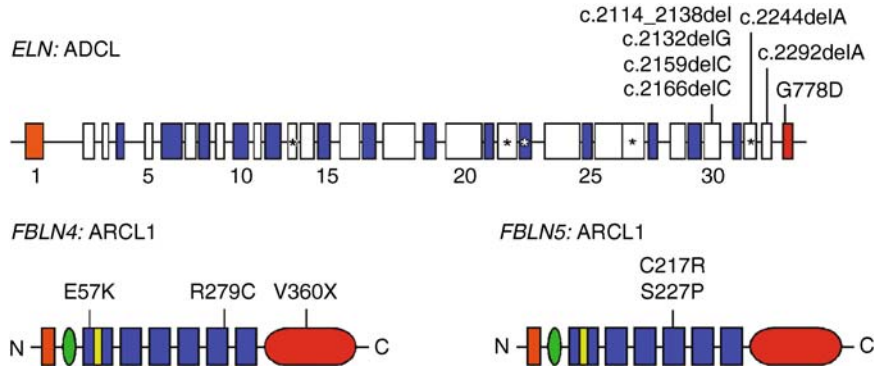
This region of tropoelastin is required for interaction with fibrillin microfibrils. Defective binding to microfibrils but relatively preserved copolymerization of mutant with wild type tropoelastin results in impaired elastic fiber structure and function. Heterozygous loss of function mutations in ELN cause a different inherited disease, familial supravalvular aortic stenosis.

Fibulin-4 and fibulin-5 facilitate the deposition of tropoelastin onto microfibris. Missense mutations in either of these two proteins can cause ARCL1. These mutations are often located in calcium-binding epidermal growth factor domains and disrupt the folding of these domains by inactivating the calcium-binding site, altering the number of highly conserved cysteines or by including a structurally restrained residue such as a proline. Structurally analogous missense mutations are found in fibrillin-1 in ►Marfan Syndrome. In ARCL1, the synthesis and secretion of fibulin-5 or fibulin-4 is reduced and the binding of these proteins to tropoelastin and fibrillin microfibrils is impaired. This leads to the formation of elastin deposits that are not integrated with microfibrils into a single structure. Loss of fibulin function in ARCL1 may be exacerbated by toxic effects of mutant proteins via increased ER stress and apoptosis.

The ATP6V0A2 protein is localized to the trans-Golgi and early endosomal compartments of the secretory pathway. ATP6V0A2 mutant fibroblasts show defective retrograde trafficking of vesicles from the Golgi apparatus to the endoplasmic reticulum [4]. Abnormal glycosylation of secreted proteins in ARCL2 may be related to impaired pH regulation within secretory vesicles. The proximal causes of impaired elastic fiber formation in ARCL2 and in De Barsy syndrome are unclear. In XCL, impaired $Cu^{2+}$ transport leads to reduced synthesis and activity of lysyl oxidases, enzymes necessary for the crosslinking of elastin and collagens.

## Diagnostic Principles

Histological evaluation of skin biopsy specimens using specialized elastin stains show diminished, fragmented or clumped elastic fibers. Electron microscopy of the dermis demonstrates either discontinuities in the elastin core of fibers or a lack of integration of microfibrillar and



**Cutis Laxa. Figure 1** Gene mutations in cutis laxa Mutations that cause ADCL are clustered in the 5 last exons of *ELN*. These mutations frequently cause a –1 shift in the reading frame. In ARCL1 patients, mutations were found in either *FBLN4* or *FBLN5* and are often missense mutations in calcium-binding epidermal growth factor domains (blue boxes in *FBLN4* and *FBLN5*).

elastin deposits into elastic fibers. However, morphological evaluation of elastic fibers cannot reliably distinguish between different forms of cutis laxa. Isoelectric focusing of serum proteins in ARCL2 shows a combined N- and O-glycosylation defect consistent with congenital disorder of glycosylation type 2. In XCL, reduced serum $Cu^{2+}$ and ceruloplasmin levels are diagnostic. In addition to pathological and laboratory tests, molecular genetic analysis can facilitate diagnosis.

### Therapeutic Principles

The treatment of cutis laxa is limited to managing each manifestation of the disease. Severely redundant skin can be disfiguring. Cosmetic surgery often shows good results, with normal healing. However skin laxity can recur, necessitating multiple surgeries. Lung transplantation has been successfully used to extend life in terminal emphysema associated with ADCL. Patients with ADCL and aortic root dilation have been treated with beta-adrenergic blockers, but the effectiveness of this treatment has not been demonstrated by trials in this group of patients. Surgical interventions have been used to repair aortic aneurysm and diaphragmatic hernia in a patient with ARCL1 caused by a fibulin-4 mutation [3]. However, infantile mortality associated with FBLN5 mutations and developmental emphysema could not be prevented by conventional treatment [2]. Seizures in ARCL2 patients are difficult to manage with antiepileptic medication.

## Cutis Marmorata Telangiectatica Congenita

Francesco Borgia, Fabrizio Guarneri, Mario Vaccaro
Institute of Dermatology, Policlinico Universitario, Messina, Italy

### Synonyms

Van Lohuizen syndrome; Congenital generalized phlebectasia; Nevus vascularis reticularis; Livedo telangiectatica; Congenital livedo reticularis; CMTC

### Definition and Characteristics

Cutis marmorata telangiectatica congenita (CMTC) (MIM 219250) is an uncommon, sporadic, congenital vascular anomaly characterized by the presence, usually at birth, of a persistent vascular “marble-like” pattern, telangiectasia, phlebectasia, occasional ulceration, with a tendency to some improvements within two years. The distribution of CMTC lesions may be widespread or, more frequently, localized, with a sharp demarcation at the midline.

Associated anomalies occur in up to 70% of patients and include body asymmetry, additional vascular anomalies, glaucoma, aplasia cutis congenita, psychomotor or mental retardation, hypospadias, macrocephaly and aberrant mongolian spots (type 5 phacomatosis pigmentovascularis) [1,2].

## Prevalence

CMTC is considered a rare disorder, with about 300 cases reported in the world literature. Females and males are almost equally affected.

## Genes

The genetic basis of CMTC are still unknown, but the usually sporadic occurrence and the clinical characteristics suggest that the lethal gene theory proposed by Happle may be applied to this disease [3]. To explain why several serious birth defects with partial cutaneous involvement of the tegument occur sporadically, Happle postulated the action of an autosomal lethal gene surviving by mosaicism, based on the assumption that the presence of certain mutations in the zygote would lead to death of the embryo at an early stage of development and that the cells bearing the mutation could only survive in a mosaic state, intermingled with normal cells. An individual with a mosaic state of a lethal gene could not transmit the mutation to the next generation; if transmitted, the zygote with the lethal gene would die in utero. CMTC appears to fulfill the clinical criteria of lethal gene theory: sporadic occurrence, mosaic distribution of skin lesions with a highly variable arrangement but without involvement of the entire tegument, sex ratio approximately equal. Autosomal dominant inheritance with low or variable expression and low penetrance has been previously proposed to explain the rare familial cases of CMTC reported in literature; recently, the concept of paradominant inheritance has been applied to these rare exceptions from the rule of nonheritability [4]. Individuals heterozygous for a paradominant mutation would be phenotypically normal so that the gene could be transmitted unperceived through many generations; the trait would only become manifest when a postzygotic mutation of the corresponding allele occurs, giving rise to loss of heterozygosity, resulting in a homozygous or hemizygous cell clone that survives in close proximity to the phenotypically normal heterozygous cell population, in a mosaic state. It should be noted that both theories have so far not been proven at the molecular level.

## Molecular and Systemic Pathophysiology

Main pathologic feature consists of extended and numerically increased dermal arterioles and venules with hyperplasia and swollen endothelial cells, plus a perivascular lymphocytic infiltrate. Abnormalities in elastin fibers (disrupted fibers and vacuole formation) have been reported with electron microscopy examination. These findings may evoke failure of development of the mesodermal vessels in the early embryonic stage or a dysfunction of the vascular innervation, secondary to a morphologic and/or functional defect in the α-adrenergic sympathetic innervation. In this scenario, the altered neurogenic tonus would lead to perfusion deficiency due to reduced erythrocyte flow velocity, as demonstrated by laser Doppler fluxmetry. This hypothesis could also explain the spontaneous recovery from CTMC over the first years of life.

## Therapeutic Principles

The disease has a good prognosis, with a marked improvement or a total disappearance of the skin lesions within 2 years. In persistent lesions, laser therapy may be considered, even if only a few reports confirm its efficacy. Children with clinically detectable abnormalities should be managed using a multidisciplinary approach.

## Cylindromatosis, Familial

Dieter Metze
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Ancell-Spiegler cylindromas; Spiegler-Brooke syndrome; "Turban Tumor" syndrome

### Definition and Characteristics

Familial cylindromatosis is a predisposition to multiple benign neoplasms of the skin appendages, particularly with sweat gland differentiation. The disorder is probably autosomal dominant with stronger expression in the female.

Multiple, large coalescing tumors arise on the scalp and forehead (turban tumors), less frequently on the trunk and extremities. Multiple cylindromas may be associated with multiple trichoepithelioma, milia, adenomas of the parotid gland, and spiradenoma, the latter being a histologic variant of cylindroma. Long-standing turban tumors of the scalp bear the risk of aggressive growth and malignant behavior (malignant cylindroma) [1].

### Prevalence

The disease is rare.

### Genes

Familial cylindromatosis is caused by mutations in a gene named CYLD 1 on 16q12-q13 acting as a tumor suppressor gene [2].

### Molecular and Systemic Pathophysiology

CYLD 1 encodes three cytoskeletal-associated-protein-glycine-conserved (CAP-GLY) domains, which are found in proteins that coordinate the attachment of organelles to microtubules. CYLD 1 also has sequence homology to the catalytic domain of ubiquitin carboxy-terminal hydrolases (UCH) [3]. The coexistence of apocrine sweat gland neoplasms and trichoepitheliomas suggest a defect in the stem cells of the folliculosebaceous-apocrine unit giving rise to different combinations of adnexal skin tumors as well as to other neoplasms [4].

### Diagnostic Principles

Biopsies show circumscribed islands and cords of basaloid cells that are surrounded by thick basement membranes immunoreactive for collagen IV and VII with apocrine sweat gland differentiation, so called cylindroma or spiradenoma.

### Therapeutic Principles

Surgical excision, carbon, dioxide laser vaporization.

### Definition and Characteristics

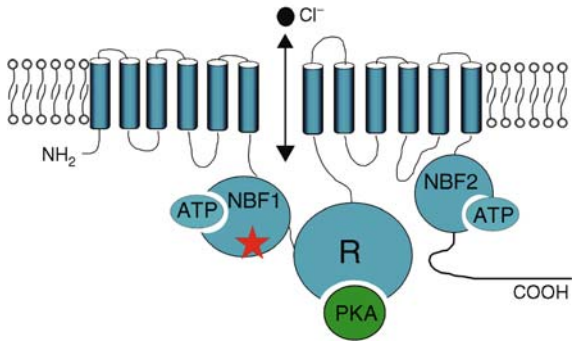
Autosomal recessive epithelial ion transport defect. Abnormalities in salt and water transport lead to dehydration of the fluid layer lining epithelial surfaces, resulting in intraluminal obstruction with viscous secretions in the airways, intestine, pancreas and hepatobiliary system. As a result, cystic fibrosis (CF) patients develop a multiorgan disease characterized by chronic pulmonary disease with chronic bacterial infection, exocrine pancreatic insufficiency (85%), meconium ileus (10%), and biliary cirrhosis. Enhanced salt excretion in the sweat and male infertility are further hallmarks of the disease [1].

### Prevalence

In Caucasians, CF affects 1 in 1,400–2,500 newborns, and thus belongs to the most common lethal hereditary diseases in Western Europe and North America [1]. The incidence is much lower in Asia, Africa and South America.

### Genes

CF is caused by mutations in ABCC7, encoding the cystic fibrosis transmembrane conductance regulator (CFTR). The gene contains 27 exons encompassing ~250 kb of DNA on chromosome 7q31. CFTR consists of 1,480 amino acids, has a molecular weight of 160–180 kDa, and belongs to the large family of plasma membrane localized ATP-binding cassette (ABC) proteins [2]. More than 1,000 different disease causing mutations have been described with a distribution over the entire gene. The most common mutation, a deletion of a phenylalanine at position 508 (ΔF508), accounts for 66% of CF alleles (Fig. 1). Only four other mutations (W1282X, G542X, G551D and N1303K) account for more than 1% of CF alleles worldwide, i.e., the majority of mutations occurs at very low frequencies [1].



**Cystic Fibrosis. Figure 1** CFTR is a regulated apical membrane $Cl^-$ channel. The $Cl^-$ channel pore is formed by 12 membrane spanning sequences. Channel activity and gating are regulated by PKA phosphorylation of the regulatory (R) domain and ATP-binding to the two nucleotide binding folds (NBF). The most common mutation, ΔF508, is located in NBF1 (*) and results in a processing defect of the protein.

## Molecular and Systemic Pathophysiology

CFTR is a cyclic adenosine monophosphate (cAMP) regulated chloride channel expressed in apical membranes of various epithelia, and also controls the function of other membrane proteins, including the epithelial sodium channel (ENaC) [3]. The molecular mechanisms, by which CFTR mutations can disrupt CFTR function include defects in protein production (class I), trafficking/processing (class II, e.g., ΔF508), $Cl^-$ channel regulation (class III), altered single channel properties (class IV), and decreased CFTR abundance (class V). These defects lead to deficient cAMP-dependant $Cl^-$ transport in affected epithelia, and enhanced ENaC-mediated $Na^+$ absorption in the airways [1,3]. Most morbidity and mortality in CF is caused by chronic progressive pulmonary disease that evolves from airway obstruction due to mucus plugging, airway inflammation and intermittent infection, to chronic bacterial infection and bronchiectasis. The mechanism by which abnormal ion transport causes CF lung disease is still controversial. A novel animal model with airway-specific overexpression of ENaC demonstrated that an imbalance of $Cl^-$ secretion and $Na^+$ absorption in vivo leads to airway surface liquid (ASL) volume depletion, increased mucus concentration and reduced mucociliary clearance, resulting in CF-like lung disease with spontaneous mucus plugging, goblet cell metaplasia, chronic inflammation and reduced clearance of CF pathogens [4]. These results indicate that volume depletion of epithelial surfaces is an early step in the pathogenesis of CF airway disease, and may also be a key mechanism leading to intraluminal obstruction and dysfunction of other organs, including the large and small bowel, pancreatic ducts, hepatobiliary system, and genitourinary tract. Other hypotheses suggested that a change in ASL ion composition (which may lead to inactivation of antimicrobial peptides), defects in airway bicarbonate transport, abnormal submucosal gland function, or modulation of epithelial inflammation may further contribute to CF pathophysiology. CFTR mutations that result in residual $Cl^-$ channel function (class IV and V) are associated with pancreatic sufficiency and a mild CF phenotype, establishing a genotype-phenotype correlation in CF. Furthermore, variations in disease severity among patients with identical CFTR mutations suggest an additional role of disease modifying genes and environmental factors in CF pathogenesis.

## Diagnostic Principles

The diagnosis of CF is based on at least one clinical feature and evidence of CFTR dysfunction [1]. Characteristic clinical features include chronic sinopulmonary disease (including persistent colonization/infection with typical CF pathogens as S. aureus, H. influenzae, P. aeruginosa, and B. cepacia), gastrointestinal abnormalities (meconium ileus, pancreatic insufficiency, malabsorption, failure to thrive and biliary cirrhosis), salt loss syndrome, and obstructive azoospermia. The clinical diagnosis is supported by a history of CF in a sibling, or an abnormal newborn screening test result. CFTR dysfunction can be documented by elevated sweat $Cl^-$ concentration (sweat test), identification of two disease causing CFTR mutations, or demonstration of characteristic ion transport abnormalities in nasal or rectal epithelia.

## Therapeutic Principles

In the absence of a causal therapy targeting the basic CF defect, established treatments comprise a comprehensive symptomatic approach aiming at prevention and treatment of pulmonary disease, nutritional status and gastrointestinal disease [1]. Systemic and inhaled antibiotics, airway clearance techniques and mucolytics (Dornase alfa), pancreatic enzyme replacement (lipase, amylase, protease), and a high high calorie diet are the cornerstones of current treatment modalities. At end-stage disease, lung or liver transplantation may be required. Experimental treatment strategies include gene therapy and novel pharmacologic approaches to correct the CF ion transport defects, including inhibition of enhanced $Na^+$ absorption (ENaC blockers), improvement of maturation and function of mutant CFTR, and activation of alternative $Cl^-$ secretory pathways [3,4].

# Cystic Hygroma

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Cystic hygroma typically presents as a swelling that is compressible, feels softly cystic, fluctuates easily, and is brilliantly translucent (Fig. 1) [1].

**Cystic Hygroma. Figure 1** Cystic hygroma presenting as a cystic swelling on the right side of the neck.

The lesion is not attached to the skin but might be attached to the underlying structures. Approximately 65–75% of cases are identified at birth, and 80–90% are diagnosed by the end of a child's third year of life [2]. Cystic hygromas rarely manifest in adulthood. Approximately 75% of cystic hygromas occur in the neck, typically in the posterior cervical triangle [2]. Cystic hygromas occur twice as often on the left side of the neck than the right [3]. Approximately 20% of the lesions occur in the axilla [4]. Other less common sites include the mediastinum, trunk, extremities, abdomen, and retroperitoneum [4]. The growth of a cystic hygroma is usually proportional to the growth of the child. The growth might increase during pregnancy. The lesion rarely regresses spontaneously.

Although cystic hygroma is a benign lesion, it has the potential for extension or infiltration into the surrounding structures. Depending on the structures involved, airway obstruction, dysphagia, and feeding problems might result. Other potential complications include infection and hemorrhage.

## Prevalence

The incidence is ~1 in 12,000 live births [3]. The male to female ratio is equal. Cystic hygroma might follow maternal exposure to alcohol, trimethadone, or aminopterin. The condition is more common in patients with chromosomal abnormalities such as Turner syndrome, Down syndrome, trisomy 13, trisomy 18, and Klinefelter syndrome [4]. The incidence is also increased in patients with Noonan syndrome, multiple pterygium syndrome, Roberts syndrome, Proteus syndrome, and Beckwith-Wiedemann syndrome [4]. The condition might also be inherited as an autosomal recessive trait.

## Molecular and Systemic Pathophysiology

The fetal lymphatic system develops around the fifth week of gestation as an endothelial outgrowth of the venous system [4]. During embryonic development, six lymphatic sacs develop in close proximity to large veins [4]. Lymphatic vessels extend in a centrifugal fashion from these lymphatic sacs through a process of branching [4]. A cystic hygroma might result from either an abnormality in the control of lymphatic growth or from arrest in the normal development of the primitive lymphatic channel, whereby the peripheral lymphatic vessel becomes sequestrated and never connects with the remaining lymphatic system [3]. The lesion arises in areas where tissue pressure is less and expansion of lymphatic tissue can occur.

## Diagnostic Principles

Cystic hygroma might be first noted during prenatal ultrasonography. After birth, the diagnosis is established by physical examination. When the lesion is in the neck, the differential diagnosis includes branchial cleft cyst, dermoid cyst, thyroglossal duct cyst, lipoma, hemangioma, fibrous dysplasia of the sternocleidomastoid muscle (fibromatosis colli), cervical lymphadenopathy, and neuroblastoma. Histologically, the lesion consists of multiloculated cysts that are lined by endothelial cells and that contain serous lymphatic fluid. Some cysts communicate with each other, whereas others are separated. For superficial lesions, ultrasonography adequately defines the size and extension of the lesion. For more complex lesions, CT or MRI imaging is necessary to define the relationship of the lesion with the adjacent structures [3]. These studies are necessary before surgery is contemplated.

## Therapeutic Principles

Indications for treatment include symptomatic lesions and cosmetic concerns. Surgery is the treatment of choice. If the lesion cannot be completely resected, recurrence is usually inevitable [3]. Other treatment

modalities include aspiration and injection of sclerosing agents such as OK-432 [5]. OK-432 is a lyophilized biologic preparation that contains the cells of Streptococcus pyogenes (group A, type 3) Su strain, which has been incubated with benzylpenicillin. OK-432 causes less fibrosis of the subcutaneous tissue and the overlying skin, and as such, the cosmetic result is better.

# Cysticercosis

Alexander K. C. Leung[1], Kam-Lun Ellis Hon[2], Paul Cheung-Lung Choi[3]

[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

[2]Department of Pediatrics, Prince of Wales Hospital, Chinese University of Hong Kong, Shatin, Hong Kong Special Administrative Region, People's Republic of China

[3]Department of Anatomical and Cellular Pathology, Prince of Wales Hospital, Chinese University of Hong Kong, Shatin, Hong Kong Special Administrative Region, People's Republic of China

## Definition and Characteristics

Cysticercosis is a tissue infection with the larval cyst of the zoonotic cestode Taenia solium (pork tapeworm), in which the human being serves as an intermediate host for the parasite. The clinical manifestations depend on the location and number of cysticerci and the response of the host. Cysts can be found anywhere in the body, notably the central nervous system, skeletal muscle, subcutaneous tissue, and eye. Neurocysticercosis is the most common and serious manifestation of cysticercosis. Parenchymal neurocysticercosis usually presents with seizures and, at times, with focal neurologic deficits and mass effects [1]. Intraventricular involvement is often complicated by hydrocephalus and increased intracranial pressure without localizing signs [1]. Affected patients may present with headache, vomiting, diplopia, and papilloedema. Subarachnoid lesions may cause chronic meningitis. Spinal neurocysticercosis may cause spinal compression, radicular pain or paraesthesia, transverse myelitis, and meningitis. Racemose cysticercosis refers to proliferation of cysts at the base of the brain, resulting in deterioration of mental function, coma, and death [2]. Ophthalmic involvement may lead to decreased visual acuity. Cysticercosis can involve the skeletal muscle and subcutaneous tissue, resulting in cystic lesions or firm nodules which might or might not be painful [3].

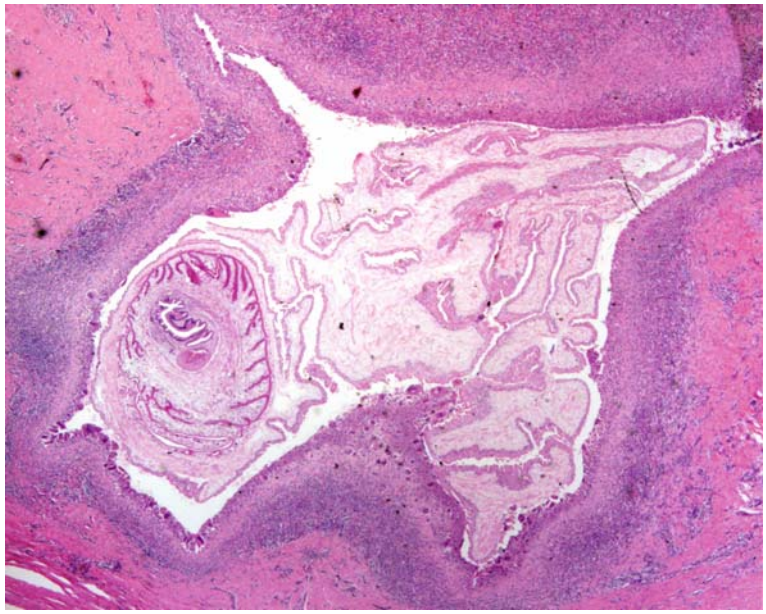
## Prevalence

The prevalence is high in areas with poor sanitation where pigs are raised under conditions in which they have access to human faeces. Other risk factors include a history of taeniasis and poor personal hygiene. Seroprevalence based on antibody detection using Western blotting, suggesting exposure to Taenia eggs but not necessarily an actual cysticercosis, has been described as follow: 2–9% in Bolivia, 5–11% in Mexico, 7–24% in Peru, 10–17% in Guatemala, and 34% in Honduras [4].

## Molecular and Systemic Pathophysiology

Taenia eggs passed out in human faeces remain viable for days or weeks. Cysticercosis is acquired primarily by the ingestion of food or water contaminated with the eggs of T. solium dispersed by a human tapeworm carrier. Eggs hatch in the human intestine to release oncospheres that penetrate the intestinal mucosa to reach the blood stream. These oncospheres then spread to many tissues, notably the brain and muscle, where they develop into cysticerci (Fig. 1) [1].

Tapeworm carriers can infect themselves by the faecal-oral route or through retrograde transmission of proglottids from the intestine into the stomach with subsequent release of eggs into the gastrointestinal tract [1,4]. The initial host and inflammatory reaction is often minimal because of encasement of the parasite and production of prostaglandins and secretory protease inhibitors by the parasite [5]. The secretory protease inhibitors block complement activation and decrease cytokine production and leukocyte chemotaxis. After months to years, the degenerating cysticerci lose their ability to control the host response and at the same time lose osmoregulation and begin to swell with release of larval antigens [5]. The leakage of larval antigens provokes a severe inflammatory response leading to infiltration of inflammatory cells and release of cytokines. The patient becomes symptomatic. Eventually, the encysted larvae die. Their cavities become collapsed and the cysts are encased by fibrous tissue and may calcify [5].



**Cysticercosis. Figure 1** Histopathology showing cysticercosis in the muscle biopsy of a Vietnamese female who presented with a painful mass in the right biceps muscle.

## Diagnostic Principles

Neuroimaging studies are the mainstay of diagnosis. CT is best for identifying calcifications. On the other hand, MRI is better than CT at detecting cysticerci in the ventricle, subarachnoid space, brainstem and spinal cord [5]. MRI may also reveal the scolex and provide more information about viability of the parasite and associated inflammation [1,5]. Both CT and MRI are adequate in the detection of parenchymal cysticerci or hydrocephalus. Serologic diagnosis using the enzyme-linked immunotransfer blot has a sensitivity and specificity >90%. Biopsy of the muscle can provide a definitive diagnosis for a suspected subcutaneous/muscular cyst/nodule (Fig. 1).

## Therapeutic Principles

Antiepileptic drugs are effective treatment for seizures associated with neurocysticercosis. The use of antiparasitic drugs such as praziquantel and albendazole is controversial. Killing of the cysticerci may provoke an intensive inflammatory reaction around the dying parasite thereby may cause worsening of the symptoms. Most investigators recommend treatment for complicated neurocysticercosis and for patients with nonenhancing or multiple neurocysticerci. Co-administration of corticosteroid may reduce the associated inflammation which may result in increased seizure activities. Antiparasitic therapy is not indicated for calcified cysts and spinal or ophthalmic cysticercosis. Surgical removal of the cyst should be considered for an intraocular cyst [4].

# Cystinosis, Nephropathic

William A. Gahl
Section of Human Biochemical Genetics, Heritable Disorders Branch, National Human Genome Research Institute, Bethesda, MD, USA

## Synonyms

Infantile nephropathic cystinosis; BOS

## Definition and Characteristics

Autosomal recessive lysosomal storage disorder leading to renal tubular Fanconi syndrome in the first year of life, renal glomerular failure by approximately 10 years of age, growth retardation, photophobia and hypothyroidism in early childhood, and sometimes myopathy, swallowing difficulty, pancreatic insufficiency, pulmonary dysfunction, retinal blindness, male hypogonadism, and neurological deterioration in the second to fifth decades, if untreated [1,2].

## Prevalence

Approximately 450 patients exist in North America, and a similar number throughout Europe. The disease occurs worldwide, with an estimated incidence of 1 in 100–200,000.

## Genes

CTNS, coding for the lysosomal membrane transporter cystinosin, on chromosome 17p13. CTNS contains 12 exons within 23 kb of genomic DNA [3].

## Molecular and Systemic Pathophysiology

Mutations causing cystinosis are distributed throughout the CTNS gene, including the promoter region [1]. Approximately half the mutations in patients of northern European ancestry consist of a 57,257-bp deletion encompassing the first ten exons of CTNS plus considerable upstream sequence. The CTNS product, cystinosin, has 367 amino acids and 7 transmembrane domains [3]. Two targeting domains direct the protein to the lysosomal membrane. Cystinosin transports cystine, the disulfide of the free thiol amino acid cysteine, from the lysosome into the cytoplasm, where cystine is reduced to cysteine. The ligand specificity is quite strict, and the Km is thought to approximate 0.5 mM [4]. The failure of the lysosomal membrane transport system for cystine causes accumulation of free (nonprotein) cystine in most cells of the body; birefringent, hexagonal and rectangular crystals form in the kidney, spleen, liver, intestine, cornea, conjunctiva, bone marrow, pancreas, testis, muscle, and other tissues due to cystine's low solubility in water. Renal tubular cells appear particularly susceptible to the cystine accumulation, losing function and resulting in renal tubular Fanconi syndrome in infancy. Other cell types, including renal glomerular cells and muscle cells, are destroyed more gradually. Once function is lost, it is generally not recoverable, although corneal cystine crystals can be dissolved with no apparent residual damage. Cystinosis variants exist with clinical courses milder than that seen in nephropathic cystinosis [1,2].

