

Neuro-genetic degenerative disorders include ►Parkinson disease (PD), ►Alzheimer's disease (AD) for which several gene loci have been identified. Alterations of amyloid precursor protein (APP) are due to point mutation in the gene of the APP localized in chromosome 21, other AD cases are due to mutation of either presenilin 1 (chromosome 14) or presenilin 2 (chromosome 1). Other rare neurodegenerative disease include mitochondrial encephalopathy lactic acidosis and stroke (MELAS), Friedreich's ataxia, several forms of hereditary spastic paraplegia (e.g. SPG7), Wilson's disease, Huntington's chorea (chromosome 4). Friedreich's ataxia is due to expansion of trinucleotide (GAA) repeats in FRDA gene, which encodes frataxin to mitochondria, a mitochondrion-targeted protein involved in iron homeostasis, excessive free iron results in damaged proteins containing iron sulphur groups including respiratory chain complexes I, II and III. MELAS is due to a mutation in nucleotide 3243 of mitochondrial DNA. Ragged red fiber (RRF) are a hallmark of the disease [2]. SPG7 gene encodes for paraplegin, (chromosome 16q24) a nuclear encoded mitochondrial protein similar to a yeast metalloproteinase. In muscle from SPG7 patients RRF were found [3]. In Wilson's disease, a disease characterized by a movement disorder and liver failure there are mutations of ATP 7B gene which encodes an isoform of mitochondrial copper-transporting ATPase. Accumulation of copper causes oxidative damage and direct damage to copper containing enzymes such as complex IV of respiratory complex or cytochrome C oxidase.

## Molecular and Systemic Pathophysiology

A number of neurodegenerative disorders are due to mutations in proteins that target to mitochondria [3].

Mitochondrial dysfunction may be a final common pathogenetic mechanism which produces reactive oxygen species (ROS) that damage human brain in PD, in amyotrophic lateral sclerosis (ALS) [4], in ►Huntington's disease, in progressive supranuclear palsy in PD or in autosomal dominant optic atrophy (OPA1 gene) [5,6]. Rearrangements and point mutations in mtDNA are accumulating over time, when they surpass a pathogenetic threshold in critical tissues for aging such as in specific brain areas of CNS for oxidative stress (basal ganglia, caudate nucleus, etc.) they cause energy failure and contribute to the neurodegenerative disorder. It is still controversial whether neurodegenerative disorders are due to cumulative effect of genetic mutations or specific effects of putative pathogenic mutations.

Dementia and cognitive decline is a brain/neuroscience major challenging issue: studies are investigating molecular mechanisms of AD and include mutation in APP and other proteins (alpha-synuclein). Familial AD and Parkinsonism plus are due to tauopathies. Familial prion gene disorders such as Gerstman-Sträussler syndrome may present as an ataxic form or a form with dementia, pyramidal signs and parkinsonism.

## Diagnostic Principles

Mutation in the specific genes have to be searched in genomic DNA when an hereditary neurodegenerative condition is suspected.

## Therapeutic Principles

Working data demonstrate a relationship of exercise to well-being in older people. Individuals with higher baseline scores for physical activity are less likely to develop cognitive decline. Being socially engaged and having productive activity appear to be good for cognitive health, in fact mitochondrial gene shifting is promoted by active training and submaximal aerobic exercise. Mitochondrial respiratory chain function in skeletal muscle of sporadic ALS patients appear to be relatively spared in earlier stages suggesting that ROS damage is restricted to central nervous system. These findings may be of relevance for developing future therapeutic strategies. The hypothesis is that exercise does a lot of positive things, not only to the cardiovascular system, but also it seems to have a direct effect on muscle and may be on neurotransmitters production in the brain.

Stem cell research continues to yield new findings. Neuroscientists report that neural stem cells seem to proliferate in the inflammatory response that occurs in the experimental model of AD or MS and point to their potential to repair defects that occur during degenerative disorders such as ALS. Further studies are needed to evaluate the full clinical potential of stem cells.

## Neurofibromatosis Type 1

Dieter Kaufmann
Department of Human Genetics, University of Ulm, Ulm, Germany

### Synonyms

NF1; von Recklinghausen disease

### Definition and Characteristics

Neurofibromatosis type 1 (NF1) is one of the most prevalent autosomal dominantly inherited genetic diseases of the nervous system [1]. Individuals with NF1 are predisposed to the development of peripheral nerve sheath tumors (neurofibromas and malignant nerve sheath tumors), astrocytomas (optic pathway gliomas), learning disabilities, seizures, strokes, patches of skin hyperpigmentations (cafe-au-lait spots), axillary freckling, Lisch nodules of the iris, vascular abnormalities, and tibial pseudarthrosis.

### Prevalence

The prevalence is about 1 in 2,500 in Europe. About half the cases are new mutations. Patients with NF1 exhibit a marked degree of variability, even in the same family.

### Genes

NF1 is localized on chromosome 17q11.2, shows 279,317 bases, at least 60 exons, and codes for neurofibromin. NF1 shows at least four alternatively spliced transcripts, with a developmental and tissue-specific regulation of expression, also a mRNA editing site in exon 23 creating an in-frame codon stop. Three genes (EVI2A, EVI2B, and OMGP) are embedded in NF1 intron 27b. There are several NF1 pseudogenes.

### Molecular and Systemic Pathophysiology

The tumor suppressor neurofibromin, a protein with 2,839 amino acids, belongs to a superfamily of proteins known as GTPase activating proteins. This activity is related to the GAP-related domain of neurofibromin, spanning the residues 1,172–1,538. It stimulates the intrinsic GTPase activity of GTP-bound Ras proteins (H-Ras, N-Ras, and K-Ras) [2]. In addition, neurofibromin interacts with kinesin-1 heavy chain and syndecan-2, a transmembrane heparan sulfate proteoglycan. In cultured Schwann cells, neurofibromin regulates growth, angiogenic or invasive properties, and morphology [3]. The functional loss of neurofibromin results in the development of benign neurofibromas, complex tumors composed of axonal processes, Schwann cells, fibroblasts, perineurial cells, and mast cells. Complete NF1-mediated tumorigenicity requires both a loss of NF1 in cells as well as heterozygosity in non-neoplastic cells [4]. The learning disabilities associated with neurofibromatosis 1 are caused by excessive Ras activity in mice. NF1 deficiency is found also in several sporadic tumors.

### Diagnostic Principles

Clinical diagnosis using the diagnostic criteria for NF1 is very sensitive. In NF1 more than 400 independent mutations having been reported [5]. NF1 shows clinical variable expressivity, with varying features even between family members.

### Therapeutic Principles

Because gene therapy or specific pharmacological therapy is yet not available, the therapy of the tumors is restricted generally to chirurgical excision.

# Neurofibromatosis Type 2

Dieter Kaufmann
Department of Human Genetics, University of Ulm, Ulm, Germany

## Synonyms

NF2; Central type of neurofibromatosis; Bilateral acoustic schwannomas; Bilateral acoustic neurofibromatosis (BANF); Bilateral acoustic neurinoma (ACN)

## Definition and Characteristics

Neurofibromatosis type 2 (NF2) is characterized by the development multiple nervous system tumors, especially of tumors of the eighth cranial nerve (usually bilateral vestibular schwannomas), schwannomas of other cranial and peripheral nerves, meningiomas, and ependymomas [1]. It is inherited in an autosomal dominant fashion with full penetrance. Affected individuals generally develop symptoms of eighth-nerve dysfunction in early adulthood, including deafness and balance disorder.

## Prevalence

The prevalence for NF2 is about 1 in 37,000 in Europe. About 20% of apparently sporadic cases are mosaic for their mutation [2].

## Genes

NF2 maps locus 22q12.2. NF2 is composed of 16 exons with 2 variably inserted exons. The tumor suppressor gene codes for merlin (moesin-ezrin-radixin-like protein)/schwannomin and shows 595 amino acids.

## Molecular and Systemic Pathophysiology

The tumor suppressor NF2 product belongs to the ERM proteins. It acts as a molecular linker between cytoskeleton and plasma membrane, probably as a membrane stabilizing protein. It inhibits cell growth, adhesion, and motility affecting actin cytoskeleton-mediated processes especially in Schwann cells [3]. Merlin interacts with several proteins as hepatocyte growth factor-regulated tyrosine kinase substrate (HRS or HGS) [4] and the molecular adaptor paxillin. Latter mediates the membrane localization of merlin to the plasma membrane. Merlin mediates contact inhibition of growth through interactions with the cytoplasmic tail of CD44, a transmembrane hyaluronate receptor [5]. It functions in Rac-dependent signaling. Mutations in NF2 are involved in all cases of sporadic schwannomas, 50–70% of sporadic meningiomas, and a subset of human malignant mesotheliomas. The enhanced proliferation of merlin-deficient NF2 schwannoma and malignant mesotheliomas cell lines could be reduced in the presence of quinidine, a K(+) channel blocker.

## Diagnostic Principles

Clinical diagnosis using the diagnostic criteria for NF2 is very sensitive in adults. Molecular diagnosis detects the corresponding germline mutation in about 50% of the NF2 patients.

## Therapeutic Principles

Gene therapy or specific pharmacological therapy is not yet available. Therefore, the therapy of the tumors is restricted generally to microsurgical resection. Because the auditory nerve is compromised, people with NF2 can be treated by an auditory brainstem implant (ABI).

# Neuroleptic Malignant Syndrome

Michael Weller[1], Johannes Kornhuber[2]
[1]Department of Neurology, University of Zurich Medical School, Zurich, Switzerland
[2]Department of Psychiatry and Psychotherapy, University of Erlangen Medical School, Erlangen, Germany

## Synonyms

Malignant dopamine deficiency; Akinetic crisis of Parkinson's disease; Malignant catatonia; NMS

## Definition and Characteristics

Classical neuroleptic malignant syndrome (NMS) is caused by exposure to neuroleptic drugs with dopamine (DA) antagonistic properties and is characterized by extrapyramidal disturbances, hyperthermia and elevated serum creatine kinase (CK) [1–3]. NMS typically develops within days of the initiation of a course of neuroleptic drug treatment. Risk factors include male gender, severe agitation, affective disorder, intramuscular drug application and higher drug dosage. Malignant dopamine deficiency resembles NMS clinically and is triggered by the withdrawal of dopaminergic agents such as L-DOPA and DA receptor agonists or of glutamate receptor antagonists such as amantadine. Akinetic Parkinson's disease (PD) crisis is a similar clinical condition not strictly associated with drug withdrawal [4]. Malignant (lethal) catatonia is a variant of schizophrenic psychosis characterized by prominent motor system abnormalities including automatisms, posturing, agitation and violent behavior [5].

## Prevalence

The risk of developing NMS in response to neuroleptic agents has been estimated at 0.1–2.5%. No prevalence data are available for the other rarer conditions.

## Genes

Genes or genetic susceptibility loci have not been identified, except for those associated with familial PD.

## Molecular and Systemic Pathophysiology

NMS is a functional DA deficiency state triggered by neuroleptic drug-mediated postsynaptic DA receptor blockade. DA antagonism in the basal ganglia explains the extrapyramidal disturbances. Autonomic dysfunction including hyperthermia is attributed to the inhibition of dopaminergic neurotransmission in the tuberoinfundibular system and to rigidity associated with impaired heat dissipation. Elevations of serum CK and other enzymes may originate from muscle and may be triggered by direct drug actions and facilitated by hyperthermia. The pathophysiological explanations for NMS are probably also valid for malignant dopamine deficiency and akinetic PD crisis. The pathophysiology of malignant catatonia is unknown.

## Diagnostic Principles

The history is most helpful for differential diagnosis. The clinical evaluation will reveal similar symptoms and signs in NMS, malignant dopamine deficiency and akinetic PD crisis whereas malignant catatonia can often be distinguished by the associated mental disturbance, lack of cooperation and motor abnormalities such as posturing. Elevated CK may be a feature whenever hyperthermia is present. Neuroimaging and cerebrospinal fluid studies are not helpful for the differential diagnosis of the conditions discussed here, but are important to exclude other conditions such as encephalitis, neoplastic disease or other neurodegenerative diseases.

## Therapeutic Principles

NMS is treated by the withdrawal of causative agents and supportive measures. Resolution of NMS after withdrawal of causative agents needs up to 2 weeks because of cumulation and the slow elimination half-life of neuroleptic drugs from brain tissue. Supportive care for NMS, malignant dopamine deficiency and akinetic PD crisis include management of hyperthermia and fluid replacement. Controversial therapeutic measures for NMS include the application of DA agonists, glutamate antagonists or dantrolene. If necessary, patients with a history of NMS may be carefully re-exposed to neuroleptic drugs, preferentially with low-order or atypical neuroleptic drugs like clozapine. Malignant dopamine deficiency requires the reinstitution of dopaminergic treatment. Similarly, akinetic PD crisis may require adequate dopaminergic treatment and supportive measures. Malignant catatonia is treated with neuroleptic agents and rarely electroconvulsive therapy.

# Neurolues

►Syphilis of the Central Nervous System

# Neuromyotonia, Autoimmune and Idiopathic

Angela Vincent[1], John Newsom-Davis[2]
[1]Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK
[2]Department of Clinical Neurology, University of Oxford, Oxford, UK

## Synonyms

Isaacs' syndrome; Continuous muscle fiber activity; Peripheral nerve hyperexcitability syndrome; NMT
*Subtypes*: Autoimmune/idiopathic; Morvan's syndrome when associated with CNS and autonomic changes; Cramp-Fasciculation syndrome when neuromyotonia is not clinically evident.

## Definition and Characteristics

Autoimmune or idiopathic neuromyotonia (NMT) is characterized clinically by spontaneous and continuous muscle fiber contraction resulting from hyperexcitability of motor nerves associated variably with muscle stiffness, cramps, myokymia (visible undulation of the muscle that persists during sleep or general anesthesia), pseudomyotonia, weakness and increased sweating. Cramp-fasciculation syndrome may represent a mild form of neuromyotonia ([1] and references therein). A minority of patients have sensory symptoms, including transient or continuous paresthesias, dysesthesias, and numbness. Morvan's syndrome describes the rare association of central nervous system symptoms such as insomnia, hallucinations, delusions, personality change and occasionally autonomic features, e.g. constipation, cardiac irregularities, increased sweating.

Autoimmune neuromyotonia can associate with thymoma, and with other autoimmune disorders (e.g. myasthenia gravis, thyroid disease). It also occurs in association with idiopathic peripheral neuropathy.

## Prevalence

This is a rare condition with unknown prevalence. Onset can be in childhood but is usually in adult life. There is a slight predominance of males.

## Genes

Genetic forms are not common but rare familial forms due to the inheritance of dominant mutations in the Kv1.1 or Kv7.2 genes (KCNA1, KCNQ2) have been described [2,3].

## Molecular and Systemic Pathophysiology

The patients can present in infancy with muscle stiffness and deformities, or in adult life. There may be associated episodic ataxia (see ►Episodic Ataxia Type 1, KCNA1 mutations) or with neonatal epilepsy (see ►Benign Familial Neonatal Convulsions, KCNQ2 mutations). It is possible that those adult onset cases of neuromyotonia who do not respond to immunological treatments may prove to have a genetic disorder.

*Autoantibodies*: Antibodies to VGKCs can be detected by radioimmunoprecipitation of VGKCs extracted from human frontal cortex and labeled with $^{125}$I α dendrotoxin, a snake neurotoxin [1]. The assay measures antibodies to Kv1 isoforms 1.1, 1.2 and 1.6. These antibodies are present in only 40% of patients with neuromyotonia, at levels usually between 100 and 400 pM (normal range <100 pM), and around 20% of patients with cramp fasciculation syndrome [1]. It is not clear yet whether antibodies to the different Kv1 isoforms relate to the clinical symptoms. Since up to 5% of community controls can have low levels of VGKC antibodies (<400 pM [4]), diagnosis should not rely on the presence of the antibodies but should depend on electrophysiological demonstration (see below).

*Immunopathology*: NMT may be associated with other autoimmune diseases or other autoantibodies, and is paraneoplastic in about 20% of patients, usually in association with a thymoma [2]. A few cases have been reported with lung or other tumors. The effector role of VGKC antibodies is supported by the response to plasma exchange, the passive transfer of disease to mice by injection of IgG and effects of purified IgG on dorsal root ganglia cultures [5]. The effects of IgG were similar to those of low concentrations of 4-aminopyridine, which block VGKCs. Cerebrospinal fluid analysis may show oligoclonal bands. The condition can associate with infections and in some patients it is a monophasic illness with recovery within 1–2 years, suggesting that infections can predispose to development of these antibodies.

## Diagnostic Principles

Electromyography (EMG) shows spontaneous motor unit discharges in distinctive doublets, triplets, or multiplets, and sometimes longer spontaneous neuromyotonic bursts, with high intraburst frequency (40–300/s) [1]. Fasciculations and after-discharges can also occur. The abnormal muscle activity may be generated at different sites throughout the length of the nerve, but

in most cases it is principally distal. EMG evidence of a peripheral neuropathy is present in some. Detection of VGKC antibodies helps to confirm the disorder. Genetic investigations of the KCNA1 or KCNQ2 genes can be considered in particular when a positive family history and/or episodic ataxia or neonatal seizures are reported.

## Therapeutic Principles

NMT can be improved by anticonvulsant drugs such as carbamazepine. Plasma exchange and intravenous immunoglobulin therapy can be temporally effective in some patients. Immunosuppressive medication should be considered in severely affected patients.

## Synonyms

Batten disease; NCL; CLN1-10

## Definition and Characteristics

Neuronal ceroid lipofuscinosis is the name of a group of autosomal recessive neurodegenerative disorders of children characterized by the accumulation of autofluorescent storage material in neuronal and non-neuronal cells. Clinical symptoms include visual failure, seizures, myoclonus, neurodevelopmental regression and a movement disorder. The most common variants are Sanatavuori-Haltia disease (CLN1, infantile NCL, INCL), Janksy-Bielschowsky disease (CLN2, late infantile), NCL (LINCL), Spielmeyer-Sjögrendisease or Spielmeyer-Vogt disease (CLN3, juvenile NCL, JNCL). Additional variants are NCL due to cathepsin D deficiency (CTSD, CLN10), variant late infantile NCL with GROD (CTSD), variant late infantile NCL with GROD (CLN1), variant juvenile NCL with GROD (CLN1), Finnish variant late infantile NCL (CLN5), early juvenile or Lake variant or variant late infantile (CLN6 ), variant late infantile NCL (CLN7, vLINCL), northern epilepsy (CLN8, late infantile), progressive epilepsy with mental retardation (EPMR) (CLN8, late infantile), Turkish variant late infantile NCL (CLN8), variant juvenile NCL (CLN9), Kufs' disease (adult) and Parry disease (adult).

Congenital NCL usually presents early in the neonatal period with a refractory seizure disorder and early death. The first symptoms of infantile onset NCL become apparent in the second half of the first year with slowing of developmental progress and head growth, a typical movement disorder resembling Rett syndrome and progressive visual failure and seizures. Children are totally dependent and have a featureless EEG by the age of 3 years. Classical late infantile onset NCL (CLN2) presents usually with refractory seizures between the age of 2 and 4 years. There is a progressive decline of motor and cognitive skills with the onset of myoclonic jerks and visual failure later. Death occurs in childhood. Variant late infantile NCLs have a slightly different clinical course – symptoms may begin later and the progression may be less rapid. Behavioral features may predominate in the early stages but eventually seizures and visual failure predominate. Juvenile onset NCL presents with visual failure in the absence of other features at around the age of 6–7 years. There is a very slow deterioration in cognitive skills several years later and onset of seizures most often during the early teenage years. Seizure onset is associated with deteriorating speech and motor skills and young adults become completely dependent. Death occurs in early adulthood. Adult onset NCL is much less common and different phenotypes have been described; motor symptoms predominate in some whereas a dementia is the presenting feature in other families. Visual symptoms are not a major feature of adult NCL.

## Prevalence

Neuronal ceroid lipofuscinosis (NCL) is distributed worldwide but the incidence of different types

varies considerably from country to country. The incidence of all types of NCL is likely to be between 1 per 10,000 and 1 per 100,000 live births depending on the location. Within European countries most cases are of juvenile or late infantile onset and in the USA cases of juvenile onset are most common. In Finland cases of infantile onset were particularly high until the advent of prenatal carrier screening for common mutations.

## Genes

Nine genes have so far been identified, listed in Table 1. Others remain to be identified.

Autosomal dominant and recessive inheritance has been reported in adult onset cases but the underlying genes have not been identified in these instances.

## Molecular and Systemic Pathophysiology

The molecular basis of Batten disease is not understood. NCL proteins are expressed ubiquitously but selective death occurs in retinal and cortical neurones. The accumulation of storage material in all NCLs suggests a contribution to a degradative pathway that centers on the lysosome, perhaps by altering enzymatic function (CTSD, CLN1, CLN2), by trafficking/forming a complex with a component of this pathway (CLN6?, CLN8?) or by affecting the maintenance of the correct

**Neuronal Ceroid Lipofuscinosis (CLN1-10), Autosomal Recessive. Table 1** Summary of NCL genes

| Disease[a] | Gene symbol (gene product) | Gene location | Diagnostics | EM histopathology[b] |
|---|---|---|---|---|
| Congenital and later ages up to adulthood | *CLN10*, *CTSD* (cathepsin D, *CTSD*) | 11p15 | CTSD enzyme activity Mutation analysis | GROD |
| Classic infantile, and later ages of onset up to adulthood | *CLN1/PPT1* (palmitoyl-protein thioesterase, *PPT1*) | 1p32 | PPT1 enzyme activity Mutation analysis | GROD ± RL or FPP in cases of later onset |
| Classic late infantile, and later ages of onset up to juvenile | *CLN2/TPPI* (tripeptidyl-peptidase I, *TPPI*) | 11p15 | TPPI enzyme activity Mutation analysis | CL |
| Finnish variant late infantile | *CLN5* (407 amino acid protein, function unknown) | 13q22 | Mutation analysis | FP/CL |
| Variant late infantile | *CLN6* (311 amino acid membrane protein, function unknown) | 15q21–q23 | Mutation analysis | FP/CL |
| Variant late infantile | *CLN7/MFSD8* | 4q28 | Mutation analysis | FP/CL |
| Variant late infantile Progressive epilepsy with mental retardation (EPMR)/Northern epilepsy | *CLN8* (286 amino acid membrane protein, function unknown) | 8p23 | Mutation analysis | FP/CL |
| Classic juvenile | *CLN3* (438 amino acid membrane protein, function unknown) | 16p12 | Mutation analysis Vacuolated lymphocytes | FP |
| Adult onset | *CLCN6*, and others still to be identified | 1p36 | Mutation analysis | FP |

[a]Further childhood onset types exist which do not map to the known NCL loci.
[b]GROD = granular osmiophilic deposits, CL = curvilinear profile, RL = rectilinear profile, FP = fingerprint profile.

intra-organelle environment (CLN3?, CLN5?). The selective vulnerability of neurons may be due to an increased sensitivity to cellular changes caused by the disease or there may be neuron-specific metabolic pathways or substrates for the NCL proteins.

## Diagnostic Principles

Coincidence of two or more of visual failure, seizures, ataxia, regression and myoclonus and/or a history of affected siblings. Neurophysiological investigations including electroencephalogram (EEG), electroretinogram (ERG) and visual evoked potentials (VEP) may support a diagnosis of NCL. Brain imaging is seldom helpful except in excluding other conditions. The assignment of NCL type is based on a combination of age of onset of symptoms, clinical disease progression, neurophysiological findings, enzyme assay for CTSD, PPT1 and TPP1, presence of vacuolated lymphocytes in the peripheral blood, appropriate mutation analysis of *CTSD*, *CLN1*, *CLN2*, *CLN3*, *CLN5*, *CLN6*, *CLN7* and *CLN8*, and if necessary the ultrastructural examination of tissue samples. All known NCL mutations are listed at http://www.ucl.ac.uk/ncl.

## Therapeutic Principles

Currently there is no available curative therapy. The results from clinical trials of gene therapy, stem cell therapy and enzyme replacement therapy for CLN1 and CLN2 disease are awaited. Bone marrow transplant has been attempted in a very small number of CLN1, CLN2 and CLN3 cases with no evidence of long-term improvement in outcome. Phosphocysteamine may theoretically benefit children in the early stages of infantile onset NCL (CLN1). Anti-oxidant therapy using vitamin E and selenium dietary supplements has not been shown to result in long-term benefit. Anticonvulsants are usually necessary to control seizures. Valproate, benzodiazepines, topiramate and levetiracetam are probably the most helpful. Carbamazepine, vigabatrin, phenytoin and gabapentin would not normally be recommended. Lamotigine may worsen symptoms especially in late infantile and variants. Spasticity can be treated with baclofen. Risperidone and other antipsychotics, together with antidepressants have been used for behavior problems in young adults with juvenile onset NCL. Bulbar function often deteriorates so that feeding by nasogastric tube or gastrostomy is necessary.

## Synonyms

Hereditary motor and sensory neuropathy; HMSN; Charcot-Marie-Tooth disease; CMT; Hereditary neuropathy with liability to pressure palsies; HNPP; Hereditary motor neuropathy; HMN; Hereditary sensory and autonomic neuropathy; HSAN

## Definition and Characteristics

Inherited peripheral neuropathies form a heterogeneous group of disorders. The most frequent and best known form is Hereditary motor and sensory neuropathy (HMSN) also known as Charcot-Marie-Tooth disease (CMT). CMT is clinically characterized by progressive distal weakness, muscle wasting, and sensory loss in legs and arms. Disease onset is usually in the first two decades of life and progression is slow in the majority of patients.

By electrophysiological criteria CMT is divided into demyelinating forms (CMT1) with reduced nerve conduction velocities (NCVs) and axonal forms (CMT2) with normal or only slightly reduced NCVs and reduced amplitudes. A third group of CMT has been delineated with NCV values "intermediate" between CMT1 and CMT2. In addition to the classic phenotype many variants exist showing a wide range in onset age and severity. The most early and severe form is congenital hypomyelinating neuropathy in which disease starts shortly after birth with hypotonia, muscle wasting, and breathing difficulties. Occasionally CMT variants start later, in the fourth or fifth decade of life.

Hereditary neuropathy with liability to pressure palsies (HNPP) is a related disorder caused by a deletion in

the region of chromosome 17 that is also involved in CMT1A, the most common CMT variant. HNPP leads to episodic, painless, recurrent, focal motor, and/or sensory peripheral neuropathies.

Hereditary motor neuropathy (HMN) encompasses a group of disorders characterized by exclusive involvement of the motor part of the peripheral nervous system. As in CMT the disease has a distal predominance. In several HMN forms the phenotype is accompanied by pyramidal tract signs indicating concomitant upper motor neuron involvement. Additional features such as vocal cord paralysis or disease-predominance in the hands are found in some variants.

Hereditary sensory and autonomic neuropathy (HSAN) is characterized by predominantly sensory and autonomic symptoms due to selective degeneration of peripheral sensory and autonomic neurons. Hallmark features are progressive sensory loss, skin changes with chronic ulceration, osteomyelitis, and amputations. The various autonomic symptoms (e.g., hypotension, anhydrosis, gastrointestinal disturbances, etc.) are not present in all sub-forms. Some HSAN forms have apparent motor involvement although not as prominent as the sensory symptoms.

Hereditary neuropathies are usually transmitted as an autosomal dominant (AD) trait; however, several autosomal recessive (AR) and X-linked forms exist as well. De novo mutations seem to be frequent as well. In general, AR forms tend to be more severe than AD forms. For more detailed information see [1] and http://neuromuscular.wustl.edu/.

## Prevalence

Hereditary neuropathies are the most common group of inherited neuromuscular disease with an estimated prevalence of 1 in 2,500.

## Genes

The most common form, CMT1A, is caused by a duplication on chromosome 17 and accounts for 70% of AD CMT1. The second most common genotype corresponds to mutations in GJB1 causing X-linked CMT, followed by mutations in MPZ. CMT2 accounts for at least one third of hereditary neuropathies with CMT2A2 caused by mutations in MFN2 being the most frequent. The HMN subgroup is less frequent and accounts for 10% of all hereditary neuropathies. HSAN is the rarest subgroup with HSN I being the most frequent form.

In total up to 36 genes have been identified causing CMT, HMN, and HSAN – see also http://www.molgen.ua.ac.be/CMTMutations/. These genes fall into various categories but the disease-causing mechanisms often remain incompletely understood. In general, AR mutations lead to loss-of-function. In AD forms, however, many of the mutated proteins result in a toxic gain-of-function that cannot be deduced directly from the normal function of the gene product. The degree of genetic and clinical heterogeneity of the different subgroups is considerable as is evident from Table 1 which gives an overview of the genes involved in different forms of CMT, HMN, and HSAN along with their corresponding protein, gene locus, clinical phenotype, phenotypic variants, and reference to OMIM (Fig. 1).

## Molecular and Systemic Pathophysiology

### General Principles

Many genes involved in hereditary neuropathies encode ubiquitously expressed proteins raising several pathophysiological hypotheses on how mutations cause selective damage to the peripheral nervous system. Some common pathways are emerging based on the putative function of specific genes and underlying mechanisms by which mutant proteins cause disease.

### Detailed Categorization and Description of the Pathophysiological Pathways

*Myelin proteins*: The duplication on chromosome 17 results in a third copy of the peripheral myelin protein 22 gene (PMP22). PMP22 is expressed by meylinating Schwann-cells (SC) and has to be present in compact myelin in precise stoichiometric amounts in order to perform its normal function. Some PMP22 point mutations also lead to CMT1 through a toxic gain-of-function i.e., mutated PMP22 fails to reach the cell surface due to retention in the endoplasmatic reticulum where it also traps wild-type PMP22. Interestingly, PMP 22 deletions and loss-of-function point mutations result in Hereditary Neuropathy with liability to Pressure Palsies (HNPP).

PMP22 interacts with myelin protein zero (MPZ), the major peripheral myelin protein. MPZ acts as an adhesion molecule and is involved in compaction of myelin lamellae and axon-SC interactions.

Mutations in gap junction associated protein B1 (GJB1) cause X-linked CMT. GJB1 is expressed by myelinating SC and forms gap junctions between myelin layers at the Schmidt–Lanterman incisures and paranodal regions. It is incompletely understood which molecules are exchanged through them and how mutations cause CMT.

Periaxin (PRX) mutations cause AR CMT1. This membrane protein is expressed by SC and is important in protein–protein interactions and SC-elongation during myelination.