## Diagnostic Principles

Nephropathic cystinosis should be suspected based either upon family history or upon the presentation of renal tubular Fanconi syndrome, usually at 6–12 months of age. This reabsorption defect manifests with polyuria, dehydration, acidosis, hypophosphatemic rickets, salt craving, and poor growth [1,2]. Feeding is often poor. The diagnosis can be confirmed by finding elevated cystine levels in polymorphonuclear leucocytes using the cystine-binding protein method; in patients over 1 year of age, pathognomonic corneal cystine crystals also make the diagnosis. Molecular diagnosis can be performed for the 57-kb deletion, and prenatal diagnosis is available using cystine measurements in cultured amniocytes or samples of chorionic villi. In general, renal, bone marrow, and conjunctival biopsies to detect crystals, as well as skin biopsies for fibroblast cystine measurements, are overly invasive and not indicated.

## Therapeutic Principles

Symptomatic therapy involves replacement of renal losses with supplements such as citrate, phosphate, potassium, calcium, sodium, and carnitine [1,2]. Vitamin D is often helpful in promoting gastrointestinal phosphate absorption. Free access to water is essential. Some patients require L-thyroxine replacement for hypothyroidism and dark glasses for photophobia. Young patients respond to growth hormone injections; some older patients require insulin; occasionally, older males benefit from testosterone supplements. Treatment aimed at the primary defect involves cysteamine, or beta-mercaptoethylamine, which depletes cystinosis cells of their lysosomal cystine content. Oral cysteamine (Cystagon) prevents or retards renal glomerular deterioration [5], enhances growth, and obviates the need for L-thyroxine replacement. Cysteamine eyedrops dissolve corneal cystine crystals, but remain investigational. If renal function is lost, dialysis serves as a temporizing measure until a renal allograft can be provided. Kidney transplants perform well in cystinosis patients.

# Cystinuria

Thomas Knoll[1], Albrecht Hesse[2]
[1]Department of Urology, Mannheim University Hospital, Mannheim, Germany
[2]Department of Urology, University of Bonn, Bonn, Germany

## Definition and Characteristics

Autosomal-recessive genetic disorder with a complex pattern of inheritance. Characterized by an impaired transport of the amino acids cystine, ornithine, lysine and arginine due to the defective transporter system $b^{0,+}$ located in the apical membrane of the proximal renal tubule. Only cystine is insoluble enough to crystallize and form stones inside the urinary tract.

Most patients with cystinuria develop cystine stones frequently during their lifetime and require repeated surgical interventions for stone removal. Today, stone removal procedures are minimally invasive. However, repeated invasive procedures eventually result in significant impairment of renal function. Available preventive treatment requires life long high patient compliance and regular follow-up examinations. However, even an optimal regimen can often only reduce the frequency of stone formation.

## Prevalence

The prevalence of cystinuria varies from 1:2,500 in a Lybian-Jewish population to 1:100,000 in Sweden. For Europe and the U.S., the data reported in the literature show a mean incidence from 1 in 1,000 to 1 in 17,000 [1]. In principal, stones may be formed at any age, with more than 80% of the patients developing their first stone within the first two decades.

## Genes

The disorder is autosomal-recessive. The $b^{0,+}$ heterodimeric transporter system is formed from two subunits, rBAT and $b^{o,+}$ AT [2,3]. A defect of rBAT, located on SLC3A1 on chromosome 2, is the most common cause of cystinuria in the Western world. The $b^{0,+}$ AT gene is located on SLC7A9 on chromosome 19. Multiple different mutations have been described for both locations.

## Molecular and Systemic Pathophysiology

Traditionally, cystinuria has been divided into three clinical subgroups: types I, II and III. New insights into the genetic and functional characteristics of the disease have led to a new classification by the International Cystinuria Consortium, dividing into type A, type B and type AB [4]. The new classification follows the chromosomal localization of the mutation with type A on chromosome 2, type B on chromosome 19 and type AB with mutations on both chromosomes (Table 1).

In contrast to earlier reports, clinical differences seem to be absent between the distinct types.

Urinary cystine concentrations do not correlate with stone event frequency. Males are often more severely affected than females and produce more stones.

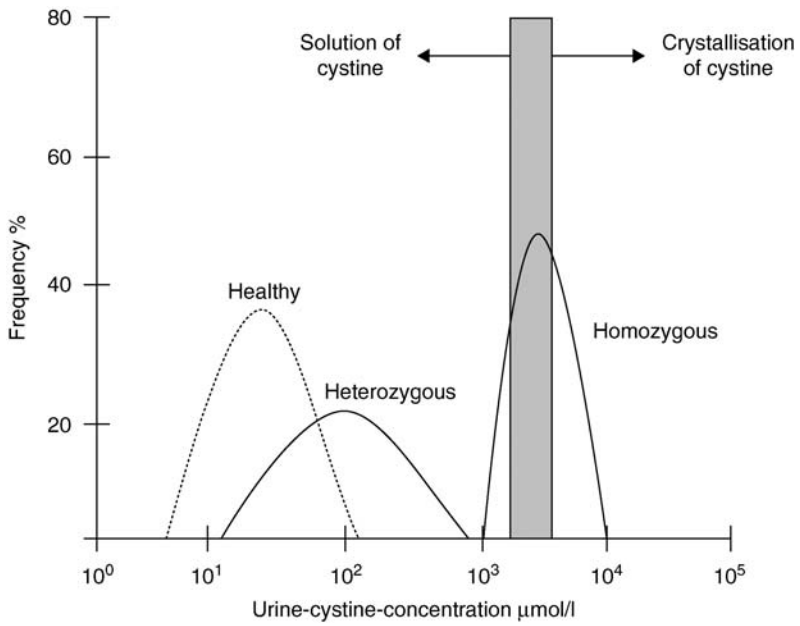
## Diagnostic Principles

Cystine stones have to be suspected in every patient, especially in the younger ones and in those with known cystinuria of any family member. Analysis includes serum analysis (creatinine), stone analysis (infrared spectroscopy), urine analysis (pH profile, i.e. minimum pH determination four times a day, specific urine gravity ≤1.010), urine sediment microscopy (typical hexagonal cystine crystals, which may, however, be absent in many patients), quantitative urinary cystine excretion (24-h. Urine, Fig. 1), qualitative urinary cystine test, gene analysis, and imaging (ultrasound, X-ray revealing poorly radio opaque stones).

**Cystinuria. Table 1** Clinical and genetic classifications of cystinuria

| Classification | Type A[a] | Type B[a] | | Type AB[a] |
|---|---|---|---|---|
| | | Type non-I[b] | | |
| | Type I[b] | Type II[b] | Type III[b] | |
| Gene locus | Chromosome 2 (SLC3A1) | Chromosome 19 (SLC7A1) | | Chromosomes 2 and 19 (SLC3A1/SLC7A1) |
| Urinary excretion of cystine and dibasic amino acids in heterozygotes | Normal | Elevated | Moderately elevated | Normal (rare, mild phenotype) |

([a]1, [b]5)



**Cystinuria. Figure 1** Urinary cystine concentration in healthy subjects as well as heterozygous and homozygous cystinuria patients (logarithm). Curves demonstrate upper and lower limits of cystine solubility in the urine.

## Therapeutic Principles

As gene therapy is so far unavailable so far, the disorder is treated by appropriate diet (reduction of methionine [metabolized to cystine], sodium reduction [reduces cystine excretion]), urine dilution (fluid intake >3.5 l day and night), urine alkalinization (potassium citrate [or sodium bicarbonate in cases with renal insufficiency] to increase urinary pH to >7.5 [threefold increase of cystine solubility]), reduction of cystine (cleavage of the disulfide bond of cystine by α-Mercaptoproprionylglycin [MPG, Tiopronin, 20–40 mg/kg BW], Captopril [75–150 mg/d] or ascorbic acid [3–5 g/day] for mild cases [weak evidence]), invasive stone removal (minimally invasive techniques like percutaneous nephrolithotomy, ureteroscopy or extracorporeal shockwave lithotripsy). Without a consistent metaphylaxis, stone relapse is unavoidable [5].

# Cytochrome-C-Oxidase Deficiency

Michaela Jaksch
Freiburg Medical Laboratory Middle East LLC, Dubai, UAE

## Synonyms

Deficiency of respiratory chain complex IV; COX deficiency

## Definition and Characteristics

Genetically and clinically highly heterogeneous (see Table 1). Early onset in neonates and infants (mostly recessive). Later onset in childhood, adolescence, or adulthood: mostly maternal inheritance: often combined deficiencies involving other complexes of the respiratory chain. Rarely recessive.

## Prevalence

COX deficiency is estimated about 1 in 10,000 to 20,000.

## Molecular and Systemic Pathophysiology

Deficiency of COX, the terminal enzyme of the respiratory chain, results in a large clinical spectrum ranging from severe neonatal onset multisystem disorders to late onset myopathies affecting mainly muscle, heart, and CNS.

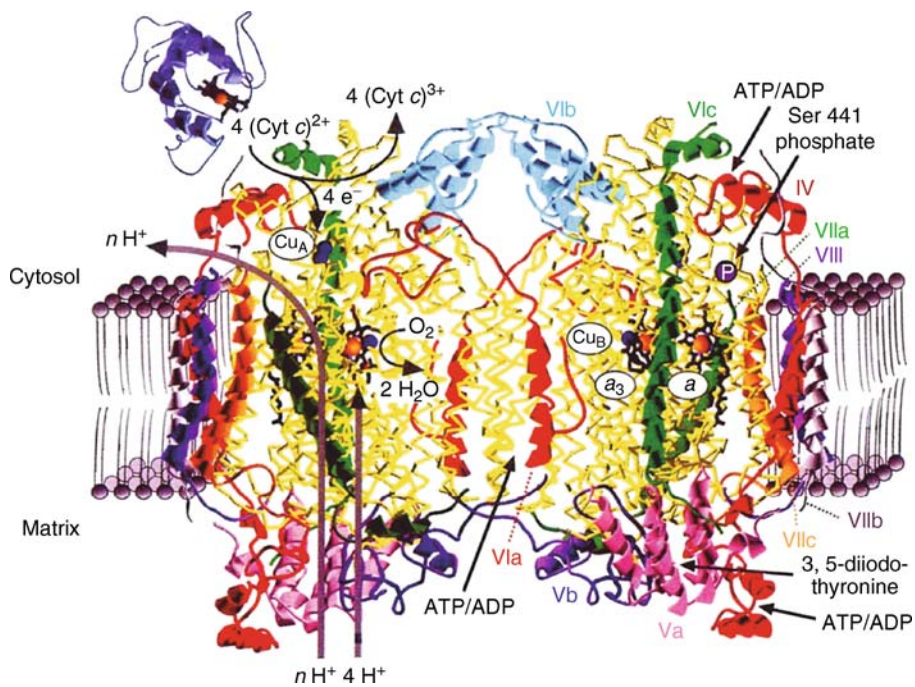
COX catalyzes the reduction of molecular oxygen by reduced cytochrome c. The complex is embedded in the inner mitochondrial (mt) membrane and is composed of 13 subunits. Three highly conserved subunits (Cox I-III) are encoded by the mitochondrial DNA (mtDNA) and form the catalytic core of the enzyme. Ten less conserved subunits, encoded by nuclear DNA, are thought to modify or to stabilize the complex. For its enzymatic function COX needs three copper ions, two hemes, magnesium, and a zinc ion. The holoenzyme is active as a dimer (see Fig. 1). Known mutations causing COX deficiency are the maternally inherited mitochondrial tRNA mutations or sporadic deletions of mtDNA, both of which generally result in combined COX deficiencies. Sporadic isolated COX deficiencies have been repeatedly described in association with mutations in mtDNA-encoded structural genes COXI-III. Several nuclear genes are known to be essential factors for assembly and maintenance of the COX complex. Six such assembly genes – SURF1, COX10, SCO1, SCO2, COX15, LRPPRC (see Table 1) – have been identified in the past 8 years in human autosomal-recessively transmitted (isolated) COX deficiency disorders.

## Diagnostic Principles

Encephalomyopathies, typical findings on MRI, morphological findings in muscle and high lactate in blood and/or CSF may point to a mitochondrial disorder. Measurement of the respiratory chain enzymes in muscle tissue is recommended to detect COX deficiencies prior to perform genetic analyses.

## Therapeutic Principles

Symptomatic therapy only. No gene therapy available. Exercise has repeatedly shown improvement in mtDNA mediated disorders. In Sco2 deficiency (deficiency of a mitochondrial copper transporter), cultivated cells



**Cytochrome-C-Oxidase Deficiency. Figure 1** Structure of the dimeric enzyme cytochrom-c-oxidase with catalytic centers (bovine): Ludwig et al. (2001) Chembiochem (with permission from WILEY-VCH Verlag GmbH, Weinheim, Germany).

**Cytochrome-C-Oxidase Deficiency. Table 1** COX deficiency causing disease genes, function of their proteins, and clinical characteristics (update 2007)

| COX deficiency causing disease gene (frequency) | Function of the resulting product/protein | Clinical characteristics (typical onset) |
|---|---|---|
| Several mtDNA tRNA genes (relatively common in combined RC deficiencies) | Translation of mitochondrial-encoded subunit genes | Encephalomyopathies (childhood, adolescence, adulthood) |
| mtDNA deletion; (relatively common in combined RC deficiencies) | Integrity of mtDNA pool | Pearson (infancy), chronic progressive external ophthalmoplegia (adolescence, adulthood), Kearns–Sayre syndrome (childhood, adolescence) |
| *DGUOK, TK* (relatively common in combined RC deficiencies with abnormal mitochondria in liver/muscle) | Concentration of mtDNA; mtDNA depletion | Depletion syndromes (muscular and hepatic forms) (infancy, childhood). Inheritance: recessive |
| *COX I-III* (isolated COX deficiency with ragged red fibers) | Highly conserved mtDNA-encoded subunits of the COX complex | Encephalomyopathy, isolated myopathy, exercise intolerance (infancy, adulthood). Inheritance: recessive/sporadic |
| *SURF1*(common in Leigh syndrome with COX deficiency) | COX-assembly factor; unknown function | Leigh syndrome (infancy). Inheritance: recessive |
| *SCO1* (rare) | COX-assembly factor; copper transporter | Encephalomyopathy, hepatopathy (infancy). Inheritance: recessive |
| *SCO2* (hypertrophic cardioencephalomyopathy with COX deficiency | COX-assembly factor; copper transporter | Hypertrophic cardioencephalomyopathy (at birth, infancy). Inheritance: recessive |
| *COX15* (two families described so far) | COX-assembly factor; heme biosynthesis | Hypertrophic cardioencephalomyopathy (around birth). Inheritance: recessive |
| *COX10* (three families described so far) | COX-assembly factor; heme biosynthesis | Hypertrophic cardioencephalomyopathy; anemia; Leigh Syndrome; tubulopathy; leukodystrophy (at birth, infancy). Inheritance: recessive |
| *LRPPRC* (common in French–Canadian Leigh Syndrome) | COX-assembly? Role in the translation or stabilization of the mRNA for mitochondrially encoded COX subunits? | French–Canadian Leigh Syndrome (infancy, childhood). Inheritance: recessive |
| *POLG/POLG2* (encephalomyopathy with hepatopathy; chronic progressive external ophthalmoplegia (CPEO) and others[a]) | Polymerase. Required to maintain the genetic integrity of mtDNA | Highly variable. Onset neonatal up to late adult life. Inheritance: recessive/dominant |

[a]Other candidates (*COX11, COX16, COX19* etc.) are known from yeast studies, but no mutations have been detected so far in human COX deficiency disorders. No mutations have been detected in nuclear-encoded structural subunits of COX.

showed a rescue of COX deficiency, when copper was added to the medium. This finding could be useful in future therapeutic approaches.

## Synonyms

CMV infection

## Definition and Characteristics

About 90% of infants with congenital cytomegalovirus (CMV) infection are asymptomatic at birth. Jaundice (62%), petechiae (58%), and hepatosplenomegaly (50%) are the most frequently noted classical triad in symptomatic infants (Fig. 1) [1].

Other clinical manifestations include oligohydramnios, polyhydramnios, prematurity, intrauterine growth retardation, nonimmune hydrops, foetal ascites, hypotonia, poor feeding, lethargy, thermal instability, cerebral ventriculomegaly, microcephaly, intracranial calcifications usually periventricular in distribution, "blueberry muffin" spots, and chorioretinitis [1]. Sensorineural hearing loss develops in 30% of symptomatic infants at birth [1]. Infants with symptomatic CMV infection may be at increased risk for congenital malformations such as inguinal hernia in males, high-arched palate, defective enamelization of the deciduous teeth, hydrocephalus, clasp thumb deformity, and clubfoot [1]. Some affected infants may develop hepatitis, pneumonia, osteitis, and intracranial hemorrhage.

CMV is the largest and most complex member of the Herpesviridae family of DNA viruses [2]. The genome is composed of a linear double-stranded DNA, approximately 240 kb in size ($150 \times 10^6$ da), and is capable of isomerization [2]. The genome has been completely sequenced and shown to contain non-overlapping open-reading frames for more than 200 potentially immunologic proteins. The genome is surrounded by an icosahedral capsid composed of 162 capsomeres [2]. The capsid is surrounded by a poorly defined amorphous tegmen which is itself surrounded by lipid envelope, giving the complete and mature viral particle a diameter of about 200 n [2]. The virus lacks the enzyme thymidine kinase, which renders it resistant to those antiviral agents that depend on this enzyme for their action. The virus is named for the intranuclear and intracytoplasmic inclusions seen with symptomatic disease, cytomegalic inclusion disease.

**Cytomegalovirus Infection, Congenital. Figure 1** A newborn infant with symptomatic congenital CMV infection presenting with petechiae, jaundice, and hepatosplenomegaly.

## Prevalence

Congenital CMV infection occurs in approximately 0.2–2.5% of all live births; infection is more prevalent in underdeveloped countries and among lower socioeconomic groups in developed countries.

## Molecular and Systemic Pathophysiology

Congenital CMV infection results from transplacental transmission of the virus during maternal viraemia [1]. Maternal viraemia is more likely to occur with primary than with recurrent infection. After transplacental transmission, the virus spreads through the foetus by a hematogenous route. Infection at an earlier gestational age often correlates with a less favorable outcome. Infants born to mothers with primary CMV infection during pregnancy are more likely to have symptoms at birth. The presence of maternal antibody to CMV before conception provides substantial protection against intrauterine transmission of the virus and severe foetal infections [3].

## Diagnostic Principles

Congenital CMV infection can be diagnosed by isolation of the virus from the urine or saliva within the first 3 weeks of life. This can be accomplished by traditional virus culture methods which may take 1–2 weeks to obtain a result or rapid culture methods ("shell vial assay") using centrifugation to enhance infectivity and monoclonal antibody to detect early antigens in infected tissue culture cells which may yield results in 24 h. Rapid diagnosis of CMV can also be accomplished by detection of CMV DNA by DNA amplification techniques via the polymerase chain reaction (PCR) or DNA hybridization techniques. Culture, however, maintains a slight advantage over PCR in terms of specificity. The presence of CMV-specific IgM in cord blood or in the infant's blood within the first 3 weeks of life suggests the diagnosis of congenital CMV infection [1]. Prenatal detection of foetal infection can be established by isolation of the virus from the amniotic fluid obtained by amniocentesis. In symptomatic infants, anaemia, thrombocytopenia, hyperbilirubinaemia, atypical lymphocytosis, elevated serum transaminases, and elevated cerebrospinal fluid protein may be found. Skull radiographs, CT scan, and MRI may demonstrate periventricular calcifications and ventriculomegaly. Radiographs of the long bones many show longitudinal radiolucent streaks ("celery stalk" appearance).

## Therapeutic Principles

Preliminary data have shown ganciclovir, a synthetic acyclic nucleotide analog of guanine, effective in the treatment of symptomatic congenital CMV infection [4]. Presently, there is insufficient data to make evidence-based recommendations about indications for the routine use of ganciclovir for the treatment of congenital CMV infection [4]. Children with congenital CMV infection are at risk for hearing loss, mental retardation, psychomotor delay, cerebral palsy, and impaired vision. As such, children with congenital CMV infection should have long-term audiologic, neurodevelopmental, and ophthalmic follow-up for early identification of these problems [1].

## Darier Disease

Dieter Metze
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Darier-White disease; Keratosis follicularis; Dyskeratosis follicularis

### Definition and Characteristics

Darier disease is an autosomal dominant skin disorder characterized by warty papules in seborrheic areas (central trunk, flexures, scalp, and forehead), palmoplantar pits, and nail dystrophy. Onset usually occurs between the age of 6 and 20 years with complete penetrance in adults, although expressivity is variable [1].

Patients present with widespread itchy malodorous crusted hyperkeratotic papules, plaques, and painful erosions. Blistering is only rarely seen. Mucosal changes include papules on the hard palate. Nails show longitudinal red and white lines, fragility, notchings and subungual hyperkeratosis. On palms and soles keratotic papules may occur alone or in combination with pits, on the backs of the hand acrokeratosis verruciformis-like lesions can be present. Rare manifestations include hemorrhagic lesions on acral sites [2]. Secondary infection by herpes virus, bacteria, or fungi is common. Sun, heat, and sweating exacerbate the disease. Neuropsychiatric abnormalities, including mild mental retardation, epilepsy, psychosis and affective disorder may be associated [1].

### Prevalence

The estimated prevalence ranges from 1 in 55,000 to 100,000 [1].

### Genes

Sakuntabhai et al identified mutations in the ATP2A2 gene on chromosome 12q23–24.1, which encodes the sarco/endoplasmic reticulum Ca2(+)-ATPase type 2 isoform (SERCA2) and is highly expressed in keratinocytes. Thirteen mutations were identified, including frameshift deletions, in-frame deletions or insertions, splice-site mutations and missense mutations in functional domains [3].

### Molecular and Systemic Pathophysiology

Mutations in ATP2A2 cause Darier disease and suggest a role for the SERCA2 pump in the Ca(2+)-signaling pathway that regulates cell-to-cell adhesion and differentiation of the epidermis [3]. Lesions following Blaschko lines could be further demonstrated to result from a somatic mutation in ATP2A2 and thus can be best regarded as segmental Darier disease induced by postzygotic mosaicism instead of "acantholytic dyskeratotic nevus" [4]. Additionally, Darier's disease and Acrokeratosis verruciformis Hopf have been demonstrated to be allelic disorders [5].

### Diagnostic Principles

Clinical diagnosis can be confirmed by a skin biopsy. Histology of the epidermis shows proliferation of basal keratinocytes, suprabasal clefts in discrete foci, acantholytic and dyskeratotic keratinocytes in the stratum spinosum and granulosum (focal acantholytic dyskeratosis), and columns of parakeratosis. In the upper dermis a sparse perivascular lymphocytic inflammation is present.

### Therapeutic Principles

Pharmacological therapy, such as Retinoids and other treatments, such as dermabrasion or carbondioxide laser vaporization.

## De Quervain's Thyroiditis

Tam Nguyen
University of Duesseldorf, Duesseldorf, Germany

### Synonyms

Subacute (granulomatous) thyroiditis; Subacute non-suppurative thyroiditis; Giant cell thyroiditis

### Definition and Characteristics

Self-limiting painful subacute thyroiditis, histologically characterized by giant cells and granulomas, and often following an upper respiratory infection.

### Prevalence

Less than 5% of all patients with thyroid pathology. Sex ratio female:male = 5:1, age of onset 20–60 years, seasonal incidence (summer/autumn).

### Molecular and Systemic Pathophysiology

De Quervain's thyroiditis is presumed to be caused by a viral infection (including coxsackievirus, mumps, measles, adenovirus, echovirus, and influenza) or by a postviral inflammatory process. An association to HLA-B35 and -B67 has been demonstrated. The current hypothesis is that a viral infection provides an antigen that binds to HLA-B35 and hence activates cytotoxic T-cells. T-cell activation leads to a damage of thyroid follicular cells and may result in unregulated release of T4 and T3. When the inflammation subsides, the follicles regenerate and thyroid function normalizes. Also, a process of apoptosis is discussed to be involved in the causes of subacute thyroiditis.

The inflammation leads to pain in the region of thyroid (radiating to neck, jaw, throat, ears), enlarged thyroid gland, fever, fatigue, malaise, and myalgia. Painful enlargement of the thyroid gland generally lasts a few weeks or even months. Rarely, pain may be absent, a condition called silent thyroiditis. In 40–50%, an initial period of hyperthyroidism occurs and may be followed by a period of hypothyroidism before thyroid function normalizes. In 5%, hypothyroidism persists, and in about 2%, subacute thyroiditis recurs.

### Diagnostic Principles

De Quervain's thyroiditis is a clinical diagnosis. Laboratory findings are a high ESR (>50), elevated values of T4 and T3 and lowered TSH in the early stage of illness, elevated thyroglobulin values, mild anemia, and mild leucocytosis. Autoantibodies to thyroidperoxidase and thyroglobulin may be positive. Other findings are an enlarged thyroid gland, diffusely or focally hypoechogenic parenchyma and low to normal vascularity in ultrasonography, and a low radioiodine uptake value. Fine-needle aspiration can define the disease.

### Therapeutic Principles

Treatment is directed primarily at controlling the symptoms of inflammation. Nonsteroidal medications or salicylates are used to control mild thyroid pain, and high doses of glucocorticoids are used for more severe thyroid pain. Beta-blockade controls the symptoms of thyrotoxicosis. Treatment with thyrostatics is not indicated, for thyrotoxicosis is due to unregulated hormone release caused by cell damage.

# Deafness, Genetic

Birgit Haack
Department of Molecular Pathology, University Hospital of Tuebingen, Tuebingen, Germany

## Synonyms

Hereditary hearing impairment; HHI

## Definition and Characteristics

Clinically and genetically heterogeneous class of disorders showing various patterns of inheritance and involving a multitude of different genes [1].

The most common classification of HHI is based on the occurrence or absence of additional symptoms next to HI (syndromic or non-syndromic HHI).

## Prevalence

One in 1,000 newborns suffers from congenital hearing impairment [2]. It is presumed that in approximately 60% of patients a genetic component is involved in the development of hearing impairment [2].

Of all HHI cases, 30% is syndromic in nature whereas 70% is non-syndromic, occurring without other clinical malformations [3].

The mode of inheritance of non-syndromic hearing loss (NSHL) can be assigned to autosomal dominant (DFNA, ~10–15%), autosomal recessive (DFNB, ~70%), X-linked (DFN, ~1–3% out of all cases), and mitochondrial forms (proportion not known).

Syndromic HHI is categorized according to the underlying defects.

## Genes

Syndromic HI is associated with other clinical symptoms, e.g., blindness (Usher syndrome), cardiac arrhythmia (Long QT syndromes), or pigment abnormalities (Waardenburg syndrome) [1]. These syndromes are based on mutations in various genes that commonly function in other tissues as well as the cochlea. More than 400 syndromes including HI have been described up to date.

To date, 39 genes for non-syndromic hearing impairment (NSHL) have been characterized [1]. Considering the extensive inner ear physiology, 100–150 genes and gene products are estimated to play a role in the inner ear and in the hearing process in general.

## Molecular and Systemic Pathophysiology

Genes known to be involved in HHI fulfil different functions in the inner ear: in the development, structure, ion exchange, and further physiological function. Based on their functions it is possible to categorize them in several subgroups [4].

*HI Genes Encoding for Proteins with Essential Role in Ion Exchange Processes*: Mutations in the GJB2 gene have been established as a major cause of NSHL in different populations with mutation frequencies varying between 10 and 75% in analyzed patients [5]. GJB2 encodes for the gap junction channel protein connexin 26 contributing to the essential ion exchange process and therefore to maintenance of homeostasis in the inner ear. Mutations in further connexin encoding genes (GJB6, GJB3) have also been associated with non-syndromic HI. Several genes encoding for ion channel components have been identified to carry mutations causing syndromic HI, e.g., KCNQ1, HERG, SCN5A, KCNE1, and KCNE2 in Long-QT syndromes.

*HI Genes Encoding for Structural Proteins*: The group of HI genes encoding for structural proteins comprise extracellular matrix proteins, cytosceleton proteins, and scaffold proteins. For instance, changes in Collagen 11A2 have been shown to be associated with autosomal dominant non-syndromic sensorineural deafness type 13 (DFNA13) as well as with different syndromic diseases like Stickler syndrome type III, Marshall syndrome, OSMED (otospondylomegaepiphyseal dysplasia) syndrome, and Weissenbach-Zweymüller

syndrome. Mutations in TECTA (alpha-tectorin), the gene encoding for the major non-collagenous component of the tectorial membrane, have been identified to be responsible for autosomal dominant as well as recessive inherited forms of non-syndromic deafness (DFNA8/12 and DFNB21).

*HI Genes Encoding for Transcription Factors and Factors for Regulation of Development*: Genes summarized in this subgroup have been associated with various syndromes and with non-syndromic hearing impairment following different patterns of inheritance. The pathways by which mutations in these genes cause hearing impairment are mostly unclear.

*HI Genes Encoding for Motor Molecules (Myosins)*: Mutations in genes encoding for myosins were proven to be involved in pathogenesis of syndromic as well as non-syndromic hearing impairment. Motor molecules like myosins are associated with actins and serving in intracellular movement. Thus, mutations are thought to disrupt both the structure and the function of the sensory epithelia.

*HI Genes Encoded by the Mitochondrial Genome*: Syndromic as well as non-syndromic HI forms have been associated with mutations in mitochondrially encoded genes. Therefore they are inherited maternally and show extreme variable phenotypes that are due to a varying number of affected mitochondria in the cells.

The A1555G mutation in the 12SrRNA gene has been the first mutation associated with aminoglycoside-induced and non-syndromic sensorineural hearing impairment. In regard to daily medical practice the mitochondrial inherited HI appears to gain clinical relevance.

*HI Genes in Cooperation with Modifier Genes*: To date, two loci have been mapped but no genes have been identified yet. The DFNM1 locus is thought to suppress recessive deafness DFNB26, while the DFNM2 locus may influence the penetrance of the mitochondrial A1555G mutation.

*HI Genes Encoding for Other Proteins and for Proteins with so far Unknown Function*: Genes summarized in this subgroup comprise genes that cannot be assigned to other subgroups like OTOF (Otoferlin, inner hair cell synapse component) or STRC (Stereocilin, stereocilia component). The function of several other genes is still unclear.

### Diagnostic Principles

Molecular diagnosis of mutations in GJB2 can be made simple and cost effective, since this gene has only one coding exon. In daily medical practice, DNA is extracted from blood, followed by polymerase chain reaction and sequencing. Based on these techniques, variations of the GJB2 nucleotide sequence can be detected.

In addition the mitochondrial gene 12SrRNA (mutation A1555G) and the Pendrin gene (Pendred syndrome) can be screened efficiently.

### Therapeutic Principles

To date, no causal therapy for HHI is available. In general, affected persons are equipped with hearing aids.

# Delayed Puberty

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Delayed puberty is defined as the onset of puberty after the age of 13 years in girls and 14 years in boys [1]. The causes of delayed pubertal are outlined in Table 1. Constitutional delay of puberty is the most common cause of delayed puberty. Affected children are usually short but otherwise healthy [2]. These children reach full sexual maturation with time. There is often a family history of late bloomers [2]. Children with hypogonadotropic hypogonadism present with hypogonadism and sexual infantilism. Patients with isolated deficiencies of LH and FH usually have normal stature whereas those with associated growth hormone deficiency are usually short. Children with hypergonadotropic hypogonadism also present with sexual infantilism. The most common forms of primary gonadal failure are associated with sex chromosomal abnormalities and they have characteristic physical findings [3].

## Prevalence

Delay puberty affects approximately 2% of boys and 0.4 and 2.3% of white and black girls, respectively [3].

## Genes

Impaired gonadotropin release can result from mutations in several genes that regulate pituitary development, namely, HESX1, LHX3, PROP1, FSHβ, LHβ, SF1, and DAX1 [1].

## Molecular and Systemic Pathophysiology

Delayed puberty may result from a lack of pubertal maturation of the hypothalamic-pituitary axis or from gonadal dysfunction. Constitutional delay of puberty is due to a physiologic delay in the maturation of the central nervous system which results in a delay in the normal decrease in the sensitivity of the hypothalamic-pituitary axis to the prepubertal levels of the sex hormones. The lack of pubertal maturation of the hypothalamic-pituitary axis may also result from a systemic illness [4]. Hypergonadotropic hypogonadism is due to primary gonadal failure. Eugonadal eugonadism may result from an anatomic defect such as vaginal agenesis or an end organ resistance such as testicular feminization syndrome.

Modified from Leung AK, Robson WL (1990) HK J Pediatr 7:124–132.

## Diagnostic Principles

Relevant investigations should be performed based on the history and the physical examination. An assessment of the bone age is the most useful screening test.

In general, the greater the disparity between the bone age and the chronologic age, the higher is the chance that an endocrine abnormality is present. Roentgenograms of the skull may identify enlargement of the sella turcica, intracranial calcifications, or increased intracranial pressure. A computerized tomographic scan of the brain may be necessary if a hypothalamic or pituitary tumour is suspected. A blood count, sedimentation rate, serum electrolytes, serum creatinine, and urinalysis should be performed to help exclude a chronic illness. A determination of the plasma sex hormone, FSH, and LH levels should be performed. Those children with elevated gonadotropins together with low sex hormone levels have hypergonadotropic hypogonadism secondary to primary gonadal failure. An elevation of both the gonadotropin and the sex hormone levels may imply that the onset of puberty is imminent in a child with constitutional delay of puberty [2]. If both the plasma gonadotropin and the sex hormone levels are low, the differential diagnosis is between hypogonadotropic hypogonadism and constitutionally delayed puberty. The determination of the secretory response of gonadotrope to GnRH may distinguish the child with constitutionally delay of puberty from the child with isolated gonadotropin deficiency [5]. Chromosomal studies should be performed if the physical examination suggests either Klinefelter's syndrome or Turner's syndrome [1]. An ovarian ultrasound may reveal gonadal streaks.

### Therapeutic Principles

The successful management of a child with delayed puberty depends upon the identification and the treatment of the underlying aetiology. Children with constitutional delay of puberty should be reassured that normal pubertal development will occur spontaneously. For boys with severe psychological problems and social disabilities as a consequence of pubertal delay, a short course of testosterone enanthate (50–100 mg/month, for 4–6 months) may be considered. For girls, a 3–4 months course of ethinylestradiol (5 μg daily) or conjugated oestrogens (0.3 mg daily) may help to initiate maturation of the secondary sexual characteristics [3].

[2]Department of Human Genetics, Yokohama City Graduate School of Medicine, Yokohama, Japan

### Synonyms

9p monosomy; Monosomy 9p syndrome; 9p-syndrome

## Definition and Characteristics

It is defined as a deletion of the distal short arm of chromosome 9. This syndrome is characterized by moderate developmental delay [present in 100% of patients with this syndrome (mean IQ is 49, ranging from 33 to 73)], trigonocephaly, midface hypoplasia, upslanting palpebral fissure, epicanthal folds, flat nasal bridge, long philtrum, small and malformed ears, digital abnormalities (long middle phalanges of the fingers with the extra flexion creases, short distal phalanges with short nails), inguinal and/or umbilical hernia, and cardiovascular abnormalities including ventricular septal defect, patent ductus arteriosus, and pulmonary stenosis [1,2]. Their social adaptation is often good [1].

## Prevalence

More than 100 patients have been reported since 1973, but the prevalence is unknown.

## Genes

Genes causing each clinical manifestation of the 9p deletion syndrome have not yet been identified. However, there are nine known genes within this critical region (Fig. 1). Among them, CER1 may be related to trigonocephaly, and ZDHHC21 could be associated with mental retardation [2].

## Molecular and Systemic Pathophysiology

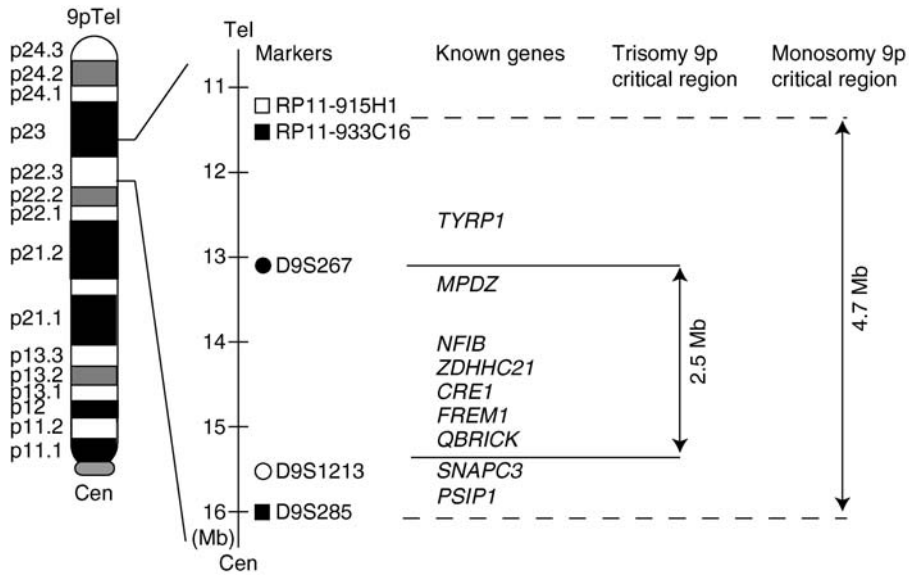
9p-syndrome is caused by a cytogenetic deletion of a region around 9p21–p24. Christ et al. reported that breakpoint hot-spots were located at the 9p22.3 region between D9S274 and D9S285 (9 cases) and other breakpoints spread throughout D9S1917 (9p22.3) and D9S162 (p22.1) (15 cases) among 24 cases of 9p deletion with phenotypic heterogeneity [3], indicating that there are no main deletion breakpoints for this syndrome. Thus it is unlikely that 9p deletions occur through low-copy-repeat-related nonallelic homologous recombination.

Almost 80–85% of deletions were de novo, the remaining being unbalanced chromosomal rearrangements, which were mostly familial. The origin of deletions was either paternal or maternal (almost even), but some preferential parental origin might exist, depending on the location of breakpoints [3,4].

The critical region for the core features including trigonocephaly has been narrowed to 4.7 Mb at 9p22.2–p23 from RP11–933C16 to D9S285 (chromosome 9 physical position: 11,355,596–16,068,221 bp based on the UCSC genome browser of March 2006 assembly) [2] (Fig. 1). Genes causing each clinical manifestations of the 9P deletion syndrome have not yet been identified. However, these are nine known genes within this critical region (Fig. 1). Among them, CER1 may be related to trigonocephaly, and ZDHHC 21 could be associated with mental retardation [2].

## Diagnostic Principles

Core clinical features are helpful including trigonocephaly, small and upward slant of the palpebral fissure (more pronounced than that of trisomy 21), flat nasal bridge, anteverted nostrils, long philtrum, and



**Deletion 9p Syndrome. Figure 1** Critical regions for trisomy 9p syndrome and monosomy 9p syndrome. The black and white circles indicate the linked and unlinked markers/clones to the critical region for trisomy 9p syndrome. The black box and white squares depict the linked and unlinked to the critical region for monosomy 9p syndrome.

microretrognathia. A definitive diagnosis should be made by either high resolution karyotyping, FISH or microarray CGH.

## Therapeutic Principles

Only symptomatic treatment is available.

# Deletion of 18q

A. J. Larner
Cognitive Function Clinic, Walton Centre for Neurology and Neurosurgery, Liverpool, UK

## Synonyms

Chromosome 18q deletion syndrome; de Grouchy syndrome; 18q- syndrome; OMIM#601808

## Definition and Characteristics

Deletion of the long arm of chromosome 18 produces a multiple-anomaly mental retardation syndrome of variable phenotype encompassing: learning disability, sometimes with non-development of language, short stature, and variable dysmorphism, such as microcephaly, mid-facial hypoplasia, prominent antihelix, and long tapering fingers [1]. Hearing loss, sensorineural or conductive, is common, the latter due to congenital aural atresia. Neurological symptoms and signs, such as hypotonia, nystagmus and incoordination, are also common [2]. Movement disorders such as tremor and dystonia have been reported, as have seizure disorders of variable semiology, including complex partial seizures with prominent autonomic features, apnoeic seizures, and benign focal seizures, most usually with childhood onset but sometimes presenting in adults [3]. Autoimmune disorders have been described, particularly autoimmune hypothyroidism. Overall, the phenotype is quite variable, and cases with normal cognition have been reported.

Magnetic resonance brain imaging typically (in about 95% of cases) shows confluent or multifocal white matter abnormalities with poor differentiation of the grey/white matter interface on $T_2$-weighted images due to increased white matter signal, reflecting abnormal myelination of the white matter. This incomplete myelination or dysmyelination has prompted some to classify 18q deletion syndrome as a leukodystrophy. There is also a reduction in size of the corpus callosum, particularly in its posterior portion which normally contains heavily myelinated fibers.

Neuropathological studies of 18q deletion are limited but generally confirm the abnormal myelination seen on brain imaging. Occasional reports of heterotopic neurones in the white matter and of polymicrogyria indicate a possible neuronal migration disorder in addition [4], that might be relevant to the pathogenesis of seizure disorders.

## Prevalence

No specific studies have been undertaken; some authors have opined that deletion of 18q is at least as frequent as cri-du-chat syndrome. An estimated incidence of one in 40,000 live births has been quoted.

## Genes

The most common deletion extends from region q21 to qter, but interstitial deletions also occur. This region includes the gene encoding myelin basic protein, and possible genes involved in the production or regulation of growth hormone production.

## Molecular and Systemic Pathophysiology

Haploinsufficiency at or near the locus encoding myelin basic protein is responsible for incomplete brain myelination, since rare cases with interstitial 18q deletions in which the myelin basic protein gene is preserved do not show imaging evidence of white matter change [5]. Growth hormone deficiency is common in 18q deletion and probably plays a role in the growth failure seen in many affected individuals.

## Diagnostic Principles

In a patient with an appropriate phenotype, the standard method of investigation has been karyotyping to look for a terminal deletion of the long arm of chromosome 18 (46, XX, del(18)(q22.2) karyotype) using cytogenetic banding techniques. This approach may be insufficient for the identification of interstitial deletions. Modern molecular analysis using polymorphic markers throughout the 18q region and cytogenetic FISH and Southern blotting techniques can identify not only terminal

deletions but also cryptic rearrangements in which the most distal portion of 18q is retained.

Magnetic resonance brain imaging demonstrating dysmyelination in a child with learning disability may also raise the clinical index of suspicion for 18q deletion syndrome.

## Therapeutic Principles

There is no specific treatment for 18q deletion syndrome. Growth hormone may improve both height and cognition. Thyroid function should be monitored and treated appropriately if abnormal. Seizure disorders may respond to antiepileptic medications. Early diagnosis may enable application of hearing aids. Principles of best practice for the management of learning disability are appropriate, including behavioral measures and, if necessary, psychopharmacology.

# Deletion of 22q13

Oliver Bartsch
Institute of Clinical Genetics, Dresden University of Technology, Dresden, Germany

## Synonyms

22q13.3 deletion

## Definition and Characteristics

The deletion of the human chromosome 22q13 is minute by cytogenetic terms and typically represents a chromosomal microdeletion. It is one of the 50 + different chromosomal microdeletions that recur and generate a genetic syndrome [1]. By removing the distal end of 22q from one chromosome 22 homolog, the deletion removes a string of neighboring genes.

Although the diagnosis, deletion of 22q13, sounds very specific, it is not. Chromosome band 22q13 includes the subbands q13.1, q13.2, q13.31, q13.32 and q13.33, and is large by molecular cytogenetic and molecular standards. It comprises the 13.6 Mb region extending from 35.8 to 49.4 Mb/pter (megabases from the p-terminal end of the chromosome 22) and contains around 200 genes. There are large variations in the location of the breakpoint, the size of the deletion, and the clinical outcome. The largest deletion, q13.1 to qter, is rare and associated with death in early infancy. The smaller deletions of q13.3-qter are more frequent and compatible with survival into adulthood. Since most cases of the 22q13 deletion syndrome result from a deletion of 22q13.3, the terms 22q13 deletion and 22q13.3 deletion are often used interchangeably.

Patients missing chromosome 22q13.3 present similar clinical features, typically including a salient speech defect (severe delay or absence of expressive speech, 100%), global developmental delay resulting in mild mental retardation with sharply limited verbal abilities (for example: overall IQ 54, verbal IQ 32, and performance IQ 70 [2]), generalized hypotonia, and normal to advanced growth, a very unusual feature with chromosomal abnormalities [3]. Minor anomalies are highly variable and include dolichocephaly, abnormal ears, ptosis (Fig. 1), and relatively large hands and feet, but these are all unspecific and also common to many other genetic disorders [4]. Other signs may include decreased sweating, increased tolerance to pain, and a shy, quiet temperament [5, in preparation]. The phenotype has been referred to as either the chromosome 22q13.3 deletion syndrome or the Nesslinger syndrome (OMIM 606232). However, aside from the remarkable speech defect, the clinical characteristics are too variable and unspecific to enable a visual diagnosis.

## Prevalence

Deletion of 22q13 is a rare disorder, with an estimated incidence of 1 in 30,000 to 1 in 100,000 newborns.

## Genes

Within the deletion of 22q13, specifically the subset of genes that exerts dominant effects can contribute to the phenotype Table 1.

Recently SHANK3/PROSAP2, resIDing very near the end of chromosome 22q, was identified as a candidate gene for the severe speech defect [2,6].

## Molecular and Systemic Pathophysiology

Around 50% of cases represent pure terminal 22q13 deletion. The other cases represent an unbalanced translocation and are associated with trisomy of another chromosome end. The parents of these patients have a high recurrence risk for retarded children of up to 50% (25% each for the deletion and for the duplication of 22q13).

**Deletion of 22q13. Figure 1** Patient with a cytogenetically cryptic deletion of 22q13.3 diagnosed by subtelomere FISH, age (a) 3 years, (b, c) 11 years, and (d) 15 years [5]. Note the near-normal face not allowing a visual diagnosis.

## Diagnostic Principles

Although the 22q13 deletion syndrome has been associated with a recognizable phenotype, the clinical signs often are unspecific and not conducive to visual diagnosis. Prior to the era of fluorescent in situ hybridization (FISH); only a few cases of 22q13 deletion were reported [7]. Presumably, standard karyotyping did not allow for proper diagnosis. Subtelomere FISH has the power to detect subtle rearrangements at the chromosome ends that are missed by karyotyping, and deletion of 22q13 is now more frequently diagnosed. Because of the variable size of the 22q13 deletion, the deletion interval should be defined at the molecular level, so that the deleted genes in each patient can be determined

**Deletion of 22q13. Table 1** Genes at human chromosome 22q13 associated with dominant disorders

using a human genome browser (Ensembl: http://www.ensemble.org, UCSC Genome Browser: http://genome.ucsc.edu).

Subtelomere FISH has remained laborious and chromosomal microdeletions such as the 22q13 deletion are still underdiagnosed. Presently, researchers are attempting to solve the diagnostic problem using microarrays ("DNA chips").

## Therapeutic Principles

Severe delay of expressive speech is consistently found in children with 22q13 deletion. Apparently there is a specific cerebral malfunction resulting in difficulties with the concept of words. There is no hearing defect, and the understanding of language is consistently well ahead of speaking skills. Treatments available are assisted writing. Digital speech output systems using a portable communication device with natural voice output (DigiVox, Siemens, Germany) may be tried [5].

There is a support group available for 22q13 families: Mary C. Phelan, Ph.D., T.C. Thompson Children's Hospital, Chattanooga, TN 37403, U.S.A., (http://www.nt.net/~a815/22q13.htm; email: PhelanK@erlanger.org). There is also an affected family contact for deletion 22q13: Randy RIDdle, 5501 Vista Sandia NE, Albuquerque, NM 87111, U.S.A. (email: the5riddles@earthlink.net).

# Delirium

Barbara C. Van Munster
Department of Clinical Epidemiology and Biostatistics, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands

## Synonyms

Acute confusional state

## Definition and Characteristics

Delirium is a neuropsychiatric syndrome caused by a somatic factor, such as any medical condition, substance intoxication or withdrawal or the use or withdrawal of medication. It is defined by an altered consciousness and a change in cognition or a perceptual disturbance [1]. The syndrome develops acutely and symptoms usually fluctuate during the day. There are different clinical subtypes of delirium, the hyperactive, hypoactive and the mixed type.

## Prevalence

The prevalence is approximately 0.4% in the total population and 1.1% in persons above 54 years [2]. In a general hospital, 10–40% of the elderly patients on a medical or surgical ward experience delirium during admission. Alcohol dependent patients have a 5–10% lifetime risk for delirium after alcohol withdrawal.

## Genes

In delirium due to alcohol withdrawal, positive associations are known with polymorphisms in three genes involved in dopamine transmission, DRD3, SLC6A3 and TH [3]. The allelic variant of DRD3 may effect the insertion of the dopamine receptor D3 into the membrane. Dopamine transporters perform presynaptic dopamine re-uptake and thus regulate extracellular dopamine concentrations. The genetic constitution of the SLC6A3 gene affects the availability of dopamine transporters in the striatum. Possibly, there might also be associations with a polymorphism in a gene involved in the glutamate pathway (GRIK3), a neuropeptide gene (BDNF) and a cannabinoïd gene (CNR1). In medical patients there are no known polymorphisms associated with the development of delirium. In medical critically ill patients, the APOE4 allele could however contribute to longer duration of delirium.

## Molecular and Systemic Pathophysiology

The pathophysiology of delirium is still poorly understood and mostly hypothetical. There are multiple challenges in research in this area including the precise definition, multifactorial etiology and broad clinical spectrum with fluctuating symptoms and different subtypes. The most important risk factors for delirium i.e., old age and cognitive impairment result in a vulnerable brain. The first known hypothesis described the pathophysiological mechanism of specific disruptions of neurological pathways and neurotransmitter systems due to global failure of cerebral oxidative metabolism. In this respect delirium could be the final common syndrome of a variety of neurotransmitter abnormalities [4]. Other scientists believe delirium is caused by a final common pathway leading to acetylcholine deficiency and dopamine excess [5].

There is proof for involvement of the neurotransmitters acetylcholine and serotonin in delirium in medical and surgical patients. Histamine blockers, opioids and glucocorticoids are known for their ability to cause delirium but this may be related to the effects on other neurotransmitter systems, especially the anticholinergic effects. Activation of the dopaminergic system, enhanced hypothalamic gamma-aminobutyric acid function or increased glutamate activity could all play a role in delirium associated with alcohol withdrawal [3]. Since delirious patients often have a disturbed sleep-wake cycle, melatonin is possibly involved. Finally, first studies support a role for the cytokines, IFN-g, IGF-1, IL-6 and IL-8 in the pathophysiology of delirium.

## Diagnostic Principles

Delirium is diagnosed on the clinical picture based on the criteria of the International Classification of Diseases, Tenth Revision (ICD-10) or the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition Text Revision (DSM IV-TR) [1]. Global cognitive functioning can be assessed by the Mini Mental State Examination and talking to a relative about premorbid cognitive functioning. The severity of delirium can be scored by the DRS-R-98. To assess possible causes of delirium repeated physical and neurological examination is necessary. Depending on information and examination additional tests may be advised.

## Therapeutic Principles

Management of patients with delirium concentrates on ensuring safety from behavioral disturbance, reorienting the patient by combining environmental and behavioral measures via intensive nursing care and supporting these by pharmacological means [2]. Treating the underlying cause and discontinuing any medication with anticholinergic effect is of the utmost importance.

The first generation antipsychotic haloperidol in a dose of 0.5–5.0 mg, 1–2 times a day is the first choice medication in delirium, except for patients with parkinsonism or Lewy body dementia. If side effects appear, there is some support for the use of second generation antipsychotic medication such as olanzapine, risperidone, ziprasidone and quetiapine. The use of benzodiazepines is limited to alcohol withdrawal delirium or to restore the sleep-wake cycle. In patients with dementia, cholinesterase inhibitors have shown success in treating delirium in some case reports.

## Dementia with Lewy Bodies

Christine A. F. Von Arnim[1], Jochen Klucken[2]
[1]Department of Neurology, Ulm University, Ulm, Germany
[2]Department of Neurology, University of Regensburg, Regensburg, Germany

### Synonyms

Lewy body dementia; LBD; Diffuse Lewy body disease; DLBD; Diffuse Lewy body disease with gaze palsy; Lewy body variant of Alzheimer's disease (AD); DLB

### Definition and Characteristics

Progressive cognitive decline leading to dementia (essential for diagnosis), with fluctuating cognition with pronounced variations in attention and alertness, recurrent visual hallucinations that are typically well formed and detailed, and motor features of parkinsonism are the core features. Two core features are sufficient for a diagnosis of probable DLB. Suggestive features include REM sleep behavior disorder, severe neuroleptic sensitivity and low dopamine transporter uptake in basal ganglia demonstrated by PET or SPECT imaging. Exclusion features are presence of cerebrovascular disease and the appearance of parkinsonism at a stage of severe dementia. DLB should be diagnosed when dementia occurs before or concurrently (in general within one year) with parkinsonism. The term Parkinson disease dementia (PDD) should be used to describe dementia that occurs in the context of well-established Parkinson's disease (PD). The International Consortium on Dementia with Lewy bodies established revised criteria for the clinical and pathologic diagnosis of DLB [1]. Brainstem or cortical Lewy bodies are the only essential pathologic features, although other pathologic changes may be present as well.

### Prevalence

The prevalence is 2% in the general population >65 of age and is increasing with age. It contributes to about 10–15% of all dementias. The incidence is estimated to be 0.1% per year for the general population and 3.2% per year for all new dementia cases.

### Genes

DLB can be caused by alterations in the alpha-synuclein (SNCA, first identified in PD) and beta-synuclein (SNCB) genes. Some patients with a diagnosis consistent with Lewy body disease or dementia have mutations in the LRRK2 gene, which is mainly associated with PD (PARK8) [2,3]. A mutation in the prion protein gene (PRNP) was identified in one patient with DLB. The epsilon-4 allele of the APOE gene and the B allele of the CYP2D6 gene, a cytochrome P-450 monooxygenase, have been shown to be associated with a higher risk for DLB.

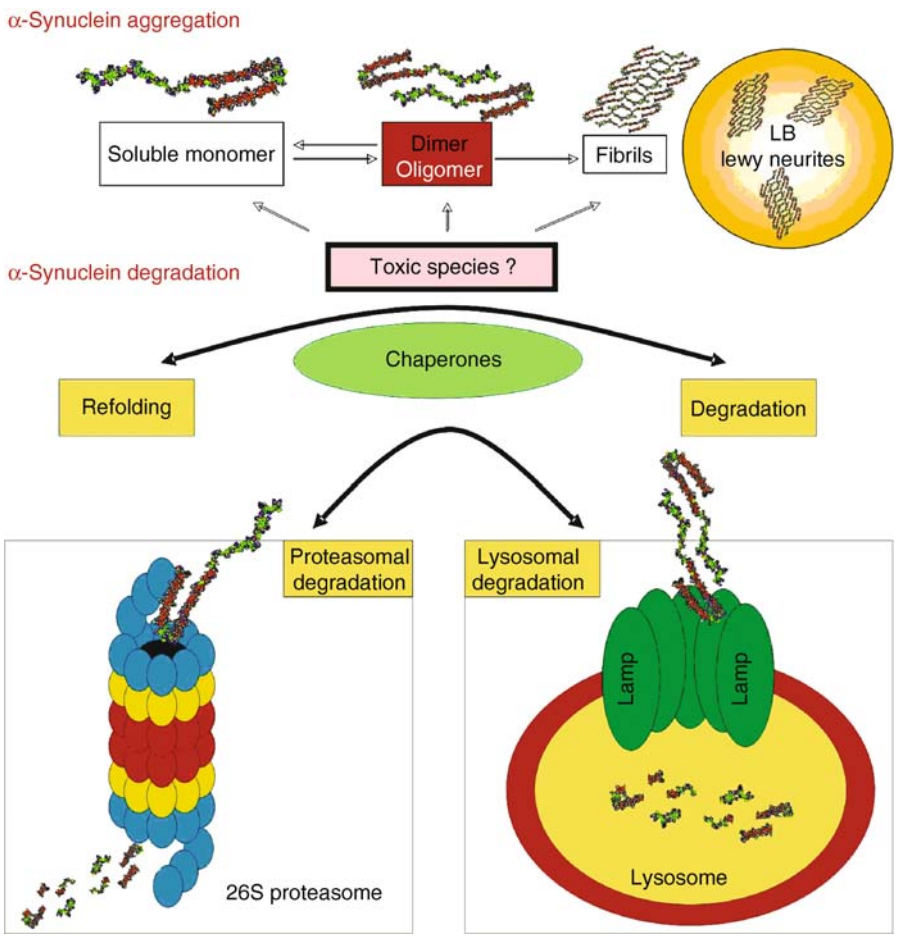
Genetic associations have been identified in few patients, families or in case-control studies Table 1.

### Molecular and Systemic Pathophysiology

In DLB, alpha-synuclein immunoreactive Lewy bodies (LBs) and Lewy neurites appear scattered throughout limbic and neocortical brain regions, as well as in subcortical structures including nucleus Basalis of Meynert, locus coeruleus, and substantia nigra. LBs are filamentous aggregates of alpha-synuclein and other proteins in the cytosol of neurons. Alpha-synuclein aggregation is also linked to PD, multiple system atrophy, and several other disorders, which are referred to collectively as "synucleinopathies." Aggregation of alpha-synuclein is thought to be aggravated by mitochondrial stress and proteasomal impairment. In addition, mutations of alpha-synuclein are associated with familial PD and have been described in patients with DLB. As shown (table), an increasing number of mutations associated with LBD features were identified in genes that are related to alpha-synuclein (beta-synuclein, LRRK2, PRNP), associated with oxidative stress (CYP2D6), or altered lipid metabolism (ApoE). This notion supports the idea that general stress factors influence the development of DLB. A protective effect has been shown for heat shock proteins (HSPs). HSPs belong to the family of chaperone proteins [4], that protect from misfolded proteins by refolding or by degradation (Fig. 1).