Early growth response 2 (EGR2), a Zinc-finger containing transcription factor controls expression of

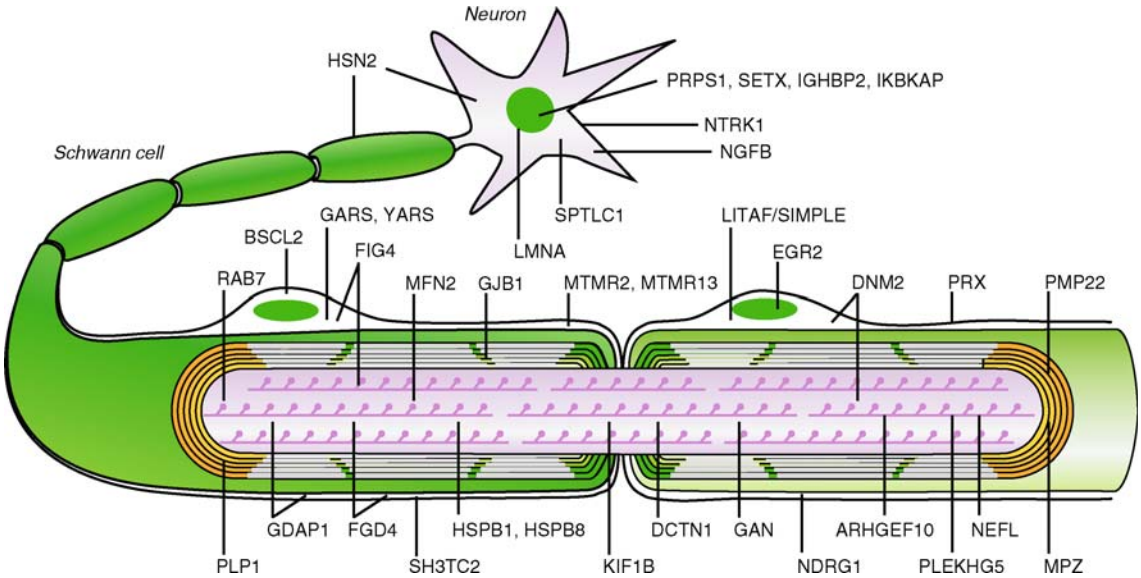
CMT RIA, recessive intermediate CMT type A; ALS 4, amyotrophic lateral sclerosis 4; SMARD, spinal muscular atrophy with respiratory distress; DSMA4, distal spinal muscular atrophy 4.



**Neuropathies, Inherited Peripheral. Figure 1** Schematic overview of the proteins mutated in CMT. (With kind permission of Humana Press.)

myelin protein genes. Mutations in EGR2 result in both AD and AR CMT. AD mutations reduce DNA binding activity. The mechanism of AR mutations remains unclear.

## Protein Synthesis, Sorting, and Degradation

*Protein Synthesis*: Mutations in glycyl-tRNA synthetase (GARS) cause AD forms of both CMT2 and HMN. Interestingly, also Tyrosyl-tRNA synthetase (YARS) is involved in an intermediate CMT variant. It remains enigmatic how mutations in such essential and ubiquitously expressed enzymes that charge tRNA with amino-acids cause nerve-specific phenotypes. Dominant negative effects are suspected but the pathomechanism is not known.

The exact function of Seipin (BSCL2) is not known but it is thought to play a role in protein translation and synthesis. In the presence of a mutation, aggregates are formed. AD BSCL2 mutations cause HMNV and Silver syndrome (a phenotypic variant of HMN V presenting with pronounced spasticity) while AR BSCL2 mutations are associated with congenital lipodystrophy, a nonneurological phenotype.

### *Endocytosis and Sorting*

Myotubularines (MTMRs) form a family of phosphatases involved in regulation of membrane dynamics (e.g., endocytosis and vesicular protein sorting). MTMRs dephosphorylate different phosphoinositide (PI) metabolites which are key regulators in peripheral nerves [2]. Mutations in myotubularine-related protein 2 and 13 (MTMR2, MTMR13) cause AR CMT1, likely by loss of phosphatase function.

Mutations in FIG4, encoding an active PI phophatase [2,3] result in severe AR CMT.

FGD1-related F-actin binding protein (frabin/FGD4) encodes for an actin-binding guanine nucleotide exchange factor (GEF) of the small Rho GTPase Cdc42 that controls actin and MT-dynamics [4]. This protein has a PI-binding motif.

Dynamin 2 (DNM2) is a large GTPase, regulating membrane trafficking, actin-based cytoskeletal dynamics, and membrane fission and fusion of cell organelles. Mutations in this ubiquitously expressed protein lead to reduced vesicle binding, reduction of receptor-mediated endocytosis, and disturbances in the cytoskeleton.

Mutations in rho guanine-nucleotide exchange factor 10 (ARHGEF10) cause an asymptomatic AD hypomyelinating neuropathy. This Rho-GTPase regulates actin cytoskeleton and is important in cell development.

Ras-associated protein Rab7 (RAB7), a ubiquitously expressed small GTPase, regulates intracellular transport. Mutations in RAB7 lead to AD CMT2 with prominent sensory features presumably by disturbances in axonal transport and early endosome formation.

### *Sorting and Degradation*

Mutations in small integral membrane protein of lysosome/late endosome (SIMPLE/LITAF) cause AD CMT1. LITAF is a putative E3 ubiquitin ligase and plays a role in degradation of PMP22 in lysosomes.

### Transport and Cytoskeleton

Neurofilaments (NFs): Mutations in neurofilament light chain (NEFL) are associated with AD forms of CMT1 and CMT2. Mutant NEFL has a dominant negative effect on wild-type NEFL and disturbs axonal transport.
Heat Shock Proteins (HSPs): Mutations in small heat-shock protein B1 and B8 (HSPB1 and HSPB8) cause CMT2 and HMN. These HSPs are interaction partners and act as molecular chaperones protecting cells from stress. Mutations in HSPB1 or HSPB8 result in abnormal aggregates, abnormal assembly of NFs, and in disturbed axonal transport.
Gigaxonin: Gigaxonin (GAN) is a member of the family of BTB/Kelch proteins that are key organizers of the cytoskeletal network and are closely linked to the ubiquitin degradation pathway. Homozygous mutations in GAN cause giant axonal neuropathy through disturbances of microtubuli (MT) dependent axonal transport.
Motor proteins: Kinesin family member 1B (KIF1B) drives anterograde axonal transport of synaptic vesicle precursors along the MT. A KIF1B-mutation has been described in a single small AD CMT2 family but the pathogenic character of this mutation is still equivocal.

Dynein-actin complexes carry out fast retrograde transport in motor axons. Mutations in Dynactin 1 (DCTN1) cause motor neuropathy (HMN) probably due to disturbances in binding of the MT.
PLEKHG5: PLEKHG5 (Pleckstrin homology domain-containing family G member 5) is a nuclear activator of the NFκB signaling pathway. Mutations in this gene cause a severe AR form of HMN. The NFκB activating function is impaired in the presence of a mutation. Eventually this leads to the formation of aggregates that are thought to generate toxic interaction with the axonal cytoskeleton resulting in the disruption of the anterograde axonal transport.

### Mitochondrial Dynamics

Mitofusin 2: MFN2, a protein located in the outer membrane of mitochondria, is a large GTPase regulating mitochondrial fusion. Mutations in MFN2 result in CMT2 by dispersion of mitochondria and reduction of their mobility probably leading to insufficient transport of mitochondria to the distal parts of axons.
Ganglioside-Induced Differentiation Associated Protein 1: Mutations in GDAP1 result in severe AR CMT1 and CMT2. GDAP is expressed in the outer mitochondrial membrane and regulates the mitochondrial network. Mutations result in fragmentation of mitochondria.

### RNA/DNA metabolism

PRPS1: Mutations in this recently identified gene cause a severe X-linked form of CMT [5]. PRPS1 encodes phosphoribosyl pyrophosphate synthetase, an enzyme of the purine-metabolism. Mutations result in reduction of enzymatic activity.
SETX: Senataxin (SETX) is mutated in an AD HMN-form with pyramidal tract signs. SETX has RNA and DNA helicase activities and is involved in the DNA repair pathway.
IGHMBP2: Like SETX, Immunoglobulin μ-binding protein 2 seems to be involved in RNA/DNA processing. Mutations in IGHMBP2 cause a severe early onset form of AR HMN with respiratory distress.
IKBKAP: This gene encodes for Inhibitor of κ light polypeptide gene enhancer in B cells, kinase complex-associated protein, which is a member of the elongator complex in DNA transcription. Mutations cause severe AR HSN III with very prominent autonomic disturbances. The underlying molecular pathomechanism remains unclear.

### Nerve Growth Regulation

NTRK1: Neurotrophic tyrosine kinase receptor type 1 is phosporylated in response to nerve growth factor (NGF), which supports the survival of sensory neurons in the dorsal root ganglia. This NGF-NTRK1 signaling has a crucial role in the development and function of the nociceptive system and thermal regulation. Mutations in NTRK1 cause congenital insensitivity to pain and anhydrosis (HSN IV).
NGFB: Nerve growth factor-β is the growth factor that binds NTRK1. Mutations in NGFB result in severely reduced binding affinity of NGF for its receptor thus hampering NGF-NTRK1 signaling. The corresponding HSN V phenotype has similarities with HSN IV.

### Miscellaneous

SH3TC2: The protein encoded by this gene has an unknown function. Mutations result in recessive demyelinating CMT with early and pronounced scoliosis.
NDRG1: N-myc downstream-regulated gene 1 is mutated in AR CMT1. NDRG1 expression is restricted to SC's but its function remains to be established.
LMNA: Lamins are ubiquitously expressed intermediate filaments that form the nuclear lamina and are important for DNA replication, gene expression, nuclear transport, apoptosis, and intracellular signaling pathways. Specific mutations in Lamin A/C cause AR CMT2 but other mutations result in diverse disorders such as muscular dystrophy, lipodystrophy, cardiomyopathy, and progeria.
SPTLC1: Serine palmitoyltransferase, long-chain base subunit 1 is suggested to be the key enzyme in the regulation of sphyngolipid levels in cell. Mutations in this protein may interfere with this regulation. It remains, however, unclear if the neuropathy is caused by actual accumulation of sphyngolipid intermediates or rather by more subtle long-term effects caused by the abnormal protein. SPTLC1-mutations cause AD HSN I.

HSN2: The exact function of this protein remains to be determined but it is suggested that HSN2 may play a role in the development and/or maintenance of peripheral sensory neurons or their supporting SC's. Mutations in this gene cause AR HSN II.

### Diagnostic Principles

Diagnosis is based on patient and family history and clinical examination. Nerve conduction studies differentiating the predominant phenotypes (i.e., motor or sensory, axonal or demyelinating) are essential to orient molecular genetic analyses. The molecular genetic diagnosis has made the need for nerve biopsies obsolete in most patients.

### Therapeutic Principles

Current therapy for CMT is supportive. A trial with ascorbic acid is ongoing in CMT1A patients since experimental evidence in a mouse model suggests that this compound can lower PMP22 expression. Onapristone, a progesterone antagonist, showed beneficial effects in a PMP22 overexpressing rat model. Finally, administration of neurotrophin-3 showed promising results in a small cohort of CMT1A patients.

### Synonyms

NARP

### Definition and Characteristics

Maternally inherited defect of mitochondrial energy metabolism leading to a chronic neurodegenerative disease that is characterized by neuropathy, ataxia, and retinitis pigmentosa [1]. Other clinical manifestations include developmental delay, dementia, seizures and pyramidal signs.

### Prevalence

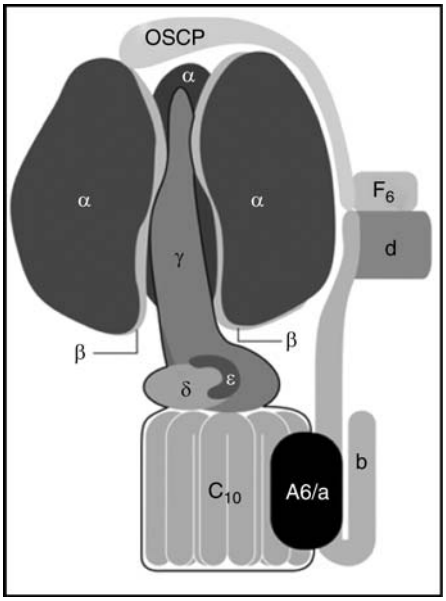
There are no population-based epidemiological data. Both the syndrome and the responsible mutation are assumed to be very rare.

### Genes

NARP is most commonly associated with a thymine to guanine transversion at nucleotide position 8,993 (T8993G) in the ATPase 6 gene of the mitochondrial DNA (mtDNA) [1]. Less frequent mutations are a T8993C transition at the same nucleotide, and T9176G and T9176C mutations in another codon of the ATPase 6 gene [2]. These mutations lead to a phenotype if the proportion of mutant mtDNAs exceeds a certain threshold.

### Molecular and Systemic Pathophysiology

ATP is the energy currency of the cell and ATP synthase is the major generator of cellular ATP. ATP synthase is dispensable in simple organisms such as yeast; in humans it is essential for life. ATP synthase is a complex multi-subunit protein (see Fig. 1) located at the inner membrane of mitochondria, it comprises two main parts; $F_1$-ATPase is the water-soluble catalytic portion of the enzyme, $F_o$-ATPase is the hydrophobic membrane-embedded portion that is required for channeling protons into mitochondria, this process drives



**Neuropathy, Ataxia and Retinitis Pigmentosa.**
**Figure 1** Mitochondrial ATP synthase.

ATP synthesis. Subunit A6 (a) is believed to mediate proton flow into mitochondria in conjunction with a rotating ring comprising ten copies of subunit c, however a detailed mechanism has yet to be elucidated. Mutations in subunit A6 cause the complex neurological disorder known as NARP. The most common T8993G mutation predicts the replacement of a highly conserved leucine residue with arginine in the fourth transmembrane spanning region of the protein. The T8993C transition at the same nucleotide position, T8993C, predicts a proline for leucine transition, which is phenotypically milder than the T8993G mutation.

The mtDNA is present in multiple copies per cell, typically several hundred. The proportion of mutant mtDNA can range from 0 and 100%. The level of mutant mtDNA varies between individuals and individual tissues, as with other mtDNA diseases (see also MELAS, MERRF and sporadic deletions). The T8993G mutation shows a clear correlation between mutant load and clinical severity. Individuals with levels of mutant mtDNA below 70% are asymptomatic, between 70 and 90% mutant mtDNA classical features of NARP manifest. Where the mutant load is greater than 90%, patients are affected with infantile Maternally Inherited Leigh Syndrome, or MILS ([3] cf chapter on ►Leigh Syndrome).

NARP and MILS may coexist in the same family, and intermediate clinical presentations have also been described. The clinical presentation in a family may change abruptly i.e. from no symptom to severe MILS, from one generation to the next [4].

## Diagnostic Principles

The combination of neuropathy, ataxia, and retinitis pigmentosa points to the disease. Additional clinical manifestations as described above and maternal inheritance narrow the differential diagnosis down to NARP. The retinitis pigmentosa is of the spicular type, rather than the "salt and pepper" variety more commonly seen in typical cases of mitochondrial myopathy. Brain imaging may show global or cerebellar atrophy, white matter lesions and striatal necrosis. Unlike most other mitochondrial disorders, there is no lactic acidosis and no ragged red fibers in muscle. The biochemical assay for measuring the specific activity of mitochondrial ATPase is of limited value in the diagnosis of NARP/MILS, as it is substantially normal even in severely affected individuals. A better biochemical assay is the measurement of ATP synthesis, whose impairment has been reported in cell cultures harboring the 8993T→G mutation, as well as in tissue-derived samples; however, this is a technically demanding assay, and it is critical to include appropriate controls such as material from cells lacking ATP synthase. The extent to which ATP synthesis is compromised correlates with the mutant mitochondrial DNA load. Diagnosis ultimately depends on DNA analysis, which is now routine in specialist centers; it entails DNA amplification and restriction enzyme digestion with any one of the following enzymes SmaI (site loss), AvaI and HpaII (site gains).

## Therapeutic Principles

There is currently no effective treatment for NARP or other mtDNA disorders. Symptomatic management may include antiepileptic therapy (cave valproate). Novel gene therapeutic approaches have been suggested but these are still at the proof of principle stage in laboratory cultured cells. Genetic counseling prior to prenatal diagnosis has been applied, as there is a relationship between the proportion of mutant mtDNA and risk of an affected offspring [5]).

Granulocytosis; Neutrophil leukocytosis

### Definition and Characteristics

Neutrophilia is a condition in which a subject has a higher than normal (3–11 million/ml in humans) concentration of neutrophils in the blood. Neutrophils are the most abundant granulocytes and, in humans and other primates, the most abundant leukocytes. Neutrophilia is common in bacterial infections. Blood neutrophil concentrations are also increased in other forms of acute inflammation, including those caused by myocardial infarction, acute lung injury and others.

In addition to increasing in number, neutrophils show other changes during neutrophilia. These neutrophils tend to be younger, as indicated by a band-shaped rather than polymorphic nucleus; this is called a “left shift”. In mice, the nucleus of mature neutrophils is ring-shaped, so immature neutrophils can be hard to detect morphologically.

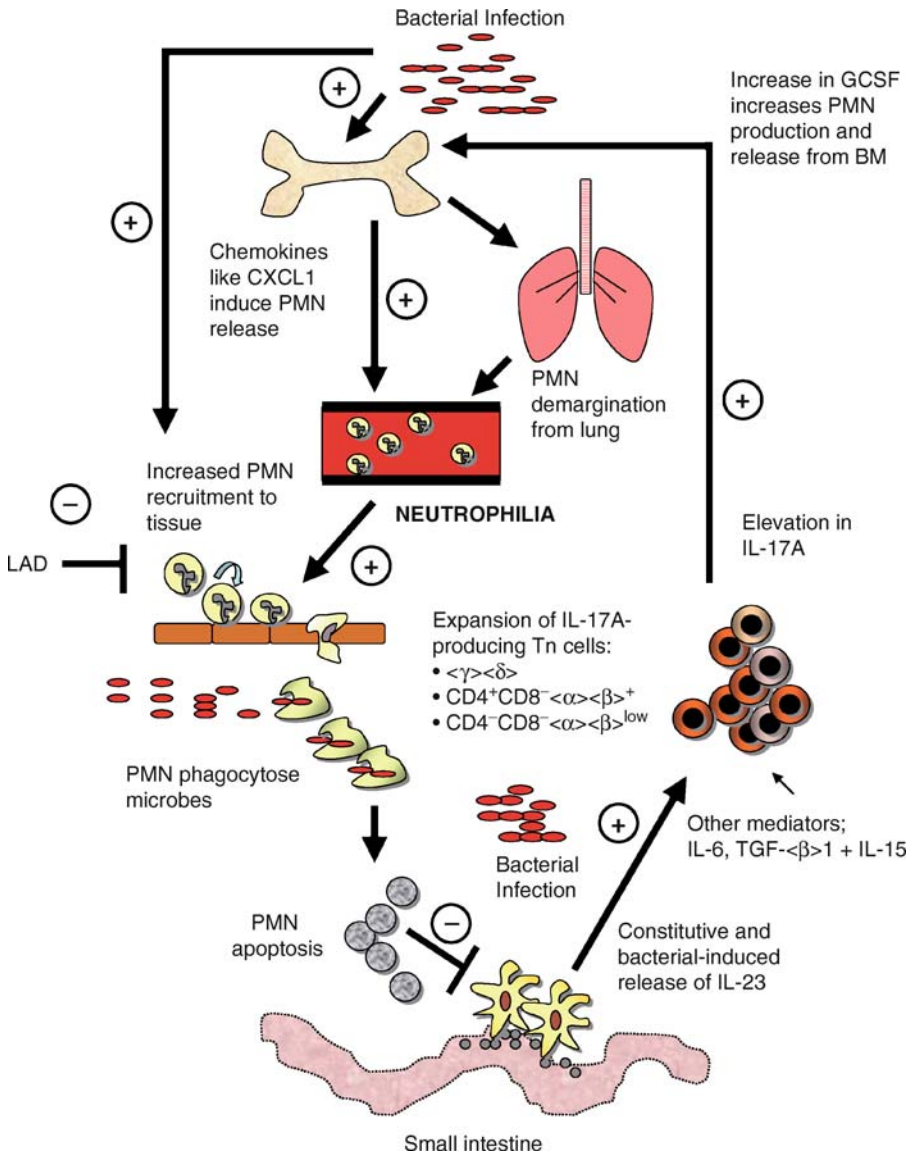
(Transient) neutrophilia is also induced by catecholamines (epinephrine, norepinephrine) or corticosteroids, which cause neutrophils previously marginated in the lung to enter the blood stream. This demargination response can be induced by exercise or other stressors. The demargination response causes neutrophilia that reaches about twice the normal blood neutrophil concentration.

In severe bacterial infections such as acute pneumonias, neutrophilia can be very significant, with a tenfold or more elevation in neutrophil counts in the blood. This is caused by (i) increased neutrophil release from the bone marrow, (ii) accelerated neutrophil maturation and

(iii) increased commitment of hematopoietic progenitor cells to the neutrophilic lineage.

## Molecular and Systemic Pathophysiology

Increased release from the bone marrow is largely controlled by chemokines that bind and activate the chemokine receptor CXCR2 [1]. In mice, the most important chemokines are CXCL1 (also known as keratinocyte-derived chemokine, KC) and CXCL2,3 (also known as Macrophage-Inflammatory Peptide-2, MIP-2). In humans, the relative importance of CXCR2-binding chemokines is not known, but CXCL1 (Gro-α), CXCL2 (Gro-β), CXCL3 (Gro-γ) and CXCL8 (also known as interleukin-8, IL-8) are likely to be involved. In



**Neutrophilia. Figure 1** The homeostatic control of granulopoiesis. Under normal conditions, granulopoiesis is positively regulated (⊕) by the release of IL-23 from macrophages and dendritic cells lining the small intestine. IL-23 induces the release of IL-17A from three subsets of IL-17A-producing Tn cells (γδ, $CD4^+CD8^-\alpha\beta^+$ and $CD4^-CD8^-\alpha\beta^{low}$), which may also be polarized by other cytokines and growth factors such as IL-6 and TGF-β1. The elevation in IL-17A results in an increase in G-CSF release and an increase in neutrophil (PMN) release from the bone marrow. Following trafficking to the tissues and the phagocytosis of microbes, neutrophils undergo apoptosis and are engulfed by resident macrophages and dendritic cells. This curbs the release of IL-23 and thus closes the feedback loop. Stress factors, such as acute bacterial infections, induce neutrophilia by increasing the release of granulocytes from the bone marrow (BM). Catecholamines or exercise induce demargination of neutrophils from the lung microvasculature. Bacterial infections also increase the recruitment of neutrophils into the inflamed tissue. This is impaired in LAD sufferers, which overrides the negative feedback loop and results in neutrophilia.

humans, CXCL8 also binds an additional chemokine receptor, CXCR1, which is not found in the mouse (Fig. 1).

Accelerated maturation of neutrophils is largely controlled by Granulocyte Colony Stimulating Factor (G-CSF) [2]. G-CSF promotes the maturation, proliferation and release of neutrophils from the bone marrow compartment by inducing a large number of intracellular signaling events [2].

Increased commitment of progenitors to the myeloid lineage and specifically to neutrophil production is caused by the balance of transcription factors PU.1 and C/EBPα [3]. In the presence of G-CSF, neutrophil precursors survive better and proliferate more rapidly. In normal bone marrow, 70–80% of all nucleated cells are neutrophils and neutrophil precursors. Under conditions of severe neutrophilia, this can reach over 90%.

Neutrophil concentration in the blood is controlled by a feedback loop involving IL-17A and IL-23 [4], in addition to some baseline production that is present even when G-CSF or its receptor are knocked out. G-CSF-independent baseline neutrophil production accounts for about 10–30% of normal blood neutrophil concentrations, which is similar to the number found in nude mice that are deficient in IL-17A production. IL-17A (and perhaps IL-17F) production is under the control of IL-23, a cytokine composed of a unique p19 peptide and a p40 peptide shared with IL-12. Macrophages and dendritic cells produce some IL-23 under normal conditions, which is reduced by the uptake of apoptotic neutrophils. Bacterial infections produce mediators that override this feedback loop and establish a new set point in the system at a higher blood concentration of neutrophils.

Inciting sufficiently rapid (within hours) and severe (tenfold or more) neutrophilia is crucial for surviving acute bacterial infections such as pneumonias. Individuals with an impaired ability to induce neutrophilia, such as IL-17 receptor knockout mice, succumb to such infections.

Neutrophilia is a diagnostic hallmark of leukocyte adhesion deficiencies (LAD). LAD-I is caused by an absence or malfunction of $\beta_2$ integrins (CD18 integrins). LAD-II is due to a defect in fucose metabolism that incapacitates selectin ligands. LAD-III is caused by a defect in the Rap small G protein-dependent mechanisms necessary for $\beta_2$ integrin activation. In all forms of LAD, neutrophilia is seen in untreated patients [5], which is thought to be caused by a broken feedback system and compensatory increase of IL-17A and IL-23.

# Neutrophil-specific Granule Deficiency

Masaaki Shiohara
Department of Pediatrics, Shinshu University, School of Medicine, Matsumoto, Japan

## Synonyms

Neutrophil lactoferrin deficiency; Neutrophil secondary granule deficiency; SGD

## Definition and Characteristics

Neutrophil-specific granule deficiency (SGD) is a congenital disorder of neutrophil morphology and function that is inherited in an autosomal recessive fashion and is characterized by serious and recurrent bacterial infections from early infancy [1,2].

## Prevalence

Five individuals with SGD have been reported worldwide.

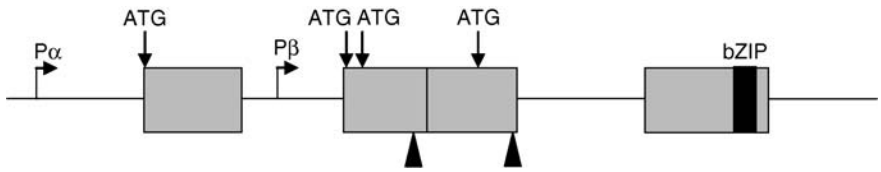
## Genes

CCAAT/enhancer binding protein (C/EBP)ε, localized on chromosome 14q11.2.

## Molecular and Systemic Pathophysiology

C/EBPε is a member of the C/EBP family of transcription factors, which share a highly conserved basic region and a leucine zipper domain. C/EBPε is expressed primarily during granulocytic differentiation and activates transcription of a subset of neutrophil granule genes. These granule proteins are important components of the oxygen independent microbicidal activity of neutrophils. Frameshift mutations in C/EBPε impair the transcriptional activities of secondary and tertiary granule genes, including lactoferrin, 18 kD cationic antimicrobial protein, transcobalamin, gelatinase B and collagenase [3,4]. In addition, primary granule human neutrophil peptides and bactericidal

N



**Neutrophil-Specific Granule Deficiency. Figure 1** The sites (see *arrowheads*) of mutations of *C/EBPε* in SGD.

permeability increasing proteins are also defective; however primary granule myeloperoxidase and lysozyme are unaffected. The known sites of mutations of C/EBPε in SGD are shown in Fig. 1.

In addition to the absence of lactoferrin, defects in up-regulation of *N*-formylmethionyl-leucyl-phenylalanine and C3bi receptors cause abnormalities in neutrophil disaggregation and chemotaxis. Deficiencies in a set of granule proteins in neutrophils lead to susceptibility to bacterial infection.

Expression of CD16, which is a low affinity IgG Fc receptor on neutrophils is reduced. Moreover, peripheral blood (PB) cells show aberrant CD45, CD11b, CD14 and CD15 expression in SGD [5]. The CD14 positive PB cells show weak staining for the monocyte specific enzyme, non-specific esterase. These abnormalities in monocytes as well as in neutrophils have been implicated in the impairment of bactericidal activity in SGD. The content of eosinophilic granule proteins, including major basic protein, eosinophil derived neurotoxin and eosinophil cationic protein is also reduced in SGD.

### Diagnostic Principles

Neutrophils show atypical bilobed nuclei (Pelger-Huët anomaly) on light microscopy and the absence of specific granules in the cytoplasm on electron microscopy. Neutrophils have no alkaline phosphatase (NAP) activity. Neutrophil chemotaxis, disaggregation, receptor up-regulation and bactericidal activity are impaired. The detection of mutations in the C/EBPε gene confirms diagnosis of this disease.

### Therapeutic Principles

Patients require administration of sulphamethoxazole-trimethoprim for prophylaxis against infections. In cases with abscess formation, surgical drainage is necessary.

## Definition and Characteristics

Nevus flammeus is a capillary malformation characterized clinically by persistent macular erythema (Fig. 1) and pathologically by ectasia of the papillary and superficial reticular dermal capillaries, which are otherwise lined by normal-appearing flat endothelial cells, and do not show evidence of mitotic activity [1].

Nevus flammeus usually presents at birth as sharply demarcated pink or red macules or patches. The lesions sometimes appear to fade during the first 12 months of life due to the natural fall in hemoglobin. The capillaries become more ectatic with age and the color thereafter gradually deepens. The lesions often become dark-red during adolescence and violaceous with advancing age. Although the lesions are initially macular, the surface might become irregular, thickened and nodular over time.

Although nevus flammeus can occur anywhere on the body, the most common site is the face. Occasionally, the mucous membrane is also affected. The lesions are usually unilateral, segmental, and do not follow the lines of Blaschko. The lesions grow with the child and persist throughout life.

Although usually an isolated finding, nevus flammeus is also a typical feature of Sturge-Weber syndrome and Klippel-Trenaunay syndrome. Sturge-Weber syndrome is characterized by a nevus flammeus in the ophthalmic distribution of the trigeminal nerve, ipsilateral leptomeningeal angiomatosis, associated intracranial calcifications that are characteristically paired and often referred to as trolley tracks, and ocular abnormalities such as glaucoma, buphthalmos, and choroidal vascular anomalies. Klippel-Trenaunay syndrome is characterized by the triad of nevus flammeus, ipsilateral hypertrophy of the soft tissue and bone, and venous varicosities. Nevus flammeus can also occur as a component of Proteus syndrome, Cobb syndrome, Beckwith-Wiedemann syndrome, Rubinstein-Taybi syndrome, Roberts syndrome, Mason syndrome, and trisomy 13 syndrome. The association of nevus flammeus with blue spots, nevus spilus, pale-pink telangiectatic nevus or cutis marmorata telangiectasia congenita constitutes phakomatosis pigmentovascularis.

A midline nevus flammeus in the occipital, thoracic, or lumbar area might be present in association with occult spinal dysraphism. When acne, atopic dermatitis, or psoriasis develops in the area of nevus flammeus, the lesion is worse than in other areas, and this is referred to as the Meyerson phenomenon. Lesions of nevus flammeus are more prone to bleeding and infection.

**Nevus Flammeus. Figure 1** A 5-year-old boy with a nevus flammeus on the face.

## Prevalence

Nevus flammeus occurs in approximately 0.3% of all newborns. The sex distribution is equal. Most cases are sporadic. An autosomal dominant mode of inheritance has been described.