**Dementia with Lewy Bodies. Table 1** Genetic associations in few patients, families, or in case-control studies

| Gene | Locus | Protein | Diseases | MIM # |
|---|---|---|---|---|
| *SNCA* | 4q21 | Alpha-synuclein | DLB, PDD, PD, MSA | 163,890, 168,601, 605,543 |
| *SNCB* | 5q35 | Beta-synuclein | DLB | 602,569 |
| *LRRK2* | 12q12 | Leucine-rich repeat kinase 2, Dardarin | PD | 609,007, 607,060 |
| *PRNP* | 20pter-p12 | Prion protein | Creutzfeld-Jakob-disease, Gerstmann-Sträussler-disease, fatal familial insomnia | 176,640.0017 |
| *APOE* | 19q13.2 | Apolipoprotein E | Hyperlipoproteinemia type III, sea-blue histiocyte syndrome, AD, myocardial infarction, DLB | 107,741 |
| *CYP2D6* | 22q13.1 | Cytochrome P-450 monooxygenase | DLB ankylosing spondylitis | 124,030 |



**Dementia with Lewy Bodies. Figure 1** A hypothetical model of alpha-synuclein aggregation is shown in the upper panel. Soluble monomeric alpha-synuclein is present in the cytosol and eventually forms dimers and oligomers that further aggregate to higher ordered fibrils leading to LB or LN formation. The toxic species is not identified yet. Chaperone proteins can protect from alpha-synuclein aggregation and toxicity by refolding misfolded alpha-synuclein or by sending it to the proteasomal or lysosomal degradation machinery.

Whether LBs are the toxic equivalent or rather sustain a protective function is discussed controversially. The normal function of alpha-synuclein is not clear yet. Thus, its putative malfunction might lead to neuronal dysfunction and loss, independently from the LBs [5].

## Diagnostic Principles

The diagnosis is based on the revised McKeith Kriteria established by the International Consortium on DLB, as described above [1], based on the clinical features such as:

1. Fluctuating cognition with variations in attention and alertness
2. Parkinsonism
3. Visual hallucinations

## Therapeutic Principles

Patient management in DLB is complex and includes symptomatic treatment of cognitive impairment, management of neuropsychiatric and behavioral symptoms, and treatment of the movement disorder. Cholinesterase inhibitors (CHEIs) may be of benefit for the fluctuating cognitive impairments. The effect size in DLB is reported as being generally larger than seen in Alzheimer's disease. When pharmacological intervention for neuropsychiatric symptoms (visual halluzinations, delusions, anxiety and behavioral disturbances) is required, CHEIs or atypical antipsychotic medication are recommended. Placebo controlled trial data exists for rivastigmine. If CHEIs are ineffective or not sufficient to control symptoms it may be difficult to avoid a cautious trial of atypical antipsychotics. The early time point of the clinical diagnosis of DLB is critical given that DLB patients are more likely to experience an adverse reaction to classic neuroleptics such as haloperidol compared to AD patients (81% compared to 29%). The clinician should warn both the carer and the patient of the possibility of a severe sensitivity reaction. Typical antipsychotics should be avoided. Clozapine is most commonly used, but quetiapine and aripiprazole are new alternatives. However controlled clinical trials are needed. For extrapyramidal motor symptoms, Levodopa can be used. Medication should generally be started at low doses and increased slowly to the minimum required to avoid exacerbation of psychiatric symptoms. Anticholinergics should be avoided.

# Dementia, Fronto-temporal

Peter Heutink
Department of Clinical Genetics, VU University Medical Center, Amsterdam, The Netherlands

## Synonyms

Frontal temporal lobar degeneration; Frontal lobe dementia; Dementia of frontal type; FTD

## Definition and Characteristics

Fronto-temporal dementia (FTD) is a neurodegenerative disorder characterized by progressive behavioral disturbance, aphasia and a decline in frontal cognitive functions. FTD usually starts between age 40 and 60 years, with a clear peak in incidence between age 50 and 60. Disease duration varies between 5 and 15 years and there is equal distribution between men and women.

Since the frontal lobe is involved in many aspects of mental function, people affected by FTD often display marked changes in personality. Onset with disinhibited behavior is typical. Roaming, impatience and gluttony are also important symptoms. However, other executive and behavioral modalities that may not be regarded as suspect for FTD can be affected as well. Because the disease usually affects people who are relatively young, the effects on families are severe.

## Prevalence

Data on prevalence of FTD are limited [1]. No door-to-door studies have been performed and therefore most estimates are based on cases admitted into the clinic or studies that use active recruitment of patients. One study from the UK reported a prevalence of 15 cases per 100,000 people in the age range 45–64 years. A much larger study from the Netherlands reported 3.6/100,000

in the age group 50–59 years, 9.4/100,000 in the age group 60–69 and 3.8 in the age group 70–79. The Lund and Manchester groups reported that 9% of total cases in their clinic fulfilled criteria for FTD, while AD accounted for 42%. Another study reported that FTD comprised roughly one third of cases before the age of 65 and ~40% before 50. Differences in prevalence estimates are probably due to differences in patient ascertainment and sample size.

## Genes

FTD has a strong familial component; in most studies 40% of cases have a positive family history of dementia. In 1998, mutations in the microtubule associated protein tau (MAPT) gene were reported in families with FTD linked to chromosome 17. Currently, ~35 mutations in over 100 families have been described that account for 10–20% of familial FTD cases. No mutations have been identified in sporadic cases [2]. However, several mutations occurred in patients with a clinical diagnosis of AD or PSP.

In 1995 a second locus was reported on the pericentromeric region of chromosome 3 in a FTD family from the Jutland region of Denmark with a non-specific dementia lacking distinctive histopathological features. Subsequently a mutation in the charged multivesicular body protein, which is also known as chromatin-modifying protein 2B (CHMP2B), on chromosome 3 was identified. The CHMP2B gene does not appear to be a common cause for FTD as two studies have now screened a large number of samples and identified no other mutations. However, several mutations have been found in patients with amyotrophic lateral sclerosis (ALS).

More recently important progress has been made in resolving a problem that has haunted researchers since the discovery of mutations in MAPT. Genetic linkage studies in FTD families revealed the locus on chromosome 17q21. However, since the identification of MAPT mutations in 1998, nine FTD families have been conclusively linked to chr17q21 but lack defined MAPT mutations (tau-negative FTD-17). In each family, affected patients lack tau inclusions but develop ubiquitin-immunoreactive pathology typical of FTD-U. It became more and more evident that a second gene on chromosome 17q21 must be responsible and indeed recently two groups simultaneously reported mutations in the progranulin gene (PGRN) [3,4].

The frequency of PGRN mutations remains to be established in different FTD populations but the data that are available so far indicate that mutations in PGRN are relatively frequent. In a cohort of Belgian families, PGRN mutations accounted for 25.6% of familial cases compared to 7% for MAPT mutations, which still leaves the majority of familial FTD cases unexplained. An additional locus on chromosome 9q21–q22 has been identified, however the responsible gene is still unknown.

## Molecular and Systemic Pathophysiology

FTD-17 patients with MAPT mutations develop tau neurofibrillary inclusion pathology [1,2]. MAPT is involved in the regulation of microtubule stability and axonal transport of proteins. In the central nervous system, six MAPT isoforms are produced. Three isoforms have three microtubule-binding domains (3R) and the other three have four microtubule-binding domains (4R). The fourth microtubule-binding domain is encoded by the alternatively spliced exon 10. The identified mutations are almost exclusively located in the vicinity of the microtubule-binding domains. The mutations in MAPT can be classified by whether their primary effect is at the level of the translated protein or at the level of alternative splicing of exon 10 of MAPT. In the first case, mutations affect the ability of MAPT to bind microtubules and increase self-aggregation of protein. In the second case, mutations disrupt the balance of 3R versus 4R isoforms. In both cases microtubule stability and axonal transport will be affected, although effects are most probably very subtle since the other allele is still normal. In addition, mutant protein is preferably incorporated into insoluble aggregates and the pathogenic effect might also be production of toxic protein (mono-, oligo- or multimer).

The discovery of mutations in MAPT has had implications beyond FTD itself, as tau pathology is a common finding in several neurodegenerative diseases such as Alzheimer's disease, progressive supranuclear palsy and cortico basal degeneration. It is now evident that abnormal MAPT by itself can lead to neurodegeneration and can thus be a primary event leading to neurodegeneration.

In autosomal-dominant FTD-U families, linkage has been observed to chromosome 9p12–p13, caused by mutations in the valosin-containing protein VCP, (this includes Paget's disease). All patients had a primary clinical diagnosis of FTD (encompassing the clinical phenotypes of FTD, FTD with motor neuron disease, semantic dementia or primary progressive aphasia) and had at least one other family member with a similar clinical diagnosis.

PGRN is a secreted multifunctional growth factor that is composed of seven-and-a-half tandem repeats of a 12-cysteine granulin motif. PGRN is expressed in many tissues and mediates its role in development, wound repair and inflammation by activating signaling cascades that control cell-cycle progression and cell motility. In brain, PGRN is widely expressed in neurons and glia cells but its actual functions are not very well understood. The mutations identified so far are loss of function mutations [3,4].

## Diagnostic Principles

The term FTD was introduced by the Manchester and Lund groups who suggested a set of clinical and pathological diagnostic criteria for FTD. Although these criteria show good discrimination between FTD and for example Alzheimer's disease, they provide no guidance as to the number of clinical features needed for diagnosis or the relative importance of symptoms. This complicates clinical diagnosis as FTD shows partly overlapping clinical and pathological features with other syndromes with circumscribed degeneration of the prefrontal and anterior temporal lobes and non-Alzheimer disease type pathology.

Neuropathology shows neuronal loss, gliosis and spongiosis of the superficial layers of the frontotemporal cortex that may vary in distribution and severity. Using immunohistochemistry, FTD can be classified into three groups [1].

1. Transcortical gliosis with tau-reactive rounded intraneuronal inclusions (Pick's bodies) or microvacuolation and tau-positive neurofibrillary tangles or Pick like bodies in neurons and sometimes tangles in glial cells of cerebral cortical white matter. This group is considered part of the tauopathies.
2. Microvacuolation with ubiquitinated rounded intraneuronal inclusions and dystrophic neuritis within layer 2 of frontal and temporal neocortex and hippocampal dentate gyrus cells; FTD-ubiquitinated (FTD-U). This group appears the most common group and represents approximately 40% of cases.
3. Microvacuolation without neuronal inclusions; dementia lacking distinctive histological features (DLDH).

Interestingly this division based on neuropathology correlates remarkably well with molecular genetics findings (see above).

## Therapeutic Principles

There is no treatment that delays or stops disease progression. Current treatment only relieves some symptoms of disease. For instance, for unrest and hallucination psychopharmaca are prescribed.

# Dementia, Vascular

Chaeyoung Lee
Department of Bioinformatics and Life Science, Soongsil University, Seoul, South Korea

## Synonyms

Vascular cognitive impairment; VaD

## Definition and Characteristics

Vascular dementia (VaD) is a progressive deterioration in memory, behavior, thinking and motor and cognitive functions, accompanied by a cerebrovascular disease. It occurs when the blood flow that supplies oxygen and vital nutrients to the brain is impaired by a cerebrovascular event of stroke, carotid stenosis or aneurysm. Its most common type is multi-infarct dementia caused by repeated minor strokes.

The VaD can be caused not only by factors that cause inflammation, but also by a number of conditions that cause damage to the vascular system in the brain. The risk factors for VaD, therefore, are most likely to be those associated with cardiovascular diseases, including high blood pressure (hypertension), high cholesterol level (hypercholesterolemia), irregular heart rhythms (arrhythmias), obesity, diabetes, smoking and heart disease. In some cases, VaD patients simultaneously have a degenerative dementia, Alzheimer's disease (AD) and this is known as mixed dementia.

## Prevalence

The VaD is the second most common form of dementia following AD in Western societies, but it is the most common type in Far Eastern Asia. VaD accounts for 50% of all dementias that occur in individuals over 65 years old in Japan [1]. The prevalence rate of VaD is approximately 1.5% in Western countries and 2.2% in Japan and the rate increases more rapidly in developing countries than in developed countries. VaD is usually more common in men than in women. This may be because its major risk factors such as hypertension and heart disease are more frequent in men than in women.

## Genes

To date, genetic factors for VaD are not well understood. One exception is a rare Mendelian hereditary cause of cerebral autosomal dominant arteriopathy with subcortical infarct and leukoencephalopathy (►CADASIL), which is caused by mutation in the NOTCH3 gene.

Furthermore, its genomic architecture is quite limitedly known. Even the role of apolipoprotein E polymorphism, associated with a high risk of developing AD is unclear in VaD, with conflicting observations [2]. Recent studies suggest the genetic association of VaD with its candidate genes in Table 1.

## Molecular and Systemic Pathophysiology

VaD can be developed from ischemic or hemorrhagic brain injury. Cognitive functions decline mostly in the white matter and the central gray matter nuclei, especially the thalamus and the striatum and various subtypes of VaD have been reported to date. Its three major pathophysiological mechanisms are single strategic infarcts, multiple infarcts and small vessel disease [3].

The single infarcts can be found in various areas such as the anterior cerebral artery, parietal lobe, thalamus and gyrus in the brain and they may cause serious cognitive deterioration. The multiple cortical infarcts can affect some neural nets by the combined effects of different infarcts, which also result in significant cognitive impairment.

Subcortical small vessel disease can affect all the small vessels in the brain and accompany two major syndromes of lacunar state and subcortical leukoencephalopathy (often called Binswanger disease) with arterial wall changes, perivascular space enlargement and perivascular parenchymal rarefaction. Lacunar state is defined as a condition with numerous and widespread lacunae. Lacunar disease can produce small cavitary parenchymal lesions as well as small vessel occlusions. The specific location of the lacuna is internal capsule, external capsule, periventricular white matter, pons or centrum semiovale in the white matter or thalamus, caudate nucleus, putamen or pallidum in the subcortical gray matter [4]. Binswanger disease is defined as a disorder with cognitive impairment caused by white matter atrophy and diffuse myelin loss, accompanied with fibrohyalinosis and fibrinoid necrosis occurring in vessels.

## Diagnostic Principles

The diagnosis of VaD is based on evaluations of clinical history, physical, neurological and neuropsychological tests, psychiatric interview and brain imaging. Only a postmortem examination can diagnose definite VaD.

**Dementia, Vascular. Table 1** Candidate genes and their variants associated with vascular dementia

| Gene | | Polymorphism | |
|---|---|---|---|
| Name | Location | Name | Location |
| Angiotensin I converting enzyme (*ACE*) | 17q23.3 | 287 bp Ins/Del | Intron |
| Angiotensinogen (*AGT*) | 1q42–q43 | T235M | Exon |
| Interleukin-1β (*IL-1β*) | 2q14 | C-511T | Promoter |

| Glutathione S-transferase omega-1 (*GSTO-1*) | 10q25.1 | Ala140Asp | Exon |
| Sterol regulatory element binding transcription factor 2 (*SREBF2*) | 22q13 | G34995T | Intron |
| Intracellular adhesion molecule 1 (*ICAM1*) | 19p13.3–p13.2 | K469E | Exon |
| Vascular endothelial growth factor (*VEGF*) | 6p12 | G-1154A | Promoter |
| | | C-7T | 5′ UTR |
| | | C13553T | 3′ UTR |

Generally employed criteria to diagnose probable VaD are the following [5]: Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV) criteria, International Classification of Diseases, tenth edition criteria, National Institute of Neurological Disorders and Stroke-Association International pour la Recherché at L'Enseignement en Neurosciences (NINDS-AIREN) criteria, Alzheimer's Disease Diagnostic and Treatment Center (ADDTC) criteria and Hachinski ischemic score. The criteria of NINDS-AIREN, ADDTC and Hachinski ischemic score enable distinction between VaD and AD. Probable VaD according to the NINDS-AIREN consensus is diagnosed with focal neurological symptoms and with imaging evidence of cerebrovascular disease. The probable VaD also requires a sudden onset dementia and progressive cognitive impairment or a temporal relationship between dementia and stroke. This is classified into single strategic infarcts, multiple infarcts, multiple lacunae, extensive white matter lesions, hemorrhages or a combination of these by imaging analysis with computed tomography (CT) or magnetic resonance imaging (MRI).

### Therapeutic Principles

Since VaD cannot be cured or reversed, treatments for the disorder are restricted to reducing or halting its progression and alleviating its symptoms. The most common treatment for VaD is to prevent subsequent strokes. Medications to control underlying diseases such as hypertension, hypercholesterolemia, diabetes and heart disease can be prescribed. Healthy lifestyles including regular exercise, a health food diet and avoidance of smoking and excessive alcohol consumption also contribute to reducing the risk of additional strokes. Sometimes drugs such as aspirin and warfarin are prescribed to prevent clots from forming in the small vessels. Currently, some drugs that have been used for neuroprotection and treatment of mild AD are under study for their effectiveness in treating VaD. The vascular surgery known as carotid endarterectomy is selectively recommended to remove plaque on which clots can form in the carotid artery of the brain.

[2]Department of Medicine, The University of Alberta, Edmonton, AB, Canada
[3]Asian Medical Centre, University of Calgary Medical Clinic, Calgary, AB, Canada

### Definition and Characteristics

Dentinogenesis imperfecta is recognized by opalescence of the teeth, softness of the dentin, and enamel

that fractures away on exposure to masticatory forces. The color of the teeth varies from brown to blue, sometimes described as amber or gray (Fig. 1) [1].

Affected teeth are small and deformed. The primary dentition is more severely affected than the permanent dentition. Three types of dentinogenesis imperfecta are recognized. Type I is associated with osteogenesis imperfecta. Type II has essentially the same clinical, radiographic and histologic features as type I, but without osteogenesis imperfecta [2]. Diminished pulp chambers are characteristic of type I and type II. Type III is characterized by enamel pitting defects, multiple pulp exposures, and enlarged non-mineralized pulp chambers surrounded by only a thin layer of dentin ("shell" teeth) [3].

## Prevalence

Osteogenesis imperfecta occurs in approximately 1 in 20,000–30,000 births [1]. The reported prevalence of dentiogenesis imperfecta type I in patients with osteogenesis imperfecta type I ranges from 8 to 40%, in type III from 43 to 82%, and in type IV from 37 to 100% [1,4]. The incidence of dentinogenesis imperfecta type II is 1 in 8,000 births. Dentinogenesis imperfecta type III is very rare and is found only in the tri-racial Brandywine population of Maryland and Washington, DC [2,3].

## Genes

Dentinogenesis imperfecta is an autosomal dominant disorder [5]. Type I is caused by mutations in either COLIA1 or COLIA2, the genes that encode type I collagen chains. Type II and III are caused by mutations in the dentin sialophosphoprotein (DSPP) gene, located at 04q21.3 [5]. DSPP encodes both dentin sialoprotein (DSP) and dentin phosphoprotein (DPP) as one precursor protein. DSP and DPP are associated with tooth mineralization. Mutations affecting DSP and DPP production result in dentinogenesis imperfecta type II and type III, respectively.

## Molecular and Systemic Pathophysiology

Type I collagen is the major structural protein of the extracellular matrix of dentin. In dentinogenesis imperfecta type I, there is decreased synthesis of structurally normal collagen or synthesis of structurally abnormal collagen. The basic defects in dentinogenesis imperfecta II and III are in the non-collagenous dentin matrix proteins, DSP and DPP, respectively. Although the enamel is often normal, hypo-mineralization of enamel has been described. Enamel tends to fracture away from the teeth because the defective dentin is unable to support the enamel, thereby exposing the underlying defective dentin to wear which result in rapid and severe attrition.

## Diagnostic Principles

The diagnosis is mainly clinical, aided by radiography.

## Therapeutic Principles

Therapeutic strategies to preserve function, vertical dimension, and normal growth of teeth should be instituted as early as possible. Treatment strategies such as the use of composite resin restorations, sealants, laminate veneers, and stainless steel crowns on the affected teeth have been used with success [1]. In cases with severe discoloration, full-coverage restorations might be required. Strict oral hygiene and preventive treatment are important to prevent caries from adding to existing problems.

**Dentinogenesis Imperfecta. Figure 1** A 6-year-old child with dentinogenesis imperfecta. Note the marked discoloration and attrition of the primary dentition.

# Dermatitis Contusiformis

►Erythema Nodosum

# Dermatitis Herpetiformis

Silke Hofmann, Leena Bruckner-Tuderman
Department of Dermatology, University Medical Center, Freiburg, Germany

## Synonyms

Duhring's disease

## Definition and Characteristics

Autoimmune blistering disease of the skin, with granular IgA deposits in the papillary dermis and circulating autoantibodies to transglutaminase(s). Association with (subclinical) celiac disease (gluten-sensitive enteropathy). Dermatological hallmarks are intensely itching small papules, vesicles and erosions, often symmetrically distributed on the extensor surfaces of the extremities [1].

## Prevalence

Dermatitis herpetiformis is more common in Northern countries. The prevalence is not known, but figures of 1:1,000–1:100,000 have been reported.

## Genes

Association with HLA class II genes HLA-DQA1*0501, DQB1*02, and to a lesser extent with the HLA-DQA1*03, DQB1*0302.

## Molecular and Systemic Pathophysiology

Both celiac disease and dermatitis herpetiformis share identical jejunal pathology and can be induced by ingestion of gluten, a mass of water-insoluble proteins found in many cereals. Autoantibodies against gliadin and transglutaminases 2 and 3, enzymes that cross-link proteins to large aggregates via their amino groups, are specific for both disorders [2]. In contrast to patients with celiac disease, dermatitis herpetiformis patients display high-affinity autoantibodies against epidermal transglutaminase (transglutaminase 3) [3]. The granular IgA deposits in the papillary dermis in dermatitis herpetiformis were shown to consist of precipitates of epidermal transglutaminase and IgA antibodies [4]. However, the molecular mechanisms of blister formation remain elusive.

## Diagnostic Principles

Diagnosis is based on skin biopsy for histological analysis, direct immunofluorescence for demonstration of granular IgA-deposits in the papillary dermis and serum ELISA tests for circulating transglutaminase antibodies. Jejunal biopsy is recommended for examination of intestinal mucosal damage.

## Therapeutic Principles

Therapy consists of gluten-free diet and dapsone (diaminodimethyl sulfone) or sulfapyridine.

# Dermatomycosis

Anca Sindrilaru, Cord Sunderkötter
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Ringworm; Tinea

## Definition and Characteristics

Infection of keratinized tissues such as the superficial cornified skin layers, hair follicle, and nails by dermatophyte fungi.

## Prevalence

The most frequent infectious disease in humans. Interdigital mycosis and tinea pedis have a prevalence of about 10%. It occurs in healthy individuals, but known risk factors include local abrasion of the dermis, minor traumas to the nail (e.g., during jogging) and local moisture combined with exposure to high fungal inoculum as found e.g., in public dressing rooms of showers or pools. Factors favoring dermatomycosis are arterial occlusive disease or venous stasis, metabolic diseases such as diabetes mellitus and immuodeficiency syndromes.

## Molecular and Systemic Pathophysiology

Dermatophytes are fungi belonging to three asexual genera, Microsporum, Trichophyton and Epidermophyton, from the genus Arthroderma. Dermatophytes characteristically are restricted to dead keratinized tissues and, unlike other fungi, they cannot cause systemic infection. Infection occurs due to direct contact with infectious arthrospores (arthroconidia) shed from other people (antropophilic), animals (zoophilic) or soil (geophilic). If a spore finds a warm, moist area of skin, it adheres to keratinocytes in the stratum corneum. Here, the conidia germinate and grow at the apical tip, forming typical hyphae. Fungi secrete keratinolytic proteases (keratinases) as they require keratin for growth. A large number of extracellular and membrane-bound keratinases from the pepsin, subtilisin and metalloprotease families have been characterized for dermatophyte species. They participate in nutrition, invasion along cornified layers and control of the host defense mechanisms. Additionally, dermatophytes produce other proteolytic enzymes, such as elastase, aminopeptidases, carboxipeptidases, chymotrypsin-like protease. Another important virulence factor is the production of antibiotic substances such as fusidanes or those related to penicillin, which allow them to compete with the local microbial flora, but which may also select a population of resistant bacteria (e.g., Staphylococcus aureus) which act as copathogens, increasing the degree of inflamation.

Although the cornified layers of the skin lack a specific immune system, innate and cell-mediated immune reactions help to wall off invasion into the deeper viable tissue and to eliminate the fungus. Polymorphonuclear leukocytes are chemotactically attracted by dermatophytes and adhere to opsonized and unopsonized hyphae. Neutrophils, and to a lesser extent, monocytes, kill dermatophyte conidia both by intra- and extracellular mechanisms, the most important one being generation of the oxidative burst. Dermatophytes produce catalase and superoxid dismutase, which may protect against the phagocytic myeloperoxidase system. The development of cell-mediated immunity via Langerhans cells and sensitized lymphocytes is essential in clearing dermatophyte infection and correlates with T-cell mediated delayed-type hypersensitivity reaction to the tricophytin skin test. Chronic infection is associated with poor T-lymphocyte-associated response to specific fungal antigens. The humoral immune response to dermatophyte infection is not very efficient in eliminating the infection, since the high levels of IgM, IgG, IgA and IgE class antibodies are found in patients with chronic infection. Non-specific immune mechanisms include increased epidermal desquamation which causes the fungus to be sloughed from the skin surface; serum inhibitory factor, which robs fungi of essential iron; activation of the alternative pathway of complement, with inhibition of fungal growth (e.g., by binding of unsaturated transferrin to hyphae); inhibition of growth by the fatty acids produced in sebaceous glands (which explains spontaneous resolution of tinea capitis in puberty).

## Diagnostic Principles

Clinically the characteristic lesion is circular, with healing centre and inflammatory margins, where pustules and vesicles may occur. This aspect results from keratin destruction and inflammatory response in the periphery and healing processes in the center. Diagnosis is confirmed by microscopy of infected material and culture.

## Therapeutic Principles

There are potent and now also well tolerated antifungal drugs, usually interfering with ergosterol synthesis. They are usually applied topically and only sometimes systemic application is required. Eliminating risk factors is another important part in the treatment.

# Desert Rheumatism

►Coccidioidomycosis

# Desmin Myopathy

►Desminopathy

# Desminopathy

Lev G. Goldfarb
Department of Health and Human Services, National Institutes of Health, Bethesda, MD, USA

## Synonyms

Desmin myopathy; Variant of "Desmin-related myopathy" or "Myofibrillar myopathy" with demonstrated presence of desmin or α B-crystallin mutations; Cytoplasmic body myopathy; Spheroid body myopathy

## Definition and Characteristics

Desminopathy is a systemic disorder in which dysfunctional mutations in desmin or α B-crystallin severely affect the intracellular filamentous network in cardiac and skeletal muscle cells, leading to accumulation of insoluble granulo-filamentous material. Desminopathy is inherited as autosomal dominant or autosomal recessive trait, and in some patients it is caused by de novo mutations.

## Genes

DES coding for desmin, located on chromosome 2q35; CRYAB coding for α B-crystallin, mapping to chromosome 11q22.3–q23.1.

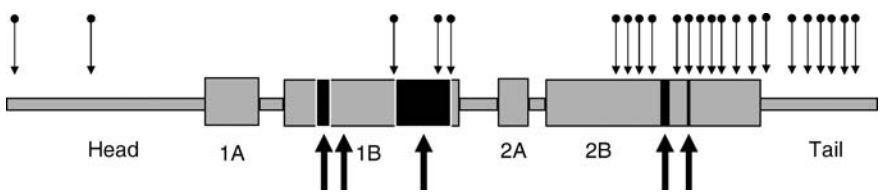
## Molecular and Systemic Pathophysiology

Desmin is a 53 kDa intermediate filament protein of the heart, skeletal and smooth muscle cells. Desmin filaments encircle the Z disks connecting the myofibrils to each other and to the plasma membrane; this integrating role of desmin is critical for sarcomere stability in the contracting muscle. Recent studies of desmin-related myopathy demonstrated that some cases are associated with mutations in desmin [1] or α B-crystallin [2] genes. Most of the known disease-causing desmin mutations are located in the highly conserved C-terminal helical domain (Fig. 1). The majority of mutations make desmin assembly-incompetent and capable of disrupting a preexisting filamentous network in dominant-negative fashion. Disease-associated desmin mutations in humans or transgenic mice cause an accumulation of disorganized intracytoplasmic aggregates containing desmin and other cytoskeletal proteins [3].

Several of the missense mutations result in changing of the naturally occurring amino acid to proline. Proline substitutions break α-helix by introducing a kink and abolishing hydrogen bonds. Misfolded desmin filaments resist turnover by the normal enzymatic machinery and eventually form insoluble aggregates. Specific interaction exists between desmin and α B-crystallin, in which α B-crystallin acts as a chaperone that in a normal muscle stabilizes desmin and prevents its aggregation, but if mutated causes desminopathy [2].

## Diagnostic Principles

Desminopathy presents as progressive weakness of limb muscle spreading to involve truncal, neck-flexor, facial, bulbar, and respiratory muscles. In many cases, skeletal myopathy is combined with cardiomyopathy manifested by cardiac conduction blocks, arrhythmias and restrictive dysfunction resulting in congestive heart failure and premature sudden death. The illness progresses slowly, over one or two decades, leaving the patient extremely disabled and needing a wheelchair, pacemaker or respirator. Sections of the affected skeletal and cardiac muscles show atrophic muscle fibers and intracytoplasmic accumulation of desmin-reactive material. Depending on the shape and location, the multifocal aggregates have been described as



**Desminopathy. Figure 1** Structural organization of desmin protein domains (***boxes indicate conserved α-helical domains 1A, 1B, 2A, and 2B, separated by non-helical linkers), and the positions of disease-causing mutations (*upper arrows*: point substitutions, *bottom arrows*: deletions or insertions).

sarcoplasmic bodies, cytoplasmic bodies, or spheroid bodies [4]. A morphologically distinct element, the patchy electron-dense granulofilmentous aggregates are scattered throughout the muscle fiber, but most prominently present beneath the sarcolemma. Myocardial desmin aggregates have largely been seen as granulofilamentous patches rather than inclusions.

### Therapeutic Principles

There is no specific treatment for desminopathy, but some of the complications and premature death can be prevented. Early detection of cardiac arrhythmias and conduction defects is essential since patients with cardiac arrhythmias are at risk of sudden death. Implantation of a pacemaker can be lifesaving. Detection of cardiomyopathy and timely treatment of heart failure is an important task. Respiratory insufficiency can be treated by intermittent or permanent positive-pressure ventilation. Risk of chest infection should be considered in these patients. Experience with myopathy patients indicates that physical therapy slows disease progression. Advances in gene and stem-cell therapy is an active area of research that promises more specific and effective treatments in the future.

# Diabetes Insipidus

Andreas Barthel
Endokrinologikum Ruhr, Bochum, Germany

## Synonyms

Lack of ADH (antidiuretic hormone) or ADH action

## Definition and Characteristics

Inability of the kidney to appropriately concentrate urine (hypostenuria) due to the lack (central diabetes insipidus) or the lack of effect (nephrogenic diabetes insipidus) of antidiuretic hormone (ADH; synonyms: vasopression; 8-arginine-vasopressin; AVP). Clinically, this results in polyuria (production of large amounts of low concentrated urine) with consecutive hypertonic dehydration and polydipsia (excessive thirst).

## Prevalence

Generally rare (estimated about 1:20.000). Central diabetes insipidus is most frequent (>70%) and often related to hypothalamic/pituitary tumors (e.g. pituitary adenoma, craniopharyngeoma, germinoma or metastasis), pituitary surgery, trauma, inflammatory (sarcoidosis, Wegner's disease) or infectious diseases (bacterial or viral meningitis, tuberculosis) or drug effects. The rare diabetes insipidus renalis may also be related to adverse drug effects and to some genetic disorders [1]. The following table summarizes commonly used drugs that may affect the secretion or the pharmacodynamic effects of ADH.

**Diabetes Insipidus. Table 1** Drugs affecting diuresis

| |
|---|
| antidiuretic effect ↑: some antidepressant drugs, nicotine, apomorphine, lithium |
| antidiuretic effect ↓: ethanol, some antiepileptic drugs, phenytoin, neuroleptic drugs, carbamazepine |

(↑) increase or (↓) decrease effect

## Genes

Some rare familial forms and genetic defects resulting in diabetes insipidus have been characterized. DIDMOAD (the combination of diabetes insipidus, diabetes mellitus, optic atrophy, deafness) (also called "Wolfram-syndrome") is a rare autosomal recessive disorder with a mitochondrial defect associated with central diabetes insipidus. Multiple mutations in the gene encoding ADH have been described resulting in a decreased production of the biologically active hormone and central diabetes insipidus. Also, mutations of the human gene encoding the ADH receptor (also called vasopressin 2 receptor; X-linked recessive) and aquaporin 2 (autosomal recessive; localized on human chromosome 12) can cause nephrogenic diabetes insipidus.

## Molecular and Systemic Pathophysiology

The ADH gene encodes a polypeptide precursor (ADH-Neurophysin II) with a signal peptide targeting the prohormone for posttranslational processing into the lumen of the endoplasmic reticulum and thereby to the secretory pathway. Some mutations within the ADH-gene result in the production of a mutant hormone precursor that fails to fold and/or dimerize properly. As a consequence, the ADH-precursor is retained in the secretory pathway by the protein quality control machinery [2].

The biosynthesis of ADH takes place in the body of hypothalamic magnocellular neurons located in the supraoptic and paraventricular nuclei. The vesicles containing ADH are transported along the axon via the pituitary stalk and stored in nerve endings of the posterior pituitary gland. ADH-specific receptors are expressed in the cells lining the collecting tubule of the kidney. Stimulation of ADH-receptors in the kidney results in activation of a stimulatory G-protein ($G_s$) and consecutive cAMP-dependent activation of protein kinase A (PKA). This results in an increased expression of the gene encoding aquaporin-2, a water channel. Increased expression and incorporation of aquaporin-2 into the plasma membrane of the epithelia lining the distal tubules of the nephron results in an increased permeability of the collecting duct and thereby an increased water reabsorption [3].

Serum osmolality is tightly controlled via hypothalamic osmoreceptors. Increased serum osmolality results in thirst with consecutive drinking behavior and increased ADH-production and -secretion. Both mechanisms (oral water uptake and renal water reabsorption) contribute to the maintenance of the fluid homeostasis of the organism. Loss of ADH-action may result in a decompensation of this balance with excessive polyuria (up to more than 20l/d), severe dehydration and impaired electrolyte balance finally resulting in hypotension, shock, coma and death.

## Diagnostic Principles

The clinical presentation with polyuria, polydipsia and dehydration is suggestive of diabetes insipidus. Typical laboratory findings include low urine osmolality (<150 mosmol/kg) in the presence of normal or high serum osmolality (>296 mosmol/kg) and high serum sodium concentrations. A definitive diagnosis can be best obtained by consecutive water deprivation (up to 18 h) under strict clinical observation and monitoring

of urine flow, urine- and plasma osmolality and plasma ADH-concentrations. In healthy subjects, urine production will decrease to about 30 ml/h and both, the urine osmolality as well as the plasma ADH-concentration will increase. In central diabetes insipidus, the urine production will persist after water deprivation and urine osmolality as well as plasma ADH-concentrations stay low. Exogenous administration of ADH or ADH-analogues (e.g. 2–4 µg desmopressin i.v.) results in an increase of urine osmolality (more than 50% within 1 h) in patients with complete central diabetes insipidus. In contrast, patients with nephrogenic diabetes insipidus have initially higher endogenous ADH plasma concentrations and fail to respond to exogenous administration of ADH under these conditions [4].

### Therapeutic Principles

Central diabetes insipidus is treated by replacement of ADH or preferably administration of the synthetic ADH analogues DDAVP. Nephrogenic diabetes insipidus is resistant to treatment with DDAVP and is treated with thiazides and amiloride together with low sodium diet. The lack of sodium enhances proximal tubular sodium and fluid reabsorption. Also, inhibitors of prostaglandin synthesis like indomethaline that reduce glomerular filtration have been used in the treatment of renal diabetes insipidus.

### Synonyms

Juvenile-onset diabetes; Insulin-dependent diabetes

### Definition and Characteristics

Type 1 diabetes is characterized by β-cell destruction leading to absolute insulin deficiency [1]. The most common cause of β-cell destruction is immune-mediated (type 1A) while in rare cases no immune markers can be found (type 1B, etiology unknown). When untreated, the patients experience ketoacidotic coma and die. The rate of β-cell destruction is very variable. Particularly in children or adolescents β-cell destruction is very rapid leading to severe hyperglycemia and/or ketoacidosis while in some cases β-cell destruction appears to proceed rather slowly leading to latent autoimmune diabetes in adults (LADA). The residual β-cell function may be assessed by plasma C-peptide concentrations. The cellular-mediated destruction of the β-cell has multiple genetic predispositions and is also related to still poorly defined environmental factors. Due to improved insulin treatment the occurrence of life-threatening ketoacidotic coma is decreasing. Therefore, currently, the major reason to adequately treat patients is the prevention/retardation of diabetic complications like retinopathy, nephropathy and neuropathy which may lead to blindness, renal failure and leg amputations etc.

Apart from the classic type 1 diabetes mellitus genetic defects of the β-cell may lead to diabetes mellitus at an early age. These forms, which are referred to as maturity-onset diabetes of the young (MODY), are characterized by impaired insulin secretion. The most common forms are caused by mutations of the glucokinase gene or by mutations of transcription factors of the hepatic nuclear factor family.

### Prevalence

The prevalence of type 1 diabetes varies by geographic location, ethnicity, gender and time. It is increasing worldwide for unknown reasons. The prevalence of type 1 diabetes in children less than 15 years ranges from 0.05 to 0.3% in most European and North American populations [2]. While in Asian countries the prevalence for type 1 diabetes is low, a large variation is observed

in Europe with highest values in Finland and Sweden (0.3%) and lowest in Greece (0.05%).

## Genes

Type 1 diabetes is a polygenetic disease in which genetic predisposition plays a necessary role for the disease to occur. Consequently the risk for type 1 diabetes in relatives of patients is:

- 50–70% in monozygotic co-twin.
- 5–15% in heterozygotic co-twin of siblings of the patient compared to a 0.3–0.5% risk in the general population. The greatest susceptibility to type 1 diabetes is determined by genes of the MHC or the HLA complex gene region located in the short arm of chromosome 6. This region determines about 40% of familiar clustering of the disease.

## Molecular and Systemic Pathophysiology

The immune-mediated β-cell destruction is associated with an infiltration of T-lymphocytes and macrophages of the pancreatic islets (insulitis). If Th2 lymphocytes dominate the infiltrate, the disease is in a latent non-destructive phase. However, when Th1 lymphocytes are activated the β-cell destruction is progressing. Plasma markers of the immune-mediated destruction of the β-cell include antibodies to islet cells, to insulin, to glutamic acid decarboxylase ($GAD_{65}$) and autoantibodies to the tyrosine phosphatases IA-2 and IA-2β. One or usually several of these autoantibodies are detected in 85–90% of the patients when diabetes is diagnosed. Up to now the initiating event leading to autoimmune attack remains unknown.

## Diagnostic Principles

Diabetes is diagnosed by determination of plasma glucose using the following criteria:

- Symptoms of diabetes and a casual plasma glucose of 200 mg/dL (11.0 mmol/L) *or*
- Fasting plasma glucose >126 mg/dL (7.0 mmol/L) *or*
- Two hour plasma glucose >200 mg/dL (11.0 mmol/L) during an oral glucose tolerance test.

Each must be confirmed on a subsequent day unless unequivocal symptoms of hyperglycemia are seen.

## Therapeutic Principles

Treatment of type 1 diabetes is strictly dependent on insulin. While previously bovine or porcine insulin isolated from the respective pancreata was used for the treatment of type 1 diabetes, recombinant human insulin or insulin analogues are now available.

To substitute the missing endogenous insulin, exogenous insulin is applied subcutaneously. To allow for complete supplementation of insulin, basal long acting insulin is given once or twice daily, and short acting bolus insulin is given before mealtimes. Mealtime insulin is adapted to the carbohydrate content of the meal and the actual blood glucose level. For this purpose, the patients have to control his or her blood sugar several times a day. Usually, the mean insulin dose is 0.5–1.0 U/kg body-weight in 24 h, which is given 40–50% as basal insulin and 50–60% as bolus insulin. Insulin can also be applied continuously using insulin pumps. The goal of insulin therapy in type 1 diabetes is to achieve near normal glucose values resulting in an HbA1c level of 6.5–7% without episodes of severe hypoglycemia. This allows prevention of diabetic complications like retinopathy, nephropathy and neuropathy.

Approaches to prevent the manifestation of type 1 diabetes e.g., by immune suppressive therapy are still at an experimental level.

# Diabetes Mellitus Type 2

Derek LeRoith
Division of Endocrinology, Diabetes and Bone Diseases, Mt. Sinai School of Medicine, New York, NY, USA

## Definition and Characteristics

Type two diabetes mellitus (T2DM) is a disorder caused by both genetic and environmental factors. It was previously classified as adult onset diabetes and subsequently non-insulin dependent diabetes (NIDDM). These previous definitions were appropriate since the disorder generally begins in adults and, at least during the early phases of the disease, the patients do not require insulin, unlike Type 1 diabetes mellitus [1].

## Prevalence

T2DM is clearly a genetic disorder as shown by studies on candidate genes, genome-wide screening and determination of polymorphisms in different populations. The strong family history involved in the disease also points to a genetic contribution. There are a number of

monogenic causes of T2DM, labeled maturity onset diabetes of the youth (MODY). However the genetic causes of the common type of T2DM in adults are not known. It is clear, however, that it is a polygenic disorder.

Type 2 diabetes is an extremely common disorder. In the US there are about 20 million diagnosed patients and about 10 million undiagnosed. In addition, there are more than twice that number that have prediabetes with impaired fasting glucose or impaired glucose tolerance. Genome-wide association studies, using single nucleotide polymorphisms, have been used to determine the genes associated with this polygenic disorder. The strongest association was found with the TCF7L2 gene; about 7% of patients in multiple populations. Pancreatic genes such as HHEX, CDKN2A/B and CDKAL1 are also associated. Since the world-wide obesity epidemic is driving the dramatic increase in Type 2 diabetes, genes for obesity have been similarly studied and the FTO gene has a strong association with obesity.

## Molecular and Systemic Pathophysiology

The environmental factors that play a role in its pathophysiology include obesity, lack of physical exercise (life style) and aging.

T2DM in many countries is associated with obesity and the metabolic syndrome, a constellation of abnormalities including visceral adiposity, hypertension and hyperlipidemia (high circulating triglycerides and low HDL cholesterol). These states precede the development of T2DM and often are characterized by impaired fasting glucose (IFG) levels or impaired glucose tolerance (IGT) levels before the advent of full blown T2DM (Table 1).

T2DM is a dual defect disease with a component of insulin resistance and dysfunction of the pancreatic beta cell. The insulin resistance component is manifested by the inability of insulin to mediate glucose uptake into muscle (and fat) in the post-prandial state, due to defective intracellular signaling and a lack of mobilization of glucose transport protein (GLUT-4) to the cell surface. Thus glucose remains in the circulation. In addition, insulin resistance in the liver allows for continued hepatic glucose production and release of glucose into the circulation. The beta cell defect is manifested by a poor glucose induced insulin secretion with a loss of the "first phase" insulin secretion, which leads to a further enhancement of liver glucose production. However, there is an exaggerated second phase insulin release, which leads to the classic hyperinsulinemia seen in T2DM.

With the growing epidemic of obesity and metabolic syndrome in adolescents, T2DM is being diagnosed at an increased rate in this age group. In the adolescent population there is also an increasing incidence of hybrid diabetes, Type 1 and Type 2 in the same individual, as a result of the obesity epidemic.

Approximately 10% of T2DM patients are not overweight and these patients are often more insulin requiring, suggesting a more pronounced defect in beta cell dysfunction. A significant percentage have autoantibodies to the beta cells and are most probably a *form frust* of Type 1 DM and are labeled latent autoimmune diabetes in adults (LADA) [2].

**Diabetes Mellitus Type 2. Table 1** Blood glucose (BG) levels in prediabetics and T2DM

| | Fasting BG | Post-prandial BG |
|---|---|---|
| IFG | >100, <126 mg/dl | <140 mg/dl |
| IGT | <100 mg/dl | >140, <200 mg/dl |
| Diabetes | >126 mg/dl | >200 mg/dl |

## Diagnostic Principles

Typically symptoms of hyperglycemia such as increased thirst, polyuria and nocturia are often not the presenting symptoms. Patients with T2DM may present with cardiovascular complications of the disease such as an acute myocardial infarction or diabetic neuropathy. The reason for this is that the disease is often undiagnosed for at least five years and/or the changes occurring in the various tissues are occurring even during the pre-diabetes period associated with the IFG and IGT states.

Classically, T2DM is associated with micro- and macro-vascular complications, with microvascular complications such as renal, retinal and neural diseases being closely linked to hyperglycemia, while macrovascular complications are linked to hypertension, hyperlipidemia and hyperglycemia.

## Therapeutic Principles

Ideally since obesity is a major factor in the disorder, life style changes including weight reduction, exercise and meal planning are both first line and necessary throughout the life of the patient. Other treatments include oral medications that affect the secretion of insulin from the beta cells, reduce liver hepatic glucose production, sensitize the tissues to insulin and delay glucose absorption from the gastrointestinal tract. These are often used in combination with each other and also in combination with insulin injections, a common requirement in later stages of T2DM [3].

# Diabetic Macular Edema

►Retinopathy, Diabetic

# Diabetic Nephropathy

Gunter Wolf, Wilgard Hunger-Dathe
Department of Internal Medicine III, University Hospital Jena, Jena, Germany

## Definition and Characteristics

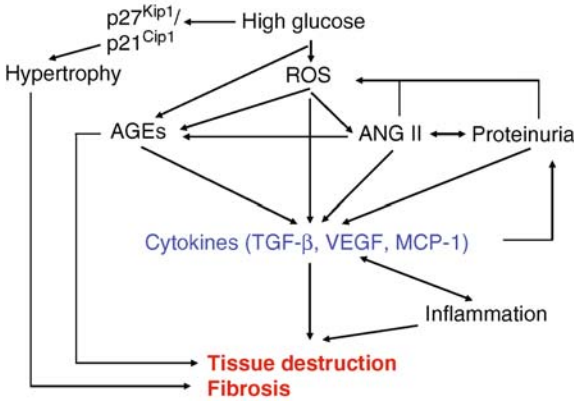
One of the major organ complications of long-term diabetes type 1 and 2 leading eventually to terminal dialysis-dependent end-stage renal disease.

## Prevalence

The risk of nephropathy is strongly determined by genetic factors, and only approximately 40–50% of patients with either type 1 or 2 diabetes will ultimately develop nephropathy [1,2]. Although the incidence of nephropathy due to type 1 diabetes is somewhat declining, diabetes mellitus type 2 is now the most common single cause of renal insufficiency in the U.S., Japan, and Europe. There are more than 10 million people with diabetes alone in the U.S. and it has been estimated that this number will double by 2030. Consequently, it is assumed that the prevalence of nephropathy will also considerably increase in the future. Diabetics with nephropathy have a significantly increased incidence of cardiovascular events (stroke, myocardial infarction) (Fig. 1).

## Molecular and Systemic Pathophysiology

Principally, pathophysiological steps leading to the development of nephropathy are similar in types 1 and 2 diabetes [1]. However, patients with type 2 diabetes may suffer from additional mechanisms such as hypertension injuring the kidney. The pathophysiological changes prior to the development of type 2 diabetes have been classified as the metabolic syndrome. This metabolic syndrome itself can additionally harm the kidneys through hyperuricemia, obesity, and insulin resistance. Diabetic nephropathy is characterized by early podocyte injury leading to proteinuria and accumulation of extracellular matrix proteins (e.g. various collagens) in renal basement membranes and the mesangium. Tubulointerstitial injury is secondary due to proteinuria, or very rarely directly caused by extreme hyperglycemia (so called Armanni-Ebstein lesions of tubules). There is ongoing research in identifying genetic loci for diabetic nephropathy susceptibility through genomic screening and candidate gene approaches [2]. Although some potential genes have been identified, linkage was only present in defined ethnic subpopulations and not in the majority of patients. Although debated for many years whether hemodynamic (hyperfiltration) or structural changes are more important in the development of diabetic nephropathy, it is now clear that these processes are interwoven [3]. On a molecular level, hyperglycemia and proteins altered by high blood glucose such as Amadori products and advanced glycation end-products (AGEs) are key players in the development of diabetic nephropathy [4]. An increase in reactive oxygen species (ROS) formation induced by high glucose-mediated activation of the mitochondrial electron-transport chain is an early event in the development of diabetic complications. A variety of growth factors and cytokines are then induced through complex signal transduction pathways



**Diabetic Nephropathy. Figure 1** Overview of mechanisms leading to diabetic nephropathy. High glucose leads to the formation of reactive oxygen species (ROS) and also stimulates $p27^{Kip1}/p21^{Cip1}$ inducing cell cycle arrest and hypertrophy. Hypertrophy itself can initiate tissue destruction and fibrosis through maladaptive hemodynamic (hyperfiltration) and metabolic mechanisms. ROS are intermediates that stimulate expression of various cytokines and angiotensin II (ANG II). High glucose and ANG II both stimulate formation of advanced glycation end-products (AGEs) that could be further modified by ROS-mediated oxidative stress. Proteinuria is induced by ANG II-mediated podocyte damage (loss of nephrin) and inhibition of proteoglycan synthesis (loss of negative charges). Proteinuria generates in tubular cells further ROS, ANG II and cytokine production initiating inflammation and damage of the tubulointerstitium. Important profibrogenic cytokines (TGF-β) and proinflammatory mediators (e.g. MCP-1) ultimately destroy renal tissue and foster the development of fibrosis.

involving protein kinase C, mitogen-activated protein kinases, and the transcription factor NF-κB [5]. High glucose, AGEs, and ROS act in concert to induce locally in the kidney further growth factors and cytokines. Particularly, transforming growth factor-β (TGF-β) is important in the development of renal hypertrophy and for accumulation of extracellular matrix components. Other growth factors implicated in the development of diabetic nephropathy are IGF-I, eicasonoids, and CTGF (connective tissue growth factor). CTGF is a down-stream mediator of TGF-β. Activation of the local renal renin-angiotensin system by high glucose, mechanical stress, and proteinuria with an increase in local formation of angiotensin II (ANG II) causes many of the pathophysiological changes associated with diabetic nephropathy [5]. It has been shown that ANG II is involved in almost every pathophysiological process implicated in the development of diabetic nephropathy (hemodynamic changes, tubular reabsorption, hypertrophy, extracellular matrix accumulation, growth factor/cytokine induction, ROS formation, podocyte damage, proteinuria, interstitial inflammation).

### Diagnostic Principles

Development of microalbuminuria in patients with diabetes type 1 for at least 5 years is suggestive of diabetic nephropathy. The situation is somewhat more complex in type 2 diabetes, and albuminuria could also develop by other mechanisms such as endothelial dysfunction caused by hypertension. However, in rare instances nephropathy may progress to end-stage renal failure without the development of proteinuria.

### Therapeutic Principles

There is no gene therapy available. Reduction of hypertension with agents including ACE-inhibitors and/or AT1-receptor blocker is essential. Optimizing control of hyperglycemia (HbA1 < 7) is mandantory. Clinical studies have shown the benefit of a therapy with statins. Although not supported by all studies, a trial with a reduction in protein intake (0.8 mg protein/kg body-weight) could be initiated.

## Diamond-Blackfan Anemia

John-John B. Schnog[1], Victor E. A. Gerdes[2]
[1]Department of International Medicine, Slotervaart Hospital, Amsterdam, The Netherlands
[2]Amsterdam Vascular Medicine Group, Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands

### Synonyms

Blackfan-Diamond syndrome; Congenital hypoplastic anemia; Chronic congenital a-regenerative anemia; Erythrogenesis imperfecta

### Definition and Characteristics

Autosomal dominant disorder which usually presents in the first year of life with macrocytic anemia and a reduced number erythroid precursor cells. In 30–50% of the cases congenital abnormalities (craniofacial dysmorphism, thumb anomalies) are present, and patients may have a short stature.

### Prevalence

In France the estimated incidence of Diamond-Blackfan Anemia is 7.3 cases per million live births, in the United Kingdom 5 per million live births.

### Genes

Ribosomal protein S19 (RBS19) on chromosome 19q13.2, another locus has been mapped to chromosome 8p23.3-p22.

### Molecular and Systemic Pathophysiology

The failure of erythroid progenitor cells to differentiate is the hallmark of this disease. However, the mechanism

is uncertain. There is neither evidence that deficiency of hematopoietic growth factors (erythropoietin, interleukin-3, granulocyte macrophage-colony stimulating factor, c-kit or stem cell factor), nor antibodies against erythropoietin, are relevant in the pathophysiology. Mutations in the RBS 19 gene are observed in approximately 25% of cases, and in approximately 50% of cases a defect on chromosome 8p can be demonstrated. However, it is unclear how these mutations are related to the clinical manifestations.

## Diagnostic Principles

Usually macrocytic anemia with normal white blood cell counts and platelets is observed. Bone marrow abnormalities are non specific. Red cell adenosine deaminase activity is increased and may be used to differentiate between Diamond-Blackfan anemia and other anemias.

## Therapeutic Principles

Treatment with corticosteroids is successful in ~60% of the patients. Red blood cell transfusion is necessary for patients not responding to corticosteroids. Hematopoietic stem cell transplantation of a HLA identical sibling is indicated for those with refractory disease. Limited responses on IL-3 and cyclosporin A administration have been reported.

# Diaphragmatic Paralysis

Michael Benatar
Department of Neurology, Emory University School of Medicine, Atlanta, GA, USA

## Synonyms

Diaphragmatic weakness; Phrenic nerve palsy; Respiratory muscle weakness

## Definition and Characteristics

Inspiratory muscle weakness that results from any disease process affecting the diaphragm or the neural structures that innervate the diaphragm. Disorders of the lower motor neuron (Phrenic nerve, neuromuscular junction or muscle) are most common, but diaphragmatic paralysis may also result from injury to upper motor neuron pathways.

## Prevalence

There are no epidemiological studies, in part because diaphragmatic paralysis is not a unitary disease entity, but rather a clinical syndrome with many diverse causes.

## Genes

Diaphragmatic paralysis may be associated with a number of different genetic disorders including the hereditary motor and sensory neuropathies (Charcot-Marie Tooth disease) [1] and the metabolic myopathies, notably acid maltase deficiency [2,3]. Although diaphragmatic weakness may be found in several of the autosomal dominant inherited neuropathies, it is most characteristic of CMT-2C (linkage to chromosome 12q23-q24; unknown gene product) [1]. Acid maltase deficiency (autosomal recessive) is due to mutations in the gene coding for the acid α-1,4-glucosidase protein (chromosome 17q23).

## Molecular and Systemic Pathophysiology

Pathophysiology varies depending on etiology. Phrenic neuropathy may result from direct trauma to the phrenic nerve during cardiothoracic surgery, from anterior horn cell dysfunction (amyotrophic lateral sclerosis), from immune-mediated inflammation as part of an acute brachial neuritis (Parsonage-Turner syndrome), from endoneurial ischemia as part of a mononeuritis multiplex secondary to large artery vasculitis (Takayasu's or giant cell arteritis), as part of inflammatory demyelination (as seen in the Guillain-Barre syndrome) or from

dysmyelination secondary to an inherited disorder to myelin proteins (Charcot-Marie Tooth disease). Diaphragmatic weakness may also result from impaired neuromuscular transmission (myasthenia gravis, Lambert-Eaton myasthenic syndrome, botulism) and from primary disorders of muscle (inflammatory and metabolic myopathies).

## Diagnostic Principles

Shortness of breath when supine (orthopnea) is the most common symptom of diaphragmatic paralysis. The characteristic finding on examination is paradoxical inward movement of the abdomen with inspiration, most readily visible in the supine position [4,5]. Direct measurement of transdiaphragmatic pressure (Pdi) is the most accurate method of assessing diaphragmatic function, but requires the placement of balloon catheters in the esophagus and stomach [4]. The clinical utility of Pdi measurements is limited, therefore, by the invasive nature of the test. Elevation of a hemidiaphgram may be apparent on chest x-ray and fluroscopy in the posteroanterior and lateral positions may show absent or paradoxical movement of the diaphragm in response to a sniff maneuver [6]. These imaging techniques are most useful in the evaluation of hemi-diaphragmatic paralysis. Ultrasound may be used to measure diaphragmatic thickness and the change in thickness (representing diaphragmatic shortening with contraction) with inspiration. Atrophy and lack of shortening (i.e., little change in thickness) with inspiration are signs of diaphragmatic paralysis [6,7]. Reduced forced vital capacity (FVC) is the characteristic finding on lung function testing, especially when supine FVC is <75% of erect FVC [4]. Reductions in maximum inspiratory and expiratory pressures (MIPs and MEPs) are also characteristic of diaphragmatic weakness, but like the FVC the diagnostic utility of these static lung volumes is limited by the effort-dependence of these measurements. Several electrophysiological techniques have been used to assess diaphragmatic function including phrenic nerve conduction studies (in response to either electrical or magnetic stimulation) and diaphragmatic electromyography (EMG) [8]. The technical difficulty of these electrophysiological tests limits their diagnostic utility.