## Molecular and Systemic Pathophysiology

The density of the perivascular sympathetic nerves in the cutaneous superficial plexus is decreased. Neural modulation of the vascular tone is reduced and this might be the cause of the progressive vascular ectasia. Nevus flammeus is usually congenital. Acquired lesions are rare and might develop following trauma, chronic sun exposure, or consumption of oral contraceptive medications. Ectasia in acquired lesions might develop due to a loss of sympathetic tone and unregulated blood flow in the cutaneous vasculature [2].

## Diagnostic Principles

The diagnosis of nevus flammeus is clinical and no laboratory test is necessary. The condition should be differentiated from a salmon patch, also known as nevus flammeus neonatorum, nevus simplex, or "angel's kiss," when the lesion occurs on the forehead or eyelid, and "stork beak mark" or "stork bite mark," when the lesion occurs in the occipital area. A salmon patch is scarlet to pink, flat, can be totally blanched, and usually deepens in color with vigorous activity and changes in ambient temperature [3]. The condition is present at

birth and usually disappears spontaneously in the first few years of life [3]. A salmon patch is composed of ectatic superficial capillaries in the dermis.

### Therapeutic Principles

Nevus flammeus is a cosmetic concern, especially when the lesion is large and located in a publicly visible area, such as the face. Since an untreated lesion lasts a lifetime, the negative psychological impact can be considerable. Since nevus flammeus is a benign lesion, the indication for treatment is based on cosmetic considerations. Masking with a cosmetic preparation is an option. The flashlamp-pumped pulsed dye laser in conjunction with epidermal cooling is the treatment of choice [4]. Favorable prognostic factors include superficially located affected capillaries, small size of the lesion, lesions in the head and neck, and lesions located over a bony surface [5].

### Synonyms

Common mole; Nevocytic nevus; Cellular nevus

### Definition and Characteristics

The term nevus refers to a variety of hamartomatous or neoplastic lesions in the skin. Melanocytic nevi are generally considered to be benign tumors of neuroectodermal origin. Nevi vary considerably in their clinical appearance. The junctional nevus is a smooth, hairless, light to brown macule from 1 to 6 mm in diameter. The junctional nevus remains flat until the nevus cells extend into the dermis. The nevus is then said to become compound – that is both junctional and intradermal. Later junctional proliferation ceases and the nevus cells

become separated from the epidermis by a band of connective tissue to produce the intradermal nevus, which is the type usually found in middle-aged persons. The typical nevus cell is oval or cuboid and has a homogenous cytoplasm. The nucleus is large, round or oval, pale, and vesicular. Nevus cells show variations in appearance. In the upper dermis they appear epithelioid, whereas in the lower dermis they may resemble fibroblasts or Schwannian cells. Nevus cells are apparently modified melanocytes without dendrites.

### Prevalence

The maximum number of nevi is present between ages 20 and 25, and the average number in Caucasians is 40. From then on the lesions flatten and fade, disappearing completely by age of 90. Nevi begin as junctional nevi. Over time, most develop into compound and finally intradermal nevi. Sun exposure appears to increase the numbers of nevi in the exposed skin. Caucasians have more nevi as blacks, and individuals with light complexion have more nevi than persons with dark complexion.

### Genes

Despite the obvious hereditability of multiple nevi phenotypes, the responsible genes have not yet been identified. Mutations in the genes BRAF and nRAS have been identified in melanomas and benign melanocytic lesions [1,2]. Both genes encode proteins of the MAPK pathway, which is therefore deregulated in the vast majority of melanocytic tumors. Activating mutations of the oncogene nRAS have also been described in melanoma-associated nevi and in congenital nevi. High levels of the tumor suppressor gene product p16INK4 in benign nevi may represent the mechanism whereby the cell cycle remains regulated in nevi, even in the presence of activated oncogene mutations [3].

### Molecular and Systemic Pathophysiology

The pathogenesis of melanocytic nevi has not been completely elucidated. In 1893 Unna presented the theory of "Abtropfung," according to which melanocytic nevi develop in the epidermis and drop off to the dermis during the time. In 1951, Masson proposed the dual origin of nevus cells from "epidermic melanoblasts" and Schwann cells. In 1984, Cramer hypothesized that during ontogenesis neural crest-derived precursor cells reach the skin via cutaneous nerves extending from the paraspinal ganglia. He suggested an upward melanocyte migration similar to the embryonic events [4].

The signs of malignant transformation in pigmented nevi are recent enlargement, an irregular border, asymmetry, changes or variegation in color, surface changes, development of palpable thickening, pain or bleeding, or the appearance of satellite pigmentation.

### Diagnostic Principles

Clinical features in combination with dermatoscopy can contribute to the distinction of benign melanocytic lesions from atypical nevi and melanomas.

### Therapeutic Principles

Cellular nevi should be removed if they show signs of malignant transformation, or if the patient desires removal for cosmetic reasons.

## NF1

►Neurofibromatosis Type 1

## NF2

►Neurofibromatosis Type 2

## Niacin Deficiency

Donatus Nohr
Department of Biological Chemistry and Nutrition, University of Hohenheim, Stuttgart, Germany

### Synonyms

Pellagrosis; Maidism; Erythema endemicum; Jolliffe syndrome; Pellagra

## Definition and Characteristics

Systemic disease resulting from deficiency of niacin (vitamin $B_3$) or its amino-acid precursor tryptophan [1,2]. Characterization by the 3 Ds: Dermatitis, Diarrhea, and Dementia. Pellagra = pelle agra = rough skin, i.e., the prominent appearance is a rough skin in light-exposed areas [3]. Symmetric appearance with a distinct border to normal skin (glove-like appearance at the hands). Gastro-intestinal-tract (GIT) disorders can be nausea, abdominal pain, increased salivation, soreness of the mouth, mucositis (mouth, vagina), and diarrhea. Early neurologic disorders are depression, anxiety, poor concentration; prolonged symptoms are disorientation, confusion, delirium.

## Prevalence

Sporadically in USA and Europe, mainly in poor and malnourished people, alcoholics, longtime parenteral nutrition with insufficient Niacin supplementation, and some psychiatric patients. Endemic in a few regions of Africa and Asia where maize (corn) represents a major part of the common food together with very low amounts of meat, fruit, and vegetables.

## Genes

Dietary niacin deficiency causes changes in NAD+ and PADPr metabolism, alters p53 expression, and impairs cellular responses to DNA damage in rats. Protection of DNA damage in patients undergoing chemotherapy is proposed [4].

## Molecular and Systemic Pathophysiology

Niacin is required for adequate cellular function and metabolism being an essential component of NAD and NADP [5]. Symmetric photosensitive skin eruptions due to loss of urocanic acid (UVB protector), accumulation of kynurenic acid (induces UV-dependent phototoxicity), atrophy of sebaceous glands, and decreased wax esters in sebum. Gastrointestinal manifestations are mainly inflammation of the mucosa together with malabsorption. Neurologic disturbances appear in the CNS and PNS including patchy demyelinization and degeneration of several nuclei. Pellagra-like symptoms can also appear under tryptophan deficiency, during dialysis, and due to intake of drugs (e.g., mercaptopurin, diazepam, isoniazid, Phenobarbital, salicylamid).

## Diagnostic Principles

Mainly clinical diagnosis of the (rough) skin, optimal in context with GIT symptoms. Laboratory diagnosis is still unsatisfactory in terms of a specific measurement to estimate niacin. Fluorometric assay of urinary metabolites *N*′-methyl-nicotinamide (NMN) and *N*′-methyl-2-pyridone-5-carboxamide (2-pyridone). NMN urinary levels below 0.8 per mg indicate niacin deficiency.

## Therapeutic Principles

Acute therapy is by oral application of 100–300 mg/day niacinamide or niacin in three doses, niacinamide having less side effects (flushing). Mental changes disappear within 24–48 h, skin lesions within several weeks. Concomitant administration of riboflavin and pyridoxine and a diet rich in calories and protein are reasonable. Prevention can be done by adequate nutrition (e.g., chicken, beef, tuna, fortified cereals).

►Pellagra

# Niacin Excess

Donatus Nohr
Department of Biological Chemistry and Nutrition, University of Hohenheim, Stuttgart, Germany

## Definition and Characteristics

Niacin is the common term for nicotinic acid and nicotinamide [1]. An excess uptake of niacin from the normal food is almost impossible, but could happen via the uptake of supplements or in pharmacological doses during therapies [2]. As niacin is a water-soluble vitamin, surplus amounts under normal conditions are quickly excreted. The plasma half-life time of nicotinic acid is about 1 h, and it can be concentrated in the liver, adipose tissue, and kidneys. “Niacin excess” per se has to be divided based on the effects of excess nicotinic acid and those of nicotinamide.

## Prevalence

About 24% and 16% of men and women, respectively, take up niacin by the nutrition above the tolerable upper level (35 mg/day), which can go up to 61% and 48% taking up fortified food [3]. However, even values up to

560 mg/day have been assumed to have no adverse effects in a healthy person with 60-kg body weight [4]. No data for pregnant women are available. Patients under pharmacological treatment with nicotinic acid or nicotinamide, e.g., people with hypercholesterolemia, may be at risk; in addition, people with abnormal liver function, diabetes, peptic ulcer disease, gout, cardiac arrythmias, inflammatory bowel disease, migraine headaches, and alcoholism may be more susceptible to adverse effects of excess niacin.

### Genes

In a rat model, supplementation with pharmacological doses of nicotinic acid or nicotinamide led to enhanced cancer latency that correlates with changes in $NAD^+$ and poly(ADP-ribose) levels. Thus, supplementation may help to protect certain tissues from the long-term effects of DNA damage [5].

### Molecular and Systemic Pathophysiology

*Nicotinic Acid*: Besides the immediate symptoms (mainly flushing and itching), hepatotoxicity (including elevated liver enzymes and jaundice) mostly appear after long-term treatment (3–9 g/day) for months or years, but have also been described with 750 mg/day for 2 months.

*Nicotinamide*: Nicotinamide is normally better tolerated than nicotinic acid. NO generally flushing, but also nausea, vomiting, and signs of liver toxicity at 3 g/day, decreased insulin sensitivity appeared at 2 g/day in adults at high risk of insulin-dependent diabetes.

### Diagnostic Principles

First symptoms of niacin excess are reddening of the skin (flushing), accompanied by itching and a hot feeling. In addition, headaches, tingling and burning, severe heartburn, nausea, vomiting, and eye problems (blurred vision) can appear as well as hyperglycemia. In contrast to niacin deficiency, no values for laboratory assays defining "niacin excess" are available.

### Therapeutic Principles

Best therapy against niacin excess is reduction of the applied dose of either nicotinic acid or nicotinamide. Prevention in healthy people is not necessary, under pharmacological dosages individual clinical symptoms have to be supervised and the respective dose to be applied under a physician's control. The RDA varies in different publications around 16 mg and 14 mg for men and women, respectively.

## Nibrin/NBS1 Deficiency

►Nijmegen Breakage Syndrome

## Nicotine Addiction

►Nicotine Dependence

## Nicotine Dependence

Jürgen Gallinat
Department of Psychiatry and Psychotherapy, Charité Berlin, Berlin, Germany

### Synonyms

Nicotine addiction

### Definition and Characteristics

In general, nicotine dependence is diagnosed with the same criteria similar to other drugs of dependencies, although nicotine dependence usually does not produce significant interpersonal, financial, legal, or psychological problems.

### Prevalence

Tobacco smoking is the most frequent substance dependence with 20–35% lifetime prevalence in western countries. In psychiatric patients with bipolar disorder, schizophrenia, and alcohol dependence the lifetime prevalence is 60–90%. In terms of addiction intensity,

nicotine is one of the most potent substances comparable with cocaine and heroin.

## Genes

Nicotine dependence as well as successful abstinence from nicotine displays substantial heritable components. Genetic variants of the cytochrome P-450 system (CYP2A6, CYP2D6) metabolizing nicotine were associated with smoking. Processing of rewarding stimuli and addictive behavior is mediated by dopamine and polymorphisms in several dopamine receptor genes (D2, D4, D1), and the dopamine transporter (SLC6A3) has been associated with tobacco addiction. The nicotinic acetylcholine α4 subunit gene CHRNA4 is a potential candidate gene for attentional network function known to be decreased in smokers, and two large family-based studies have associated measures of nicotine dependence with single nucleotide polymorphisms within exon 5 of CHRNA4. Recent genomewide association studies in nicotine-dependent individuals identified candidate genes for successful abstinence from smoking which play a role in cell adhesion, enzymes, transcriptional regulators, neurotransmitters and receptors, and regulation of DNA, RNA, and proteins [1] indicating that nicotine dependence is a complex psychiatric disorder.

## Molecular and Systemic Pathophysiology

Nicotine is thought to be responsible for maintenance of smoking due to intrinsic reinforcing properties. Similar mechanisms are discussed for additives in cigarettes, for instance menthol. Nicotine initially acts as an agonist at nicotinic acetylcholine (nACh) receptors and is known to facilitate synaptic release of several neurotransmitters including dopamine (presumable via ß2 subunit of the nicotinic receptors) mediating ventral striatal activity which is an important correlate for rewarding behavior. Nicotine has been found to induce release of β-endorphin and metenkephalin, and rewarding effects of nicotine are also mediated via the cannabinoid type 1 (CB1) receptor.

Brain imaging studies of acute nicotine effects in healthy subjects observed activation in the frontal, cingulate, and visual cortex as well as in the cerebellum and thalamus under resting or task conditions [2]. This activation profile shows similarities with cerebral networks known to play a role in the reinforcing effects of different kinds of drugs, but also with brain circuitry mediating working memory and attention processes. Compatible with this activation profile, nicotine administration improves cognition particularly attention and working memory performance. In addicted individuals, stronger than normal activation of the reward network was observed in response to addiction-associated cues or during craving. However, although acute administration of nicotine improves cognition, cognitive impairments have been consistently found in chronic smokers and tend to be enduring despite abstinence and more pronounced in earlier age of onset of smoking [3].

Nicotine exposition in rats is accompanied by reduced cell numbers and increased markers of apoptosis in the studied regions, comprising the cerebral cortex, hippocampus, midbrain, and cerebellum [4]. In smokers compared with nonsmokers, voxel-based morphometry investigations reported reduced gray matter volumes in the prefrontal cortex, parietal, and occipital cortex, which are in part related to lifetime cigarette exposure [5]. Effects of nicotine on cerebral activation and cognition may be mediated by the high density of nicotine binding sites in the occipital cortex, frontal cortex, and thalamus, however, direct vasoconstrictive properties of nicotine may also be involved. Nicotine and its metabolites tend to accumulate in the brain reaching substantially higher concentrations than those in the blood.

## Diagnostic Principles

Nicotine dependence is a clinical diagnosis based on the criteria of the ICD-10 or DSM IV. The severity of dependence can be scored by the Fagerström Test for Nicotine Dependence (FTND).

## Therapeutic Principles

Most nicotine-dependent persons report annual attempts to quit smoking, but less than 15% are successful over the long term. More effective than placebo is transdermal nicotine (patch) and the dopamine and norepinephrine uptake inhibitor bupropion. However, the long-term abstinent rates for both treatments are low. Rimonabant, the first potent cannabinoid receptor antagonist, demonstrated efficacy in smoking cessation, among other pharmacological activities, and may be a new pharmacological approach in the treatment of nicotine dependence. Also treatment response to transdermal nicotine may be modulated by genetic variations. This was reported for the D2 dopamine receptor (DRD2), the dopamine β-hydroxylase (DBH), and the μ opioid receptor (OPRM1). Gene-by-gene interaction of polymorphisms in the dopamine transporter (SLC6A3) gene and the DRD2 gene may be relevant for bupropion response.

# Niemann-Pick Disease Types A and B

Edward H. Schuchman, Robert J. Desnick
Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York University, New York, NY, USA

## Synonyms

Acid sphingomyelinase deficient Niemann-Pick disease

## Definition and Characteristics

Autosomal recessive lysosomal storage disease caused by deficient activity of the enzyme acid sphingomyelinase (ASM), leading to accumulation of sphingomyelin, cholesterol, and several other lipids within lysosomes and in cell membranes [1]. There are two major subtypes: Type A presents in early childhood and follows a severe, neurodegenerative course leading to death before age 5. Type B may present in childhood or adulthood and affected individuals have little or no neurological involvement. Intermediate forms of ASM deficiency also have been described.

## Prevalence

Both disease subtypes are panethnic. Based on molecular screening for three common mutations, the carrier frequency of Type A disease among Ashkenazi Jewish individuals is ~1:80. The carrier frequency for either form in other populations is unknown.

## Genes

The gene encoding ASM (SMPD-1) is located on the short arm of chromosome 11 (11p15). It is ~5 kb and contains six exons. Exon 2 encodes about 45% of the mature enzyme. Over 100 SMPD-1 mutations have been described in Type A and B NPD patients, some of which are common in specific ethnic groups [2]. Examples of these are the three Ashkenazi Jewish Type A mutations (L302P, fsP330 and R496L) and the common Type B mutation, ΔR608. The SMPD-1 gene is paternally imprinted (preferentially expressed from the maternal chromosome), which may influence the disease phenotype [3].

## Molecular and Systemic Pathophysiology

The primary accumulating substrate in both forms of the disease is sphingomyelin. Additional lipids, including cholesterol and some gangliosides, accumulate as a secondary consequence of the sphingomyelin storage. Lipid accumulation occurs in most cell types, although cells of the reticuloendothelial system are primarily affected. Thus, the reticuloendothelial organs (e.g., liver, spleen, lung) are major sites of pathology. In Type A NPD patients, lipid accumulation also occurs in the brain, leading to severe neurodegeneration. The major difference between Type A and B NPD is the presence or absence of neurological disease, which is directly dependent of the amount of residual ASM activity expressed from the individual ASM mutation(s).

## Diagnostic Principles

Type A patients usually have evidence of neurodegeneration before 6 months of age. Type B patients may not present until late childhood or adulthood, usually with hepatosplenomegaly. Pulmonary deficiency, hematological defects (e.g., low platelet counts), and/or lipoprotein abnormalities (e.g., low HDL-cholesterol) also may be present at the time of diagnosis. Confirmed diagnosis of Types A and B NPD is accomplished by determining the residual ASM activity in white blood cells or cultured skin fibroblasts, where it is generally less than 10% of normal controls. Diagnosis also can be accomplished by mutation analysis.

## Therapeutic Principles

A mouse model of ASM-deficient NPD has been constructed and preclinical studies have been carried out evaluating enzyme replacement therapy, bone marrow transplantation, and gene therapy [4,5]. Each of these approaches is very effective at treating the non-neurological pathology, and clinical trials of enzyme replacement therapy are underway in Type B patients. Improved approaches for expressing ASM in the brain are currently being evaluated in the mouse model.

# Night Blindness, Congenital Stationary

Christina Zeitz
Institut de la Vision, Département de Génétique, INSERM, Université Pierre et Marie Curie, Paris, France

## Synonyms

CSNB

## Definition and Characteristics

Congenital stationary night blindness (CSNB) is a nonprogressive retinal disorder, which can be associated with other ocular symptoms like myopia, nystagmus, and strabismus. During the night, if artificial light is limited, the patients with CSNB are not able to detect the border of the street or road signs. Some patients are not even able to recognize stars. The adaptation from bright light to dim light conditions can be delayed. Contrast vision is also reduced. CSNB is a group of genetically and clinically heterogeneous retinal disorders. The genes involved in the different forms of CSNB encoding proteins, which are located in the phototransduction cascade, are important for the retinal signaling from the photoreceptors to the adjacent bipolar cells.

## Prevalence

CSNB has been described as a rare disorder but exact numbers are not available. A possible reason could be the patients' lack of awareness of a visual deficiency in an artificially illuminated, nighttime environment. Additionally, the disease may be overlooked by clinicians because specific electroretinographic examinations have to be performed to establish a precise diagnosis.

## Genes

Mutations in RHO, GNAT1, and PDE6B lead to autosomal dominant CSNB, while GRK1 and SAG variants are associated with the autosomal recessive form of Oguchi disease 1 and 2. However, only a small number of variants in few families have been described in these genes. Many mutations in RDH5 lead to autosomal recessive fundus albipunctatus, although the most striking phenotype of this disease is described by fundus abnormalities and not night blindness [1].

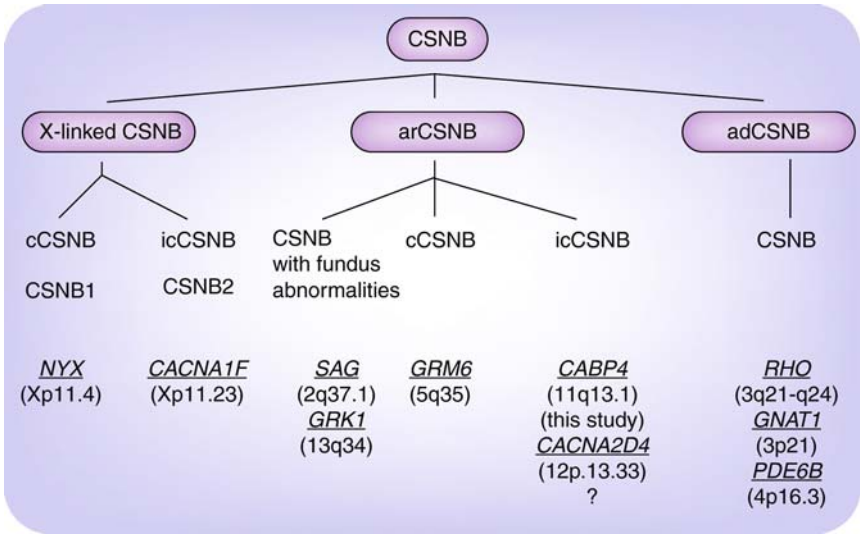
Most of the mutations leading to CSNB are located in genes involved in the retinal signaling from the photoreceptors to the adjacent bipolar cells, resulting in an incomplete or complete Schubert Bornschein ERG [2]. To date, for each form, mutations in two different genes have been described. Mutations in CACNA1F and CABP4 are associated with the incomplete X-linked and autosomal recessive form of CSNB respectively, while mutations in NYX and in GRM6 lead to the X-linked and autosomal recessive complete form of CSNB, respectively. In two other patients, initially diagnosed with incomplete CSNB and later described with a mild cone-dystrophy, a mutation was found in CACNA2D4 [3] (Fig. 1).

## Molecular and Systemic Pathophysiology

The pathophysiology underlying the gene defects of the phototransduction cascade is due to either constitutive activation (mutations in RHO, PDE6B), decreased visual signaling due to loss of transducin effector function (mutation in GNAT1), or reduced recovery of inactive rhodopsin (mutations in GRK1, SAG, and RDH5).

However, most of the mutations leading to CSNB have been identified in genes involved in the retinal signaling from photoreceptors to bipolar cells. CACNA1F encodes the $\alpha_1$-subunit of an L-type $Ca^{2+}$ channel (Cav1.4, α1F subunit), which is specific to photoreceptor synaptic terminals. This subunit is part of a protein complex in which the $\alpha_1$-subunit forms the pore, which carries the calcium influx across the synaptic membrane, and β, γ, and α2δ are auxiliary subunits. CABP4 is a member of a neuronal $Ca^{2+}$-binding protein family. It is directly associated with the C-terminal domain of the Cav1.4 subunit and is thought to modulate Cav1.4. *In vitro* studies, transcript and protein expression analysis of these genes, suggest that the amount of the respective proteins are crucial for the fine tuning of the calcium current, which then is important for the continuous release of glutamate from the photoreceptor synapses to bipolar cells. If these genes are mutated, this signaling is not warranted anymore, which results in incomplete CSNB.

*In vitro* studies show that the complete arCSNB phenotype due to mutations in GRM6 results from the lack of the glutamate receptor at the cell surface. The released glutamate from the photoreceptors can not be taken up correctly by the bipolar cells, resulting in the blocking of the signal transmission via this receptor.



**Night Blindness, Congenital Stationary. Figure 1** The different forms of human CSNB are classified according to their mode of inheritance, the phenotype and mutated genes. Abbreviations: cCSNB = complete CSNB; icCSNB = incomplete CSNB; ar = autosomal recessive, ad = autosomal dominant. Genes are written in italics and underlined. Chromosomal location is given in parentheses. The question mark indicates that *CACNA2D4* may also lead to incomplete CSNB.

The function of NYX is unknown. Immunohistological studies indicate a role for NYX in synaptic transmission and/or synapse formation at ribbon synapses in the retina. *In vitro* studies have shown that trafficking defects do not seem to be the pathogenic cause of this form of night blindness. Therefore, the role of this protein in signal transmission has still to be discovered [3].

## Diagnostic Principles

In the past, most of the CSNB patients revealed either an incomplete or complete Schubert Bornschein type of ERG with mutations in the two X-linked inherited genes CACNA1F and NYX, respectively. Recently, two autosomal recessively inherited genes, CABP4 and CACNA2D4, have been also associated with incomplete CSNB, while mutations in the autosomal recessively inherited gene, GRM6, have been linked to the complete type of CSNB. While, to date, CSNB patients with mutations in CACNA1F and CABP4 cannot be discriminated clinically, patients with NYX and GRM6 show a different pattern by applying the 15-Hz flicker ERG [4]. Nowadays, it must be evaluated if also mutations in CABP4 display a major cause of incomplete type of CSNB. If this holds true, incomplete CSNB patients should be first tested for mutations in the small gene, CABP4 (six exons), and only after exclusion of mutations in this gene, further investigated in the larger gene, CACNA1F (48 exons). Future studies will show if mutations in CACNA2D4 are also a common cause of incomplete CSNB, and if this gene should also be included in diagnostic screenings. Since the phenotype of patients with the incomplete type is variable and can also be progressive, one should be aware that patients with cone or cone-rod diseases may also show mutations in these genes. For the complete type of CSNB, patients should be first classified with 15-Hz flicker ERG and then should be investigated in either NYX or GRM6. If such a discrimination is not available, the smaller gene, NYX (three exons), should be first analyzed and only after exclusion of this gene, GRM6 (ten exons) further investigated.

## Therapeutic Principles

Although at the moment no cure for CSNB is available, the progress, which has been made to identify genes underlying this disease and to elucidate the respective pathogenic mechanism will be helpful in the future toward therapeutic approaches.

## Niikawa-Kuroki Syndrome

►Kabuki Syndrome

## Nijmegen Breakage Syndrome

Shuki Mizutani
Department of Pediatrics and Developmental Biology, Graduate School of Medicine, Tokyo Medical and Dental University, Tokyo, Japan

### Synonyms

Nibrin/NBS1 deficiency; AT-V1; AT-V2

### Definition and Characteristics

Nijmegen breakage syndrome is an autosomal recessive genetic disorder belonging to a chromosomal instability syndrome and is characterized by a characteristic facial appearance, microcephaly, radiosensitivity, immunodeficiency and high frequency of malignancies [1,2].

### Prevalence

The majority of patients live in Poland and Czechia. Over 90% of patients are homozygous for a founder mutation of NBS1 gene, 657Δ5. The incidence of homozygotes is estimated to be 1/68,000 live births in Czechia.

### Genes

The NBS1 gene is mapped to chromosome 8q21, is 50 kb in size and consists of 16 exons, encoding NBS 1 or p95 protein (Fig. 1) [3].

### Molecular and Systemic Pathophysiology

NBS1 forms a multimeric complex with hMRE11/hRAD50 nuclease (MRN complex) and recruits it at the vicinity of sites of DNA damage. Thereafter the MRN complex proceeds to rejoin double strand breaks by homologous and non-homologous recombination repair. These processes collaborate with cell cycle checkpoints to facilitate DNA repair. These molecular characteristics account for the radiosensitivity and cancer susceptibility of the patients.

### Diagnostic Principles

NBS patients have a characteristic facial appearance with a combination of receding forehead, receding mandible and prominent midface. Epicanthal folds, large ears and sparse hair are additional characteristics. The patients are mentally retarded and are born with microcephaly; in some of them this becomes apparent after a few months. Short stature is apparent by 2 years of age. In addition to clinical and cellular hypersensitivity to DSB inducing agents, NBS cells are characterized by increased spontaneous chromosome breakage. Spontaneous chromosome abnormalities involving immune system genes at chromosomes 7p13, 7q35 and 14q11 are frequently seen in patients' peripheral blood lymphocytes. Agammaglobulinemia has been reported in one third of patients. Cellular immunity is more consistently deficient in NBS patients. NBS patients have a high risk of developing cancers such as malignant lymphoma, the majority of which are B-cell type. The similarity of the cellular phenotype to that of ataxia telangiectasia (AT) cells, for example radiosensitivity and translocations involving chromosomes 7 and 14 in addition to immunodeficiency and cancer predisposition, originally led to the term A-T variant. However, AT patients are not microcephalic nor mentally retarded and manifest ataxia or telangiectasia. Some NBS patients demonstrate hematological abnormality compatible with aplastic anemia, sharing overlapping clinical features with Fanconi anemia [4,5].

### Therapeutic Principles

Therapeutic options other than symptomatic treatment are limited for NBS patients. Live vaccines and blood transfusions containing viable T-cells should be avoided. Exposure to X-irradiation should also be avoided. Preventive therapy for P. carinii in the form of trimethoprim-sulfamethoxazole should be considered. Immunoglobulin infusions are also recommended for those with low serum levels of IgG. Future study is needed as to whether bone marrow transplantation has a beneficial role.

# NK Cell Deficiency

►NK Cell Deficiency Syndromes

# NK Cell Deficiency Syndromes

Jordan S. Orange
Children's Hospital of Philadelphia, Philadelphia, PA, USA

## Synonyms

NK cell deficiency; NK cell lymphopenia

## Definition and Characteristics

Natural killer (NK) cells are lymphocytes that do not rearrange their germline DNA and thus do not express a T cell or a B cell receptor [1]. They are induced to mediate one of three general categories of functions after the ligation of single or combinations of activation receptors. These receptors can recognize pathogen-associated patterns such as viral hemagglutinins, or danger ligands such as CD48 expressed by other cells. Activation signals induced after ligation of NK cell activation receptors are restrained when the NK cell recognizes a target cell as having determinants of self. Specifically, NK cells have inhibitory receptors that can recognize class-I MHC molecules to induce phosphatase activity and block the transmission of activation receptor signals. This protects healthy cells from NK cell activities. NK cell functions are most likely accessed when activation signaling surpasses a threshold set by inhibitory signals. Increased expression of activation receptor ligands and decreased expression of inhibitory receptor ligands by a target cell ultimately makes it susceptible to NK cell function. This can occur after infection with particular viruses or after undergoing malignant transformation. NK cell functions include cytotoxicity, cytokine and chemokine production, and co-stimulation. These can result in the direct eradication of the target cell, control of target cell functions, and amplification or maturation of immune responses. A major role for these functions, as demonstrated through the use of in vitro systems and animal models, is in the defense against viral infections. NK cells are also believed to be essential in the normal surveillance of tumor cells as well as in controlling spread of malignancies.