## Therapeutic Principles

Symptomatic treatment takes the form of mechanical ventilation when diaphragmatic weakness is sufficiently severe to result in respiratory failure. Specific treatment depends on the underlying cause. Diaphragmatic paralysis due to the Guillain-Barre Syndrome is treated with either intravenous immunoglobulin (IVIg) [9] or plasma exchange (PE) [10]. Myasthenia gravis is also treated with IVIg [11] or PE [12], often in combination with steroids [13] and cholinesterase inhibitors.

## Synonyms

Diarrhoea

## Definition and Characteristics

The normal consistency of stool and frequency of bowel movements varies in a wide range due to diet composition (e.g. rate of vegetables) and individual factors. Diarrhea is characterized by alterations away from normal behavior and is defined, alone or together, by increases of:

1. Water content >80%, making feces more fluid than usual
2. Number of bowel movements per day, e.g. from usually 1 to >3 or from usually 2 to >5
3. Feces weight per day, e.g. from 100 g/d to >200 g/d or from 200 g/d to >400 g/d [1,2]

Acute diarrhea (<2–4 weeks) is usually caused by bacterial, viral, or parasitic infection. In children, infection with rotavirus is the most common cause of acute diarrhea.

Chronic diarrhea (>4 weeks) is usually related to either organic disorders like the inflammatory bowel diseases (IBD) ulcerative colitis and Crohn's disease or celiac disease or to functional disorders like the irritable bowel syndrome (IBS) [3].

Usually acute diarrhea in adults is mild and self-limiting so that it deserves no diagnostic or therapeutic efforts. In contrast, in newborns and small children severe diarrhea, even if lasting only 1 or 2 days, can lead to critical dehydration. Diarrhea is one of the major causes of infant morbidity and mortality worldwide. At any age, cholera induces a severe life-threatening diarrhea which must be treated.

## Prevalence

Acute diarrheal episodes are very common. Diarrheal illnesses account for >10,000 deaths per day in children in Asia, Africa, and Latin America. The causes of diarrhea include a wide array of viruses, bacteria, and parasites.

Compared to this, several genetically determined forms of chronic diarrhea e.g. congenital lactase deficiency, congenital chloridorrhea, and glucose/galactose malabsorption are very rare. As an exception, celiac disease is relatively common, affecting 1 of every 100–300 persons.

## Molecular and Systemic Pathophysiology

In general, all types of diarrhea are driven by osmotic forces inasmuch as an inappropriate amount of solutes remains in the gut lumen which is accompanied by an equivalent volume of fluid. An additional osmotic effect can occur by brake up of non-absorbable large molecules to small ones due to bacterial overgrowth. Often diarrhea is caused by more than one mechanism alone.

There are numerous classifications of diarrhea, most of them based on clinical criteria. However, from a functional viewpoint the situation is clear. Diarrhea is caused by quantitatively altered transepithelial net transport, i.e. impaired absorption and/or increased secretion, of solutes plus osmotically equivalent amounts of water. These alterations can be created through five different general mechanisms (Table 1).

Osmotic diarrhea as defined here results from the presence of solutes in the intestinal lumen, for which no epithelial transport mechanism exists. The mechanism of this type of diarrhea is identically to that renal osmotic diuresis caused by non-absorbable solutes. Osmotic diarrhea can be caused by

1. Non-absorbable laxatives, e.g. lactulose, mannitol, Glauber's salt ($Na_2SO_4$)
2. Nutrients, which were not digested into an absorbable form, e.g. lactose in lactase deficiency (congenital form: OMIM #223000)
3. Low-calorie sweeteners, e.g. cyclamate, saccharin, aspartame
4. $Mg^{2+}$-based antacids
5. Contrast agents containing sulfate, phosphate or citrate

Malabsorptive diarrhea is caused by impaired absorption of solutes for which under normal circumstances transport pathways exist. This may have two reasons:

1. Transport proteins can be defective congenitally, like SGLT1 (SLC5A1) in glucose/galactose malabsorption (OMIM #606824) or DRA (SLC26A3) in congenital chloridorrhea (OMIM #214700).
2. The number of transport proteins can be insufficient due to a reduced area of absorptive epithelium. This can be caused e.g. by celiac disease (celiac sprue, gluten-sensitive enteropathy; OMIM #212750), tropical sprue, bacterial overgrowth, short bowel syndrome, and Crohn's disease.

Motility-driven diarrhea is caused by accelerated transit time leaving a too short time for proper absorption

although the absorptive mechanisms are working properly. The rectum then is overspilled by solutes and an osmotically equivalent amount of water. Typical reasons are hyperthyreosis or abuse of laxatives.

Secretory diarrhea is mainly driven by excessive chloride secretion plus some inhibition of NaCl absorption. Normally, in the intestine absorptive processes exceed the secretory ones, so that the net effect is absorption. Secretion is driven by the apical channel CFTR, in conjunction with SLC26 anion exchangers, which mediate electrogenic $Cl^-$ and $HCO_3^-$ secretion. If, however, secretagogues cause opening of CFTR, large net secretion of chloride occurs which is followed by water. Numerous regulatory endocrine, paracrine, and neural compounds stimulate active $Cl^-$ secretion and at the same time inhibit active absorption in villus cells. Typical secretory diarrheas are:

Traveler's diarrhea is caused by food, contaminated with enterotoxins, mostly of E. coli.

Cholera leads to a life-threatening diarrhea which is mediated by two toxins: Cholera toxin stimulates $Cl^-$ secretion (and inhibits NaCl absorption) via cAMP. Zonula occludens toxin causes a disruption of the tight junction, leading to a leak flux diarrhea [4].

As listed in Table 2, numerous other microbiota and parasites cause secretory diarrhea and/or leak flux diarrhea.

Leak flux diarrhea is the result of impaired epithelial barrier function, caused either by opening of tight junctions or by significant loss of epithelial cells [1,5], the latter also named exudative diarrhea (synonym: exudative diarrhea).

Colon and rectum are tight epithelia with well developed tight junctions. However, numerous intestinal diseases which cause mucosal inflammation, ulceration or increased apoptotic rate (e.g. ulcerative colitis [3], Crohn's disease, cholera-ZOT [4], Clostridium perfringens) induce a break-down of the epithelial barrier,

**Diarrhea. Table 1** Classification of diarrheal diseases according to pathophysiological criteria. Note that osmotic diarrhea as defined here may differ from clinical usage, where malabsorptive diarrhea is included into the term osmotic diarrhea

| Type | Mechanism | Typical causes |
|---|---|---|
| *Altered absorption* | | |
| Osmotic diarrhea | Presence of non-absorbable solutes | Mannitol, sweeteners, $SO_4$, $PO_4$, citrate, antacids, non-digested macromolecules, lactase deficiency |
| Malabsorptive diarrhea | Defective absorptive transporters | Congenital chloridorrhea, glucose/galactose malabsorption |
| | Reduced absorptive epithelial area | Celiac disease, bacterial overgrowth |
| Motility-driven diarrhea | Insufficient absorptive contact time | Hyperthyreosis, laxatives |
| *Altered secretion* | | |
| Secretory diarrhea | Increased chloride secretion | Cholera toxin, *E. coli* toxins |
| Leak flux diarrhea | Back leak across tight junctions into the lumen | Ulcerative colitis, Crohn's disease, cholera-ZOT, *Clostridium perfringens* |

**Diarrhea. Table 2** Most prominent microbiota and parasites causing secretory diarrhea and/or leak flux diarrhea

| Bacteria | Viruses | Parasites |
|---|---|---|
| Enterotoxigenic *Escherichia coli* | Adenovirus | *Cryptosporidium parvum* |
| *Campylobacter jejuni* | Human immunodeficiency virus (HIV) | *Entamoeba histolytica* |
| *Clostridium difficile* | *Norovirus* | *Giardia lamblia* |
| *Listeria monocytogenes* | *Rotavirus* | *Strongyloides stercoralis* |
| *Salmonella* | | |
| *Shigella* | | |
| *Staphylococcus aureus* | | |
| *Vibrio cholerae* | | |

allowing for a back leak of osmotically relevant amounts of solutes and water from the interstitium into the lumen across tight junctions or the defective cell layer.

### Diagnostic Principles

Osmotic diarrhea as well as malabsorptive diarrhea cease after leaving out the suspected substances from the meal. This improvement after fasting is typical for a type of diarrhea due to insufficient absorption, as a result of which this can be used for differential diagnosis. Secretory diarrhea and leak flux diarrhea cannot be terminated by fasting.

### Therapeutic Principles

Acute diarrhea mostly ceases without specific therapy. However, severe acute diarrhea requires proper fluid and electrolyte replacement to avoid dehydration and acidosis. In infants dehydratation can occur within a few hours, therefore it is essential to start rehydration immediately.

If infusion therapy is not available, secretory diarrhea (e.g. cholera, traveler's diarrhea) can be effectively treated by oral rehydration solution (ORS). The essential components of ORS are glucose, NaCl, and $NaHCO_3$. This simple therapy takes advantage of the fact that in secretory diarrhea the intestinal sodium-glucose symporter SGLT1 (SLC5A1) is not affected. Although chloride (and bicarbonate) secretion may continue, osmotically driven water loss is prevented due to the counterbalancing effect of increased sodium-glucose absorption.

Chronic diarrhea due to osmotic effects of non-absorbable or malabsorbed solute [5] can be treated by avoiding the respective solutes.

►Enteritis

## Dicarboxylic Aminoaciduria

Stefan Bröer
School of Biochemistry and Molecular Biology, Australian National University, Canberra, ACT, Australia

### Definition and Characteristics

Dicarboxylic aminoaciduria is a rare disorder of autosomal recessive inheritance [1]. It is characterized by

highly elevated amounts of glutamate and aspartate in the urine. In several reported cases the clearance exceeded the glomerular filtration rate, indicating active secretion of glutamate [2]. Glutamate levels are usually significantly higher than aspartate levels, reflecting their relative concentration in blood plasma. Newborn urine screening programs suggest that dicarboxylic aminoaciduria is a benign condition [3]. A few cases with mental retardation have been reported, however, in these cases the aminoaciduria was detected retrospectively. Dicarboxylic aminoaciduria is often accompanied by hyperprolinemia.

## Prevalence

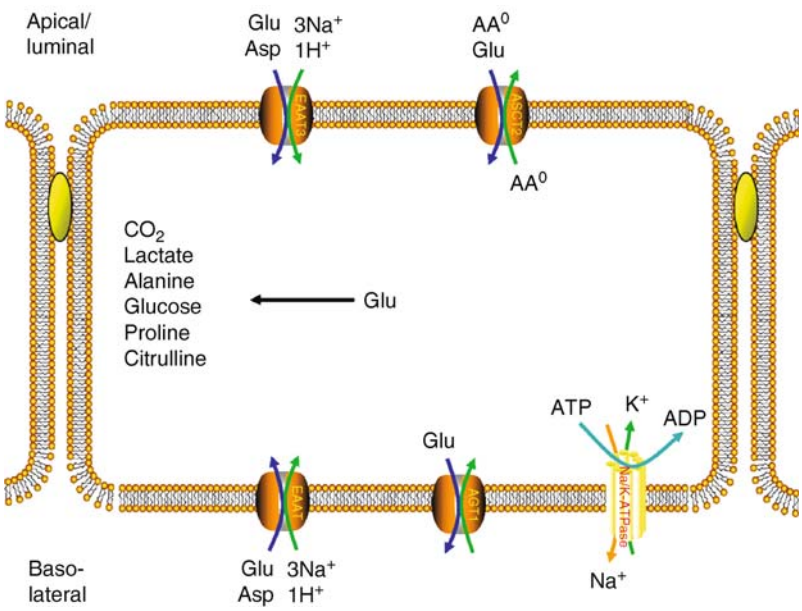
1:29,000 in the French-Canadian population (probably closer to 1:40,000 in other populations).

## Genes

No genes have been reported as yet, which harbor mutations in dicarboxylic aminoaciduria. Since the renal physiology is fairly well understood a candidate gene has been identified, which is involved in glutamate and aspartate transport in kidney and intestine, i.e. the glutamate and aspartate transporter EAAT3 (SLC1A1, 9p24.2).

## Molecular and Systemic Pathophysiology

Glutamate and aspartate are actively absorbed in kidney and intestine. The apical transporter mediating the uptake of anionic amino acids has been identified as the glutamate transporter EAAT3 (alias EAAC1, SLC1A1) [4] (Fig. 1). Uptake of glutamate and aspartate is coupled to the cotransport of $3Na^+$ and $1H^+$ and the antiport of $1K^+$. The transporter prefers D-aspartate over L-aspartate or L-glutamate. In the kidney nephron EAAT3 expression increases from the S1 to the S3 segment in the cortex but is also found in the medulla. More than 90% of glutamate is absorbed in the early segments of the proximal tubule where expression of EAAT3 is relatively low, yet the stereospecificity of the transport activity suggests that it is mediated by EAAT3. Glutamate is also accumulated inside the cytosol by a glutamate transporter in the basolateral membrane which is similar to the apical transporter. Some evidence has been presented that the basolateral transporter could be EAAT2 (SLC1A2) (Fig. 1). It is thought that the active secretion of glutamate observed in dicarboxylic aminoaciduria is caused by the active accumulation of glutamate in the cytosol by the basolateral transporter, followed by its release across the apical membrane by an unknown route. In contrast to most amino acids, glutamate is largely metabolized



**Dicarboxylic Aminoaciduria. Figure 1** Transporters involved in glutamate and aspartate transport in kidney and intestine. Glutamate/aspartate transport in both kidney and intestine is largely mediated by the transporter EAAT3 (Excitatory amino acid transporter 3). The neutral amino acid transporter ASCT2 might serve as a low affinity glutamate transporter. Both amino acids are also accumulated across the basolateral membrane. Inside epithelial cells glutamate is largely metabolized to $CO_2$, lactate and alanine or is used as a precursor for gluconeogenesis.

by epithelial cells in kidney and intestine. Metabolism of glutamate among other metabolites generates proline. Whether this metabolic pathway is upregulated in some cases of dicarboxylic aminoaciduria and causes prolinemia is unclear. The basolateral membrane in the kidney also harbors the glutamate/aspartate transporter AGT1 (Fig. 1). This transporter belongs to a family of heteromeric transporters (SLC7A13). Usually light-chains of this family associate with either the rBAT or 4F2 heavy-chain forming a heteromeric transporter. The AGT1 light-chain, however, does not interact with any of these two heavy-chains. The transporter has been proposed as a basolateral transporter for glutamate and aspartate, but its physiological role has not been clarified. It is expressed only in the kidney where it is localized in the same segments as EAAT3. In addition to EAAT3 and AGT1, the neutral amino acid transporter ASCT2 (SLC1A5) could also play a role in glutamate transport, particularly in the intestine. ASCT2 is an antiporter for small neutral amino acids. At acidic pH glutamate is a low-affinity substrate for ASCT2, allowing it to be exchanged for neutral amino acids. Expression of ASCT2 has been reported in the apical membrane of kidney and intestine (Fig. 1).

EAAT3 is expressed in neurons throughout the brain where it is thought to be involved in glutamatergic neurotransmission. Although its capacity to remove glutamate from the synaptic cleft is limited it has been implicated in glutathione metabolism and the defense against oxygen radicals. EAAT3 knock-out mice have large amounts of glutamate and aspartate in the urine and develop neurodegeneration when aging [5]. In all studies published thus far, dicarboxylic aminoaciduria was detected in infants or children. Since the disorder is benign at this age no follow-up studies have been performed in older individuals.

### Diagnostic Principles

The disorder is identified by urine analysis. Large amounts of glutamate and aspartate are found in the urine, whereas in healthy individuals only trace amounts are detected.

### Therapeutic Principles

Despite the proposed roles of EAAT3 in brain neurotransmission, the disorder appears to be benign. Whether neurodegeneration may occur at an advanced age remains to be clarified.

D

### Definition and Characteristics

Autosomal recessive disease leading to 5,6-dihydrothymine-5,6-dihydrouraciluria; DHD.

### Prevalence

Population screening of 21,200 healthy Japanese individuals indicate that the prevalence of dihydropyrimidinase (DHP) deficiency is 1 in 10,000.

### Genes

The human DHP gene (DPYS) is present as a single copy gene on chromosome 8q22 and consists of ten exons. A physical map indicates that DPYS spans >80 kb with an open reading frame of 1560 bp. To date, six different mutations have been identified in DPYS including one frameshift mutation and five missense mutations [1] (Fig. 1).

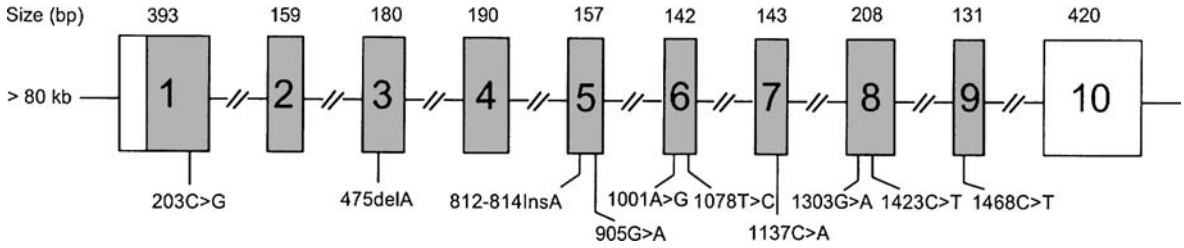
### Molecular and Systemic Pathophysiology

To date, only nine individuals suffering from a complete DHP deficiency have been reported which, to some extent, may be due to the lack of specific and efficient methods to detect the dihydropyrimidines in most laboratories. Four unrelated cases showed variable clinical symptoms, epileptic or convulsive attacks, dysmorphic features and severe developmental delay. On the other hand, three unrelated infants and two adult cases without clinical symptoms were discovered during neonatal screening [1]. An altered dihydrouracil and dihydrothymine homeostasis might underlie the various clinical abnormalities encountered in patients with a dihydropyrimidinase deficiency.

### Diagnostic Principles

Patients present with strongly increased levels of dihydrouracil and dihydrothymine in urine, plasma and cerebrospinal fluid and moderately elevated levels of uracil and thymine. Analyses of these dihydropyrimidines can be performed with conventional cation-exchange amino acid analysis, GC/MS or HPLC/tandem MS [2,3]. No activity of DHP could be detected in a liver

*deceased



**Dihydropyrimidinase Deficiency. Figure 1** Genomic organization of the *DPYS*. *DPYS* consists of ten exons encoding an open reading frame of 1560 bp. The different mutations identified in patients with a deficiency of DHP are indicated, numbers correspond to the cDNA position.

biopsy of a patient [4]. Analysis of DPYS allows the identification of the underlying mutations in this disease.

## Therapeutic Principles

No specific therapies have been reported for patients with a dihydropyrimidinase deficiency. Treatment with β-alanine and β-aminoisobutyric acid might be a possibility.

# Dihydropyrimidine Dehydrogenase Deficiency

André B. P. Van Kuilenburg,
Albert H. Van Gennip*
Laboratory for Genetic Metabolic Diseases, Academic Medical Center, Amsterdam, The Netherlands

## Definition and Characteristics

Autosomal recessive disease leading to thymine-uraciluria.

## Prevalence

The prevalence of the common IVS14+1G>A mutation in the normal population is 1.8% and one can estimate that the number of individuals homozygous for the IVS14+1G>A mutation is 1.2 in 10,000.

*deceased

## Genes

The human DPD gene (DPYD) is present as a single copy gene on chromosome 1p22 and consists of 23 exons. A physical map indicates that DPYD is at least 950 kb in length with 3 kb of coding sequence and an average intron size of about 43 kb. To date, 32 different mutations and polymorphisms have been identified in DPYD including one splice-site mutation, five frameshift mutations, two nonsense mutations, 21 mutations/polymorphisms and three intronic mutations. The vast majority of these mutations have been detected in patients with a complete deficiency in dihydropyrimidine dehydrogenase (DPD) accompanied by a wide variety in clinical presentations [1].

## Molecular and Systemic Pathophysiology

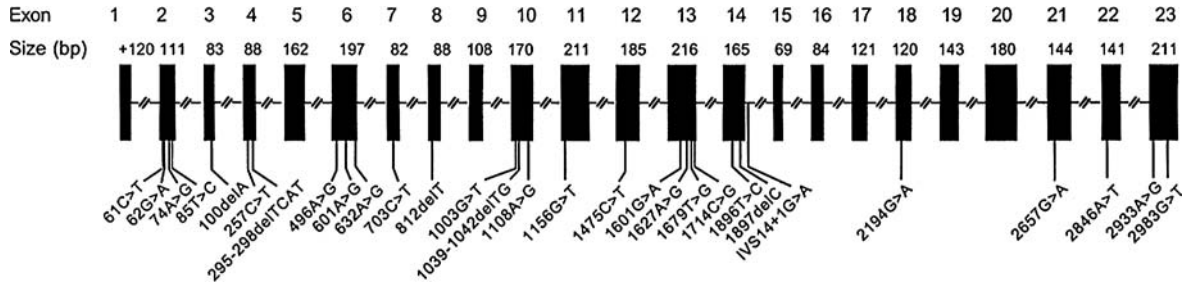
In children, a deficiency of DPD is often accompanied by a neurological disorder but a considerable variation in the clinical presentation among these patients has been reported. Convulsive disorders (seizures and epileptic insults), motor retardation and mental retardation were observed in approximately half of the patients, whereas growth retardation, microcephaly, autism and dysmorphy were less frequently observed. An altered β-alanine, β-aminoisobutyric acid, uracil and thymine homeostasis might underlie the various clinical abnormalities encountered in patients with a DPD deficiency [2].

## Diagnostic Principles

Patients present with increased levels of uracil, thymine and 5-hydroxymethyluracil in urine, plasma and cerebrospinal fluid. No activity of DPD can be detected in fibroblasts and mononuclear cells. Analyses of the pyrimidines can be performed with TLC, HPLC/UV, GC/MS or HPLC/tandem MS [3]. Analysis of DPYD allows the identification of the underlying mutations in this disease.

## Therapeutic Principles

It has been reported that the clinical condition of a DPD-patient suffering arthogryposis multiplex congenital improved considerably when he was treated with both β-alanine and β-aminoisobutyric acid. Therefore,



**Dihydropyrimidine Dehydrogenase Deficiency. Figure 1** Organization of the *DPYD*. *DPYD* consists of 23 exons with an open reading frame of 3075 bp. The different mutations and polymorphisms identified in patients with a partial or complete deficiency of DPD are indicated; numbers correspond to the cDNA position.

treatment with β-alanine and β-aminoisobutyric acid might be a possibility.

# 2,8-Dihydroxyadenine (2,8-DHA) Urolithiasis

►2,8-Dihydroxyadeninuria
►Adenine Phosphoribosyltransferase Deficiency

# 2,8-Dihydroxyadeninuria

Michael Straub[1], Albrecht Hesse[2]
[1]Department of Urology and Pediatric Urology, Urolithiasis Research Group, University of Ulm, Ulm, Germany
[2]Department of Urology, University of Bonn, Bonn, Germany

## Synonyms

2,8-Dihydroxyadeninuria; Denine phosphoribosyl transferase (APRT) deficiency; 2,8-Dihydroxyadenine (2,8-DHA) urolithiasis

## Definition and Characteristics

Autosomal recessively transmitted hereditary disease. Mutations in the adenine phosphoribosyl transferase gene cause deficiency of the enzyme APRT. As a result, adenine is directed through an alternative metabolic pathway, resulting in the production of 2,8-dihydroxyadenine (2,8-DHA). Elimination of this metabolite takes place in the kidney by active secretion into the urine. Under physiological conditions, urinary pH 2,8-DHA is insoluble. However, marked supersaturation with 2,8-DHA may occur, so disease manifestation appears with variable severity, including interstitial nephritis, recurrent nephrolithiasis and renal failure.

## Prevalence

Worldwide, more than 300 cases of 2,8-dihydroxyadeninuria have been diagnosed. The disease is not confined to any specific ethnic group, but appears predominantly in Japanese and Iceland populations. Among the In Middle Europe, the proportion of 2,8-DHA calculi in urinary stones amounts to roughly 0.04–0.06% in large series [1]. For the homozygote form of the APRT gene mutation, an incidence rate of 1 per 100,000 to 200,000 nativities is estimated [2], while 0.4–1.2% are reported for the heterozygote state [3].

## Genes

The defect is transmitted by an autosomal recessive heredity. There exist two types of APRT deficiency: *Type I*, detected in all non-Japanese cases, has the allele APRT*QO resulting from various point mutations or large gene abnormality. *Type II*, called the Japanese form, presents at least one APRT*J allele with an ATG(Met) to ACG(Thr) base substitution at codon 136. Roughly 78% of the Japanese patients are of APRT deficiency *type II* [4]. Complete and partial deficiencies are described. It looks as if *type I* patients develop earlier symptoms than *type II* patients do. In Iceland, the mutation D65V is found predominantly

in 2,8-DHA patients [5]. Recently, two novel mutations for the Japanese state of deficiency were published: G133D and V84M [6].

## Molecular and Systemic Pathophysiology

Under normal metabolic conditions, the APRT converts adenine into AMP. APRT deficiency blocks this salvaging pathway for adenine into the purine metabolism. Subsequently oxidative metabolization of adenine into 2,8-DHA occurs, mediated by the xanthine oxidase (see Fig. 1).

Additional to 2,8-DHA, high amounts of adenine, hydroxyadenine and hypoxanthine are excreted in the kidney. However, only 2,8-DHA shows extremely poor solubility in urine under physiological conditions and crystallizes immediately. Improvement of the solubility would require pH levels lower than pH 2 or higher than pH 9. It is hence impractical in humans.

APRT deficiency often becomes symptomatic even in infants. Clinical presentation of 2,8-dihydroxyadeninuria comprises interstitial nephritis, highly recurrent urolithiasis, and acute and chronic renal failure. After kidney transplantation 2,8-DHA urolithiasis recurs in the transplant and can endanger its function [7], if the patient's xanthine oxidase is not blocked by allopurinol.

Severity of the disease seems to be guided by genetics. Individuals homozygote for *type I* defect tended to have severe disease, while homozygote *type II* individuals showed milder courses. Heterozygosity for the APRT-allele protects from clinical symptoms.

## Diagnostic Principles

*Diagnostic Imaging*: Normally 2,8-DHA stones are radiolucent [8]. Confusion may occur with uric acid concrements, therefore further metabolic evaluation is mandatory to establish the correct diagnosis. However, Japanese authors have published a case with radiopaque 2,8-DHA urolithiasis [3].

*Urine Microscopy*: Crystals of 2,8-DHA in freshly voided urine are easy to recognize and establish the diagnosis unequivocally. They appear as brown spherical bodies under the microscope [9] (see Fig. 2).

*Urinalysis*: Quantitative analysis of 2,8-DHA in a 24 h urine sample needs HPLC [9,10]. The presence of 2,8-DHA in urine confirms APRT deficiency. Alternatively capillary electrophoresis can be used to determine 2,8-DHA and other adenine metabolites in unprepared samples [11].

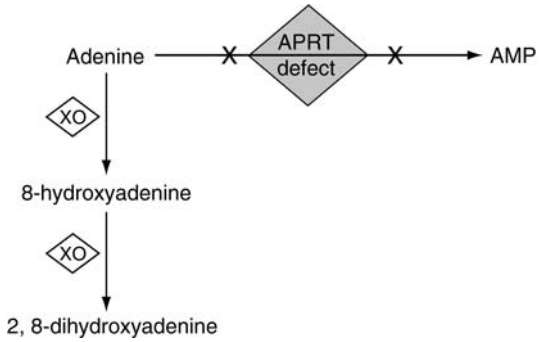
*Measurement of APRT Activity*: Further or alternative confirmation of the diagnosis is possible by assessing adenine phosphoribosyl transferase activity in an erythrocyte lysate [8,10].

- Caution: correct diagnosis is impossible after blood transfusion. APRT activity
- Normal activity 24.7 ± 4.8 nmol adenine/mg Hb/h
- Homozygote deficiency: severe or complete loss of activity
- Heterozygote deficiency: moderate loss of activity

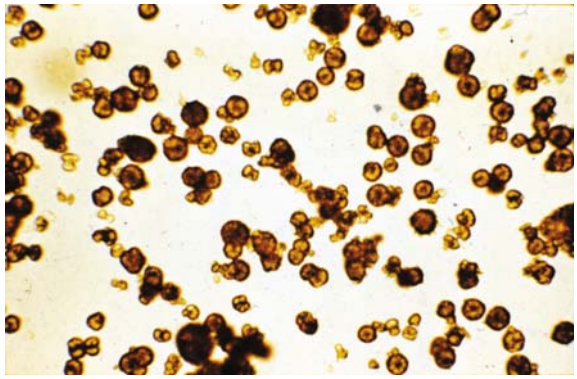
## Therapeutic Principles

Gene therapy for 2,8-dihydroxyadeninuria is not available. Effective treatment can be offered, though, based on the experience of some specialized centers. Randomized therapy trials or long-term studies do not exist. Patient's individual prognosis depends upon the renal function at diagnosis and the compliance to the therapeutic measures. Treatment consists of adequate fluid intake, a low-purine diet and administration of allopurinol [8,10].