## Prevalence

The prevalence of isolated NK cell deficiencies is unknown. The first case was described in 1982, but a majority of the cases have been reported since 2000.

## Genes

Currently only one gene has been identified to result in an isolated NK cell deficiency syndrome. This is FNKD caused by mutation of FCRGR3A. This gene encodes the IgG receptor CD16 that is used by NK cells to induce activation.

An NK cell deficient familial cohort study has identified a chromosomal region through linkage analysis (8p11.23-q11.21) likely to be responsible for the phenotype [2]. This region contains a number of interesting

**NK Cell Deficiency Syndromes. Table 1** Classification of the isolated NK cell deficiencies[a]

| Diagnosis[b] | NK cell function[c] | NKT cells[d] | NK cells[e] |
|---|---|---|---|
| Absolute NK cell deficiency (ANKD) | Absent | Absent | Absent |
| Classical NK cell deficiency (CNKD) | Absent | Present | Absent |
| Functional NK cell deficiency (FNKD) | Deficient | Present | Present[f] |

[a]This table is reproduced from [3] with the permission of Lippincott, Williams & Wilkins.
[b]In NK cell deficiency the observed defect must be consistent over time and non-NK cell immune components or non-NK cell-dependent immune components should be normal.
[c]NK cell function as typically defined by cytotoxicity, but can include any function that can be attributed to NK cells. As many of these functions are also performed by other cells, it is important that the deficit be specifically attributed to the NK cell.
[d]NKT cells as defined by the presence of $CD3^+$, $CD56^+$ cells. This at least in theory includes the iNKT cell population expressing the V alpha24 and V beta11 combination of TCR genes.
[e]NK cells as defined by, but not limited to $CD3^-$, $CD56^+$ cells.
[f]Although NK cells by definition are present in FNKD, there may be phenotypic abnormalities or absence of particular NK cell subsets.

candidate genes, but none have been specifically identified as mutated.

## Molecular and Systemic Pathophysiology

Some of the in vivo importance of human NK cells has been demonstrated by isolated and presumably genetic deficiencies of NK cells. These are distinct from a variety of known rare disorders with impact upon the immune system that effect NK cells. These diseases have been reviewed extensively and may provide some insight into the role of NK cells in maintenance of human health as well as the role of specific gene functions in NK cells [3,4]. These include the Wiskott-Aldrich syndrome, Familial Hematophagocytic Lymphohistiocytosis, and Griscelli syndrome, among others. Isolated NK cell deficiencies, in contrast are even more rare, but an increasing number of cases have been identified as the experimental technologies and reagents to study NK cells have improved. In general, patients with NK cell deficiencies have susceptibility to recurrent or severe infection with herpesviruses or papillomaviruses. Other susceptibilities have also been described including to fungal infection, malignancy, and autoimmune diseases.

The isolated NK cell deficiency syndromes can be classified into one of three groups (Table 1).
These are: (i) Absolute NK cell deficiency (ANKD), (ii) Classical NK cell deficiency (CNKD), and (iii) Functional NK cell deficiency. All three diagnoses are characterized by stably deficient NK cell function. ANKD also includes stable absence of all recognizable NK cells and lymphocytes expressing the characteristic NK cell marker CD56. In CNKD NK cells are also absent, but $CD56^+$ T cells are present. In FNKD NK cells are present although they may be phenotypically abnormal.

## Diagnostic Principles

NK cell deficiencies are diagnosed by establishing the absence of NK cells (ANKD, CNKD), $CD56^+$ lymphocytes (ANKD), and NK cell functions (ANKD, CNKD, FNKD) – see Table 1. The most common and accepted methods include immunophenotyping by flow cytometry and cytotoxicity function testing by $^{51}$Cr-release assay. These and alternative approaches to diagnosis are described in greater detail elsewhere [3,4]. As a matter of definition, for a patient to be considered as having an isolated NK cell deficiency, they must have minimal impairment within other components of their immune system. Similarly, other known potential immunodeficiency syndromes must be excluded. A number of pharmacologic agents have also been described to affect NK cells and their functions and need to be considered before any patient is given a NK cell deficiency diagnosis [5]. Finally the identified defect must be stable over time and not just found in a single evaluation or repeated evaluations within a narrow time window. The value added in establishing this diagnosis, however, relates to certain diagnostic, therapeutic and prophylactic interventions that may be useful for patients.

## Therapeutic Principles

There have not been any controlled studies of therapeutic intervention for patients with NK cell deficiencies. Anecdotal reports, however, have suggested benefit to targeted treatment of infections as well as prophylaxis with immunoglobulin and anti-herpesvirus medications including acyclovir, ganciclovir and/or related molecules. One patient (reviewed in [4]) has been successfully treated with hematopoietic stem-cell transplantation.

[1]Department of Urology, Weill Medical College of Cornell University, New York, NY, USA
[2]Department of Urology, Suny Downstate Medical School, New York, NY, USA

### Synonyms

Nocturnal micturition

### Definition and Characteristics

Nocturia is defined as micturition occurring during the intended hours of sleep (irrespective of day or night) in the awake state and is generally preceded and followed by sleep. In contrast, nocturnal enuresis is defined as micturition during sleep unaccompanied by awakening.

### Prevalence

The prevalence of nocturia increases with age in both men and women [1–3]. Approximately two thirds of healthy elderly men and women (>60 years) have some degree of nocturia; one quarter void at least twice nightly [4].

### Genes

No genetic markers for nocturia have been identified.

### Molecular and Systemic Pathophysiology

Four general categories distinguishing causes of nocturia have been identified: (i) nocturnal polyuria, or nocturnal urine overproduction, (ii) diminished nocturnal bladder capacity (low NBC), (iii) mixed, which is a combination of the previous 2, and (iv) global polyuria, urine overproduction throughout a 24-h period [5]. The following table lists the common causes of nocturia.

### Diagnostic Principles

The mainstay for diagnosis of nocturia is analysis of the frequency-volume chart (24 h voiding diary) to determine the patient's maximum and usual voided volumes in comparison with nocturnal bladder capacity. The proportion of urine excreted at night should be less than 35% of the 24 h excreted volume. If 35% is exceeded, nocturnal polyuria is diagnosed and its underlying causes should be specifically treated (Table 1). Diminished nocturnal bladder capacity (Table 1) is usually a result of lower urinary tract dysfunction whose causes should be investigated by a

**Nocturia. Table 1** The common causes of nocturia

| Category | Causes |
|---|---|
| Nocturnal polyuria | Congestive heart failure |
| | Diabetes mellitus |
| | Obstructive sleep apnea |
| | Peripheral edema |
| | Excessive nighttime fluid intake |
| Diminished nocturnal bladder capacity | Prostatic obstruction |
| | Nocturnal detrusor overactivity |

| Global polyuria | Diabetes mellitus |
| | Diabetes insipidus |
| | Primary polydipsia |

urologist and treated appropriately. If diary analysis reveals that the patient excretes more than 40 ml/kg body weight per 24 h, global polyuria (Table 1) is diagnosed and its root cause investigated and treated.

### Therapeutic Principles

Pharmacological therapy includes antimuscarinics (for diminished nocturnal bladder capacity); desmopressin, timed diuretics (for nocturnal polyuria), dietary therapy involves avoidance of sodium, caffeine and alcohol and fluid intake during the hours prior to sleep.

Fluid restriction should not be recommended in patients with polyuria unless the latter is strictly a behavioral problem unrelated to either renal or endocrine disease. Other treatments include nasal continuous positive airway pressure (CPAP; treatment for obstructive sleep apnea as cause for nocturnal polyuria); compressive leg stockings (for third spacing as cause for nocturnal polyuria). Afternoon nap in recumbent position when possible.

## Nocturnal Enuresis

William Lane M. Robson[1],
Alexander K. C. Leung[2]
[1]The Children's Clinic, Calgary, AB, Canada
[2]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

### Synonyms

Bedwetting

### Definition and Characteristics

Nocturnal enuresis refers to night wetting at an age when control of micturition is expected. The International Children's Continence Society separates nocturnal enuresis (NE) into primary (PNE) and secondary (SNE) forms [1]. Children with PNE have never experienced consistent dryness [2]. Children with SNE have experienced a minimum of six consecutive months of dryness [2].

### Prevalence

The prevalence of NE declines throughout childhood and is present at the age of 5 years in about 23%, 6 years in 9%, 10 years in 4%, and from 18 years through adulthood in 2%. In older children NE is more prevalent in males [3,4].

### Genes

Numerous studies report a varying but high prevalence of NE in other family members; the problem has been linked to chromosomes 8, 12, 13, 16 and 22 [4].

### Molecular and Systemic Pathophysiology

A disorder of arousal from sleep, a low nocturnal functional bladder capacity, and nocturnal polyuria are considered the three main pathophysiological factors. More than one factor might be operative in an affected individual. PNE and SNE likely share a common pathogenesis [5]. Disorders directly associated with NE include urge syndrome, dysfunctional voiding, cystitis, constipation, emotional stress, obstructive sleep apnea, neurogenic bladder, urethral obstruction, ectopic ureter, nocturnal seizure, diabetes mellitus, and diabetes insipidus.

### Diagnostic Principles

A careful history, a thorough physical examination, and a urinalysis are all that are necessary in the majority of individuals to establish a working diagnosis and to develop a helpful management plan. Invasive diagnostic imaging studies should be reserved for individuals with dysfunctional voiding, neurogenic bladder, urethral obstruction, ectopic ureter, or no response after three months of diagnosis-directed therapy.

### Therapeutic Principles

The psychological impact of bedwetting can be considerable and treatment is indicated in any individual who is embarrassed about the problem. Treatment per se, regardless of the therapy offered, even without resultant improvement in the bedwetting, has been shown to have a positive effect on the self-esteem of an individual who wets the bed [2]. Whenever possible, an underlying cause should be treated. Preliminary non-invasive therapeutic principles include voiding regularly by day, never deferring voiding to the point of urgency, treatment of associated constipation and cystitis, minimizing fluid intake in the evening before bed, emptying the bladder before bed, and obtaining sufficient and restful sleep [3–5]. Incontinence underwear and pads are practical considerations [3–5]. Alarm therapy has proven efficacy.

The recommended pharmacological approach is with desmopressin, a synthetic analogue of vasopressin, which results in dryness in 38–55% of children. Anti-muscarinic medications are useful in selected children with a reduced functional bladder capacity.

Throughout childhood the spontaneous resolution rate of NE is about 15% per year [3]. With modern therapy, complete dryness is achievable in the majority of individuals. NE can be improved in all individuals; the success rate of modern therapy is greatest in pre-school and elementary-aged children, and declines through adolescence and into adulthood.

## Synonyms

Isolated left ventricular noncompaction; Left ventricular hypertrabeculation; Left ventricular noncompaction; Noncompaction of the ventricular myocardium; Noncompacted myocardium; Spongy left ventricular myocardium; NCCM

## Definition and Characteristics

Noncompaction cardiomyopathy (NCCM) is a primary genetic cardiomyopathy that involves mainly the left ventricle (LV) where there is an altered myocardial wall with prominent trabeculae and deep intertrabecular recesses that are characteristic of the loose interwoven messwork that makes up the fetal myocardial primordium. The result is a thickened myocardium with two layers formed: thin epicardial compacted myocardium (CM), and thickened endocardial noncompacted myocardium (NCM). The deep intertrabecular recesses are filled with blood and are connected to the LV cavity. NCCM has been found with congenital anomalies associated with obstruction of right or left ventricular out-flow tracts [1]. In NCCM with cyanotic congenital heart disease (COHD), the deep intertrabecular recesses communicate with both the LV cavity and the coronary circulation [2]. LV segmental wall motion abnormalities and reduced coronary flow reserve are common in NCCM. The characteristic clinical manifestations are congestive heart failure, atrial and ventricular arrhythmias and thrombo-embolic events. Symptoms include dyspnoea and chest pain. Sudden cardiac death may account for half of the deaths in patients with NCCM. Prognosis of NCCM is poor for symptomatic patients [3]. Asymptomatic patients and related family members have much better prognosis.

## Prevalence

The prevalence of NCCM in the general population is not known. NCCM is found in 0.014% of patients referred to the echocardiographic laboratory. Men appeared to be affected more often representing 50–82% of all cases [4].

## Genes

NCCM can be familial or sporadic [2]. Several genes have been identified in familial forms [5]: G4.5, the gene coding for alpha-dystrobrevin, and cipher/ZASP. A locus on chromosome 11p15 has been linked to autosomal dominant NCCM.

## Molecular and Systemic Pathophysiology

In early embryonic development, the myocardium is a loose network of interwoven fibers separated by deep recesses (which regress to capillaries in later life) linking the myocardium with the left ventricular cavity. The gradual compaction of the myocardium occurs between 5 and 8 weeks of embryonic life, proceeding from the epicardium to the endocardium, from the base to the apex. In NCCM, it is thought that there is an arrest in the normal process of endo-myocardial morphogenesis. Familial NCCM is characterized by persistent embryonic myocardial morphology found in the absence of other cardiac abnormalities. It is hypothesized that the normal cardiac compaction is hindered by the mutation of the cytoskeleton protein genes. In NCCM associated with COHD, pathogenesis is explained by pressure overloads and possibly myocardial ischemia, preventing the regression of the embryonic sinusoids to capillaries, resulting in the characteristic deep intertrabecular recesses acting as fistulas communicating with both the LV and coronary circulation. Systolic dysfunction may result from subendocardial ischemia (SEI) as documented by nuclear positron emission tomography, cardiac magnetic resonance perfusion imaging and postmortem analysis. The SEI may be related to the failure of the coronary microcirculation to grow with the increasing ventricular mass and the compression of the intramural coronary bed by the hypertrophied myocardium. The SEI and the histological findings of myocyte necrosis and subendocardial fibroelastosis may be the basis of heart block, cardiac arrhythmias and sudden cardiac death. The depressed LV systolic function, atrial fibrillation, and the stasis of blood within the extensively trabeculated recesses enhance to the occurrence of thrombo-embolic events.

### Diagnostic Principles

ECG may show left or right bundle branch block, fascicular and complete heart blocks, paroxysmal supraventricular tachycardia, chronic atrial fibrillation and ventricular tachycardia. Cardiac magnetic resonance and echocardiography (especially with contrast) are very specific and sensitive diagnostic tools for NCCM. A ratio of NCM to CM of >:2:1 with echocardiogram and >2:3 with cardiac magnetic resonance are considered diagnostic of NCCM. Other diagnostic imaging modalities include computed tomography and left ventriculography.

### Therapeutic Principles

No specific therapy exists thus far for NCCM. Implantable cardioverter-defibrillators should be considered for secondary prevention of sudden death and for primary prevention if LVEF <35%. Cardiac transplantation is reserved for patients with refractory end-stage heart failure.

## Nongoitrous Congenital Hypothyroidism 2 - CHNG2 (Mutations of PAX8/TTF-1/TTF2)

Peter E. H. Schwarz, Jiang Li
Technical University Dresden, Medical Faculty Carl Gustav Carus, Medical Clinic III, Dresden, Germany

### Synonyms

Thyroid dysgenesis; Thyroid agenesis; Thyroid hypoplasia; Thyroid ectopic; Hypothyroidism; Congenital due to thyroid dysgenesis; Hypothyroidism, athyreotic; Athyreotic hypothyroidism; Resistance to thyrotropin; Rtsh; Thyrotropin resistance

### Definition and Characteristics

Congenital hypothyroidism is frequently (in 80–85% of cases) associated with thyroid dysgenesis. In these cases, the thyroid gland can be absent (agenesis), ectopically located, and/or severely reduced in size (hypoplasia). The most serious effect of untreated congenital hypothyroidism is mental retardation. Absolute arrest of linear growth and bone maturation may also occur. When thyroid hormone therapy is not initiated within the first 2 months of life, neurological complications, such as spasticity and gait abnormalities, dysarthria or mutism, and autistic behavior may develop.

### Prevalence

In whites, CHNG2 affects 1 in 5,526 newborns. However, it is strikingly different in blacks: 1 in 32,377 [1].

### Genes

CHNG2 is caused by mutations in three genes. They are PAX8, TTF1, and FOXE1. PAX8 (MIM 167415) is on the gene locus 2q12-q14. It is a member of gene family Paired BOX. TTF1 (MIM 600635) is also named TITF1, is the abbreviation of Thyroid Transcription Factor 1. They are on chromosome 14q13. The TTF1 gene spans approximately 3.3 kb and contains three exons. FOXE1 (also called TITF2 or TTF2, the full name is Forkhead Box E1 MIM 602617) is located on chromosome 9q22. It consists of a single exon.

### Molecular and Systemic Pathophysiology

TTF1, TTF2, and PAX8 are present from the start of thyroid morphogenesis. PAX8 and TITF1 were first expressed in the median thyroid primordium. TTF2 is expressed in most of the foregut endoderm, in the craniopharyngeal ectoderm involved in palate formation,

and in the Rathke pouch is transiently expressed at these sites from embryonic day (E) 8–8.5 to E13.5. The mRNA encoding TTF2 is downregulated in TFC (thyroid follicular cell) precursors following their migration and just before their differentiation.

In the thyroid gland, PAX8 is essential for the formation of thyroxine-producing follicular cells. PAX8 is sufficient to activate expression of endogenous genes encoding thyroglobulin, thyroperoxidase, and sodium/iodide symporter, all thyroid-specific genes [2]. Moreover, it was showed that PAX8 and TTF1 cooperate in the activation of the thyroglobulin promoter.

### Diagnostic Principles

Newborn thyroid screening, the thyroid-stimulating hormone screening (TSH screening) is the standard for diagnosis.

### Therapeutic Principles

Thyroid hormone therapy. Replacement therapy with thyroxine is the standard treatment. Prognosis for the patients is very good, if the disorder is detected within the first few weeks.

## Non-Islet Cell Hypoglycemia

Derek LeRoith
Division of Endocrinology, Diabetes and Bone Diseases, Mount Sinai School of Medicine, New York, NY, USA

### Definition and Characteristics

Non-islet cell tumor induced hypoglycemia is an uncommon cause for fasting hypoglycemia in adults, drug induced hypoglycemia (by insulin and other therapies for diabetes) being the commonest and insulinomas being the second most frequent cause. Hypoglycemia associated with non-islet cell tumors maybe due to extreme cachexia in the more advanced stages of the cancer or due to release of insulin-like growth factor-2 (IGF-2) as is the case of a number of mesenchymal tumors found in the thorax, abdomen and pelvis. In the cases where the etiology is due to release of IGF-2 by the tumor, the tumors are not necessarily large nor are there necessarily any signs of metastases. Removal of the tumor often leads to complete relief of the hypoglycemia [1,2].

Patients present with classic symptoms of fasting hypoglycemia, namely weakness, hunger, shakiness, dizziness and faintness that appear upon fasting; the symptoms disappear upon eating or drinking glucose containing juices. The definitive diagnosis requires a blood glucose measurement that coincides with the symptoms. In the work up of suspected fasting hypoglycemia, the universal test is the 72 h fast. Once symptomatic hypoglycemia develops, bloods are drawn and the hypoglycemia relieved by appropriate means. Usually, serum insulin, C-peptide and glucose levels give an indication as to the potential cause (Table 1).

### Prevalence

Rare condition.

### Molecular and Systemic Pathophysiology

Most tumors producing hypoglycemia are associated with the secretion of an IGF-2 molecule that contains an uncleaved extension peptide (E peptide); gene expression is normal in the tumors but the peptidase that is required for processing is apparently not adequately expressed. This molecule is incompletely neutralized by the IGF binding proteins and interacts with the insulin receptor on various tissues, resulting in hypoglycemia (Figure 1).

### Diagnostic Principles

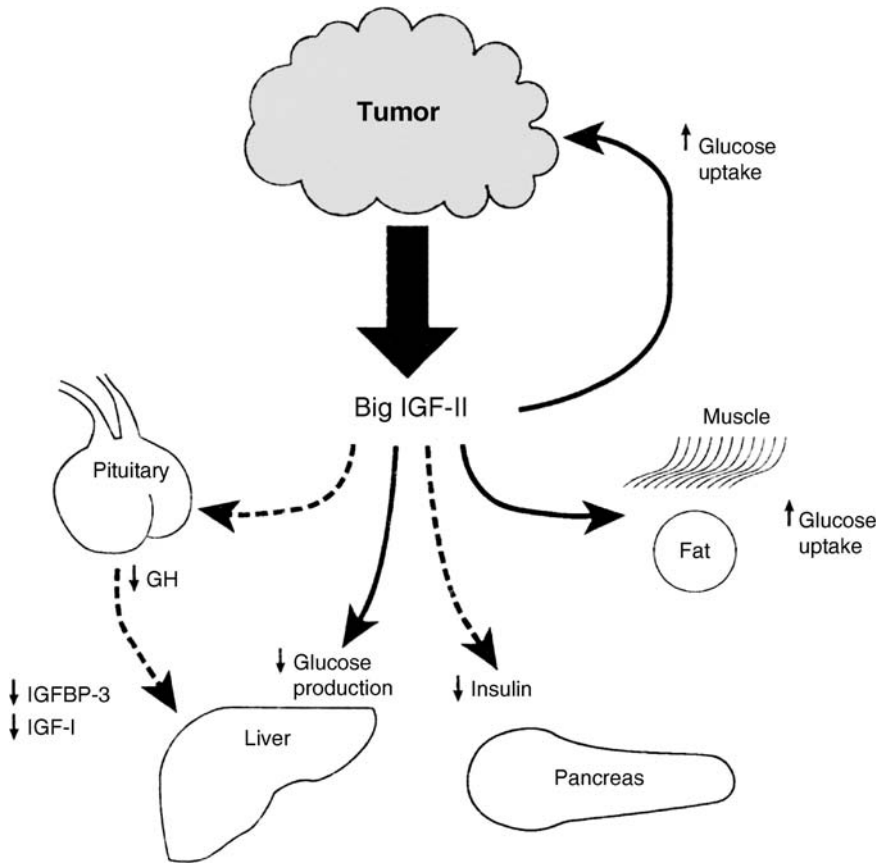
Hypoglycemia in the face of suppressed insulin and C-peptide levels in the blood strongly points to the possibility of NICTH and should be investigated accordingly with CT scans and MRIs to identify the tumor site. Meanwhile since IGF-2 is the most likely factor involved, blood levels of IGF-2 (and IGF-1, which is usually suppressed) should be measured, in addition to GH and IGFBP-3, which are also commonly reduced (Fig. 1).

The larger precursor form of IGF-2 (“big IGF-2”) may interact with IGFBP-3 but that the affinity for ALS was reduced and this could result in a molecule that transited the circulation more rapidly and was more available for interactions with cell surface receptors [3].

Using positive emission tomography studies with 18-F glucose, it was established in patients that the hypoglycemia was not associated with enhanced glucose uptake by the tumor itself, but the major portion of glucose disposal was into skeletal muscle [4]. Furthermore, hepatic glucose production, which should compensate for the lowered blood glucose levels, was totally inhibited.

**Non-Islet Cell Hypoglycemia. Table 1** Initial diagnostic steps in the diagnosis of fasting hypoglycemia

| Syndrome | Serum insulin | C-peptide |
|---|---|---|
| Drug induced (diabetic or factitious) | | |
| Insulin | +++ | Suppressed |
| Insulin secretagogues | ++ | ++ |
| Insulinoma | ++ | ++ |
| NICTH | Suppressed | Suppressed |



**Non-Islet Cell Hypoglycemia. Figure 1** NICTH involves the release of "big IGF-2" that stimulates glucose uptake in muscle and inhibits hepatic glucose production, with minimal effects on the uptake of glucose by the tumor. It also suppresses GH release, thereby lowering IGF-1, IGFBP-3 and ALS levels in the circulation.

## Therapeutic Principles

Surgical removal of the tumor or reduction in size by radiation or chemotherapy will reduce the circulating levels of "big IGF-2" and cure the hypoglycemia. This effect is apparently due to the return to normal in the proportion of mature processed IGF-2 in the circulation with a reversal of the hormonal changes described above, particularly the ternary complex of IGF-2, IGFBP-3 and ALS. In cases where debulking the tumor is not possible, GH therapy by increasing IGFBP-3 and ALS expression and release into the circulation has been beneficial, as has use of corticosteroids and somatostatin.

# Nonketotic Hyperglycinemia

Shigeo Kure, Keiya Tada
Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan

## Synonyms

Glycine encephalopathy; NKH

## Definition and Characteristics

Autosomal recessive deficiency of glycine cleavage system (GCS), a mitochondrial enzyme complex that serves as a main catabolic pathway of glycine, causes accumulation of glycine in body fluids [1]. Neonatal coma, seizures, and profound hypotonia associated with accumulation of large amount of glycine are typical presentations of NKH. In milder cases delayed psychomotor development and behavioral abnormality are main symptoms.

## Prevalence

Incidence of NKH patients is estimated to be approximately 1 per 250,000 live births in many countries. The incidence is higher in Finland (1/12,000 live births) [2] and British Colombia (1/63,000 live births) [3].

## Genes

The GCS consists of four individual proteins (Table 1). P-, T-, and H-proteins are specific to GCS while L-protein is a house-keeping enzyme. GLDC mutations were identified in ~70% of the mutant alleles while the rest of the alleles carried AMT mutations. GCSH mutation was identified in only one case with transient form of NKH. GCSL mutations cause Leigh syndrome, but not NKH.

## Molecular and Systemic Pathophysiology

Glycine plays two major roles as a neurotransmitter in the central nervous system. In brain stem and spinal cord, glycine binds inhibitory glycine receptors. Glycine also modulates *N*-methyl-D-aspartate (NMDA) type glutamate receptor complex in cerebrocortex, hippocampus, and cerebellum, which colocalized with the GCS. Glycine overflowing from the synaptic clefts is efficiently removed into astrocytes by a glycine-specific transporter, GLYT1. The GCS resides in mitochondria of astrocytes and digests the incorporated glycine. Deficiency of the GCS causes accumulation of glycine in astrocytes, which inhibits uptake of glycine from neural clefts. Overexcitation of those receptors is supposed to be a major cause of NKH. CT and MRI scan analyses revealed frequent association between NKH and brain malformations such as gyral malformations and hypogenesis of corpus callosum and/or cerebellum [4]. Pathogenesis of the brain malformation remains to be elucidated.

## Diagnostic Principles

Patients with NKH are often found in neonatal intensive care units. "Neonatal encephalopathy without evidence of infection" may be a common first presentation of patients. Characteristic EEG patterns (hypsarhythmia or burst suppression) points to NKH. Screening of amino acids reveals accumulation of glycine in urine, serum, and CSF. CSF and serum glycine ratio exceeds 0.09 in typical cases, and is greater than 0.04 in mild cases. Detection of reduced GCS activity or mutations in GLDC, AMT, or GCSH gene confirms the diagnosis of NKH.

## Therapeutic Principles

Ventilator support and/or intensive care for convulsion are often required in neonatal periods. A third of

**Nonketotic Hyperglycinemia. Table 1** Genes encoding the GCS components

| Gene | Chromosome | Coding exons | Product | Abbreviation | Number of amino acid residue |

# Non-Langerhans' Cell Histiocytoses

Jochen Utikal, Alexei Gratchev, Sergij Goerdt
Department of Dermatology, Venereology and Allergology, University Medical Center Mannheim, Ruprecht-Karls-University of Heidelberg, Mannheim, Germany

## Synonyms

Non-X-histiocytosis; Classification and subgroups: (i) systemic Non-Langerhans'cell histiocytosis (hemophagocytic lymphohistiocytosis, Rosai-Dorfman disease); (ii) cutaneous Non-Langerhans' cell histiocytosis: (i) juvenile xanthogranuloma (juvenile xanthogranuloma sensu strictu, benign cephalic histiocytosis, generalized eruptive histiocytoma of childhood), (ii) adult xanthogranuloma (adult xanthogranuloma sensu strictu, papular xanthoma, generalized eruptive histiocytoma, xanthoma disseminatum, multicentric reticulohistiocytosis, Erdheim-Chester disease), (iii) necrobiotic xanthogranuloma, (iv) spindle cell Non-Langerhans'cell histiocytosis (hereditary progressive mucinous histiocytosis, progressive nodular histiocytosis); N-LCH.

## Definition and Characteristics

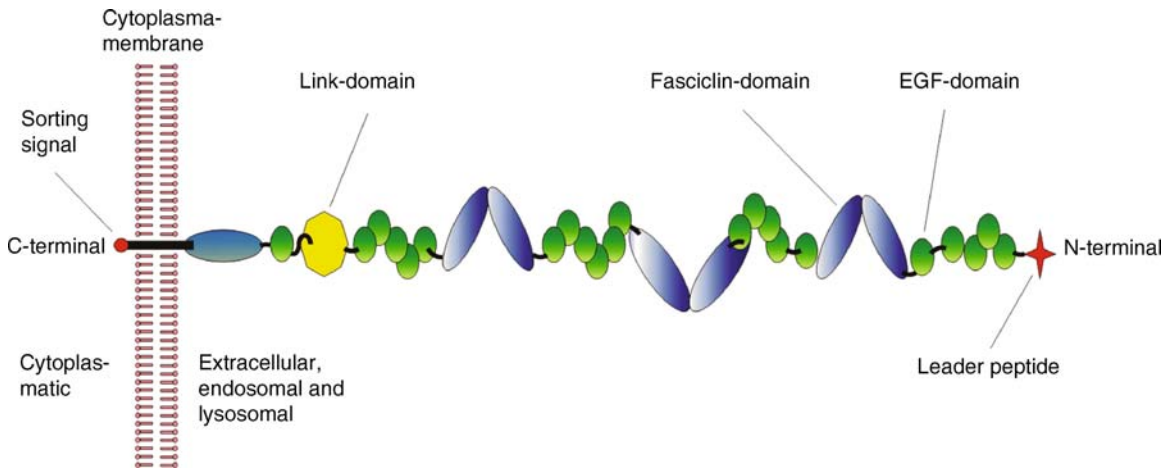
The systemic form of Non-Langerhans' cell histiocytosis (N-LCH) is regarded as an accumulation of classically activated macrophages (Mφ1). In contrast, the lesions of cutanous N-LCH are caused by alternative activated macrophages (Mφ2) (see also diagram histogenesis and classification of histiocytic disorders in the chapter ►Langerhans' cell histiocytosis).

## Prevalence

No information available.

## Molecular and Systemic Pathophysiology

In lesions of systemic N-LCH classically activated effector macrophages (Mφ1) are found. Mφ1 develop in response to pro-inflammatory stimuli such as TH1 cytokines (IFNγ) or bacterial products (LPS). They are characterized by secretion of pro-inflammatory cytokines such as TNF-α, interleukin (IL)-1, IL-6 and IL-12, expression of Fcγ receptors I, II and III, a strong oxidative burst and profound anti-microbial activity. In contrast to systemic N-LCH the lesions of cutaneous N-LCH show



**Non-Langerhans' Cell Histiocytoses. Figure 1** Structure of stabilin-1.

alternatively activated effector macrophages (Mφ2). Mφ2 are induced by Th2 cytokines, including IL-4, IL-10, IL-13 and TGF-β or by anti-inflammatory mediators such as glucocorticoids. They are shown to express anti-inflammatory cytokines such as IL-1R antagonist and IL-10, chemokine receptor antagonists such as AMAC-1, broad-spectrum receptors of innate immunity such as macrophage mannose receptor (MMR), the β-glucan receptor, scavenger receptor type I and the haptoglobin receptor CD163. Stabilin-1 (see Fig. 1), formerly described as MS-1 antigen or MS-1-HMWP, is expressed selectively by Mφ2 and by the lesional histiocytes of cutaneous N-LCH. Due to its specific expression in all subgroups of cutaneous N-LCH it serves as a specific marker for cutaneous N-LCH, though its function is yet unclear.

### Diagnostic Principles

Positivity for CD68 and stabilin-1 (MS-1-HMWP). No staining of S100B and CD1a.

### Therapeutic Principles

Local skin manifestations of the disease can be treated by excision, Laser therapy or intralesional steroid injection. Radiotherapy is also used for the treatment of skin lesions as well as of cerebral lesions. For the treatment of patients with visceral lesions systemic glucocorticoids and chemotherapy are useful. In addition it has been shown that imatinib is effective in the treatment of N-LCH [1].

## Nonvariceal Upper Gastrointestinal Bleeding

Marco Senzolo[1], Elena Piovesana[1], Lajos Okolicsanyi[1], Andrew K. Burroughs[2]
[1]Gastroenterology Unit, Liver Transplantation Unit, Department of Surgical and Gastroenterological Sciences, University Hospital of Padua, Padua, Italy
[2]Department of Liver Transplantation and Hepatobiliary Surgery, Royal Free Hospital, Hampstead, London, UK

### Definition and Characteristics

Gastrointestinal (GI) bleeding is the most common emergency for gastroenterologists, and it almost always requires hospitalization. Nonvariceal upper gastrointestinal bleeding (NUGB) is clinically characterized by hematemesis (vomiting blood or coffee ground material), melena (black, tarry stool i.e., melena), coffee ground particles from naso-gastric lavage, and rarely with hematochezia (red or maroon blood per rectum). Sometimes bleeding can be occult and the only

manifestation could be a positive fecal occult blood test or a secondary sign, such as hypotension, asthenia, iron deficiency anemia or shock (history of syncope or systolic blood pressure < 100 mm Hg and pulse rate > 100 beats/min).

## Prevalence

Estimated incidence for acute upper GI bleeding is about 100 per 100,000 adults per year and is more frequent in the elderly or middle age with male:female ratio more than 2:1. Mortality during admission for acute upper gastrointestinal hemorrhage is about 10% and it has not changed in the recent years.

## Molecular and Systemic Pathophysiology

*Peptic ulcer* is the most frequent cause of major, life threatening acute gastrointestinal bleeding. Significant hemorrhage derives from erosion of an underlying artery (posterior duodenal ulcer may erode gastroduodenal artery).

A history of NSAID use and Helicobacter Pylori infection are common.

*Gastroduodenal erosions* are mostly due to the damage caused by NSAIDS, but they can be also seen in cases of *H.p.* positive gastritis (in this last condition it is rare to have an important GI bleeding).

*Esophagitis* is common in the elderly presenting with coffee–ground hematemesis and ranges between 5 and 15% of all UGIB.

*Mallory-Weiss tear*, account for about 10% of UGIB, is a laceration of the mucosa at the gastroesophageal junction, often caused by repeated retching. Bleeding usually stops spontaneously and endoscopic intervention is seldom required.

*Vascular malformations*, accounts for about 5% of NUGIB. Small arteriovascular malformations are common in elderly and can result in significant bleeding. This can be exacerbated by anticoagulant drugs. Gastric antral vascular ectasia is a rare disorder characterized by linear easily bleeding red streaks in the gastric antrum. Delafoy's lesion is an erosion of a submucosal artery which often is misdiagnosed because is not accompanied by any visible mucosal lesion.

Another rare cause of NUGIB, is *aorto-enteric fistula*, which is primarily the result of arteriosclerosis, aortic aneurysms, aortic infections, or secondary to aortic repair.

*GI tumors* are responsible for 5% of all UGIB with a higher rate of rebleeding.

About a 5% of all UGIB remains of uncertain origin, including bleeding that originates from the proximal small bowel and bleeding not visible at urgent endoscopy [2].

## Diagnostic Principles

Endoscopy has the diagnostic role in UGIB, and should be performed after initial patient stabilization and resuscitation, with a particular attention to any signs of shock, patient comorbidities and drugs use.

Risk assessment has to take into consideration severity of hemorrhage and presence of comorbidities.

First of all it is important to evaluate at physical examination the systolic blood pressure, pulse rate, and any clinical sign of chronic liver disease (i.e., splenomegaly). Establish a history concerning medications, abdominal pain, past bleeding or surgery. Rectal examination is necessary top eliminate any confusion about rectal bleeding viz a viz melena. If there is evidence of severe hypovolemia, shock or ongoing blood loss, in addition to crystalloid fluid infusion or red blood cells, the patient should be evaluated for transfer in to an intensive care unit. Antisecretory therapy with a proton pump inhibitor is recommended with PPI 80 mh bolus followed by 8 mg/h for 72 h, because it has been shown to reduce rebleeding and need of emergency surgery, although not mortality.

Acute gastrointestinal bleeding during hospital stay for other serious comorbidities is accompanied by a 40% mortality.

Endoscopy provides important prognostic information on the risk rebleeding (Table 1) and the endoscopic appearance is enclosed in the Rockall score which is recognized as a useful risk assessment tool. This evaluates age, shock, comorbidities, cause of bleeding and active bleeding during emergency endoscopy. The major drawback is the necessity to undertake endoscopy.

## Therapeutic Principles

The principles of airway, breathing and circulation also apply to these patients.

Intravenous fluid to maintain blood pressure and urine output is first step of management. Blood transfusion is to be administered in patients who are shocked (blood pressure < 100 mmHg and pulse > 100 beats/min) and bleeding actively. Blood is transfused when hemoglobin is less than 10g/dL.

All patients should undergo endoscopy as soon as the resuscitation is adequate or within 24 h of a gastrointestinal bleeding. Rates of recurrent bleeding are then reduced.

**Nonvariceal Upper Gastrointestinal Bleeding. Table 1** Endoscopic findings in nonvariceal upper gastrointestinal bleeding

| Endoscopic finding | Risk of rebleeding (%) |
|---|---|
| Clean base | 3 |
| Flat spots | 7 |
| Oozing only | 10 |
| Adherent clot | 33 |
| Non-bleeding visible vessel | 50 |
| Active bleeding | 90 |

Treatment for peptic ulcer bleeding can be guided by the Forrest classification which helps stratifying the risk of rebleeding and need for surgery. Both Rockall' and Forrest scores could be used to decide whether a patient can be discharged or whether hospitalization is required in an intensive-care unit or in a general ward. Endoscopic includes laser therapy, monopolar/bipolar electrocautery, heat probe, clip application, epinephrine injection (and epinephrine injections with sclerosants). All of these techniques are effective in treat peptic ulcer bleeding. It is preferable to use combined therapy, which consists in epinephrine injections with another technique among those mentioned above as it has been demonstrated that combined therapy reduces rebleeding, need for surgery and mortality [4].

Esophagitis usually doesn't require endoscopy therapy, while bleeding from Mallory-Weiss tear often stops by itself and seldom requires endoscopic therapy. Vascular abnormalities can be treated endoscopically and all the modalities have been demonstrated to be effective. Aorto-enteric fistulas must be treated by surgery.

Rebleeding occurs in 15–20% of cases, usually within the first 24 h; no difference has been shown between repeated endoscopy and surgery as approach in a single randomized controlled trial.

Patients with bleeding ulcers due to NSAIDS use and H.p. negative, who are treated with long-term antisecretory drugs, have an important decrease in rebleeding rates [5].

Surgical intervention is recommended for major bleeding, and also when a second therapeutic endoscopy is unsuccessful.

# Noonan Syndrome

►Lymphedema

# Noonan Syndrome 1

Erik A. Sistermans
VU University Medical Centre, Amsterdam, The Netherlands

## Synonyms

Male Turner syndrome; Female Pseudo-Turner syndrome (both should not be used anymore, as they mistakenly suggest an overlap between Turner syndrome and Noonan syndrome)

## Definition and Characteristics

Autosomal dominant syndrome, main characteristics are short stature, facial dysmorphology, webbed neck, and cardiac anomalies [1]. Children with Noonan syndrome have an increased risk of developing malignancies, especially juvenile myelomonocytic leukemia (JMML, depending on the genotype).

## Prevalence

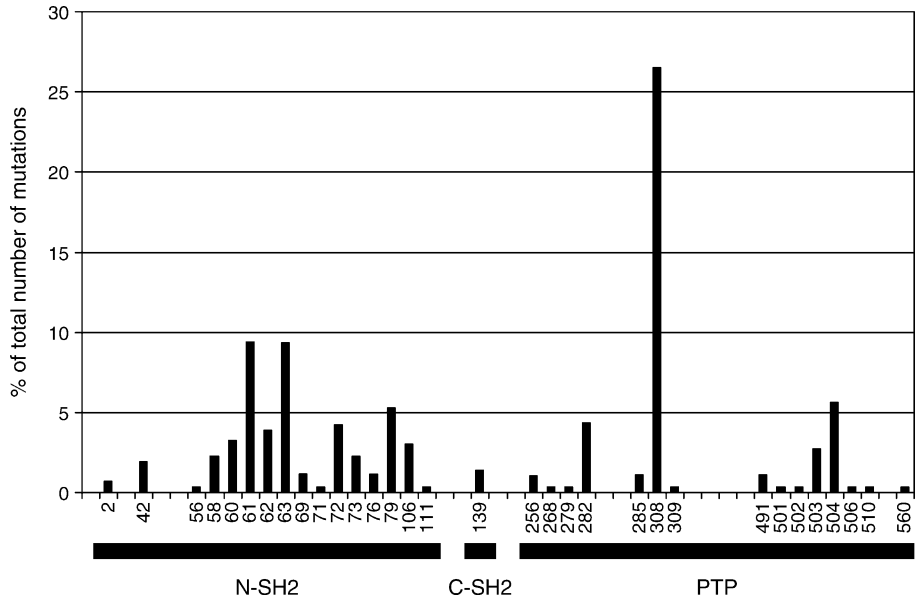
The estimated prevalence is 1 in 1,000–2,500 live births, but no population study is available.

## Genes

This chapter focuses on Noonan syndrome 1 (NS1), caused by germline mutations in the PTPN11 gene (Protein- Tyrosine Phosphatase, nonreceptor-type, 11, located on chromosome 12q24.1). Mutations in PTPN11 are found in approximately 50% of patients fulfilling strict clinical criteria [2,3]. Germline mutations in the same gene also cause LEOPARD syndrome (lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonic stenosis, abnormalities of genitalia, retardation of growth, and deafness). Somatic mutations in PTPN11 are found in 30% of patients with non-syndromic JMML and in a small fraction of patients with myelodysplastic syndrome (MDS) and de novo acute myeloid leukemia (AML). Recently, mutations have also been described in other genes [4], leading to a redefinition of Noonan syndrome in NS1 (PTPN11), NS2 (autosomal recessive, gene unknown, rare), NS3 (KRAS, <5% of cases), NS4 (SOS1, ±15% of cases) and NS5 (RAF1, ±10% of cases).

## Molecular and Systemic Pathophysiology

PTPN11 codes for SHP-2, a protein-tyrosine phosphatase that contains two cytoplasmic Src homology 2 (SH2) domains, N-SH2 and C-SH2, and a protein-tyrosine phosphatase (PTP) domain. The protein acts as an intracellular signal transducer in several pathways that



**Noonan Syndrome 1. Figure 1** Distribution of PTPN11 mutations in 254 patients from 6 published patient groups [2]. Vertical numbers below the bars indicate the mutated amino acid. The three domains are indicated as horizontal bars (figure not drawn to scale).

control diverse developmental processes. This includes cardiac valvulogenesis, linking it to the cardiac lesions often observed in Noonan syndrome. Regulation by SHP-2 can be both positive (RAS/MAPK) and negative (JAK/STAT), although in most cases it acts as a positive regulator. SHP-2 has two different conformations. In the inactive state, the N-SH2 domain interacts with the PTP domain, thereby blocking its catalytic activity. In the presence of phosphotyrosil ligands that can bind to the N-SH2 domain, the interaction between the N-SH2 domain and the PTP domain is lost, causing a conformational change that results in activation of the phosphatase. Most mutations found in patients with Noonan syndrome are affecting the amino acid residues that are directly involved in the interaction between the N-SH2 domain and the PTP domain (Fig. 1). As a consequence, the protein cannot assume its inactive conformation, and will be constitutively active. Noonan syndrome is therefore caused by gain of function mutations of SHP-2. It is not exactly known why this general gain of function effect can cause such a broad phenotypic spectrum. A likely explanation is that it is a consequence of the many complex pathways SHP-2 is involved in. The many other factors involved in the same pathways will contribute to the phenotype as well. Although Noonan syndrome follows a monogenic mode of inheritance, the individual phenotype in carriers of a PTPN11 mutation is therefore multigenically determined. Three mutations in PTPN11 are associated with a specific phenotype. Two of them, c.836A> G (p.Tyr279Cys) and c.1403C> T (p.Thr468Met), are found in patients with LEOPARD syndrome, whereas c.218C> T (p. Thr73Ile) is associated with a very high risk of developing JMML. Somatic mutations in PTPN11 are frequently found in patients with JMML, MDS, and AML. These mutations are different from the Noonan mutations, although they also result in gain of function. The somatic mutations result in a greater increase of phosphatase activity than the Noonan mutations, which suggests that they may be embryonically lethal when present in the germline.

## Diagnostic Principles

Physical examination based on specified diagnostic criteria, known as the van der Burgt criteria [5]. This includes cardiac examination and ECG. The diagnosis can be confirmed in approximately 50% of patients by mutation analysis of the PTPN11 gene.

## Therapeutic Principles

No pharmacological therapy is available although experiments with growth hormone therapy have been performed.

# Norrie Disease

Jutta Engel[1], M. Dominik Fischer[2]
[1]Institute of Physiology Dept. II and Tuebingen Hearing Research Centre, Tuebingen, Germany
[2]Centre for Ophthalmology, Institute for Ophthalmic Research, University Tuebingen, Tuebingen, Germany

## Synonyms

Atrophia bulborum hereditaria; Episkopi blindness

## Definition and Characteristics

X-linked recessive disorder characterized by congenital or early childhood blindness and sometimes deafness and mental retardation.

## Prevalence

Rare.

## Genes

NDP gene (Norrie disease and pseudoglioma) coding for norrin, localized on chromosome Xp11.4.

## Molecular and Systemic Pathophysiology

Norrin is a cysteine-rich extracellular protein of 133 amino acids belonging to the cysteine knot growth factor family and is expressed in fetal and adult brain and retina [1]. In humans, the mutation spectrum includes chromosomal rearrangements and more than 70 point mutations [2]. A knockout mouse model exists with severe impairment of retinal function and progressive hearing loss – similar symptoms as in human ND patients [3]. Detailed studies on this animal model provide evidence for a pivotal role of norrin in regulating the development of retinal and cochlear vasculature [4,5]. In ND, the resulting pathologic configuration of vascular structures is thought to cause chronic, hypoxia-induced formation of new, leaky vessels in the eye and ear. In turn, this might lead to characteristic secondary pathologies (see below) and ultimately to a complete loss of function.

## Diagnostic Principles

Congenital or early childhood blindness.
*Characteristic Features*: Retrolental fibrovascular masses (pseudoglioma) and complete retinal detachment (early stages), cataract and corneal opacities (later stages), and finally atrophy of the bulbus.
*Differential Diagnoses*: Retinoblastoma, Coat's disease, juvenile retinoschisis, retinal detachment, persistent hyperplastic primary vitreous, retrolental fibroplasia, metastatic endophthalmitis, massive retinal fibrosis.
*Extraocular Features*: Sensorineural deafness (30%) and/or progressive mental disorders (50%). Several atypical ND patients with a more complex phenotype (growth retardation, microcephaly, hypogonadism, mental retardation, epileptic seizures) have been reported.

## Therapeutic Principles

Neither gene therapy, pharmacological therapy nor dietary therapy is available.

Other treatments are symptomatic such as a hearing aid or cochlear implant.

## Norrie Syndrome

►Hearing Impairment, Syndromal

## Norrinopathies

Wolfgang Berger
Division of Medical Molecular Genetics and Gene Diagnostics, Institute of Medical Genetics, University of Zurich, Schwerzenbach, Switzerland

### Definition and Characteristics

Norrinopathies are caused by mutations in the NDP (Norrie disease pseudoglioma) gene and include Norrie disease (ND or Norrie-Warburg syndrome), X-linked recessive exudative vitreoretinopathy (EVR or Criswick-Schepens syndrome), Coats disease (retinal telangiectasis), and retinopathy of prematurity (ROP)[1–6]. The most severe form is Norrie disease, which is characterized by congenital or childhood blindness and may be associated with mental retardation and progressive deafness. EVR, ROP, and Coats disease are usually not associated with extraocular features. The ocular hallmarks of ND comprise fibrotic retrolental material reminiscent of a persistent hyperplastic primary vitreous (PHPV), retinal folding and detachment, and vitreoretinal hemorrhages. The lens becomes cataractous during the first months or years of life. Also, cornea, iris, ciliary body, and retinal pigment epithelium may be affected by the disease.

EVR is characterized by an abnormal retinal blood vessel development with an avascular retinal periphery. Additional features can include retinal traction and tears leading to retinal detachment, vitreoretinal hemorrhages, neovascularization, and blood vessel leakiness due to oxygen deficiency. Disease onset is observed in childhood or adolescence.

ROP also develops as a consequence of oxygen deficiency in the retina of preterm babies after oxygen treatment. Due to the incomplete retinal vasculature, hypoxia develops and leads to pathological neovascularization. The trait can be classified into mild and severe cases.

Coats disease predominantly occurs in male patients and affects one eye only (unilateral retinal telangiectasis). It is caused by a defect in retinal vascular development that results in vessel leakage, subretinal exudates, and eventually retinal detachment. Upon angiography, obliterated as well as dilated capillaries and aneurysm-like structures are observed.

### Prevalence

Norrie disease is rather rare and a few hundred patients were described worldwide. For ROP, a few cases were reported to be associated with NDP mutations while the majority is not. Familial and sporadic forms of EVR can be associated either with mutations in NDP, FZD4 (Frizzled 4, a Wnt-receptor and possibly norrin receptor), or LRP5 (low-density lipoprotein receptor-related protein 5, a co-receptor of FZD4). Regarding Coats disease, a unique case was reported in the literature [6]. Because of the rareness of these cases, it is difficult to estimate a reliable figure for the prevalence of norrinopathies.

### Genes

The gene was designated Norrie disease pseudoglioma (NDP) gene. The NDP gene consists of three exons, contains an open reading frame of 133 amino acids, and is located on the short arm of the human X chromosome in Xp11.4. Partial gene deletions or larger X chromosomal deletions encompassing NDP and adjacent genes can be found in 10–20% of patients while the remaining cases are caused by point mutations in NDP. The gene encodes a small extracellular protein (norrin) with structural similarities to cystine knot motif containing growth factors, including TGFbeta. According to a three-dimensional model generated by computer modeling, there are six cysteine residues responsible to form three intramolecular disulfide bridges and one cysteine residue (position 95) for the formation of norrin dimers [7].

## Molecular and Systemic Pathophysiology

The common basis of ocular symptoms in norrinopathies may be an abnormal retinal angiogenesis since all these traits most prominently involve the retinal vasculature. A mouse model for norrinopathies shows delayed outgrowth of the superficial retinal vascular network, lack of the deeper retinal blood vessels (secondary and tertiary vascular networks), an avascular retinal periphery, aneurysm-like lesions, leakiness of blood vessels, and delayed regression of the hyaloid vasculature. As a consequence, retinal hypoxia develops and Vegfa is being upregulated [8]. The increase in Vegfa may then be responsible for vasoproliferative processes and leakiness of blood vessels, which are observed in all these diseases.

Strikingly, identical amino acid substitutions in norrin can lead to the classic and severe form of ND, or other phenotypes like EVR or ROP. This suggests the contribution of additional factors, either genetic or environmental. Because of this variable expressivity of identical mutations, it is difficult to predict the clinical outcome of a particular familial mutation. NDP mutations are X-chromosomal recessive, and female mutation carriers are asymptomatic (with a very few exceptions due to skewed X chromosome inactivation). The disease recurrence risk for sons of female mutation carriers is 50%, and half of their daughters are unaffected mutation carriers.

## Diagnostic Principles

Differential diagnoses of Norrie disease comprise retinoblastoma, persistent hyperplastic primary vitreous (PHPV), ROP, EVR, Coats' disease, retinal dysplasia of Reese, and retinoschisis. In the vast majority of the cases, differential diagnosis is possible clinically or by a combination of clinical examinations and DNA analysis. Molecular genetic diagnostics of norrinopathies can be performed by DNA sequencing of the NDP gene in patients. Diagnostic testing is fast since the gene is rather small. Genetic testing revealed that mutations in the NDP gene are associated with ND, EVR, PHPV, and few cases of ROP.

## Therapeutic Principles

There is no causal treatment available currently but several symptoms of norrinopathies may be treated individually, which can save much vision. Symptomatic treatment may include laser photocoagulation and cryotherapy to destroy selected intraocular structures including abnormal blood vessels, vitrectomy for replacement of the vitreous with saline air or silicon oil, and retinal detachment surgery to reattach the retina to the back of the eye and sealing of tears or holes.

## 5′-Nucleotidase Hyperactivity

Maria Grazia Tozzi[1], Vanna Micheli[2]
[1]Department of Biology, University of Pisa, Pisa, Italy
[2]Department of Molecular Biology, University of Siena, Siena, Italy

### Synonyms

PU-NT hyperactivity; 5′-NT

### Definition and Characteristics

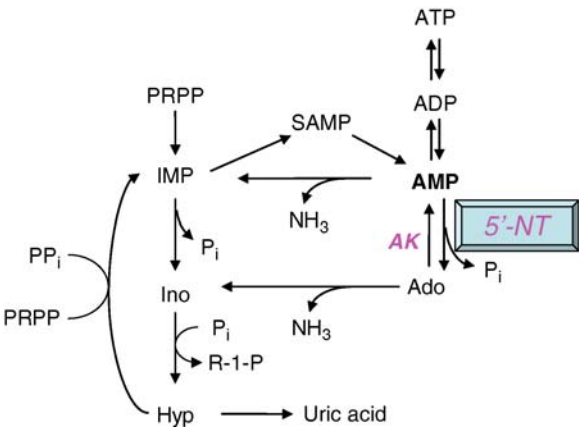
Developmental delay, seizure, ataxia, recurrent infections, severe language deficit, hyperactivity, short attention span, poor social interaction and decreased excretion of uric acid associated with an increased rate of AMP hydrolysis (Fig. 1).

### Prevalence

Extremely rare, four patients, two males and two females, were reported initially in the USA [1] and two more cases, one male from Australia and one female from Italy, have been described since [2]. All six patients have been of Caucasian origin. Hypouricuria can be mild and no other abnormality has been described in the blood or urine of any of the reported patients, thus rendering diagnosis and knowledge of the real prevalence of the disorder very difficult.

### Genes

The locus of the gene is unknown. No genetic studies have been performed as yet.



**5′-Nucleotidase Hyperactivity. Figure 1** Turnover and catabolism of purine nucleotides showing the role of 5′-Nucleotidase (5′-NT) in converting AMP to adenosine (Ado). Ado can be recycled via adenosine kinase (AK) to AMP or deaminated to inosine (Ino). AMP can also be regenerated via the single step salvage of hypoxanthine (Hyp) to IMP and thence AMP via succinyl adenosine monophosphate (SAMP). (Degradation of Hyp to uric acid occurs only in liver and intestinal mucosa in humans).

### Molecular and Systemic Pathophysiology

All patients show markedly delayed developmental milestones, especially language. All have had seizures, ataxia, an awkward gait and mildly impaired fine motor control. All patients also display an unusual behavioral phenotype that is characterized by extreme hyperactivity, distractibility, a strange "delirious" attitude and abnormal social interaction. All patients experience frequent ear and sinus infection, but there are no consistent reasons for immunodeficiency (reduced antibody titer or abnormal T cell response). It has been noted that during infection, behavioral, language and neurological abnormalities worsen. All patients excrete reduced quantities of uric acid [1]. The specific nucleotidase responsible for the disease has not yet been identified among the four existing forms now known, nor has any scientific evidence been produced to explain how molecular events following the enzyme hyperactivity cause both neurological and metabolic symptoms.

### Diagnostic Principles

Plasma/urine uric acid lower than age and sex matched controls. Hypouricuria can be mild and no other abnormality has been described in blood or urines of any of the reported patients, thus rendering biochemical analysis essential for diagnosis. Analysis of 5′-NT activity must be performed on a primary culture of fibroblasts. Very high rates of AMP hydrolysis in extracts from fibroblasts (from four to ten times higher

than controls), low uptake of uridine, low content of ATP, ADP and AMP and a low rate of purine "de novo" synthesis have been reported [1,2].

### Therapeutic Principles

Treatment with 1 g/kg uridine was demonstrated to improve behavior and speech ability. During therapy with uridine, seizure activity and ataxia decreased and improved performance on standardized tests of cognitive function was observed [1].

## Nummular Dermatitis

►Nummular Eczema

## Nummular Eczema

Alexander K. C. Leung[1],
William Lane M. Robson[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Childrens' Clinic, Calgary, AB, Canada

### Synonyms

Discoid eczema; Nummular dermatitis; Orbicular eczema

### Definition and Characteristics

Nummular eczema is characterized by coin-shaped eczematous plaques [1]. The initial lesions are uniform groups of papules and vesicles, which with time and itching, become inflamed and might weep [2]. The lesions enlarge by confluence or peripheral extension to form the discrete, round or oval, erythematous, scaly, lichenified, hyperkeratotic, and hyperpigmented plaques that are typical of chronic nummular eczema (Fig. 1) [1].

The lesions are usually symmetric [3]. The knees, elbows, and scalp are often spared [3]. In contrast to atopic dermatitis, the unaffected skin is not xerotic [3]. Itching is moderate to intense. The course is variable, but usually chronic, and characterized by relapses and remissions.

**Nummular Eczema. Figure 1** Coin-shaped lesions of nummular eczema on the posterior thighs.

### Prevalence

The reported prevalence varies widely from 0.1 to 9% [1]. The high rates in some studies might be due to the inclusion of patients with disseminated eczema. The condition is rare in the first year of life and thereafter the incidence increases with age [3]. The age at onset peaks between 15 and 25 years, and again between 55 and 65 years [3]. The condition is slightly more common in males than in females.

### Molecular and Systemic Pathophysiology

The exact pathogenesis has not been clarified. Neuropeptides substance P, calcitonin gene-related peptide, and mast cells are more frequent in the epidermis and papillary dermis. The increase in neuropeptides substance P and calcitonin gene-related peptide might stimulate keratinocytes to release cytokines, which enhance inflammation. Neurogenic stimulation is maintained by mast cells through activation of neuropeptides substance P and calcitonin gene-related peptide [4]. Bacteria might play a role, either directly or through a hypersensitivity mechanism. Nummular eczema is more frequent in persons with atopy and can develop after contact with nickel, chromate, fragrances, wool, soaps, rubber, or topical medications (neomycin and thioglycolate) [1]. Systemic medications such as isotretinoin, streptomycin, isoniazid, and methyldopa have also been implicated in the pathogenesis [5]. Nummular eczema is exacerbated by conditions that promote very dry or xerotic skin such as frequent bathing, low humidity, windy environments, and the winter season. Emotional stress can precipitate or exacerbate nummular eczema in a susceptible individual. Other predisposing factors include alcohol or tobacco consumption, trauma, venous stasis, and edema of the lower limbs. Histological findings in the acute stage include intercellular edema, intra-epidermal vesicles, and perivascular lymphocytic infiltration [1]. Chronic changes include hyperkeratosis, acanthosis,

an increase in the granular cell layer, and hyperplasia of the epidermis [1].

### Diagnostic Principles

Nummular eczema should be distinguished from tinea corporis, impetigo, psoriasis, granuloma annulare, and allergic contact dermatitis. Lack of central clearing helps distinguish lesions of nummular eczema from tinea corporis. Impetigo is characterized by a thick, golden-yellow "struck-on" crust. The scales in nummular eczema are thin and sparse, unlike the thick, silvery scales of psoriasis. Pinpoint bleeding after removal of the superficial scales (Auspitz sign), pitting of the nails, and arthropathy suggest psoriasis. Granuloma annulare is characterized by necrobiotic dermal papules, which often assume an annular configuration. In allergic contact dermatitis, the site, configuration, and chronicity of the skin lesions help differentiate the lesion from nummular eczema.

### Therapeutic Principles

Successful treatment requires avoidance of precipitating factors, optimal skin care, and pharmacotherapy. Hydration of the skin is important. Daily baths in lukewarm, but not hot water, for up to 5–10 min, followed by gently patting rather than rubbing the skin dry is helpful. A moisturizer or emollient should be applied within 3 min of bathing to minimize evaporative losses. Topical corticosteroids or immunomodulators result in prompt improvement.

# Obesity

Marc Slawik, Felix Beuschlein
Medical Clinic, Ludwig-Maximilians-University, Munich, Germany

## Synonyms

Adiposity

## Definition and Characteristics

Obesity as a clinical condition is currently defined as excess accumulation of body adipose tissue, resulting in a BMI greater than 30 kg/m$^2$ [1,2]. This definition is based on the fact that increased "body mass index" (BMI) is strongly associated with increased morbidity and mortality. The BMI, which is a measure of heaviness (weight in kg/height in m$^2$), correlates reasonably well with body fat content, when sex, age, and race are taken into account; the only exception are some athletes (e.g., body builders). Using direct measurements of body fat, young females with approximately more than 32% and males with more than 19% are considered to be obese.

## Prevalence

There has been a strong increase in obesity over the last 30–50 years, which is not restricted to populations with a "western" lifestyle. Presently, more than 300 million people are affected worldwide; an additional of 800 million people are overweight. The USA has the highest prevalence, and currently more than 34% of females and 28% of males are considered to be obese (1980: 17% and 12%, respectively) (see http://www.cdc.gov/nchs/hus.htm). There is also a dramatic increase in obesity in children with a prevalence of overweight schoolchildren of 24% in Europe (BMI > 90 percentile).