*Fluid Intake*: Adequate urine dilution minimizes the supersaturation with 2,8-DHA. For this purpose circadian drinking – including the nocturnal period – is necessary. The recommended fluid volume amounts 3.5 l of neutral beverages per day.



**2,8-Dihydroxyadeninuria. Figure 1** Metabolic pathways of adenine. APRT deficiency diverts adenine into an oxidative pathway resulting in 2,8-DHA. (APRT – adenine phosphoribosyl transferase, XO – xanthine oxidase).



**2,8-Dihydroxyadeninuria. Figure 2** 2,8-DHA crystals in urine sediment.

*Low-Purine Diet*: Reduced purine intake lowers the supply with exogenous precursors of the adenine metabolism.

*Allopurinol*: The substance interferes directly with the nucleotide metabolism by providing a false allopurinol-ribonucleotide and inhibiting xanthine oxidase. This decreases the levels of 2,8-DHA [10]. The daily allopurinol dose is normally adjusted between 300 and 600 mg in adults and 5–10 mg/kg body weight/d in children. Note that impaired renal function demands dose reduction.

*Stone Therapy*: Today, endoscopic interventions with intracorporeal lithotripsy and/or stone removal or extracorporeal shock wave lithotripsy, guided radiologically or sonographically, provide comfortable stone management. Open stone surgery has become – at least in the Western world – a rarity, performed in less than 1% of the cases.

*Risk Evaluation*: Genetic counseling and ante-natal diagnosis are ineffective.

# Disseminated Intravascular Coagulation

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis,
Department of Internal Medicine,
Maastricht University, Maastricht, The Netherlands

## Synonyms

Defibrination syndrome; Acquired afibrinogenemia; Consumptive coagulopathy, and consumptive thrombohemorrhagic disorder; Disseminated intravascular fibrin formation; Diffuse intravascular coagulation; DIC

## Definition and Characteristics

Defined by the International Society for Thrombosis and Haemostasis, DIC is "an acquired syndrome characterized by the intravascular activation of coagulation with loss of localization arising from different causes [1,2]. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction." One consequence of DIC may indeed be fibrinous occlusion of small and midsize vessels contributing to multi organ failure (MOF).

*Causes:* Any severe acute disease can trigger DIC; important examples are bacterial sepsis, multiple trauma, particularly brain injury, eclampsia and amniotic fluid embolism. More chronic forms of DIC may be seen in malignancies, particularly hemato-oncological forms, and in abdominal aortic aneurysms.

## Prevalence

DIC is very frequent in severe sepsis, multiple trauma and gynecological emergencies, at a rate of 60–90%, according to ISTH criteria. In other diseases lower rates are seen.

## Genes

This syndrome is considered an acquired condition and it is still uncertain whether specific gene mutations are involved in susceptibility.
*Gene map locus*: Not linked to specific locus.

## Molecular and Systemic Pathophysiology

No specific genetic traits that predispose to DIC are known. Given the importance of the natural anticoagulants in the defense against sepsis, a genetic predisposition may be expected. However, evidence for a greater risk of DIC in individuals with a genetic defect in protein C, S, or antithrombin, is so far limited.

DIC occurs upon inflammatory stimulation resulting in the liberation of cytokines, including tumor necrosis factor alfa and interleukin-6. These two cytokines have been related with specific steps in the DIC process, i.e. downregulation of fibrinolysis and anticoagulant activity and induction of tissue factor, respectively. Induction of tissue factor on circulating cells (monocytes and to some extent platelets and neutrophils) and on microparticles shed from activated cells, triggers coagulation activity by assembling with factor VIIa. Due to downregulated activity of natural anticoagulants (thrombomodulin and endothelial cell protein C receptor), and suppressed fibrinolysis (due to increased concentrations in blood of plasminogen activator inhibitor 1, PAI-1) leads to ongoing fibrin generation. Fibrin deposits in end organ blood vessels may contribute to tissue ischemia. In addition, the generation of a number of coagulation proteases may, through inflammatory-coagulation cross-talk by protease activated cell receptors (PARs) further enhance inflammation and cause cell death.

*Clinical features:* The clinical syndrome is characterized by a bleeding diathesis, due to depletion of coagulation proteins and platelets [1]. The severity of bleeding ranges from localized oozing from puncture sites to more systemic complications, such as petechiae, purpura, ecchymosis, intestinal bleeding such as hemoptysis, or frank hematuria. *Purpura fulminans* is observed in the course of bacterial infections with meningococci and pneumococci, as well as in other bacterial and viral infections. The typical thrombohemorrhagic syndrome described by Waterhouse and Friderichsen includes fever, cyanosis, a purpuric rash and circulatory collapse. In chronic diseases, like several types of malignancies, DIC is merely a laboratory diagnosis, lacking overt symptomatology except for a mild bleeding tendency; here, a prolonged APTT or lowered platelet count may be indicative of a "mild" form of DIC.

## Diagnostic Principles

The diagnosis of DIC is merely based on clinical grounds, including bleeding and/or signs of tissue ischemia such as liver and kidney failure. As such patients are already at such high clinical suspicion for DIC, only a few readily available laboratory tests are necessary to confirm the diagnosis. These include the prothrombin time (PT), partial thromboplastin time (aPTT), platelet count, blood smear and one test for activated coagulation such as a FDP or D-dimer test. Laboratory diagnosis to support the formal criteria of DIC is according to ISTH recommendations, which is particularly useful for clinical research purposes [3].

## Therapeutic Principles

The only relevant treatment is curation of the underlying disease. In addition, supportive care is often needed in the form of supplementation with platelets or plasma proteins (plasma products) to reduce the risk of

bleeding. The latter policy is always disputed, because of the potential to "fuel the fire," however, the risk of bleeding is usually the major determinant for clinical care. The use of anticoagulants such as low molecular weight heparin (LMWH) or low dose heparin is not evidence based care, but may have some protective effect. The administration of antithrombin may be warranted in patients with a severe acquired deficiency, although the phase 3 trial with recombinant AT was negative for the entire sepsis population studied [4]. There is a limited indication for use of recombinant activated protein C (recAPC), but only in those with most severe sepsis (APACHE score >24) [5].

## Distal Myopathy, Autosomal Dominant

Nigel Laing[1], Frank Mastaglia[2]
[1]Molecular Neurogenetics Centre for Medical Research, Western Australian Institute for Medical Research, University of Western Australia, Nedlands, WA, Australia
[2]Centre for Neuromuscular and Neurological Disorders, University of Western Australia, QEII Medical Centre, Nedlands, WA, Australia

### Synonyms

MPD1; Laing myopathy

### Definition and Characteristics

Autosomal dominant childhood onset distal myopathy, with predominant weakness in the anterior compartment of the leg and finger extensors [1, 2]. The condition is very slowly progressive, compatible with life into adulthood. One characteristic sign is said to be the "hanging big toe" [2,3].

### Prevalence

This is a very rare condition. No prevalence figures have been published.

### Genes

The disease was first linked to chromosome 14 in 1995 [1]. A large US family linked to the same region of chromosome 14 [4]. Mutations were identified in the slow skeletal/beta cardiac myosin gene (MYH7) in both of these families, in other small families compatible with linkage to the same region and in sporadic cases [5]. The sporadic cases had de novo mutations not present in either parent [5] (MIM 160500).

### Molecular and Systemic Pathophysiology

Electromyographic studies show a myopathic pattern of low amplitude, brief duration motor unit potentials and a full, low amplitude interference pattern. This is seen particularly in affected distal limb muscles, but also to a lesser extent in more proximal muscles, indicating that there is a gradation of involvement. Spontaneous fibrillation potentials and positive sharp waves may be found in some affected muscles on EMG and mildly increased jitter and blocking in some muscles on single-fiber EMG. Nerve conduction studies are normal. The muscle biopsy changes are those of a primary myopathic disorder, but pleomorphic [2]. There are no pathognomonic features. There are occasional necrotic and regenerating fibers, as well as other non-specific myopathic changes and no evidence of denervation. Rimmed vacuoles were not present in the original family, but have been described in the family reported

by Voit et al. (2001). Type I fibers, in which MYH7 is expressed may be more affected [2]. The published mutations in MYH7 that cause the disease are missense mutations to proline or deletions of single amino acids within the light meromyosin (LMM) region of the rod domain of the myosin heavy chain [5]. The LMM normally forms a coiled coil. Prolines are incompatible with coiled coils and deletion of an amino acid will disturb the seven amino acid repeat necessary for making coiled coils. The Laing distal myopathy mutations will thus locally disturb the ability of the LMM to make a coiled coil [5]. The Laing distal myopathy mutations in MYH7 overlap with mutations of the LMM that cause cardiomyopathy but are N-terminal of mutations of MHY7 associated with myosin storage myopathy [5]. The exact effects of the mutations on normal myosin functions are currently unknown. Equally unknown are the reasons why the mutations in this myosin, expressed in every slow muscle fiber, cause a distal myopathy largely restricted to certain muscles.

### Diagnostic Principles

The condition may be suggested by the gradual onset of bilateral foot drop, with weakness of the ankle and toe extensors manifesting initially in the teens or late 20s, but as early as birth in some individuals [2]. This weakness results in the "hanging big toe" [3]. There is also weakness and atrophy of the sternocleidomastoid in many but not all cases [4]. Weakness of the extensors of the little fingers, and subsequently of the other fingers, does not usually develop until the 40s. The serum creatine kinase levels are normal, or mildly elevated. There are no specific EMG or muscle biopsy findings. The diagnosis is supported by selective atrophy and signal change in the tibialis anterior and extensor hallucis longus muscles on CT or MRI scans of the lower leg. The conclusive diagnosis is by identification of mutations within the MYH7 gene. The clinical phenotype is not specific and we have failed to identify mutations in MYH7 in other patients with very similar phenotypes.

### Therapeutic Principles

No specific pharmacological treatment or gene therapy is available for the condition. Although more proximal limb muscle groups may be affected in the later stages, the condition is very slowly progressive and is compatible with preservation of mobility into the 60s and 70s. However, ankle orthoses may be required when the foot drop begins to interfere with walking.

DBH, Dopamine–beta–hydroxylase; Gene locus 9q34; Inheritance autosomal recessive.

### Molecular and Systemic Pathophysiology

Autonomic function studies indicate that complete DBH deficiency includes sympathetic noradrenergic failure and adrenomedullary failure with intact vagal and sympathetic cholinergic function. Affected neonates may show a delay in opening of the eyes and ptosis of eyelids. Hypotension with hypoglycemia and hypothermia may occur early in life. Reduced exercise tolerance, ptosis of the eyelids, nasal stuffiness, and delayed or retrograde ejaculation are features.

### Diagnostic Principles

The diagnosis of DBH deficiency is based on clinical findings resulting from noradrenergic inactivation including orthostatic hypotension, hypoglycemia, ptosis and impaired ejaculation and intact cholinergic functions including sweating. Biochemical features unique to DBH deficiency include minimal or undetectable plasma norepinephrine and epinephrine AND a five- to tenfold elevation of plasma dopamine, a finding probably pathognomonic of DBH deficiency.

### Therapeutic Principles

Treatment for DBH deficiency is supportive and directed at relieving orthostatic symptoms. Administration of DL or L-threo-3,4-dihydroxyphenylserine (DOPS) alleviates the orthostatic hypotension and other symptoms. This therapeutic agent bypasses the DBH deficiency, since it is converted to noradrenaline by decarboxylation of the terminal carboxyl group.

Individuals do not respond well to standard therapeutic approaches for autonomic failure.

## Synonyms

Segawa syndrome; Dystonia 5; Hereditary progressive dystonia with marked diurnal fluctuation; HPD; DRD

## Definition and Characteristics

DRD is a mostly autosomal dominant childhood onset dystonia characterized by diurnal fluctuation of symptoms in about 75% of cases, parkinsonism and a dramatic therapeutic response to L-dopa. Penetrance is incomplete and expressivity is highly variable. The phenotypic spectrum can range from generalized and focal dystonia via postural anomalies, parkinsonism and subjective complaints to subtle signs only seen upon induction during clinical examination. Age of onset also varies widely. While DRD usually starts during childhood, onset can also occur during adolescence or adulthood [1,2].

## Prevalence

$0.5/10^6$, probably higher owing to under diagnosis. Females are more frequently affected than males (2.5/1).

## Genes

The most common form of DRD is caused by mutations in the gene GCH1 on chromosome 14q22.1–q22.2 [3]. GCH1 codes for GTP cyclohydrolase I, the rate limiting enzyme in the biosynthesis of tetrahydrobiopterin ($BH_4$), an essential cofactor of tyrosine, tryptophan, and phenylalanine hydroxylase (Fig. 1).

Heterozygous GCH1 mutations (nonsense, missense, splice-site mutations as well as deletions and insertions) account for more than 50% of autosomal dominant forms of DRD. In one instance, a heterozygous mutation was observed in the gene SPR (chromosomal location: 2p14–p12) encoding sepiapterin reductase (Fig. 1) [4]. Homozygous or compound heterozygous mutations of SPR result in progressive psychomotor retardation and severe dopamine and serotonin deficiencies in addition to dystonia [5]. Rare autosomal

recessive forms of DRD or infantile parkinsonism are caused by homozygous or compound heterozygous mutations in the gene *TH* (chromosomal location: 11p15.5) encoding tyrosine hydroxylase (reviewed in [1]).

## Molecular and Systemic Pathophysiology

All three genes identified in DRD affect synthesis of dopamine. GTP-cyclohydrolase (GTPCH1), the gene product of GCH1, is the enzyme catalyzing the first and rate-limiting step in the synthesis of $BH_4$. $BH_4$ is an essential cofactor of tyrosine, phenylalanine and tryptophan hydroxylases, which catalyze synthesis of L-dopa/dopamine, tyrosine and 5-hydroxy-tryptophan/serotonin respectively (Fig. 1). SPR encodes sepiapterin reductase, which catalyzes synthesis of $BH_4$ from 6-pyruvoyl tetrahydropterin (Fig. 1). While mutations in GCH1 and *SPR* affect synthesis of L-dopa/dopamine indirectly in autosomal dominant DRD, partial or complete loss of tyrosine hydroxylase activity directly interferes with normal synthesis of L-dopa/dopamine in autosomal recessive DRD. The clinical phenotype of DRD is the immediate cause of insufficient synthesis of L-dopa and dopamine.

Given that GTPCH1 activity is reduced by more than 50% in several affected heterozygous mutation carriers, haploinsufficiency may not be the sole cause of reduced synthesis of L-dopa and dopamine. Rather GCH1 mutations might exert a dominant-negative effect. According to this notion, mutant and wild type polypeptides would form dys- or non-functional GTPCH1 heterodecamers. This suggestion was supported by cotransfection experiments using wild type and mutated GCH1 cDNA (summarized in [1]). On the other hand, formation of heterodecamers was not found for at least two mutations (R88W and R184H) of GTPCH1 [1]. Furthermore, heterozygous deletions of GCH1 were detected in patients, ruling out dominant-negative effects at least in these cases and showing that haploinsufficiency can be sufficient to cause DRD.

## Diagnostic Principles

Clinical diagnosis of DRD is based on the responsiveness to L-dopa of abnormal movements dominated by dystonia and/or parkinsonism. A positive family history of abnormal movement further suggests autosomal dominant DRD. Diagnosis is borne out by the detection of a mutation in one of the six exons of GCH1 or a partial or complete deletion or duplication of one allele of this gene. Given the extreme rarity of autosomal recessive forms of DRD, routine molecular analysis of the TH gene is currently not warranted unless the patient is the product of a consanguineous marriage and/or several siblings of healthy parents are affected and GCH1 mutations have been excluded.

## Therapeutic Principles

Therapy is based on substitution of L-dopa and results in complete remission of symptoms in the majority of cases. None of the adverse effects that often occur in the therapy of Parkinson's disease, such as "on-off phenomena" or "freezing episodes," are observed in patients with DRD even after long-term treatment.

# DORV

►Double Outlet Right Ventricle

# Doss Porphyria

►ALA Dehydratase Porphyria

# Double Outlet Right Ventricle

Mary Redmond Hutson, Margaret L. Kirby
Department of Pediatrics, NPRI, Duke University, Durham, NC, USA

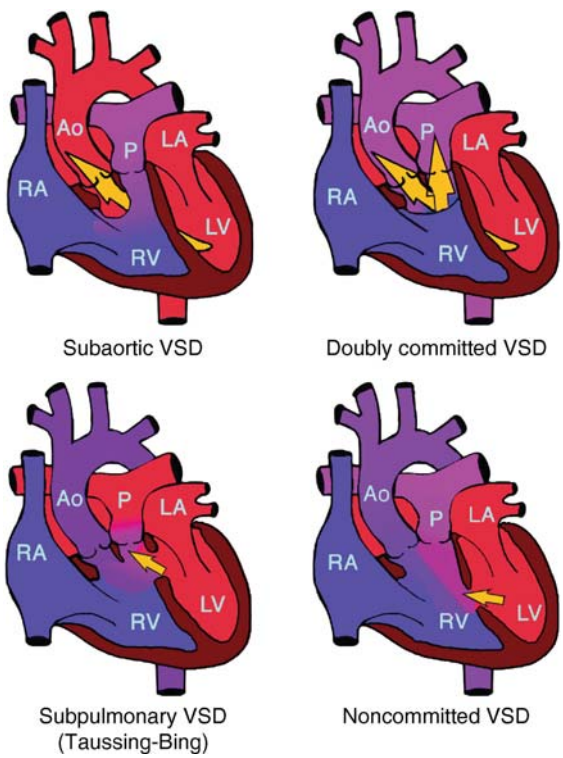
## Synonyms

DORV; Dextroposed aorta; Overriding aorta; Taussig-Bing anomaly; Tetralogy of Fallot

## Definition and Characteristics

DORV encompasses a range of heart defects, in which the great vessels are misaligned with respect to the ventricles. Normally the pulmonary trunk arises from the right ventricle (RV) and aorta from the left ventricle (LV). In DORV, both the pulmonary artery and the aorta arise completely or mostly from the RV. If the aorta obtains 50% of its blood from the RV, the defect is classified as DORV [1]. Because both outflow vessels originate predominately from the RV, there is a concomitant ventricular septal defect (VSD).

The DORV is categorized based on the position of the VSD in relation to the outflow vessels [1] (Fig. 1). A VSD below the aorta is called DORV with sub-aortic VSD. The great arteries are in a "side-by-side" position with the aortic valve shifted to the right of the pulmonary valve. A VSD below the pulmonary artery is called DORV with sub-pulmonary VSD or Taussig-Bing anomaly. In this defect, both of the great arteries arise from the RV with the pulmonary valve positioned to the right and slightly posterior or side-by-side with the aortic valve. In doubly committed DORV, the VSD is below both outflow vessels. In noncommitted DORV, the VSD is remote and not dedicated to either vessel with the distance between the VSD and the aorta and pulmonary trunk at least equal to the aortic valve diameter. Often DORV does not occur as an isolated defect, classification and description also may take into consideration pulmonic or systemic obstructions, ventricular anomalies, coronary artery defects, atrioventricular valve anomalies, as well as conduction system abnormalities. For example, Tetralogy of Fallot includes DORV, pulmonary stenosis and RV hypertrophy.



**Double Outlet Right Ventricle. Figure 1** Common variants of DORV.

## Prevalence

In its many forms, DORV is present in 1–3% of all congenital heart defects [2].

## Genes

DORV malformations can be traced to the early stages of heart tube looping (3–4 weeks post conception) [3]. After initial heart tube formation, the heart tube continues to lengthen producing a looped heart tube. This lengthening is essential for proper positioning of the outflow and inflow to establish correctly aligned pulmonary and systemic circuits. The lengthening of the heart tube is accomplished by the addition of the myocardium and smooth muscle produced from the field of cardiac progenitors in the pharynx called the secondary heart field [4]. Failure of these precursors to lengthen the heart tube results in a shortened heart tube and later the failure of the outflow vessels to align properly with the ventricles (i.e. DORV) [4,5]. In humans, environmental and genetic factors both have been implicated, but a few single-gene defects have been linked to DORV. Most cases of DORV are sporadic, but there are rare reports of familial cases. Human chromosome 22q11 deletion or DiGeorge Syndrome, is frequently seen in patients with other types of conotruncal defects (e.g., interrupted aortic arch, truncus arteriosus, and tetralogy of Fallot) but is rarely found in patients with isolated DORV [2]. A mutation or microdeletion in Jagged 1, a Notch ligand expressed in the developing heart is associated with human Allagile syndrome and tetralogy of Fallot. In animal models, DORV has also been induced using a variety of experimental methods including mechanical, teratogens, targeted genetic modification, and neural crest ablation [3]. In chick, ablation of the secondary heart field leads to DORV with pulmonary stenosis or atresia [3]. Reduced dosage of the cardiac transcription factor, GATA4, results in DORV in the mouse. The secondary heart field in mouse and chick is sensitive to reduced dosage of the fibroblast growth factor, FGF8, with phenotypes that look much like DORV and Taussig-Bing [5]. The growth factor, neurotrophin 3 (NT3) is essential for the normal cardiac myocyte development and regulates proliferation during looping and trabeculae formation. NT3 null mice have atrial and ventricular septal defects, and tetralogy of Fallot [3]. Disruption of nonmuscle myosin heavy chain B is

associated with abnormal myocardial development and both tetralogy of Fallot and DORV.

### Molecular and Systemic Pathophysiology

Pathophysiology depends on the location of the VSD in relation to the origin of the great vessels [2]. Because of the VSD, oxygen saturated and desaturated blood is mixed to varying degrees in the RV. The degree of mixing depends on the position and size of the VSD, the position of the great vessels, and the presence of or absence of a stenotic outflow vessel. Oxygen saturation levels in the aorta may range from near normal to very cyanotic. In DORV with subaortic VSD, the VSD is close to the aorta, consequently oxygenated blood from the LV is directed to the aorta while desaturated blood from the RV is directed largely to the pulmonary artery. Clinically this presents as a large VSD. High systolic pressure is equalized between both ventricles and outflow vessels. Ultimately abnormally high pressure in the RV and the pulmonary artery leads to pulmonary hypertension and congestive heart failure. DORV with noncommitted or remote VSD has a physiology similar to isolated VSD or atrioventricular canal defect. In DORV with subpulmonic VSD, the LV outflow is directed toward the pulmonary artery, leading to oxygen saturations greater than aortic saturations and physiology similar to transposition of the great arteries.

### Diagnostic Principles

Echocardiography and cardiac catheterization are used to localize the position of the VSD, determine pulmonary vascular resistance and to identify coexistent conditions [2].

### Therapeutic Principles

Surgical repair is usually required with the ultimate goal of normalizing biventricular function [2]. In DORV with subaortic VSD, the repair involves placing a patch to direct LV blood toward the aorta. Additional procedures may involve pulmonary artery banding in cases of excessive pulmonary blood flow, or the placement of systemic-pulmonary shunts in cases of pulmonary stenosis. In Taussig-Bing type, the intraventricular patch repair is often not feasible because of the position of the VSD. The patch is placed to direct flow from the LV to the pulmonary artery, followed by an arterial switch procedure whereby the pulmonary artery is connected to the RV and the aorta to the LV.

### Synonyms

Hereditary conjugated hyperbilirubinemia

### Definition and Characteristics

Autosomal recessive conjugated hyperbilirubinemia without other liver function abnormalities. Black lysosomal liver pigment. Normal total urinary coproporphyrin, elevated urinary coproporphyrin isomer I excretion.

### Prevalence

Rare, gene frequency (in Japan) ~1:800,000.

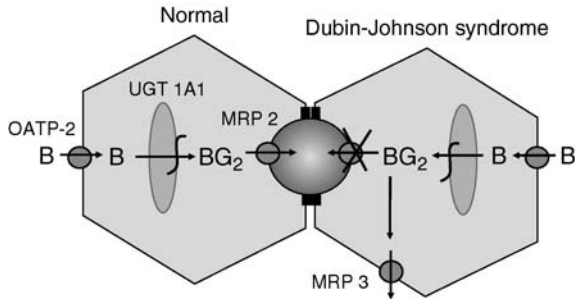
### Genes

ABCC2, MRP2, cMOAT on chromosome 10q24.

### Molecular and Systemic Pathophysiology

In the liver bilirubin is conjugated to a diglucuronide and this is secreted into the bile. The hepatobiliary secretion of conjugated bilirubin is mediated by a protein called MRP2 (ABCC2; canalicular Multispecific Organic Anion Transporter, cMOAT). The protein is located in the canalicular membrane of hepatocytes (Fig. 1).

It is a member of the large family of ATP-binding cassette transporters. These are active transporters in which ATP hydrolysis is directly coupled to transport activity. MRP2 transports a large number of glucuronide- and glutathione-conjugates hence the name "multispecific organic anion transporter." In Dubin–Johnson syndrome this protein is non-functional [1,2]. The ABCC2 gene is located on chromosome 10q24 [3]. The described gene mutations (Fig. 2). either preclude synthesis of an intact active protein, causes the synthesis of a protein that cannot be targeted correctly from the endoplasmic reticulum to the canalicular membrane or produces a protein that is correctly targeted but is inactive or less active. As a result conjugated bilirubin cannot be secreted into bile.

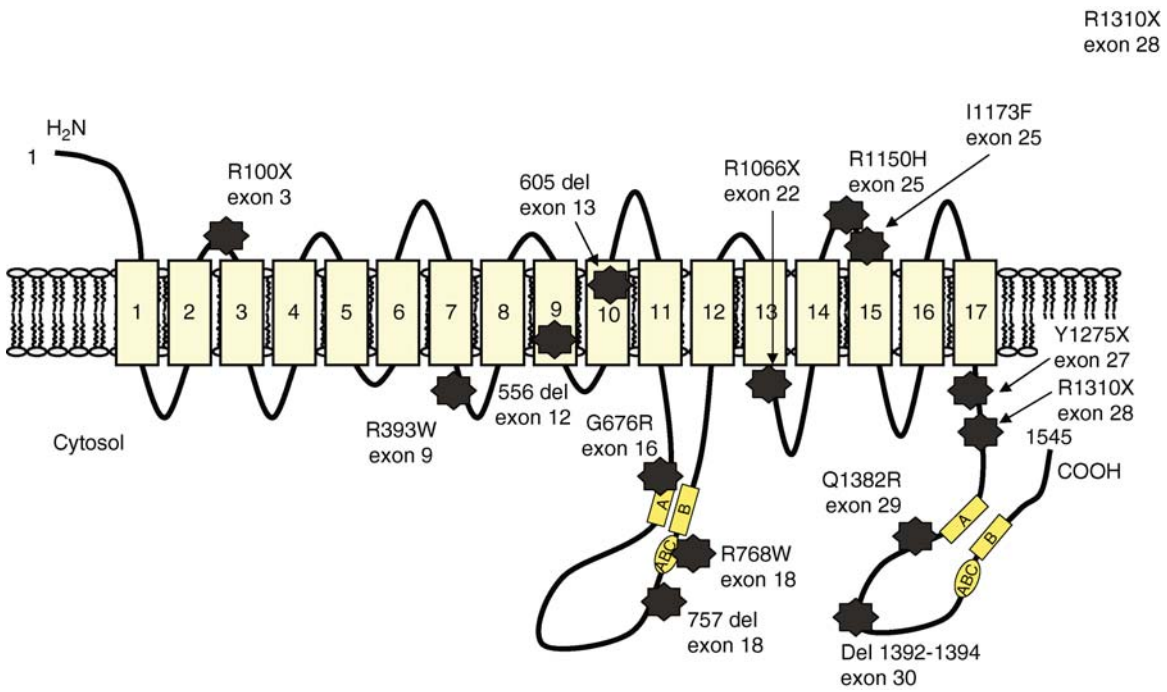


**Dubin-Johnson Syndrome. Figure 1** Bilirubin uptake into the hepatocyte is facilitated by OATP-2. In the endoplasmic reticulum unconjugated bilirubin is conjugated with glucuronic acid. This glucuronidation is mediated by UGT1A1, a member of a large family of UDP-gluronosyltransferases. At the canalicular membrane transport of conjugated bilirubin from liver to bile is mediated by MRP2 (ABCC2). In Dubin–Johnson syndrome the gene encoding this transporter carries a mutation. Dubin–Johnson syndrome is an autosomal recessive disease.