## Genes

When considering obesity, clearly heritability is not a fixed entity, as the proportion of the phenotype that can be explained by the genotype will be influenced by varying exposure to obesogenic environmental factors in different individuals and families. According to data obtained from twin studies, the estimated heritability of BMI ranges between 64 and 84% [1]. There are now several studies showing significant evidence of linkage (log odds ratio (LOD) scores greater than 2.5). The QLT (quantitative trait loci) includes leptin levels, BMI, and respiratory quotient (RQ). Some candidate genes linked with obesity are POMC, CART, PPARα, Glut2, and Glut4. In summary, the vast majority of obese people have a polygenetic susceptibility, which leads to weight gain in an obesogenic environment [3,4]. In association studies of common obesity, as of now, no single variant is widely accepted as unequivocally associated with an alteration in human adiposity. For a comprehensive list see the human obesity gene map (http://www.obesity.chaire.ulaval.ca/genemap.html).

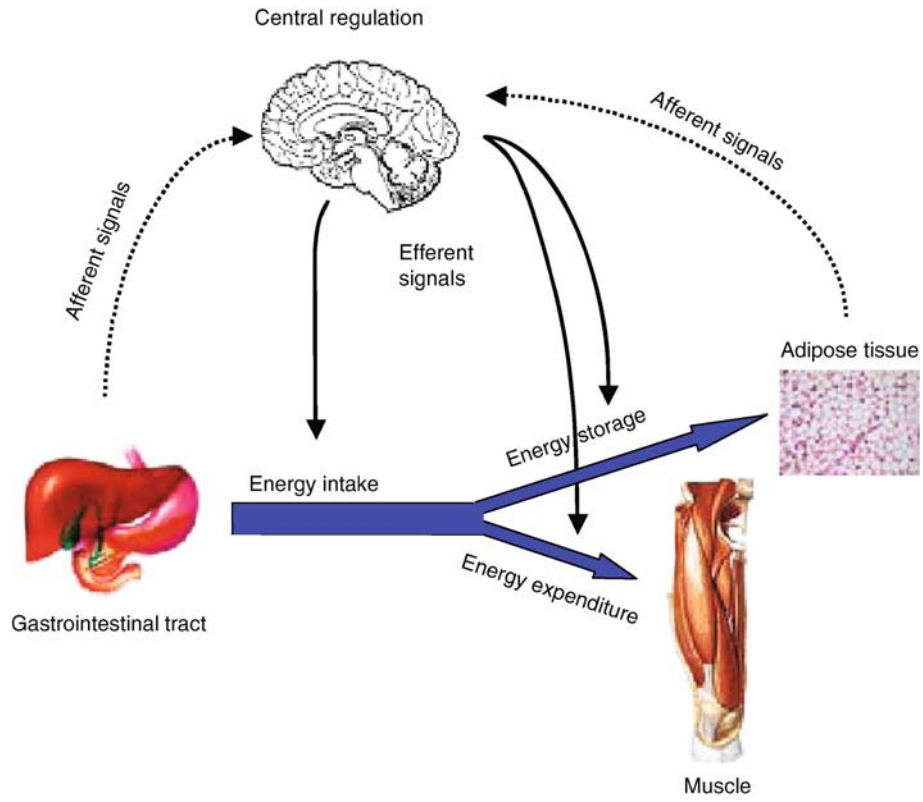
There are rare monogenetic syndromes of human obesity with a Mendelian pattern of inheritance (pleiotropic syndromes), and the recent decoding of the molecular mechanisms has yielded novel insights into potential mechanisms implicated in obesity (see www.endotext.org) [1].

## Molecular and Systemic Pathophysiology

From a thermodynamic perspective, the regulation of body weight can be described as a linear equation, balancing both food intake and energy expenditure to derive the amount of fat stored (Fig. 1).

Obesity is the result of sustained disequilibrium between energy intake and energy expenditure. Globally, energy homoeostasis should be considered as a complex, integrated system designed to prevent negative energy balance, as illustrated by the decrease of energy expenditure during fasting. The system counteracts further weight loss, but facilitates weight regain.

The availability of cheap, palatable food and "unhealthy eating habits" (eating out, fast food, soft drinks) are main factors contributing to increased energy intake. However, the overall calorie intake, and in particular the percentage of fat in the food has been constant or even decreased. Thus, the pandemic of obesity is mainly explained by reduced energy expenditure due to changes in "non-exercise physical activity" [2–4]. This includes substitution of domestic work and labor by machines, but also intensive use of cars, public transport, elevators, etc. Increased body weight due to fat leads to the metabolic



**Obesity. Figure 1** Regulation of energy homoeostasis.

syndrome followed by diabetes mellitus type 2 and cardiovascular diseases [3]. It is predicted that life span will fall for the first time since more than 100 years due to complications of obesity [3,4].

## Diagnostic Principles

Methods for direct measurement of body fat are time consuming and expensive (DEXA, double labeled water, CT). Thus, the BMI is the most common method used in clinical practice. On the BMI (kg/m$^2$) scale, people with an index <18.5 are underweight, between 18.5 and 24.9 normal weight, >25 but <30 are said to be overweight, and with an index ≥ 30 are defined obese (obesity class I: 30–34.9; II: 35–39.9; III: ≥ 40) [2,3]. However, this classification has limitations, e.g., not considering fat distribution and the particular increased risk due to central obesity. This is the reason why waist circumference (normal: females <80 cm, males <94 cm; obesity: females ≥88 cm, males ≥102 cm) and the waist to hip ratio (WHR) (normal: females <0.8, males <0.9; obesity: females ≥0.85 males ≥1.0) provide better predictive values for the metabolic syndrome and cardiovascular disease [2,3].

## Therapeutic Principles

Efforts to reverse increase in obesity by dietary or behavioral counselling have not been successful in general [5]. Only in extensive settings, involving medical doctors, nurses, psychologists, dietary advisors, and physiotherapist, a sustained weight loss could be achieved [3,5]. Therefore, the main aim has to be prevention of obesity by education on diet and on increasing daily physical activity (e.g., walking, cycling). Pharmacotherapy approaches have not been very successful regarding weight loss, although they reduce significantly the development of the metabolic syndrome [5]. The most efficient, but also most drastic, procedure to achieve weight loss are surgical interventions (e.g., gastric banding). This maneuver should only be considered for patients with a BMI above 35 kg/m$^2$, but improves obesity-associated co-morbidities and quality of life.

## Obesity Related Diabetes

►Metabolic Syndrome

## Obliterative Bronchiolitis

►Bronchiolitis Obliterans Syndrome

## Obsessive-compulsive Personality Disorder

Katrina Light, Roger Mulder
Department of Psychological Medicine, Christchurch School of Medicine and Health Sciences, University of Otago, Christchurch, New Zealand

### Synonyms

Anankastic personality disorder; OCPD

### Definition and Characteristics

Obsessive-compulsive personality disorder (OCPD) begins before age 18 and is evident as a preoccupation with orderliness, perfectionism and mental and interpersonal control, across a variety of contexts. Affected individuals are often uncomfortable taking time for leisure, unless they take work with them or the time is spent on a structured task. OCPD is characterized by rigid compliance with authority and rules, which are strictly applied to themselves and others. Patients find it difficult to acknowledge others' viewpoints and consider compromise; this often prevents them from delegating tasks to others and can cause them to redo tasks that are not completed exactly to their satisfaction. Patients with OCPD are often frugal but can end up with a cluttered home by storing up worthless or worn out objects that they cannot discard.

### Prevalence

Overall, 1–2% of individuals within community samples suffer from OCPD and the rate is slightly higher amongst individuals accessing mental health services (3–10%) [1].

### Genes

To date only two studies have been published that reported a genetic association with OCPD [2, 3]. Both studies, conducted within the same research group, found that a nonsynonymous polymorphism within the dopamine D3 gene (*DRD3*) is associated with the occurrence of OCPD. Individuals possessing the Gly/Gly genotype (at position 9 of the N-terminal extracellular domain of the receptor) had up to a three-fold increased risk for OCPD. Three independent samples of individuals were analyzed across these studies. A limitation of these studies is that all participants had a history of major depression. Therefore, these findings remain tentative. Based on the widespread use of selective serotonin reuptake inhibitors for OCPD, it has been hypothesized that serotonergic factors may be associated with OCPD, but as yet no findings have been reported.

### Molecular and Systemic Pathophysiology

There are no analyses that have directly examined the biological basis of OCPD, partly due to the difficulty of representing OCPD behaviors within an animal model. Some of the symptoms of OCPD, such as hoarding and perfectionism, also occur within obsessive-compulsive disorder (OCD) and eating disorders (ED), respectively. Investigations relating to these disorders have commonly suggested that modulation of the frontal-subcortical circuitry by serotonin neurons underlies obsessional traits, although no specific gene or biological pathway has been unequivocally implicated. Investigations into the pathophysiology of OCPD, OCD and ED are complicated by the multifactorial nature of the way in which the disorders arise and are expressed.

### Diagnostic Principles

The most widely accepted diagnostic criteria are those listed in DSM-IV [1]. The diagnosis of OCPD requires the presence of at least four of the following behaviors:

1. Is preoccupied with details, rules, lists, order, organization or schedules to the extent that the major point of the activity is lost.
2. Shows perfectionism that interferes with task completion.
3. Is excessively devoted to work and productivity to the exclusion of leisure activities and friendships (not accounted for by economic necessity).
4. Is over-conscientious, scrupulous and inflexible about matters of morality, ethics or values (not accounted for by cultural or religious identification).
5. Is unable to discard worn-out or worthless objects even when they have no sentimental value.
6. Is reluctant to delegate tasks or to work with others unless they submit to exactly his or her way of doing things.

7. Adopts a miserly spending style towards both self and others; money is viewed as something to be hoarded for future catastrophes.
8. Shows rigidity and stubbornness.

Such traits may be adaptive in certain situations, but are maladaptive and diagnosable when individuals incur ongoing significant functional impairment or distress. OCPD differs from OCD by the presence of obsessions and/or compulsions. The majority of individuals with OCPD (>70%) do not have an additional diagnosis of OCD [4].

### Therapeutic Principles

There are no evidence-based treatments for OCPD.

[2]Infection, Inflammation and Repair, University of Southampton School of Medicine, Southampton, UK
[3]Southampton General Hospital, University of Southampton, Southampton, UK

### Synonyms

COPD; Chronic obstructive airways disease; Chronic obstructive lung disease; COLD

### Definition and Characteristics

COPD represents a spectrum of disease, largely caused by tobacco smoking and ranging from a condition in which the airways are primarily affected, causing chronic bronchitis, to one in which destruction of the alveolar walls causes emphysema. These two features overlap to varying extents in COPD [1]. Bronchitis is inflammation of the bronchi, resulting in coughing, dypsnoea, wheezing and excessive mucus production. In emphysema, the tethering of the alveoli to the surrounding tissues is reduced, resulting in diminished elastic recoil and trapping of air. On forced exhalation, the alveolar walls may collapse, resulting in airflow limitation and impaired gas exchange. As emphysema progresses, there is a decline in lung function, leading to breathlessness. Reduced lung function may lead to pulmonary hypertension and cor pulmonale.

### Prevalence

Statistics from the NIH indicate that 13.5 million Americans may have COPD, and it is the fifth leading cause of death in the USA.

### Genes

A deficiency in the levels of the protease inhibitor $\alpha_1$-protease inhibitor ($\alpha_1$-PI) is known to cause emphysema in non-smokers, and much earlier disease in those who do smoke [1]. Some loss of lung function occurs in the majority of smokers, but the fact that only 15–20% develop symptomatic COPD suggests that individual susceptibility may vary. A number of different studies have examined the possible contribution to COPD of a variety of other genes such as $\alpha_1$-antichymotrypsin and xenobiotic metabolizing enzymes. However, the results of these studies have not always concurred and clear associations remain to be determined.

### Molecular and Systemic Pathophysiology

Cigarette smoking is the most important factor in causing COPD. Passive smoking and exposure to inhaled pollutants also increase the risk of COPD. Cigarettes contain large quantities of reactive oxygen species, and components of the smoke cause mucosal inflammation, with recruitment of macrophages, neutrophils and cytotoxic T lymphocytes. Chronic inflammation of the bronchi leads to peribronchiolar fibrosis and contraction of the scar tissue reduces airway caliber [2]. Inflammatory leukocytes generate proteases, which may degrade the extracellular matrix, leading to loss of structural integrity, and which, along with epidermal growth factor (EGF) receptor ligands, are highly potent stimulators of mucus generation. Mucous hypersecretion occurs and the clearance of mucus by ciliated cells is impaired, leading to occlusion of the

bronchioles, reducing lung function further. Deficiencies in the clearance of the mucus may lead to pulmonary infection, resulting in the generation of purulent sputum by severely affected patients. Animal studies support important roles for neutrophil elastase and matrix metalloproteinase 12 (MMP12), a product of macrophages, as well as deficiencies in antiproteases such as secretory leukoprotease inhibitor (SLPI), tissue inactivators of metalloproteases (TIMPs) and elafin (Fig. 1).

## Diagnostic Principles

Diagnosis is based on the symptoms experienced and the results of lung function tests. Symptoms may include coughing, wheezing, sputum production, breathlessness (especially upon exertion). Exercise tolerance, measured by 6-min walking distance, is reduced. Spirometry should demonstrate consistent reductions in lung function, the majority of which will be irreversible [3]. However, it may be possible to achieve some degree of improvement with treatment (see below). The extent and nature of emphysematous changes can be observed by computed tomography (CT) or magnetic resonance imaging (MRI).

## Therapeutic Principles

Some degree of bronchodilation may be achieved by reducing vagal cholinergic tone using antagonists of muscarinic cholinoceptors (tiotropium has a longer duration of action) or the use of $\beta_2$-adrenoceptor agonists acting directly on the bronchial smooth muscle to cause relaxation [1,4]. These different classes of bronchodilators may be used singly or in combination, with theophylline also providing benefit in some cases [5]. Muscarinic antagonists also reduce airway mucus secretion. Inhaled corticosteroids are able sometimes to improve lung function by reducing inflammation, and oral steroids, acting systemically may have a beneficial effect in the patient with advanced disease [1]. Intravenous aminophylline (theophylline ethylenediamine) may be indicated for the treatment of acute exacerbations although the precise mechanism of action is not known. Antibiotics should be given when infection is suspected, the type of which will depend on the nature of the infection.

## Synonyms

Ureteral obstruction; Urinary tract obstruction

## Definition and Characteristics

Obstruction to the flow of urine anywhere along the urinary tract that results in damage to the renal parenchyma.

## Prevalence

Unknown as the possible causes of obstructive uropathy are numerous.

## Molecular and Systemic Pathophysiology

Urinary tract obstruction (UUO) has deleterious effects on the kidney. Molecular and cellular changes that occur in UUO, including interstitial inflammation, tubulointerstitial fibrosis, and renal cell apoptosis, result in loss of renal mass and function.

The most notable growth factors and cytokines implicated in fibrosis and apoptosis include transforming growth factor-β1 (TGF-β1), angiotensin II (AT II), nuclear factor-κB (NF-κB), and tumor necrosis factor-α (TNF-α).

### Renal Fibrosis

In the obstructed kidney, extracellular matrix is synthesized and deposited more rapidly than it is degraded. Alterations in matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMP) result in collagen deposition and fibrosis. Interstitial fibroblasts proliferate increasing collagen synthesis, and infiltrating macrophages produce inflammatory cytokines and growth factors, including TGF, TNF, IL-1, IL-6, FGF, and PDGF, which further contribute to fibrosis.

*Transforming Growth Factor-β1*: Increased TGF-β1 and TGF-β1 receptor expression have been observed in renal obstruction models. TGF-β1 stimulates fibroblast proliferation and production of collagen types I, III, and IV while inhibiting collagenase. TGF-β1 also stimulates plasminogen activator inhibitor-1 production inhibiting fibrinolysis, decreases the activity of degradative MMPs, and stimulates the production of matrix protein receptors.

*Angiotensin II*: AT II's production rises rapidly following UUO and has been linked to alterations in renal hemodynamics, fibrosis, and apoptosis. Additionally, an increase in renal AT II may upregulate the expression of other cytokines and transcription factors involved in fibrosis including TGF-β1, TNF-α, and NF-κB.

*NF-κB*: NF-κB is an inducible transcription factor activated by obstruction and is elevated in renal cortical tissue after 5–7 days of UUO. Activation correlates with increases in tubular and interstitial proliferation and fibrosis. NF-κB appears to be an important upstream regulator of AT II expression and a transcription factor for a number of cytokines, including TNF-α.

*TNF-α*: TNF-α is a pro-inflammatory cytokine implicated in UUO. Macrophages are a major source of TNF-α and infiltrate the obstructed kidney as little as 4 h after the onset of obstruction.

### Apoptotic Renal Cell Death

Apoptosis is the major mechanism by which renal tubular cell death and a reduction in renal mass occurs following UUO. Renal tubular and interstitial cells are most susceptible to apoptosis during UUO.

*Growth Factors*: In addition to its profibrotic effects, TGF-β1also stimulates renal tubular cell apoptosis during UUO.

*Angiotensin II*: The role of angiotensin II in obstruction-induced apoptotic renal cell death remains controversial and requires further investigation.

*Nuclear Factor κB*: NF-κB has been shown to have both pro and anti-apoptotic properties, however its role in obstruction-induced renal cell apoptosis is unclear.

*TNF-α*: TNF-α is a directly cytotoxic cytokine that can induce apoptosis in many cells, including renal tubular cells. An increase in the expression of both TNF-α mRNA and TNFR1 has been well documented in rat models of renal obstruction. While TNF-α activity has not been directly linked to obstruction-induced apoptosis, these studies as well as the known cytotoxic properties of TNF-α suggest an important role for TNF-α in obstruction-induced renal tubular cell apoptosis.

## Diagnostic Principles

The clinical signs of urinary tract obstruction vary and are often nonspecific. The patient rarely has a palpable abdominal mass or signs of volume overload including hypertension or edema. Hematuria, proteinuria, crystalluria, pyuria, and urinary casts may be found on urinalysis. With continued obstruction, an elevated urinary sodium concentration, a decreased urine osmolality, and a decreased urine-to-plasma creatinine ratio may be noted. Elevated serum blood urea nitrogen (BUN) and creatinine levels, hyperkalemia, and acidosis may be evident on serum chemistry studies.

Numerous imaging techniques are available to detect the obstruction of urine flow. Distension of the urinary tract (hydronephrosis, hydroureter, or a distended bladder) may be identified on ultrasonography, CT scan, MRI, excretory urography, and diuretic renography. Occasionally, a Whitaker test may be employed. Ultrasonography with duplex doppler and renal-resistive indices may also demonstrate obstruction.

## Therapeutic Principles

*Pharmacological Therapy*: Available for obstructive uropathy secondary to prostatic hyperplasia (alpha adrenergic antagonists; 5-alpha redutcase inhibitors).

*Other Treatments*: Surgical therapies are available for obstruction at the level at the ureteropelvic junction (pyeloplasty, endoscopic incision, pyelotomy); vesicoureteral junction (ureteral reimplantation, ureterostomy); bladder outlet (prostatectomy). Temporary drainage may

be achieved using ureteral or urethral stents and percutaneous nephrostomy.

### Synonyms

OPMD

### Definition and Characteristics

Late-onset autosomal dominant muscle disorder characterized by progressive ptosis, dysphagia and proximal limb weakness. The pathologic hallmark of the disease is the accumulation of unique 8.5 nm tubulofilamentous inclusions within skeletal muscle fiber nuclei demonstrated by electron microscopy [1].

### Prevalence

OPMD has a worldwide distribution with a higher prevalence in the French-Canadian and Bukhara Jewish populations. It is usually inherited as an autosomal dominant trait with complete penetrance and no sexual preference.

### Genes

PABPN1 coding for the poly (A) binding protein nuclear 1 (PABPN1, PABP2, PAB II) localized on chromosome 14q11.1 [2].

### Molecular and Systemic Pathophysiology

PABPN1 is an abundant nuclear protein binding with high affinity to the poly(A) tail of mRNA and involved in mRNA polyadenylation that has been identified as a component of the muscle intranuclear inclusions of OPMD [3]. The normal PABPN1 gene has, at its 5′ end, a $(GCG)_6$ trinucleotide repeat followed by a $(GCA)_3GCG$ coding for a 10-alanine stretch. In OPMD

patients this $(GCG)_6$ repeat is expanded to $(GCG)_{8–13}$ resulting in an elongation of the length of the polyalanine tract to 12–17 alanines at the N-terminus of the mutated protein (mPABPN1). mPABPN1 induces intranuclear protein aggregation, formation of the intranuclear inclusions and cellular toxicity by sequestering mRNA and interfering with mRNA export from the nucleus to the cytoplasm [4]. Because in other polyalanine-diseases the pathological expansions require at least 22 alanines while in OPMD a 12-alanine stretch in the PABPN1 gene induces protein aggregation and a clinical phenotype, oligomerization of mPABPN1 which is mediated by other parts of the protein seems critical for pathogenesis in addition to the expanded polyalanine stretch. Normal PABPN1 when bound to poly (A) and even in absence of mRNA tends to oligomerize in vitro and two potential oligomerization domains are located far from the N-terminus. Expansion of the polyalanine stretch in mPABPN1 acts as a gain of function mutation causing misfolding of the protein, which exposes hydrophobic regions normally not exposed. These become able to perform weak self-association, while oligomerization of mPABPN1 increases the formation of protein aggregation by linking together mPABPN1 molecules. Inactivation of mPABPN1 oligomerization has been shown to reduce cell death by preventing abnormal protein aggregation in a cellular model of the disease suggesting a potential therapeutic approach [4]. Possible molecular mechanisms causing the short meiotically stable expansions in the PABPN1 gene are related to replication of DNA (from slipped mispairing between repeated sequences according to the slippage model) or, alternatively, to recombination (from unequal crossing-over of the two alleles), the latter being more likely as it also explains the reported mutant PABPN1 alleles caused by insertions or duplications in Cajun, Japanese and Dutch patients [5]. The reason why, in spite of ubiquitous expression of PABPN1, the clinical and pathological phenotypes are restricted to skeletal muscle and particularly to the levator palpebrae superioris and pharyngeal muscles is unknown.

## Diagnostic Principles

Progressive dysphagia, ptosis and proximal limb weakness presenting in the fifth or sixth decade suggest the diagnosis of OPMD. A positive family history may reveal the genetic origin and indicate autosomal dominant transmission (rarely an autosomal recessive form of OPMD is caused by a double dose of the polymorphic $(GCG)_7$ PABPN1 allele). Muscle biopsy shows myopathic changes, often with a few muscle fibers containing "rimmed vacuoles" and more rarely also the presence of small angulated muscle fibers and mitochondrial abnormalities. Electron microscopy reveals the typical 8.5 nm diameter intranuclear inclusions in skeletal muscle fibers. Molecular analysis demonstrates PABPN1 gene mutations and confirms the diagnosis of OPMD.

## Therapeutics Principles

Surgical correction of the ptosis when the visual axis is obscured and cricopharyngeal myotomy or percutaneous gastrostomy for severe dysphagia are the only therapies currently available.

# Odynophagia

Thomas Frieling
Medical Clinic II, Helios Klinikum Krefeld, Krefeld, Germany

## Definition and Characteristics

Odynophagia is a cardinal symptom that indicates esophageal disease. It can be due to a variety of implying disorders. Odynophagia usually occurs during the transit of the bolus and disappears once the swallowed material has left the esophagus. It can be of such intensity that the patient refuses to swallow any solids or liquids and expectorates saliva. On the other hand, odynophagia may be mild in intensity, so that the patient is merely aware of the location of the swallowed bolus. Odynophagia can be due to involvement of the mucosa by reflux, radiation, viral or fungal infection, or can be a manifestation of carcinoma, Schatzki ring and webs, or of a localized ulcer caused by a lodged tablet. Odynophagia may be overlap in patients presenting with functional esophageal disorders that were categorized according to the Rome III Consensus Conference as functional heartburn, functional chest

pain of presumed esophageal origin, functional dysphagia, and globus [1].

## Prevalence

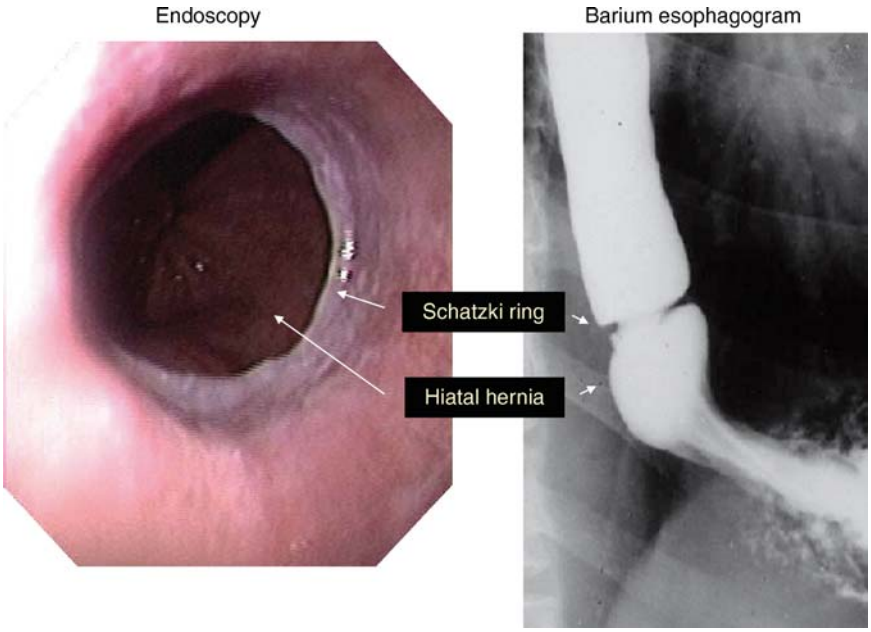
Epidemiological data on odynophagia are not available yet. However, 20–40% of subjects in Western populations claim to suffer from heartburn, of whom a minority seek medical attention. Similarly, the prevalence of functional chest pain of presumed esophageal origin is not known precisely but may occur in up to 15–30% of chest pain patients who show normal coronary angiograms.

## Molecular and Systemic Pathophysiology

Odynophagia may be caused by disturbances of esophageal bolus transit leading to esophageal wall distension and stimulation of sensory afferents mediating pain. Esophageal contractions of elevated amplitudes that try to overcome the obstruction may lead to increased esophageal wall tension and the development of pain. In addition, inflammation of the mucosa by reflux, radiation, viral or fungal infection may sensitize sensory afferents by release of inflammatory mediators. ►Gastroesophageal reflux disease (GERD) is by far the most common cause of noncardiac chest pain. Other gastrointestinal-related etiologic factors that have been proposed include esophageal motility disorders, abnormal mechanophysical properties of the esophagus, sustained esophageal muscle contractions, visceral hypersensitivity, altered central processing of intraesophageal stimuli, autonomic dysregulation, and psychological comorbidity (panic attack, anxiety, depression) [2].

## Diagnostic Principles

It is crucial to perform careful patient history and to rule out carcinoma by endoscopy. Key elements of the history for patients with odynophagia are the differentiation of the bolus consistency (solid foods, liquids, or both) that may initiate odynophagia, the location where the patient perceives pain, the characterization of accompanying symptoms (oropharyngeal dysfunction, intermittent or progressive dysphagia, history of chronic heartburn, intake of medications likely to cause pill esophagitis, history of collagen-vascular disease, immunosuppression) [3]. Diagnostic principles include the search for structural disorders by endoscopy (with biopsy) and barium esophagogram (with videofluorosocopy, if possible). Endoscopy as a gold standard is more sensitive than radiology for identification of subtle mucosal lesions of the esophagus. In contrast, barium contrast examination appears to be more sensitive than endoscopy for the detection of diverticula and of subtle narrowings of the esophagus such as those caused by rings (Fig. 1) and by peptic strictures. Vasalva maneuver or swallow a solid bolus may increase the sensitivity of the radiographic evaluation.



**Odynophagia. Figure 1** Endoscopy (*left*) and barium esophagogram (*right*) illustrating Schatzki ring at the level of the lower esophageal sphincter.

Furthermore, fluoroscopic examination can identify abnormalities in esophageal motility. Esophageal manometry is the gold standard test for esophageal motility disorders. Esophageal manometry has been shown to be especially useful for establishment of diagnoses of achalasia and diffuse esophageal spasm and for detection of esophageal motor abnormalities associated with collagen-vascular diseases. Combined multichannel intraluminal impedance and manometry may add information on bolus transit. Due to the introduction of the proton pump inhibitors (PPI) test or the PPI empirical therapy, the role of the 24-h esophageal pH testing has evolved during the last decade. However, 24-h esophageal pH testing may be helpful in patients who failed PPI therapy.

## Therapeutic Principles

Treatment of odynophagia should be directed to the underlying mechanisms. This includes the surgical and/or medical treatment of carcinoma, dilation of esophageal stenoses and rings by bougienage or balloon distension, and the placement of esophageal stents in malignant stenoses. Patients with GERD-related odynophagia should be treated with at least the double-dose PPI until symptoms remit. A substantial increase in stricture diameter may be achieved with chronic, aggressive acid suppression that decreases the need for subsequent esophageal dilations. Laparoscopic antireflux surgery with improvement of gastroesophageal barrier function is the causative treatment for GERD and may improve odynophagia. Consequent acid suppression may also be helpful in odynophagia due to inflammation of the mucosa by radiation, viral or fungal infection. In addition, viral or fungal infections should receive specific medical therapy. In patients with specific esophageal motility disorders such as diffuse esophageal spasm (DES), smooth muscle relaxants such as nitrates, calcium-channel blockers, phosphdiesterase inhibitors, or peppermint oil, injection of botulinum toxin at several levels in the esophagus, esophageal dilation of lower esophageal sphincter (LES), or long surgical esophageal myotomy may be helpful. In patients with achalasia, pneumatic dilation of LES and surgical cardiomyotomy are treatments of choice. An alternative therapeutic principle is to modulate sensory perception by application of visceral analgetics (tricyclic antidepressants, serotonin reuptake inhibitors).

# Oesophageal Atresia

Alexander K. C. Leung[1], Andrew L. Wong[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Department of Surgery, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Infants with esophageal atresia usually present with excessive salivation at birth. Choking, coughing, and cyanosis may occur with an attempt at feeding [1]. A history of maternal polyhydramnios and prematurity is common. Esophageal atresia with a distal tracheo-esophageal fistula accounts for more than 85% of all cases. Four other variations seen include esophageal atresia without a tracheo-esophageal fistula, "H-type" tracheo-esophageal fistula, esophageal atresia with both proximal and distal tracheo-esophageal fistulas, and esophageal atresia with proximal tracheo-esophageal fistula [1]. Associated anomalies include VACTERL association (*v*ertebral, *a*norectal, *c*ardiac, *t*racheo-esophageal, *r*adial, *r*enal, and *l*imb abnormalities), CHARGE association (*c*oloboma, *h*eart defects, *a*tresia choanne, *r*etarded growth and development, *g*enital hypoplasia, and *e*ar deformities), hypospadias, undescended testis, and duodenal atresia [2]. Trisomy 18 and 21 occur more commonly in patients with esophageal atresia than in the general population.

## Prevalence

Esophageal atresia occurs in 1 of every 2,000 to 5,000 live births [3]. The majority of cases are sporadic and non-syndromic.

## Genes

Sonic hedgehog (Shh) is the candidate gene.

## Molecular and Systemic Pathophysiology

Presumably, esophageal atresia results from abnormal partitioning of the foregut into the esophagus and trachea and inadequate recanalization of the esophageal lumen. Such process is associated with a precise temporospatial pattern of expression of Shh which encodes for an intracellular signaling molecule [2]. Loss-of-function mutations of Shh and other members of its signaling pathway (Gli2, Gli3, and Foxfi) lead to esophageal atresia and intrinsic defects in the esophagus and trachea [4]. In esophageal atresia, the peristalsis of the esophagus is always affected even after surgical repair and there is an absolute deficiency of tracheal cartilage and an increase in the length of the transverse muscle in the

posterior tracheal wall [5]. The pathogenesis is likely multifactorial and involves multiple genes and complex gene-environment interactions.

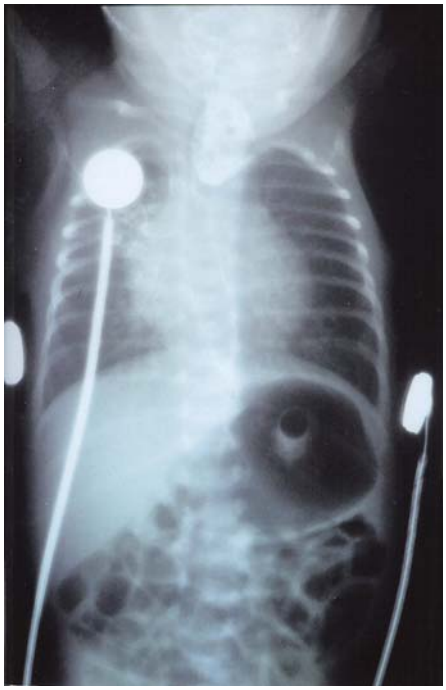
## Diagnostic Principles

The inability to pass a nasogastric tube into the stomach confirms the clinical diagnosis [1]. A plain radiograph of the chest shows the tip of the catheter in the blind proximal pouch. The presence of air in the stomach suggests a coexisting distal tracheo-esophageal fistula. Rarely, 0.5–1 ml of diluted barium can be used as a contrast to delineate the upper pouch (Fig. 1).

The H-type tracheo-esophageal fistula is best identified by the instillation of a water-soluble contrast medium through the tip of a nasogastric tube with moderate pressure to distend the esophagus while the tube is slowly withdrawn from the stomach into the esophagus. This tends to force the fistula open and allows visualization. The tracheal orifice of the fistula may be detectable by bronchoscopy.

## Therapeutic Principles

Esophageal atresia is a surgical emergency. Pre-operatively, aspiration can be prevented by keeping the infant's head elevated at a 30° angle and by repeated suctioning of the upper esophageal pouch [1]. Under no circumstances should the infant be fed. Broad spectrum antibiotics should be started. Treatment consists of division and repair of the tracheo-esophageal fistula and end-to-end anastomosis between the proximal and distal esophagus [1]. In high risk cases, the surgery is usually performed in stages. The first stage usually consists of surgical division and repair of the tracheo-esophageal fistula followed by anastomosis of the esophageal remnants at a later date. If the esophagus cannot be used, esophageal substitution by a gastric tube, jejunum or colon may have to be performed.



**Oesophageal Atresia. Figure 1** A newborn infant with esophageal atresia. The upper esophageal pouch is outlined by 1 ml of diluted barium.

# OFG

►Orofacial Granulomatosis

# Ogilvie's Syndrome

Marcus Schmitt
Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

Acute colonic pseudo-obstruction; ACPO; Colonic pseudoobstruction; Nontoxic megacolon; Intestinal pseudo-obstruction; Acute intestinal pseudo-obstruction

## Definition and Characteristics

Acute intestinal (colonic) pseudo-obstruction with dilatation and obstipation of the colon and/or the cecum. It is characterized by signs of large bowel obstruction without a mechanical cause [1].

"Intestinal pseudo-obstruction" indicates a syndrome characterized by a clinical finding suggestive of mechanical obstruction in the absence of any demonstrable evidence of such an obstruction in the intestine. Based on clinical presentation, pseudo-obstruction syndromes can be divided into acute (Ogilvie's syndrome/acute intestinal pseudo-obstruction) and chronic forms.

If inappropriately managed, it may result in ischemic necrosis and colonic perforation, with a mortality rate as high as 50%.

The mean age of patients with acute colonic pseudo-obstruction appears to be increasing: reviewed 400 cases of colonic pseudo-obstruction occurring between 1970 and1985 documented the mean age of patients to be 56.5 years for females and 59.9 years for males. Most recent reports now indicate the mean age to be in the seventh and eighth decades of life. Unlike age, the male-to-female ratio (1.5–4:1) has apparently remained constant over the years.

## Prevalence

This condition usually develops in hospitalized patients and is associated with a range of medical and surgical conditions.

The prevalence of acute colonic pseudo-obstruction is about 0.29%. The incidence is likely about 0.65–1.3%. Moreover any exact data are missing because of the possibility of spontaneous resolution.

## Molecular and Systemic Pathophysiology

Since Ogilvie's original description of the syndrome [1], the exact pathophysiology remains unknown. Autonomic nerve dysregulation may be due to acute colonoc pseodo-obstruction:

Colonic motility is under autonomic regulation, being increased by parasympathetic and inhibited by sympathetic nervous system. Several conditions e.g. drug therapy, surgery, traumata can alter the balance between these two systems leading to excessive parasympathetic suppression, sympathetic stimulation or both. This imbalance results in extreme suppression of colonic motility leading to colonic atony or pseudo-obstruction [2].

This imbalance in the autonomic innervations (sympathetic over activity and parasympathetic suppression) has been thought to be the pathophysiological factor in the causation of Ogilvie syndrome. One hypothesis relies on the fact that increased sympathetic tone to the colon results in the inhibition of colonic motility. This is supported by reports about using epidural anesthesia to block the splanchnic sympathetics as a successful therapy for Ogilvie syndrome. Etiological predisposing factors include trauma, surgery, drugs (narcotic analgesics, antidepressants, antipsychotic, calcium channel blockers, narcoleptics) and infections. Furthermore the imbalance of electrolytes, after surgery and traumata, coincident with metabolic diseases may be a predisposing condition.

Nevertheless several genetic disorders were identyfied leading to recurrent or chronic intestinal pseudo-obstruction. Among a variety of disorders forms of MNGIE (*M*yopathy and external ophthalmoplegia; *N*europathy; *G*astro-*I*ntestinal; *E*ncephalopathy) should be mentioned: 100% of these patients have a visceral neuropathy due to affected Thymidine phosphorylase. *Genetic Characterisitic:* Chromosome 22q13.32-qter; recessive. Most common are missense mutations furthermore insertions, deletions or splice acceptor change in intron occur.

## Diagnostic Principles

Diagnosis is based on physical examination and radiology, either as abdominal X-ray (sign: distension of the cecum 10–14 cm in diameter) or CT-scan.

Clinical signs impress like an ileus of the right colonic frame: abdominal distension, tympanic percussion, abnormal bowel sounds (e.g. high-pitched, hyperactive, hypoactive) and /or abdominal pain and nausea and vomiting.

Laboratory investigations are of little diagnostic value.

## Therapeutic Principles

*General Therapeutic Recommendations*: Correction of water and electrolyte hemostasis, cessation of predisposing drug therapies.

*Drug Therapy*: First choice is the treatment of Ogilive syndrome with parenteral neostigmine (in doses of 1–2 mg intravenously over a period of 3–5 min and to be repeated once if required in 2–3 h).

One randomized case controlled trial established efficacy and the relative superiority of neostigmine over other promotility agents (e.g., cisapride and erythromycin) [3]. Neostigmine reversibly inhibits acetyl cholinesterase and thus potentiates the activity of acetylcholine, resulting in increase in colonic motility (a parasympathomimetic effect) [4].

*Colonoscopy/endoscopic Decompression*: Colonoscopic decompression for acute colonic pseudo-obstruction was first described in 1977 and colonoscopic decompression has been documented to be a safe and effective method of treatment: success rates for decompressive colonoscopy range from 77 to 86%, morbidity rates range from 0.2 to 2%.

Success rates can be improved by placement of long-indwelling decompression tubes. Adequate decompression may be obtained by reaching the transverse colon, though successful decompression is more likely reaching the ascending colon.

*Surgery*: Surgery is indicated when a failure of conservative medical management and colonoscopy/endoscopic decompression occurs or when clinical signs of ischemia, abdominal sepsis, or perforation are present.

The choice of procedure is then dictated by the status of the cecum. The cecum must be resected if perforation, necrosis or ischemia is evident. The remaining large bowel must be inspected to exclude any remaining areas of ischemia, necrosis, or perforation.

# OHDS

►Orthostatic Hypotensive Disorder, Familial, Streeten Type

# OHS

►Cutis Laxa

# Okihiro Syndrome

Jürgen Kohlhase
Center for Human Genetics, Freiburg, Germany

## Synonyms

Duane-radial ray syndrome; DRRS; Acro-renal-ocular syndrome; AROS

## Definition and Characteristics

Okihiro syndrome/DRRS is characterized by uni- or bilateral Duane anomaly and radial ray malformations. The radial limb anomalies can include thenar hypoplasia and/or hypoplasia or aplasia of the thumbs; hypoplasia or aplasia of the radii; shortening and radial deviation of the forearms; triphalangeal thumbs; and duplication of the thumb (preaxial polydactyly). AROS is characterized by radial ray malformations, renal abnormalities (mild malrotation, ectopia, horseshoe kidney, renal hypoplasia, renal agenesis, vesico-utereral reflux, bladder diverticula), ocular coloboma, and Duane anomaly. Identical SALL4 mutations were found in both AROS and Okihiro syndrome patients, and clinical overlap is extensive. Additional clinical features include sensorineural and/or conductive deafness, abnormal pinnae, slit-like opening of auditory canals, and small ears. The eyes may exhibit microphthalmia (rare), iris, retinal, and chorioidal colobomata, cataract, and optic disc hypoplasia. At the upper extremities concomitant shortening of ulnae, syndactyly, radial clubhand, shortened humeri, and hypoplasia of deltoid muscles may be observed. Heart defects are common, mostly atrial and ventricular septal defects, and rarely tetralogy of Fallot. Anal stenosis and imperforate anus can occur. Dysmorphic features can include epicanthic folds, ocular hypertelorism, flat nasal bridge, and hemifacial microsomia. At the lower extremities talipes, clubfoot, tibial hemimelia, and syndactyly of toes can be present. Fused vertebrae, growth hormone deficiency, postnatal growth retardation, and pituitary hypoplasia are further features. Developmental delay or mental retardation is not associated with SALL4 defects, but may occur in patients with multigene deletions including SALL4 [1].

## Prevalence

The prevalence is unknown, partly due to the fact that Okihiro syndrome has not been differentiated from Holt-Oram syndrome in many countries. It is unlikely to occur with a frequency higher than one in 200,000 births (author's estimate based on referrals for SALL4 testing in Germany from 2002–2007).

## Genes

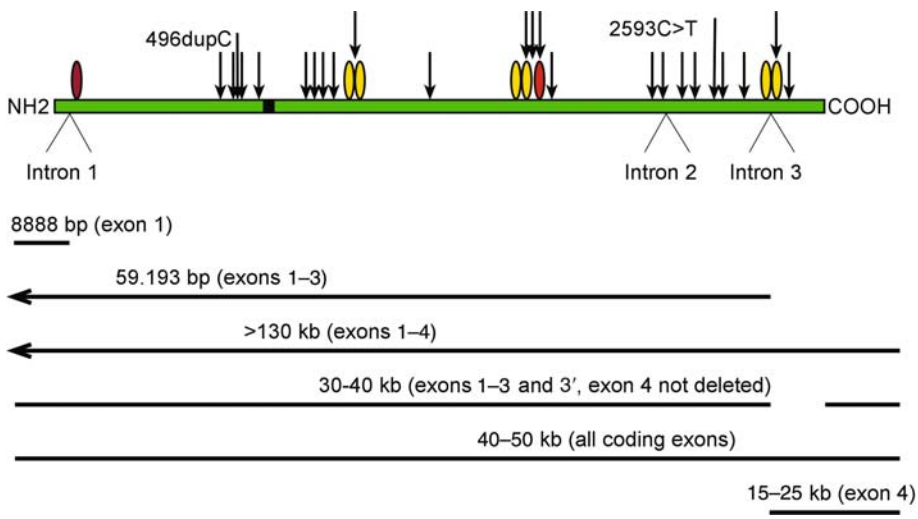
Okihiro syndrome is caused by mutations in the gene SALL4 on chromosome 20q13.13-13.2 [2]. The SALL4 protein is a member of the SAL-like family of zinc finger transcription factors sharing similarity with the Drosophila melanogaster protein SAL (Spalt). About 80–85% of patients with typical Okihiro syndrome carry point mutations in SALL4, and 5–10% have larger deletions including single exon deletions as well as deletions of the whole gene not detectable by sequencing. 13% of patients with reported SALL4 mutations show the triad of Duane anomaly, radial ray malformation, and sensorineural hearing loss characteristic for Okihiro syndrome, 45% have radial defects and Duane anomaly, and 21% have only radial defects. In 82.6% of families, at least one person has Duane anomaly and in 48%, at least one person has hearing loss. Radial ray malformations have been found in all families with SALL4 mutations and in 91.3% of individuals with a mutation. Sixty-five percent of individuals with a mutation have Duane anomaly and 16% have hearing loss of any kind. Reduced penetrance has been described in one family without molecular confirmation and in one family with known SALL4 mutation, but this seems to be a rather rare event.

## Molecular and Systemic Pathophysiology

The SALL4 coding region extends over 18 kb (start codon to stop codon). The gene contains four exons and three introns. All but two mutations are truncating and distributed over exons 2 and 3 of the gene [3]. One missense mutation has been found in exon 3, and one truncating mutation at the border of intron 3 and exon 4 (Fig. 1). It is likely that all but two truncating mutations result in nonsense-mediated messenger decay and therefore haploinsufficiency of SALL4, since larger deletions are not causing significantly different phenotypes. All but two known mutations are private mutations with two exceptions. The recurrent mutation c.2593C> T caused a mild phenotype in one family and a severe phenotype in another family. Six deletions were found in families with DRRS/Okihiro syndrome or acro-renal-ocular syndrome and four multigene deletions were found in patients with Okihiro syndrome plus developmental delay. Single exon deletions of exon 1 and 4, respectively, have been observed in more than two cases each. The detection of lager deletions confirmed that SALL4 haploinsufficiency is the pathogenic mechanism leading to the phenotype. Some mutations lead to slightly different phenotypes. The mutations p.Q905X and c.2607delA in exon 3 are both expected to escape nonsense-mediated mRNA decay and to result in truncated proteins with one non-functional zinc finger domain. Another mutation in exon 3, H888R, exchanges one of the essential amino acids for zinc coordination in a zinc finger and is predicted to result in an increased DNA binding of the respective zinc finger.

Sall4 appears to be an essential developmental regulator. In the mouse, Sall4 is essential for the development of the epiblast and primitive endoderm from the inner embryonic cell mass [4]. No embryonic or extraembryonic endoderm stem cell lines can be established if Sall4 is missing. Sall4 interacts with Nanog and co-occupies Nanog genomic sites in embryonic stem cells. Sall4 cooperates with Sall1 in anorectal, heart, brain and kidney development. Together with TBX5, SALL4 is required for patterning and morphogenesis of the first digit of the upper limbs, with Sall4 being regulated by Tbx5 in mouse and zebrafish [5] models and acting together with Tbx5 on Fgf signaling, shown only in the mouse. In the heart, Sall4 and Tbx5 act synergistically on the Gja5 promotor, but antagonistically on the NPPA gene. Nothing is known yet about the function of SALL4 in brain, especially brainstem development. Heterozygous Sall4 knockout mice, however, exhibit exencephaly with reduced penetrance. Otherwise, they show anal stenosis and ventricular septal defects, but do not mimic completely the phenotype of human Okihiro syndrome. No limb malformations or anomalies of the abducens nuclei in the brain stem were observed.

SALL4 is a target of WNT signaling, being directly activated by TCF/LEF in the canonical Wnt pathway. SALL4 interacts with Cyclin D1, which might explain



**Okihiro Syndrome. Figure 1** Schematic representation of the SALL4 protein and localization of the mutations and deletions identified to date. Zinc fingers are indicated as oval symbols. SALL4 encodes three C2H2 double zinc finger domains distributed over the protein. A single C2H2 domain is attached to the second double zinc finger. At the aminoterminus, a single C2HC domain is found. Horizontal bars indicate the positions of bigger deletions with respect to the coding exons. The interrupted bar indicates that this deletion spares exon 4 but continues farther 30. Note that the mutations c.496 dupC and c.2593C> T have each been found in three unrelated families each. Deletions of exon 1 have been detected in two and of exon 4 in three independent families respectively. All other mutations have been found only once. Positions of the introns are indicated. Numbers refer to the amino acid sequence (1053 aa). The four larger multigene deletions including SALL4 [1] are not indicated.

why Sall4 null embryonic stem cells have an inefficient G1/s phase progression and Sall4 null mutant embryos show a proliferation defect. Overexpression of SALL4 in mice leads to myelodysplastic syndrome (MDS)-like symptoms and eventually to the development of acute myeloid leukemia (AML). This is reflected by the direct regulation of Bmi-1, a marker for disease progression from MDS to AML, by SALL4.

## Diagnostic Principles

Okihiro syndrome can be clinically diagnosed by the presence of Duane anomaly and radial ray defects of the upper limbs. However, only 58% of patients with SALL4 mutations have radial defects and Duane anomaly. Therefore, clinical diagnosis can be challenging. The clinical diagnosis is confirmed by detection of a SALL4 mutation or deletion by direct sequencing or deletion testing. In unclear cases, especially if a Duane anomaly is not present, the main differential diagnosis is Holt-Oram syndrome, characterized by radial upper limb malformations, congenital heart malformations, and cardiac conduction defects. Holt-Oram syndrome is (in about 74% of cases) caused by mutations in the gene TBX5. Cardiac conduction defects have been observed less commonly with SALL4 mutations as compared to TBX5 mutations. Presence of a renal or urogenital malformation (especially position anomalies of the kidneys), but without Duane anomaly, as well as other features not seen in Holt-Oram syndrome will point towards an underlying SALL4 defect. Townes-Brocks syndrome (TBS) is another differential diagnosis characterized by a triad of dysplastic ears, imperforate anus, and triphalangeal thumbs/preaxial polydactyly. Duane anomaly can also occur in TBS, but the radius is not shortened in Townes-Brock syndrome caused by mutations in SALL1. Individuals with radial ray malformations may also have Fanconi anemia. Additional features in Fanconi anemia include other skeletal anomalies, heart defects, urogenital- and renal anomalies, hypogonadism, ear anomalies, hearing loss, eye anomalies, imperforate anus, growth retardation, pigmentation anomalies and developmental delay. Fanconi anemia often involves anomalies of the blood cell count and progressive bone marrow failure with pancytopenia, and confers a significant risk for leukemia and solid tumors. Developmental delay is not a feature of Okihiro syndrome but occurs with multigene deletions including the SALL4 gene, and Duane anomaly is not a feature of Fanconi anemia.

Individuals with Thrombocytopenia-absent radius (TAR) syndrome have radial aplasia, but in contrast to SALL4-related disorders, the thumbs are never absent, although they may appear malformed. Thromobocytopenia does not typically occur in Okihiro syndrome. TAR syndrome is caused by a 1q21.1 microdeletion in the presence of a yet unknown modifier. Other rare diffential diagnoses include Arthrogryposis-ophthalmoplegia syndrome with Duane anomaly, deafness, muscle wasting and contractures, but not typical radial limb malformations, and Wildervanck syndrome which consists of congenital perceptive deafness, Klippel-Feil anomaly and Duane anomaly. The causes of Wildervanck and Arthrogryposis-ophthalmoplegia syndromes are unknown.

In patients born between 1957 and 1962, and patients whose mothers were exposed to Thalidomide during pregnancy at present days (for treatment of multiple myeloma, HIV, or leprosy), it may be difficult to differentiate Okihiro syndrome from Thalidomide embryopathy. Thalidomide exposure during pregnancy may result in amelia, phocomelia, radial hypoplasia, external ear abnormalities (including anotia, microtia, micropinna), facial palsy, eye abnormalities (anophthalmos, microphthalmos, Duane anomaly, cranial nerve misrouting resulting in "crocodile tears"), and congenital heart defects. Alimentary tract, urinary tract, and genital malformations also occur.

## Therapeutic Principles

No specific treatment or gene therapy is available at present for Okihiro syndrome. Therapies focus on surgical correction of the observed malformations of the upper limbs, anus, heart, and the eyes. If Okihiro syndrome is suspected, a complete eye examination by an ophthalmologist with special attention to extraocular movements and structural eye defects is required. Heart defects should be ruled out as well as renal anomalies and renal dysfunction. Hearing test are also required. Growth hormone testing and replacement therapy should be considered for treating growth retarded children with SALL4 mutations.

## Synonyms

Ollier disease; Enchondromatoses

## Definition and Characteristics

Ollier's disease is a disorder of endochondral bone formation, leading to the formation of multiple cartilage rests, known as enchondromas, in bone, generally on the metaphyseal side of growth plates. Enchondromas can cause pain, pathologic fracture and skeletal deformity during growth and may also undergo malignant transformation to chondrosarcoma, usually in adulthood [1]. The extent of skeletal involvement is variable in enchondromatosis, and may include dysplasia that is not directly attributable to enchondromas [2].

## Prevalence

Enchondromatosis is rare.

## Genes

Obvious inheritance of the condition is unusual, although cases suggestive of vertical transmission have been reported in the literature. It is not yet clear whether enchondromatosis results from the mosaic distribution of a mutant protein, or from a germline mutation with variable penetrance.

The genetic cause of most cases of enchondromatosis is not yet clear. A heterozygous missense substitution of arginine 150 for cysteine in the extracellular portion of the type I parathyroid hormone/parathyroid hormone related protein receptor (PTHR1 – gene located on chromosome 3p22-p21.1), has been identified in two cases [3] this is not a common mutation [4]. There is also an association between the occurrence of cartilage tumors including enchondromas and breast cancer [5] and achondroplasia [6].

## Molecular and Systemic Pathophysiology

Enchondromas represent foci of incomplete endochondral ossification of growth plate cartilage. PTHR1 is a G protein coupled seven-pass transmembrane receptor, which together with the Indian hedgehog signaling pathway, in large part regulates the differentiation of growth plate chondrocytes. The mutant PTHR1 identified in some cases of Ollier's disease alters intracellular cAMP second messenger activation and Hedgehog signaling. These effects likely delay maturation of proliferating chondrocytes, allowing the persistence of foci of cartilage in sites of endochondral bone formation [3]. Excessive Hedgehog signaling may be a common mechanism of pathogenesis of other causal mutations that have yet to be identified. Malignant transformation to chondrosarcoma likely requires secondary mutations [7].

## Diagnostic Principles

Affected children may present with skeletal deformity or limb foreshortening with variable, sometimes unilateral, distribution during growth. Radiographs demonstrate well-defined radiolucent bone lesions, which may be relatively destructive in the hands. These lucencies may appear as streaks extending into the metaphysis directly from the growth plate in children, and generally accumulate punctate calcifications as they mature. Malignant transformation may be heralded by increasing pain and enlargement of the lesion with associated radiographic endosteal erosion and loss of distinct margins. Histological differentiation between enchondroma and low grade chondrosarcoma is difficult from biopsy specimens and usually requires an appropriately experienced pathologist.

## Therapeutic Principles

There is no medical management of enchondromatosis yet available. Asymptomatic lesions do not require routine follow-up. Intralesional curettage and bone graft procedures adequately address painful lesions. Deformities may be corrected by osteotomy and limb-lengthening procedures. Biopsy of lesions that grow, erode cortex and are persistently painful, especially after skeletal maturity, is warranted. Chondrosarcoma is usually treated with wide resection and reconstruction without adjuvant therapy.

[3]Department of Surgery, Alberta Childrens Hospital, The University of Calgary, Calgary, AB, Canada

### Synonyms

Exomphalos

### Definition and Characteristics

An omphalocele is a congenital anomaly of the anterior abdominal wall in which the abdominal viscera herniated through a central defect at the site of the umbilical ring (Fig. 1) [1].

**Omphalocele. Figure 1** Omphalocele in a newborn infant.

The herniated viscera are covered by a translucent membrane that is composed of peritoneum on the inner surface, amnion on the outer surface, and Wharton's jelly between the layers [2]. The umbilical vessels insert into the membranous sac and the rectus abdominis muscles insert laterally on the costal margins [2]. The defect is usually in the mid abdomen and rarely occurs in the upper or lower abdomen. Omphaloceles vary in size and can contain small intestine, large intestine, stomach, liver, spleen, urinary bladder, or gonads [3]. Affected infants are usually born at term. Chromosomal and cardiac anomalies are found in up to 30 and 50% of patients, respectively [2]. Other associated anomalies such as gastrointestinal, genitourinary, skeletal, and neural tube defects are common [1,4]. Beckwith-Wiedemann syndrome (omphalocele, macroglossia, visceromegaly, early hypoglycemia) is found in up to 10% of cases [2]. An omphalocele is a presenting feature of the pentalogy of Cantrell (supraumbilical omphalocele, anterior diaphragmatic hernia, cleft sternum, pericardial defect, and cardiac defect). An infraumbilical omphalocele can be associated with bladder or cloacal exstrophy [2].

### Prevalence

The incidence is ~1 in 3,000 to 10,000 live births [3]. There is a slight male predominance. The incidence increases with advancing maternal age, and is highest in mothers over 30 years of age [2].

### Molecular and Systemic Pathophysiology

At around the fifth week of gestation, the gut tube starts to elongate and to develop into the various viscera within the umbilical coelom. The viscera normally return to the abdomen at around the tenth week of embryonic life. An omphalocele results when the viscera do not return from the umbilical coelom into the abdomen and when the lateral embryonic folds do not close at that site [1].

### Diagnostic Principles

The diagnosis is usually made during prenatal ultrasonography. The diagnosis should be considered when the maternal serum α-fetoprotein level is elevated. The amount of α-fetoprotein secreted across the membrane is usually directly proportional to the size of the omphalocele [3]. The maternal serum α-fetoprotein is usually an average of four multiples over the normal mean [2].

### Therapeutic Principles

There is no difference in the outcome, for survival or for complications, between infants with omphaloceles who are delivered vaginally versus those delivered by cesarean section [4]. Delivery by cesarean section is the preferred route in obstetrical practice, especially for infants with a giant omphalocele [2]. After delivery, the cardiorespiratory status should be assessed and stabilized. The lesion should be covered with a warm, moist saline gauze and a water-tight dressing [4]. The stomach should be decompressed by nasogastric suction [1]. A digital rectal examination helps to decompress the bowel by stimulating the passage of meconium. Prophylactic parenteral broad-spectrum antibiotics should be administered. Small defects can be managed by excision of the sac and primary closure of the fascia and skin. Larger defects might require a staged approach with application of a Silastic silo and gradual reduction of the protruding viscera, with delayed closure of the defect when the overlying abdominal wall expands [1].

## Ophthalmoplegia, Chronic Progressive External and Kearns Sayre Syndrome

Maria Judit Molnar
Clinical and Research Center of Molecular Neurology, Semmeiwers University, Budapest, Hungary

### Synonyms

CPEO; KSS

### Definition and Characteristics

Chronic progressive external ophthalmoplegia (CPEO) is a common manifestation of mitochondrial dysfunction. Single heteroplasmic deletions of muscle mitochondrial DNA (mtDNA) is associated with ∼40–50% of CPEO cases. These patients present as sporadic cases. In other patients CPEO is maternally transmitted and caused by mtDNA point mutations, ore associated with multiple mtDNA deletions that arise secondary to nuclear gene defects [1]. The earliest symptoms of the disease are ophthalmoplegia and ptosis. Isolated CPEO is the mildest variant. Individuals who are initially classified as isolated CPEO can progress to CPEO plus, which means that further symptoms and signs supervene, such as retinitis pigmentosa, cardiomyopathy, skeletal myopathy, ataxia, renal insufficiency [2]. CPEO Plus refers to a disorder of intermediate severity, which has an adolescent or adult onset and variable degree of involvement of tissues other than eyelids and eye muscles. A more severe variant is Kearns-Sayre syndrome (KSS) which is characterized by onset of disease manifestations by the second decade and significant multisystem involvement that can include cardiac conduction defects, diabetes mellitus, cerebellar ataxia, retinitis pigmentosa, increased CSF protein and multifocal neurodegeneration.

### Prevalence

The prevalence of mtDNA disease due to mtDNA deletions in Northern England is 1.33/100,000 [3]. No epidemiological data are available about other mtDNA and nDNA mutations resulting in CPEO.

## Genes

Approximately 70% of patients with CPEO plus and 40% with CPEO harbor mtDNA rearrangements [4]. The large scale rearrangement of mtDNA consists of mtDNA deletion, which removes multiple tRNA and protein encoding genes. Most patients with large deletions presents as sporadic cases, although there are rare reports of germline transmission. In 60% of CPEO the symptoms are due to nDNA mutations and point mutations in mtDNA encoded tRNAs. The described sporadic point mutations have been detected in the following tRNA genes of the mtDNA: $tRNA^{Leu(UUR)}$, $tRNA^{Gln}$, $tRNA^{Ile}$, $tRNA^{Ala}$, $tRNA^{Lys}$, while maternally transmitted CPEO mutations were detected in the $tRNA^{Ile,\ Asn,\ Tyr,\ LEU(UCN)}$ genes [5]. The nuclear genome encoded CPEOs can be transmitted as an autosomal dominant (adPEO), or more rarely as an autosomal recessive (arPEO) trait. Southern blot analysis in these cases reveals the presence of multiple mtDNA deletions in postmitotic tissues. Most families with adPEO carry heterozygous mutations in one of four genes: ANT1 encoding the muscle – heart specific mitochondrial adenine nucleotide translocator; Twinkle, encoding a putative mtDNA helicase; POLG1, encoding the catalytic subunit of the mtDNA-specific polymerase- γ (pol- γ); and POLG2, encoding a protein from the mitochondrial replication machinery. The most common cause of the nuclear PEOs is the POLG1 mutation (45% of the familial PEO with multiple mitochondrial DNA deletions). Mutations in both POLG1 alleles were also found in arPEO sibships with multiple affected members.

## Molecular and Systemic Pathophysiology

The mechanism by which deletions in mtDNA are generated is unknown although slip replication and recombination have been suggested. Most deletions are flanked by direct repeat sequences and most occur between the two replication origins (OH and OL) of mtDNA. A so-called common deletion of ~5 kb, present in 30–40% of cases, is flanked by a perfect 13 bp repeat sequence [4]. All patients with large-scale deletion are heteroplasmic and the disease phenomenon depends on the load and distribution of mutated copies at birth. The mtDNA deletion occurs in all tissues with different ratio of heteroplasmy. This suggests that the deletion arises early in the oogenesis, likely during the generation of primary oocytes. MtDNA deletions arise at random in these oocytes, exactly when they appear during oogenesis which determines their proportion in any oocyte. Patients who inherit mtDNA deletions have similar proportions of deleted mtDNA in every tissue at birth, but the percentage varies largely between individuals. During life, the presence of these mutants in dividing cells mostly will be lost by a drift. By contrast, in postmitotic cells the ratio of heteroplasmy will increase with age [2]. This is the reason why mtDNA deletions are not usually found in rapidly dividing tissues as blood. The exact size and nature of the deletion has very little effect on the phenotype. The particular susceptibility of extra-ocular muscles is explained by the 3–4 times greater mitochondrial volume fraction compared to limb muscles.

## Diagnostic Principles

The most important laboratory parameters are resting serum lactate and pyruvate, which are frequently increased [1]. The ratio of lactate/pyruvate is increased [3]. Serum creatine kinase levels are either normal or slightly elevated. Serum lactate increases during slight exercise in CPEO patients and 30 min after the exercise will not decline to the baseline. In some cases the CSF protein is elevated. ENG may reveal slight axonal neuropathy. EMG is normal, neurogenic or myogenic, or not specific. The muscle biopsy always displays the characteristic ragged red or ragged blue fiber pathology. The relative portion of wild type mtDNA in the affected fibers is reduced and they stain negative for cytochrom oxydase. The ultrastructural analysis of the muscle reveals aberrant, enlarged mitochondria usually with paracrystalline inclusions or abnormally organized cristae. Biochemical investigations by spectrophotometry detect the reduced activity of the affected enzyme. Polarography determines the respiratory chain activity, the OXPHOS activity, the integrity of mitochondrial membranes and the efficiency of the substrate transport. Genetic testing should be carried out on postmitotic tissue (e.g. muscle biopsy specimen). Southern blot analysis is suggested for detecting the size and location of the mtDNA deletion. In cases with point mutation of mt or nDNA direct sequencing of the DNA molecule is the adequate diagnostic test.

## Therapeutic Principles

Gene shifting. See [1].
Dichloracetate reduces the serum lactate level.
No fasting. Ketogenic diet, no glutamate, instead of fat carbohydrates.
Surgical therapy of the ptosis.
Supplementation therapy with coenzyme Q10 and carnitine, free radical scavengers (vitamin C, K).

►Opioid Dependence

## Opioid Dependence

Andrew J. Saxon
University of Washington School of Medicine and Veterans Affairs Puget Sound Health Care System, Seattle, WA, USA

### Synonyms

Opioid addiction; Opiate dependence; Opiate addiction

### Definition and Characteristics

The syndrome of opioid dependence is described in both the International Classification of Diseases-10 (ICD-10) [1] and the Diagnostic and Statistical Manual of Mental Disorders-IV Text Revision (DSM-IV TR) [2]. Considerable overlap exists between the two systems of diagnosis. ICD-10 defines dependence as "A cluster of behavioural, cognitive, and physiological phenomena that develop after repeated substance use and that typically include a strong desire to take the drug, difficulties in controlling its use, persisting in its use despite harmful consequences, a higher priority given to drug use than to other activities and obligations, increased tolerance, and sometimes a physical withdrawal state". DSM-IV defines dependence as "A maladaptive pattern of substance use leading to clinically significant impairment or distress as manifested by three or more" of seven criteria, which include tolerance and withdrawal, present in the same 12-month period. Signs and symptoms of opioid withdrawal include dysphoric mood, muscle aches, intestinal cramping, nausea, vomiting, diarrhea, yawning, sneezing, rhinorrhea, lacrimation, mydriasis, sweating, piloerection, tremor, insomnia and fever.

### Prevalence

Prevalence of opioid dependence is difficult to determine precisely because individuals with this disorder do not always come to medical attention, because the prevalence varies over time with availability of opioids and because it varies across geographic regions based upon local laws and customs. Nevertheless, recent epidemiologic studies in regions as disparate as the USA, Copenhagen, Denmark, and various provinces in China suggest an average prevalence of 1% of the population.

### Genes

Twin studies demonstrate that risk for development of opioid dependence is roughly 50% genetic and 50% environmental. As a complex disorder opioid dependence does not follow classical patterns of Mendelian inheritance but is probably polygenic [3]. Some studies have demonstrated association of opioid dependence with single nucleotide polymorphisms in the genes coding for the μ-opioid receptor (OPRM), δ-opioid receptor (OPDR1), proenkephalin (PENK), prodynorphin (PDYN) and the dopamine $D_2$ (DRD2), $D_3$ (DRD3) and $D_4$ (DRD4) receptors, but other studies have not always confirmed these findings. The opioids codeine, oxycodone and hydrocodone are prodrugs that require metabolism by the cytochrome P450 enzyme 2D6 to become active. Poor metabolizers at 2D6 show less likelihood of dependence on these oral opioid drugs. Two genome wide linkage studies both found evidence for linkage to opioid dependence at unidentified loci on chromosome 17.

### Molecular and Systemic Pathophysiology

Endogenous opioid peptides acting through three subtypes (μ, δ, κ) of G-protein coupled opioid receptors modulate many important physiologic functions including nociception, intestinal motility, cardiovascular function, respiratory drive, inhibition of corticotropin releasing hormone, inhibition of gonadotropins, temperature regulation, arousal, reinforcement (acting primarily through the mesolimbic dopamine system), memory,

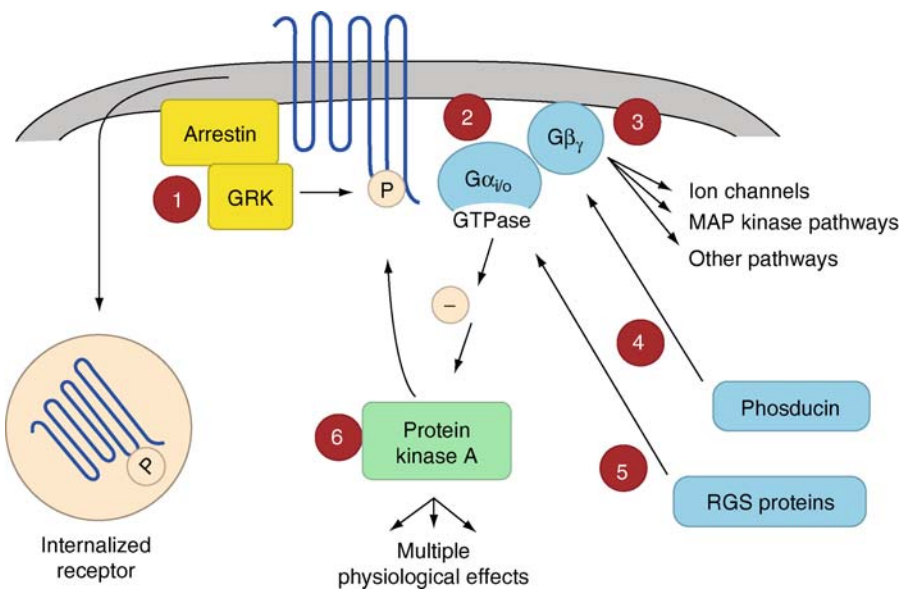
immune function and emotional regulation. Individuals who develop opioid dependence typically begin opioid use with the intention of reducing pain or to induce reinforcement experienced as euphoria. Repeated exogenous opioid administration leads to perturbation of many of these normal physiological responses and tolerance to the effects of opioids develops in part as a means to maintain homeostasis. Although the mechanisms of tolerance have yet to be fully elucidated, preclinical studies indicate that binding of opioids to their receptors can induce receptor phosphorylation with G protein uncoupling and desensitization. Binding of some opioids may further result in receptor internalization [4]. Desensitization of receptors results in a cascade of intracellular changes including an increase in cyclic AMP and the transcription factor cyclic AMP response element binding protein (CREB) as well as increases in the transcription factors c-fos and jun-B. A number of genes including those coding for proteins involved in μ-opioid receptor trafficking, and dopamine, glutamate and gamma amino butyric acid neurotransmission show changes in expression following these events [5]. These cellular changes undoubtedly contribute to the emergence of the withdrawal syndrome when opioids are abruptly discontinued. Individuals with opioid dependence then continue opioid use to avoid withdrawal as well as to reduce pain and to experience euphoria (Fig. 1).

## Diagnostic Principles

The diagnosis is made primarily by taking a history and confirming the presence of the DSM-IV or ICD-10 criteria. Support for the diagnosis can come from more objective observations such as signs of opioid intoxication (drowsiness, miosis) or withdrawal, presence of injection sites or presence of opioids in biological fluids.

## Therapeutic Principles

Optimal treatment approaches involve a combination of behavioral interventions and pharmacotherapy. Behavioral interventions alone typically fail to maintain patients in treatment. The mainstays of pharmacotherapy are oral methadone (full agonist) and sublingual buprenorphine (partial agonist). Both medications have long half-lives and prevent the emergence of withdrawal symptoms when adequate, stable doses are attained. Generally they should be prescribed for indefinite periods to keep patients in treatment and out of relapse. They can also be used over shorter periods to achieve medically supervised withdrawal. The $\alpha_2$ adrenergic agonists, clonidine and lofexidine also have efficacy for medically supervised withdrawal. Patients who have completed withdrawal can be treated with naltrexone, a μ-opioid antagonist.



**Opioid Dependence. Figure 1** Scheme illustrating possible mechanisms of opioid-induced changes in opioid receptor sensitivity. Drug induced changes in efficacy of receptor-Gi/o coupling could contribute to aspects of drug tolerance or sensitization. Possible mechanisms include: receptor phosphorylation by G-protein receptor kinases (GRK) [1], alterations in the abundance of G protein α [2] or βγ [3] subunits or of other proteins such as phosphoducin [4] or regulators of G protein signaling (RGS) proteins [5] that modulate G protein function or up-regulation of protein kinase A (PKA) [6] after chronic drug administration which could phosphorylate and regulate receptor function during withdrawal states. Also shown is agonist induced receptor internalization, which may be mediated by receptor phosphorylation. Adapted and used with permission from [4].

Simone Schimpf
Molecular Genetics Laboratory, Institute for Ophthalmic Research, Centre for Ophthalmology, University of Tuebingen, Tuebingen, Germany

## Synonyms

adOA

## Definition and Characteristics

Autosomal dominant optic atrophy Kjer type (adOA) is a progressive disorder characterised by an insidious onset of loss of visual acuity, temporal optic nerve pallor, development of central, paracentral or coeco-central scotomas and tritanopia. Penetrance and disease expression of adOA, as well as the age of onset, are highly variable both inter- and intrafamiliar.

Histopathological examinations of affected donor eyes show degeneration of the retinal ganglion cells and loss of myelin and nerve fibres in optic nerve sections [1].

## Prevalence

Autosomal dominant optic atrophy Kjer type is the most common hereditary disease of the optic nerve. The estimated prevalence ranges from 1:10,000 in Denmark (due to a founder effect) and 1:50,000 worldwide.

## Genes

Autosomal dominant optic atrophy is caused by mutations in the OPA1 gene located on chromosome 3q28–q29. 30–40% of all adOA patients carry mutations in this gene. The gene spans more than 90 kb and consists of 30 coding exons including three alternative exons – 4, 4b and 5b – that give rise to eight different transcript isoforms by alternative splicing [2]. More than 100 different OPA1 mutations have been identified (for overview see eOPA1 database, http://lbbma.univ-augers.fr/eOPA1/). Although the mutations are distributed over the whole OPA1 polypeptide, there are two mutation hotspots: the GTPase domain and the carboxy terminus. Most missense mutations are located in the GTPase domain, most probably resulting in altered GTPase hydrolysis activity and in loss of function of the OPA1 protein. The majority of OPA1 mutations are predicted to result in truncated OPA1 proteins due to nonsense, frameshift or splice site mutations. Therefore haploinsufficiency has been proposed as a major mechanism underlying the molecular pathogenesis in OPA1-associated adOA [2].

Recently, mutation in the OPA3 gene located on chromosome 19q13.2-q13.3 have been identified that cause adOA with cataract. In addition to the OPA1 and OPA3 gene, two more loci, OPA4 and OPA5 have been mapped to chromosomes 18q12.2-12.3 and 22q12.1-q13.1. However, the respective genes remain to be identified.

## Molecular and Systematic Pathophysiology

OPA1 encodes a dynamin-related GTPase that is imported into the mitochondria and is anchored in the inner membrane. Functional analyses have shown that OPA1 plays an important role in the formation and maintenance of the mitochondrial network and morphology, as well as in the mitochondrial fusion process. Downregulation of OPA1 by RNA interference causes mitochondrial fragmentation and disruption of the cristae structures, leading to a loss of the mitochondrial

membrane potential and to an apoptotic process in cultured cells [3]. Reports on overexpression of OPA1 indicate fragmentation as well as elongation of mitochondrial tubuli [3].

To control the apoptotic process or the morphology of mitochondria, OPA1 is proteolytically processed by one or more yet unknown proteases, leading to a short and long form for OPA1 [4]. These results indicate that the N-terminal domain of OPA1 is important for functional and regulatory mechanisms.

A first mouse model carrying a heterozygous splice site mutation in the OPA1 gene that leads to an inframe deletion of exon 10 on cDNA level showed an age-related progressive loss of retinal ganglion cells and optic nerve axons that is very similar to histopathological studies in patients with adOA [5].

### Diagnostic Principles

To determine reduction in visual acuity and temporal or complete pallor of the optic disc ophthalmic examinations including best-corrected visual acuity, slit lamp biomicroscopy and fundus photography are performed. Further, due to the appearance of tritanopia in many adOA patients, a color vision testing with Farnsworth panel D-15 plates is done. To examine scotomas, the visual field is tested by kinetic and static perimetry. To test the optic nerve and its functionality pattern, VEPs and retinal nerve fiber layer (RNFL) thickness are measured.

### Therapeutic Principles

No adequate therapy is available yet. Dependent on the loss of visual acuity, magnifying visual aids are prescribed.

## Orchitis

Stefan R. Bornstein
Medical Clinic III, University Hospital of Dresden, Dresden, Germany

### Definition and Characteristics

Orchitis is an acute inflammatory reaction of one or both testis due to a viral or bacterial infection. It is characterized by painful swelling of the testis.

### Prevalence

Orchitis develops in 15–25% of postpubertal patients with mumps. Bacterial orchitis is even more rare.

### Molecular and Systemic Pathophysiology

Orchitis may be caused by numerous bacterial and viral organisms. The most common viral cause is mumps virus. Orchitis will develop during the course of the illness in 15–25% of men who have mumps after puberty. Most commonly, mumps causes isolated orchitis. It presents unilaterally in 70% of cases. Orchitis may also occur in conjunction with infections of the prostate or epididymis and, like those conditions, may occur as a manifestation of sexually transmitted diseases such as gonorrhea or chlamydia. The incidence of sexually transmitted orchitis or epididymitis is highest in men aged 15–25 years.

Autoimmune orchitis with inflammatory cell infiltrates in the testis can follow after treatment of infertility, but it is very rare.

Risk factors for non-sexually transmitted orchitis include:
- inadequate immunization against mumps
- older age (age greater than 45)

Risk factors for sexually transmitted orchitis include:
- multiple sexual partners
- other high risk sexual behaviors
- history of a sexual partner with a previously diagnosed sexually transmitted diseases (STD)
- personal history of gonorrhea or other STD

*Clinic:*
- Orchitis is characterized by testicular pain and swelling. The course is variable and ranges from mild discomfort to severe pain.
- Associated systemic symptoms
  - Fatigue
  - Malaise
  - Myalgias
  - Fever and chills
  - Nausea
  - Headache
- Mumps orchitis follows the development of parotitis in 4–7 days.

*Complications:*
- Up to 60% of affected testes demonstrate some degree of testicular atrophy.
- Impaired fertility is reported at a rate of 7–13%.
- Sterility is rare in cases of unilateral orchitis.
- An associated hydrocele or pyocele may require surgical drainage to relieve pressure from the tunica.

## Diagnostic Principles

Physical examination may reveal tender and enlarged lymph nodes in the inguinal area on the affected side and enlarged testicle on the affected side.

Diagnosing mumps orchitis can be made based on history and physical examination alone. However, if there is a question of epididymo-orchitis, testing including urinalysis, urine culture, screening for chlamydia and gonorrhea, and blood chemistry should be obtained.

Diagnosing mumps orchitis can be confirmed with serum immunofluorescence antibody testing.

Most importantly, testicular torsion and epididymitis must be ruled out. As the two syndromes often present with similar symptoms, color Doppler ultrasound has become the imaging test of choice for the evaluation of an acute scrotum.

## Therapeutic Principles

No medications are indicated for the treatment of viral orchitis. Supportive treatment like bedrest with elevation of the scrotum and ice packs for analgesia is recommended. Other appropriate medications include analgesics or anti-emetics, as needed.

Bacterial orchitis or epididymo-orchitis requires appropriate antibiotic treatment for suspected infectious agents. In patients with a bacterial etiology who are younger than 35 years and sexually active, antibiotic coverage for sexually transmitted pathogens (particularly gonorrhea and chlamydia) with ceftriaxone and either doxycycline or azithromycin is appropriate. Sexual partners must also be treated. Patients older than 35 years with bacterial etiology require additional treatment for other gram-negative bacteria with a fluoroquinolone.

*Prognosis:*
- Most cases of mumps orchitis resolve spontaneously in 3–10 days.
- With appropriate antibiotic treatment, most cases of bacterial orchitis resolve without complication.

*Prevention*: Immunization against mumps will prevent mumps-associated orchitis. Safer sex behaviors, such as monogamy and condom use, will decrease the chance of developing orchitis as a result of a sexually transmitted disease.

## Synonyms

Organic acidemias: Maple syrup urine disease (MSUD), isovaleric aciduria (IVA), propionic aciduria (PA) and methylmalonic aciduria (MMA)

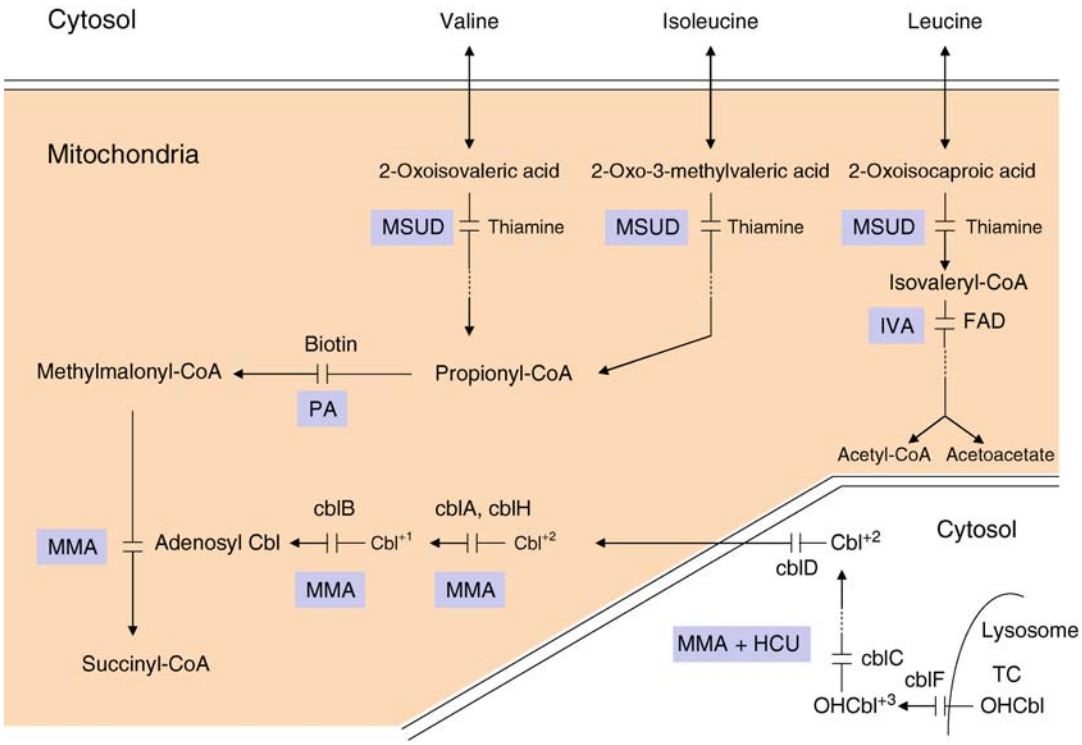
## Definition and Characteristics

The classical organic acidurias result from deficiencies of mitochondrial enzymes involved in the catabolism of branched chain amino acids (BCAAs); leucine, isoleucine and valine (Fig. 1).

Mitochondrial accumulation of toxic organic acid metabolites is a characteristic finding. Inheritance is autosomal recessive. The most common organic acidurias are maple syrup urine disease (MSUD), isovaleric aciduria (IVA), propionic aciduria (PA) and methylmalonic aciduria (MMA) (Fig. 1). Clinically they span a wide range of symptoms involving multiple organic systems [1]. Generally, there are three types of presentation. Patients with a severe neonatal-onset type present with metabolic acidosis, lethargy, emesis and respiratory distress (toxic encephalopathy). A lesser percentage of patients present with recurrent attacks of lethargy, ataxia, chronic vomiting or Reye-like illness, typically after a symptom-free interval in childhood or even later (acute intermittent late-onset form). The third group comprises patients with a chronic progressive form presenting as failure to thrive, hypotonia, and developmental delay. In addition, asymptomatic forms have been elucidated since the recent advent of expanded newborn screening (NBS) by tandem mass spectrometry (tandem MS) and associated family screening of siblings of newborns with an abnormal newborn screening finding [2].

## Prevalence

The disease frequencies in the general population (NBS population) are listed in comparison to the frequencies



**Organic Acidurias. Figure 1** Reduced scheme of the pathways of the most common organic acidurias involved in the metabolism of the branched-chain amino acids Valine, Isoleucine, and Leucine. The cytosolic, mitochondrial and lysosomal compartments are depicted. *MSUD* maple syrup urine disease; *IVA* isovaleric aciduria; *FAD* flavin adenine dinucleotide; *PA* propionic aciduria; *MMA* methylmalonic aciduria; *HCU* homocystinuria; *Cbl* cobalamin; *OHCbl* hydroxycobalamin; *cbl A, B, H* mutations in the genes responsible for the synthesis of adenosylcobalamin; *cbl C, D, F* mutations in the genes responsible for the synthesis of adenosylcobalamin and methylcobalamin; *TC* transcobalamin.

based on patients diagnosed clinically prior to NBS (symptomatic population) [1,2].

*MSUD*: 0.9 per 100,000 births (NBS population) versus 0.5 per 100,000 births (symptomatic population).

*IVA*: 0.9 per 100,000 births (NBS population) versus 0.2 per 100,000 births (symptomatic population).

*PA and MMA*: 1.0 per 100,000 births (each NBS and symptomatic population).

## Genes

*MSUD*: Mutations in BCKDHA (E1alpha, 9q13.1–q13.2), BCKDHB (E1beta, 6q14), dihydrolipoamide transacylase DBT (E2, 1p31) and dihydrolipoamide dehydrogenase DLD (E3, 7q31–q32). A heterogeneous profile of approximately 100 different mutations has been identified so far. In general a given phenotype is caused by a variety of genotypes.

*IVA*: Single gene disorder caused by highly heterogeneous mutations in the IVD gene (5q14–q15). One mutation, p.A282V, was found to be recurrent in patients with a mild biochemical phenotype diagnosed by NBS but who have remained asymptomatic to date [3].

*PA*: Mutations in PCCA (13q32) or PCCB (3q21–q22), encoding the two subunits of propionyl-CoA carboxylase (PCC). Cells from patients with rearrangements in PCCA fall into complementation group pccA, whereas those from patients with PCCB mutations fall into complementation groups pccB and pccC. Defects in the pccB subgroup occur in the N terminus of the PCCB gene, which includes the biotin-binding site, whereas mutations in the pccC subgroup occur in the C terminus of the PCCB gene. More than 40 mutations in PCCA and 60 in PCCB have been reported. Whereas PCCA alterations in Caucasians are heterogeneous, three mutations (c.922–923insT, c.1644-6C>G, and p.R399Q) were found to be predominant in Japanese PCCA alleles. In both Caucasians and Asians the variability of PCCB mutations is limited.

*MMA*: The variability of MUT (6p21) rearrangements in Caucasian and Japanese populations is large [4], however, among the more than 80 known mutations two recurrent variants (p.E117X and p.N219Y) have been described. Different mutations have been identified in MMAA (4q31.1–q31.2) and MMAB (12q24) causing adenosylcobalamin (AdoCbl) deficiency and MMA.

## Molecular and Systemic Pathophysiology

Defects in any of the enzymes involved in the complex metabolism of BCAAs causes organic aciduria, typically with systemic illness caused by toxic metabolites. In MSUD branched-chain 2-oxo acids accumulate in the brain cortex of affected patients. In contrast, deficiencies of enzymes below the second step of BCAA catabolism that is defective in MSUD (Fig. 1) lead to elevation of only branched chain organic acid metabolites (CoA activated carboxylic acids), without increased concentrations of the BCAAs or branched-chain 2-oxo acids, because this reaction is irreversible.

*MSUD*: Mutations in the gene encoding the mitochondrial branched-chain 2-oxoacid dehydrogenase (BCOAD) complex result in MSUD. BCOAD consists of four subunits E1 alpha, E1 beta, E2 and E3. Thiamine pyrophosphate (vitamin B1) is used as a coenzyme for the E1 subunits. Enzyme deficiency leads to accumulation of the three branched-chain 2-oxo acids and BCAAs (Fig. 1) as well as the respective 2-hydroxy acids. There is a characteristic odor of the urine resembling maple syrup. Leucine and 2-oxoisocaproic acid are considered to be most neurotoxic. The severity of clinical manifestations and response to thiamine substitution determine four known phenotypes, i.e. classic, intermediate, intermittent, and thiamine-responsive. A specific phenotype with congential lactic acidosis is caused by deficiency of the E3 component (dihydrolipoamide dehydrogenase (E3) deficiency).

*IVA*: Deficiency of the mitochondrial flavoenzyme isovaleryl-CoA dehydrogenase responsible for the third step in leucine catabolism (Fig. 1) results in accumulation of isovaleric acid, which is toxic to the central nervous system. An alternative pathway through glycine-*N*-acylase allows detoxification by producing isovalerylglycine, which is excreted. Conjugation with carnitine leads to the formation of isovalerylcarnitine. Two clinical forms are distinguished: an acute form leading to neonatal encephalopathy and a sweaty feet odor, and a chronic form with periodic attacks; as well as a mild or potentially asymptomatic phenotype diagnosed by NBS [3].

*PA*: Defects in the genes encoding the α- and β-subunits of biotin-dependent PCC, PCCA or PCCB, result in PA. Biotin binds to the α-subunit. However, no biotin-responsive patient has been reported. PA leads to massively increased blood and urine concentrations of propionic acid and multiple propionyl-CoA derivatives including propionylcarnitine, 3-hydroxypropionic acid and methylcitric acid as the major diagnostic byproducts. Inhibition of several additional pathways of the intermediary metabolism by propionyl-CoA may result in ketotic hyperglycinemia, hyperammonemia, hyperlactatemia, and hypoglycemia. Bone marrow depression may cause pancytopenia.

*MMA*: Genetically heterogenic disorder of methylmalonate and cobalamin metabolism. Isolated MMA is caused either by defects in the MUT gene which impair the conversion of methylmalonyl-CoA to succinyl-CoA by methylmalonyl-CoA mutase, or by mutations in MMAA and MMAB resulting in cobalamin A/B/H defects, both responsible for the synthesis of the MUT coenzyme AdoCbl (Fig. 1). There is a good correlation between the MUT mutation and enzyme deficiency,

which can be partial (*mut*−) or complete (*mut*°), resulting in accumulation of methylmalonyl-CoA and methylmalonic acid. Propionyl-CoA metabolites are also produced by secondary inhibition of PCC, leading to similar metabolic disturbances as in PA. Patients with defects in the synthesis of AdoCbl are usually responsive to vitamin B12 therapy.

MMA with homocystinuria is a genetically and clinically heterogeneous disorder caused by defects in the transformation of vitamin B12 into the coenzymes methylcobalamin and AdoCbl, due to mutations in the respective genes encoding cobalamin C/D/F (Fig. 1).

### Diagnostic Principles

Classically, organic acidurias have been diagnosed by urine gas chromatography-mass spectrometry revealing a typical urine organic acid pattern [5]. In recent years, tandem MS has evolved as a diagnostic tool to identify accumulating disease-specific acylcarnitines in plasma and urine. Analysis of acylcarnitines in blood spots by use of tandem MS has allowed early postnatal detection of this group of disorders by newborn screening. Propionylcarnitine (C3 carnitine) is the abnormal acylcarnitine in PA and MMA, and isovalerylcarnitine (C5 carnitine) in IVA. In MSUD no abnormal acylcarnitines accumulate, however, the diagnosis can be made by plasma/dried blood amino acid analysis alone detecting elevation of the BCAAs and alloisoleucine, an endogenously formed diastereomer of isoleucine. Enzymatic and/or molecular genetic analyses are helpful for confirmatory purposes and identification of the type of severity.

### Therapeutic Principles

Outcome correlates with early diagnosis and initiation of treatment. Emergency treatment aims at reversal of protein catabolism by high-dose energy substitution (intravenous glucose, insulin, lipids), intermittent (short-term) stop of protein intake, early toxin (and ammonia) removal (carnitine, glycine, sodium benzoate, hemodialysis, hemofiltration), and disease-specific vitamin therapy (vitamin B12 in MMA). The goals of long-term treatment are (i) the reduction of chronic toxic metabolite accumulation, (ii) maintaining normal physical development and avoiding malnutrition, and (iii) preventing catabolic episodes during times of "metabolic stress", such as infection, fasting or surgery. This includes dietary protein restriction and supplementation with an amino acid mixture lacking the affected amino acids [5]. An adequate daily intake of minerals, vitamins and trace elements is required. For specific detoxifying therapy in patients with IVA, PA and MMA oral carnitine and, in patients with severe types of IVA, additional oral glycine is used. In PA and MMA, metronidazole may be helpful to suppress the production of propionic acid by anerobic gut bacteria.