Serum bile salt levels are normal. MRP3 (ABCC3) is a protein that is able to transport many of the MRP2 substrates [4]. Under normal conditions MRP3 is hardly expressed in the liver but in patients with Dubin–Johnson syndrome its expression is increased. As a basolateral protein it transports conjugated bilirubin from hepatocytes to blood. Conjugated bilirubin is removed from the blood via renal secretion. However, this is less efficient than removal via the hepatobiliary route and therefore patients with the Dubin–Johnson syndrome are permanently jaundiced. The liver of these patients looks grossly black. Liver histology shows a normal liver architecture but a pathognomic black–brown lysosomal pigment. The pigment is an oxidized metabolite [5].

### Diagnostic Principles

Serum conjugated bilirubin is usually between 50–85 micromol/L but can be elevated up to 385 micromol/L. It increases during pregnancy (8). Total urinary coproporphyrin is normal, coproporphyrin isomer I is relatively elevated (>80%; normal < 27%). Hepatobiliary secretion of the scintigraphic agent HIDA is delayed. The initial plasma disappearance of sulfobromophthalein is normal, with a normal 45 min. retention value,



**Dubin-Johnson Syndrome. Figure 2** Protein structure of ABCC2/MRP2 with transmembrane domains, Walker motives and a number of common mutations.

but there is a secondary rise after 90 mins. The liver is grossly black and this is due to a black lysosomal pigment in hepatocytes. Routine liver function tests are normal with normal bile acid levels.

## Therapeutic Principles

This disease has an excellent prognosis and therapy is not needed.

►Dermatitis Herpetiformis

# Dumping Syndrome

Sönke Von Weihe, Jan Schulte Am Esch, Wolfram Trudo Knoefel
Department of General-, Visceral- and Pediatric Surgery, University Hospital Duesseldorf, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

Post gastrectomy syndrome

## Definition and Characteristics

Dumping syndrome is a disease that manifests itself in a variety of symptoms which may occur after gastric surgery, especially after total gastrectomy and billroth-2-reconstruction. An early and a late type is distinguished. Affected patients complain of immediate postprandial gastrointestinal discomfort, which may include nausea, vomiting and abdominal cramps. Also, vasomotoric symptoms such as diaphoresis, tachycardia and hypotension are common. The latter appears 1–3 h after meals with the characteristic symptoms of hypoglycemia [1].

## Prevalence

Anatomic and physiologic changes introduced by gastric surgery result in clinically significant dumping syndrome in up to 10% of patients [2].

## Molecular and Systemic Pathophysiology

Whereas the precise mechanism is incompletely understood, the severe symptoms of dumping syndrome are seen early after surgery. Therefore, the syndrome is frequently attributed to the rapid emptying of hyperosmolar chyme (particularly carbohydrates) into the small bowel. This leads to net fluid retention due to an osmotic fluid shift and ensues in combination with postprandial peripheral and splanchnic vasodilation in relative hypovolemia. This is pivotal in the pathophysiology of early systemic symptoms. Subsequently the postprandial noradrenaline level is increased. Due to sympathic activation, there is a secondary release of gut hormones including glucagone like peptide 1 (GLP-1), vasoactive intestinal peptide (VIP), neurotensin and serotonin [3].

The phenomenon of late dumping is thought to be secondary to hypoglycemia as response caused by the exaggerated release of GLP-1.

## Diagnostic Principles

It is often difficult to discern symptoms from dumping from other postoperative complaints after gastric surgery. The diagnosis can be made with the aid of a provocation test using 50 g glucose orally. An increase in heart rate of ≥10 beats/min within the first hour is typical for early dumping. Also, GLP-1 levels are significantly increased 30 min after application. Abnormally rapid emptying found in most affected patients can be detected by gastric emptying scintigraphy, e.g. 99mTc-labeled solid test meal. Late dumping is better recognized by the occurrence of subjective symptoms during provocation, as the nadir blood glucose concentration is not specific [4].

## Therapeutic Principles

Most patients can be treated conservatively, unless a mechanical cause is present, with advice on diet and lifestyle. Frequent small meals that are high in protein and fat and low in carbohydrates to minimize ingestion of simple carbohydrates are recommended for early dumping. Patients should also be advised to avoid foods that provoke the symptoms. For late dumping syndrome increased carbohydrate consumption is recommended.

Pectin and guar is useful by increasing the viscosity of intraluminal contents to prolong transit time. Daily subcutaneous octreotide application effectively alleviates the signs and symptoms of dumping syndrome in patients refractory to standard alimentary therapy. It acts through inhibitory effects on insulin and gut hormone release, decrease of intestinal absorption of water and sodium and increase of intestinal transit time as well as prevention of hemodynamic changes. Its long-term use is somewhat limited by side effects, particularly diarrhea and steatorrhea. Alternatively long-acting release octreotide (Sandostatin-LAR®) can be injected i.m. every 4 weeks to increase quality of life. However, economic aspects set limits to long term octreotide therapy. Treatment with acerbose, a potent alpha-glucosidase inhibitor, can be of value in preventing reactive hypoglycemia in late dumping by reducing the early hyperglycemic stimulus to insulin secretion [5].

The rare patient with intractable symptoms and therefore anticipated poor nutrition status may be considered for operative treatment with the goal of delaying gastric emptying. A conversion to an antrectomy with Roux-en-Y reconstruction instead of a Billroth reconstruction can provide help. Feasibility trials showed the absence of dumping symptoms after construction of a functional surrogate pylorus made by the means of a pantaloon jejunoplastic pouch. If possible from an oncological point of view, occurrence of dumping syndrome can be avoided at all by performing a function preserving or restoring resectional technique instead of a total gastrectomy, e.g. a limited proximal gastrectomy with reconstruction by single jejunal interposition (Merendino-procedure) or preservation of the vagal nerve, lower esophageal and pyloric sphincters.

# Duncan Disease

►Lymphoproliferative Syndrome, X-linked

# Duodenal Atresia

Alexander K. C. Leung[1], Andrew L. Wong[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Department of Surgery, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Duodenal atresia usually manifests as vomiting within 24 h after birth [1]. The vomitus may or may not be bile stained, depending on whether the obstruction is proximal or distal to the ampulla of Vater [1]. In ~85% of cases, the atresia occurs in the second part of the duodenum, distal to the ampulla of Vater [2]. Three types of duodenal atresia are recognized [3]. Type I defect is the most common and represents a mucosal diaphragmatic membrane (web) with an intact muscle wall [3]. Type II defect has a short fibrous cord which connects the two blind ends of the atretic duodenum. In type III defect, there is no connection between the two blind ends of the atretic duodenum with a V-shaped mesenteric defect. Abdominal distention is often absent, but visible peristalsis may be seen passing from left to right. Maternal polyhydramnios occurs in 30–65% of cases due to impairment of reabsorption of amniotic fluid. Premature delivery occurs in 30–50% of cases as polyhydramnios may lead to premature labor. Associated anomalies include esophageal atresia, annular pancreas, malrotation of the bowel, anorectal anomalies, renal anomalies, congenital heart disease, corporal asymmetry, bilary atresia, and gallbladder agenesis [1].

## Prevalence

Duodenal atresia, which accounts for 50% of all cases of intestinal atresia, occurs in 1 of 5,000–10,000 live births [1]. Boys are affected more commonly than girls [4].

## Genes

Most cases are sporadic but some are familial [5]. The latter may be secondary to chromosomal abnormalities notably Down syndrome. The Down syndrome-specific region has been mapped to chromosome 21q22.2–22.3. Familial cases may also form part of a recognizable syndrome. Syndromes with an autosomal recessive mode of inheritance include Fryns syndrome and Martinez-Frias syndrome [5]. Syndromes with an autosomal dominant mode of inheritance include Feingold syndrome. The gene responsible for Feingold syndrome has been mapped to chromosome 2p23–24 [5].

## Molecular and Systemic Pathophysiology

Duodenal atresia is thought to result from a failure of recanalization of the duodenal lumen that occurs during the first trimester [2]. Fibroblast growth factor-10 serves as a regulator in the normal development of the duodenum as mutant mice deficient in fibroblast growth factor-10 have duodenal atresia [3]. Teratogenic causes include maternal diabetes mellitus and antenatal exposure to thalidomide, alcohol, cocaine and valproic acid [5].

## Diagnostic Principles

When the atresia occurs in the second part of the duodenum, plain radiographs of the abdomen typically show the classic "double-bubble" sign with absence of air distal to the site of obstruction (Fig. 1).

The larger bubble is the distended stomach; the smaller bubble is the distended duodenal bulb proximal to the atresia. When the atresia occurs in the first part of the duodenum, air is seen only in the distended stomach. The diagnosis is often made prenatally by ultrasonography.

## Therapeutic Principles

The initial treatment consists of nasogastric decompression and correction of fluid and electrolyte disturbances. A duodenoduodenostomy is the procedure of choice for surgical repair of duodenal atresia [4]. Blind loop syndrome is more common in patients treated with duodenojejunostomy [4]. Because of the high incidence of multiple atresias, the rest of the bowel should be thoroughly inspected before the bypass procedure is performed. Late complications occur in ~12% of patients with duodenal atresia [4]. Long-term follow-up is therefore essential. Other associated anomalies should be excluded by appropriate investigations. The

**Duodenal Atresia. Figure 1** Abdominal radiograph of a newborn with duodenal atresia. Note the "double bubble" sign with an absence of distal bowel air.

prognosis is a function of the presence and types of associated anomalies.

# Duplication 9p Syndrome

Noriko Miyake[1], Naomichi Matsumoto[2]
[1]Department of Medicine (Genetics), Children's Hospital Boston and Harvard Medical School, Boston, MA, USA
[2]Department of Human Genetics, Yokohama City Graduate School of Medicine, Kanazawaku, Yokohama, Japan

## Synonyms

Trisomy 9p syndrome

## Definition and Characteristics

It is defined as a duplication of the partial short arm of chromosome 9. This syndrome is one of the most frequently observed autosomal anomalies with relatively good longevity, but approximately 5–10% of reported patients died in early childhood.

Major clinical findings in duplication 9p syndrome include mental retardation, small stature, microcephaly/brachycephaly, down-slanting palpebral fissures, deep set eyes, hypertelorism, "globular"/prominent nose, down-turned mouth, low-set ears, single palmar crease, hypoplasia of some phalanges, and hypoplastic nail dysplasia [1]. Postnatal growth deficiency is observed. The extent of the duplicated region is associated with the degree of clinical severity rather than the abundance of phenotypes.

## Prevalence

Duplication of various partial segments of 9p has been found in almost 150 cases since 1970. Pure 9p duplication without concurrent chromosomal abnormalities is rare. The rate of prevalence is unknown.

## Genes

Genes causing each clinical manifestation of the 9p duplication syndrome have not yet been identified. However, six known genes, MPDZ, NF1B, ZDHHC21, CRE1, FREM1 and QBRICK, are located within the current critical region between D9S267 to D9S1213.

## Molecular and Systemic Pathophysiology

The critical duplicated region for the phenotype has been defined through the analysis of isolated 9p duplications without concurrent deletions or other chromosomal abnormalities. McGuire et al. concluded that the region between D9S162 (9p22.1) and D9S267 (9p23) was critical [2]. Bonaglia et al. reported an atypical 9p duplication between D9S1213 and D9S52 manifesting a different phenotype from typical 9p duplication syndrome which narrowed the critical region to a 2.5-Mb segment between D9S267 (9p23) and D9S1213 (9p22.3) (chromosome 9 physical position 12,903,285–15,369,034 bp based on UCSC genome browser, March 2006 assembly) [3].

It is interesting that critical regions for deletion and duplication of 9p syndromes overlapping. One or more genes in the region may determine both syndromes in a dosage sensitive manner or different genes might be responsible for each syndrome. Maternal and paternal duplications have been reported [3,4].

## Diagnostic Principles

9p duplication syndrome is clinically recognizable by the major phenotypic findings. A definitive diagnosis can be made by high resolution karyotyping, FISH, or microarray CGH.

## Therapeutic Principles

Only symptomatic treatment is available.

## Synonyms

Type III hyperlipoproteinemia; HLP; Broad beta or remnant removal disease

## Definition and Characteristics

Autosomal recessive lipid disorder caused by mutations in the apolipoprotein E (apoE) gene. Less common, dominant negative mutations may also cause the disorder.

## Prevalence

Homozygosity for APOE*2 (1 in 170 persons) causes FD or type III hyperlipoproteinemia in less than 20% of the adult APOE*2 homozygotes.

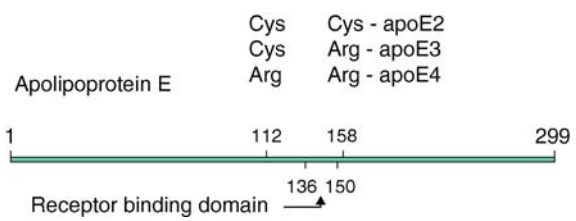
## Genes

ApoE gene coding for apolipoprotein E, localized on chromosome 19q13.

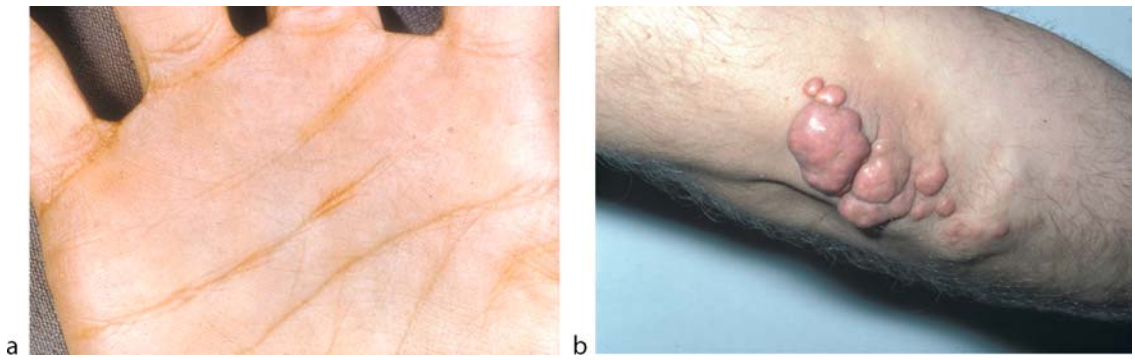
## Molecular and Systemic Pathophysiology

In humans, apolipoprotein E is a polymorphic protein of which three common isoforms can be distinguished, designated apoE2, apoE3 and apoE4. This genetic variation is associated with different plasma lipoprotein levels, different response to diet and lipid-lowering therapy, and with a variable risk for cardiovascular disease and Alzheimers' disease [1,2]. The three isoforms of apoE each differ in isoelectric point by one charge unit, apoE4 being the most basic and apoE2 the most acidic isoform. The biosynthesis of these isoforms is under the control of three independent alleles. ApoE3 (Cys112; Arg158) is the most frequently occurring isoform. ApoE2 (Arg158→Cys) and apoE4 (Cys112→Arg) differ from apoE3 by single amino acid substitutions at position 158 and 112, respectively (see Fig. 1).

The primary metabolic defect in FD is the impaired binding capacity of apoE2 for the hepatic low-density lipoprotein (LDL)-receptor (LDLR), leading to an accumulation of chylomicron and very-low density lipoprotein (VLDL) remnants and intermediate density lipoprotein (IDL) in plasma. Although Arg158 is located outside the LDLR-binding domain, apoE2



**Dysbetalipoproteinemia, Familial. Figure 1** Three isoforms of apolipoprotein E (apoE): apoE2 and apoE4 differ from apoE3 by single amino acid substitution at position 158 and 112, respectively.



**Dysbetalipoproteinemia, Familial. Figure 2** Xanthochromia striata palmaris (a) and tuberous xanthomas (b) of a patient with familial dysbetalipoproteinemia.

(Arg158→Cys) displays less than 1% binding capacity for the LDLR as compared to apoE3, because residue 158 affects the receptor binding by altering the conformation of the 136–150 region.

Despite the accumulation of remnants, only a minority of the APOE*2 homozygous subjects develop overt hyperlipoproteinemia, indicating that type III HLP is a multifactorial disorder requiring additional genetic and environmental factors for its clinical manifestation. Secondary factors influencing the expression of type III HLP include factors leading to (i) an overproduction of lipoproteins, (ii) an impaired lipolysis of lipoproteins or (iii) an impaired hepatic uptake of remnants [1,2]. Although the exact factors remain to be elucidated, hyperinsulinemia [3], and less common hypothyroidism, diabetes mellitus and excessive alcohol consumption may exacerbate the hyperlipidemia. On the other hand low estrogen levels during menopause coincide with the development of hyperlipidemic FD, whereas estrogen substitution effectively reduces the elevated lipid levels in female FD patients.

Hyperinsulinemia has a stimulatory effect on hepatic VLDL production. VLDL overproduction in combination with the impaired hepatic remnant clearance in APOE*2 homozygotes might lead to an increased accumulation of cholesterylester enriched lipoproteins in the circulation and, as a consequence, overt hyperlipidemia. Furthermore, insulin is a regulator of both LPL and apoC3 activity. Possibly, mutations in the lipoprotein lipase (LPL) and APOA1C3A4A5 gene cluster affect their insulin sensitivity, causing overexpression or down-regulation of these genes and an effect on lipolysis.

FD is occasionally associated with apoE variants, usually single amino acid substitutions (Arg136→Ser/Cys; Arg142→Cys/Leu; Arg145→Cys; Arg147→Trp; Lys146→Asn and Lys146→Gln/Glu). An exception is apoE3-Leiden, which is also a dominant negative mutation. The APOE*3-Leiden allele is identical to the APOE*4 (Cys112→Arg) allele, but includes a tandem repeat of codon 120–126 or 121–127. The disorder is associated with peripheral and coronary artery disease.

## Diagnostic Principles

The diagnosis of type III HLP is based on elevated levels of both plasma cholesterol and TG, and homozygosity for APOE*2 (Arg158→Cys) or the presence of a rare APOE variant. Other indicators are the presence of xanthochromia striata palmaris (Fig. 2a), tuberous xanthomas (Fig. 2b), a ratio of VLDL-cholesterol to plasma TG > 0.689 reflecting the presence of β-VLDL, and the presence of a broad β band on agarose gel electrophoresis of plasma. To ascertain the diagnosis apoE fenotyping or genotyping is required.

## Therapeutic Principles

Patients with type III HLP are usually very responsive to therapy. In some cases only dietary intervention, possibly in combination with treatment of other associated disorders (e.g. overweight, hypothyroidism, diabetes mellitus), will normalize plasma lipid levels. Since environmental factors are considered to contribute to type III HLP expression, diet therapy with restricted caloric intake for weight loss, a reduced intake of alcohol, saturated fat and cholesterol should be the first-line strategy.

Therapy with fibric acid derivatives and HMG-CoA reductase inhibitors are effective in the treatment of type III HLP.

Dieter Metze
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Zinsser-Engman-Cole syndrome

### Definition and Characteristics

The disease is characterized by reticulate skin pigmentation, nail dystrophy, and mucosal leukoplakia. Progressive bone marrow failure occurs in over 80% of cases and is the main cause of early mortality. Age of onset, severity of bone marrow failure, and range of congenital abnormalities vary with the mode of inheritance (X-linked recessive, autosomal recessive and dominant forms) [1].

Skin changes include hyper/hypo pigmentation, atrophy, telangiectases, palmoplantar keratoderma, nail dystrophy, alopecia, or hyperhidrosis. Mucosal complications are esophageal or urethral strictures, ulcerations, and malignancies arising from leucoplakia. Cytopenia affects one or more lineage. Other organs affected are teeth (caries/loss), eyes (epiphora, blepharitis, conjunctivitis), liver (liver cirrhosis), bone (abnormal bone trabeculation, osteoporosis, aseptic necrosis), lung (pulmonary fibrosis), and ears (deafness). Growth and mental retardation, intracranial calcifications, immune dysfunction, or hypogonadism are possible. An increased risk of developing different types of malignancies (lymphoma, carcinomas) exists [2].

### Prevalence

The disease is rare.

### Genes

Heiss et al. identified missense mutations in the DKC1 gene that maps to the Xq28 region and encodes dyskerin [3].

### Molecular and Systemic Pathophysiology

Sequence homology assessment predicted that dyskerin is a nuclear protein that is responsible for some early steps in ribosomal RNA processing. Dyskerin also seems to be a centromere or microtubule protein and, if mutated, may give rise to abnormalities with chromosome segregation and consequent malignant predisposition [3].

### Diagnostic Principles

Clinical features, blood abnormalities and skin biopsies, the latter showing features of acute graft-versus-host disease.

### Therapeutic Principles

Therapy is supportive.

## Synonyms

Reading and spelling disorder; Legasthenia

## Definition and Characteristics

According to ICD-10, dyslexia is "a disorder manifested by difficulty learning to read despite conventional instruction, adequate intelligence and sociocultural opportunity." The cognitive processes upon which reading and spelling are based are complex and differing cognitive dimensions facilitate the separate skills of reading and spelling. Such processes include those of short-term memory, phonological awareness, rapid naming and phonological and orthographic coding. A number of theories have been developed with the aim of characterizing the basic processes underlying dyslexia. These have taken into consideration the increasing body of knowledge obtained from neurophysiological and imaging research. The "phonological deficit theory," which assumes a disturbance in phonological processing, is currently the most salient theory [1]. According to this, affected individuals have difficulties in perceiving and segmenting phonemes, leading to difficulties in establishing a connection between phonemes and graphemes. Another theory is the "rapid auditory processing theory." This theory proposes that phonological deficits are secondary to an auditory deficit in the perception of short or rapidly varying sounds. However, individuals with dyslexia also have visual perceptual deficits that these theories cannot adequately explain. A theory that accounts for disturbances in visual processing is the "magnocellular theory." The magnocellular theory proposes that, in a proportion of individuals with dyslexia, the perception of visual, rapid moving stimuli and stimuli of low spatial frequency and low contrast is impaired. A theory suggesting that the automatization of cognitive processes and motor control in the cerebellum are disturbed in individuals with dyslexia is the "cerebellar deficit theory." The "double deficit hypothesis" assumes disturbances in phonological processing and the speed of processing.

## Prevalence

Dyslexia is amongst the most common neurodevelopmental disorders with a prevalence of 5–12% [2,3]. The prevalence rate varies with the use of different diagnostic criteria and, since reading and spelling are normally distributed in the population, is influenced by the cut-off point applied to the psychometric tests. Whether dyslexia is more frequent amongst boys than girls has been a subject of controversial past discussion, though recent epidemiological studies indicate a two-fold increase in the risk for boys compared to girls. The sex ratio is influenced by severity, IQ and assessed cognitive profiles.

## Genes

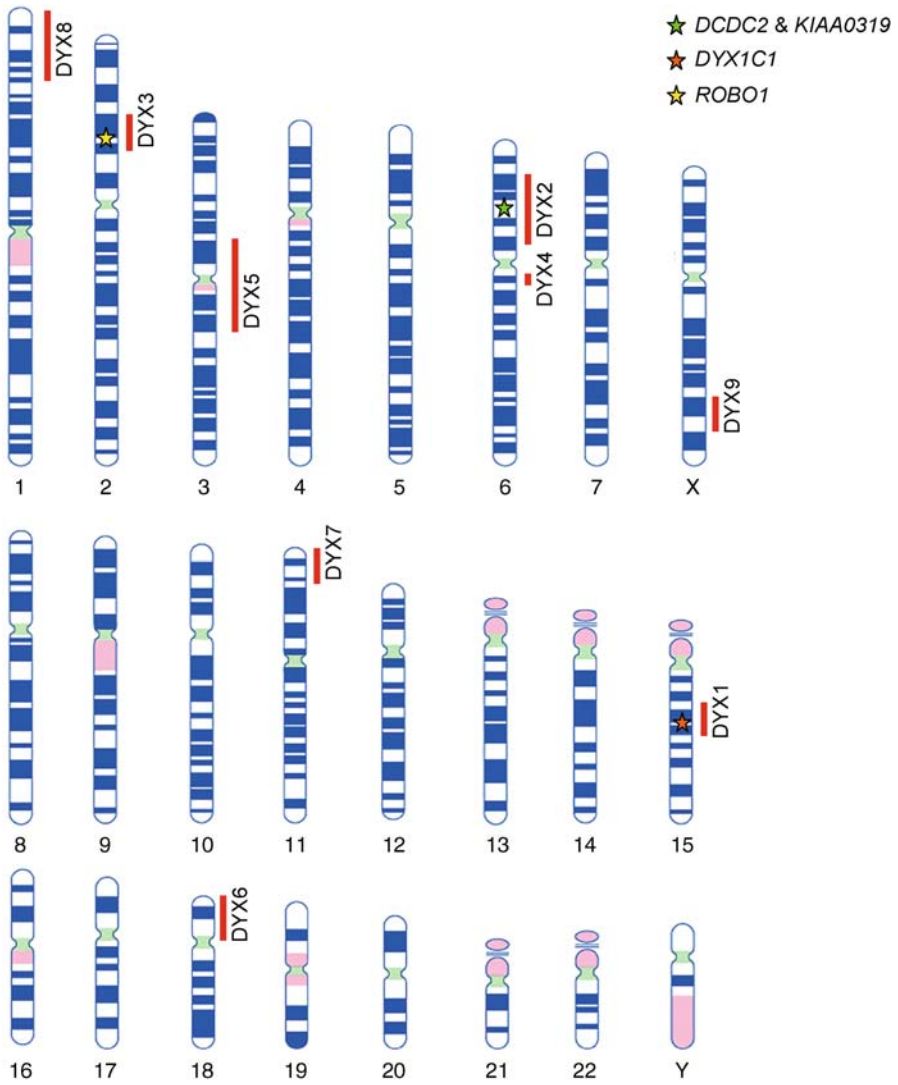
Family and twin studies have confirmed that genetic factors are substantially responsible for the familial clustering of dyslexia. It is generally accepted that the proportion of inherited factors involved in the development of dyslexia is between 40 and 80%, the highest estimates being reported for the phenotype dimensions word reading and spelling. Although in occasional families a single gene may play a major role, most family studies support the view that the majority of cases of dyslexia have a complex genetic basis.

The pattern of linkage findings in dyslexia is typical for a complex disorder: Levels of statistical significance and estimated effect sizes in individual studies are modest, chromosomal regions of interest are typically broad and no findings are replicated in all data sets. Despite these obstacles, several promising loci have been identified in dyslexia by genome wide linkage studies [4]. To date, nine chromosomal linkage regions (DYX1–DYX9) have been listed by the HUGO Gene Nomenclature Committee in which the presence of susceptibility genes is suspected (Fig. 1).

The best evidence for dyslexia susceptibility genes presently exists for the doublecortin domain containing protein-2 gene (DCDC2) and the KIAA0319 gene, which were identified through systematic investigation of linkage disequilibrium within DYX2 on chromosome 6p22 [4]. Initial findings for both genes have been replicated in independent samples, with the strongest findings having been observed among severely affected individuals. In contrast, the genes DYX1C1 and ROBO1, which were identified through breakpoint mapping in Finnish patients, appear to be less involved in the development of dyslexia across different populations. Their contribution may be limited to a few families in the Finnish population.

## Molecular and Systemic Pathophysiology

The nature of the genes identified to date suggests that a disturbance in cortical neuron migration and reduced activity in left hemispheric brain regions are pathophysiological correlates of dyslexia [5]. With DCDC2, as with KIAA0319, inhibition leads to poorer neuronal migration in the neocortex of fetal rats through specific siRNAs. This concept of disturbed neuronal migration



**Dyslexia. Figure 1** Chromosome ideogram showing locations of genome wide linkage findings in dyslexia (*given in red*) and genes implicated in the pathogenesis of dyslexia.

is also supported by the few results available from post mortem brain studies of affected individuals, which report cortical malformations in the region of the perisylvian cortex. In view of the fact that DCDC2 and K1AA0319 only contribute a limited part to the development of dyslexia and that the majority of susceptibility genes are still unknown, it may be possible in the future to identify completely new pathophysiological mechanisms.

## Diagnostic Principles

The diagnosis of dyslexia can only be made clinically, on the basis of existing symptoms and psychometric tests. However, a detailed clinical examination has to be performed to rule out other causes of reading and spelling difficulties (e.g., hearing or vision impairment, presence of a neurological or psychiatric disorder).

## Therapeutic Principles

The only effective treatment in dyslexia so far is reading and spelling exercises under supervision of a professional psychologist or teacher.

# Dyslipidemia

►Hyperlipidemia

# Dysmenorrhea

Andrea Schuppenies
Medical Clinic III, University Hospital Dresden, Dresden, Germany

## Definition and Characteristics

Dysmenorrhea is a complex of symptoms that may occur regularly with menstruation. Pain is the most striking symptom of dysmenorrhea.

The symptoms may arise as primary dysmenorrhea without any pathologies in the female reproductive system, or as secondary dysmenorrhea with organic alterations such as endometriosis, adenomyosis, uterine leiomyomata, or chronic pelvic inflammatory disease.

Apart from pain, symptoms may involve nausea, migraine, vomiting, diarrhea, cardiovascular dysregulation and syncope [1].

## Prevalence

Up to 60% of fertile women experience dysmenorrhea [2].

## Genes

Main genetic association for (primary) recurrent dysmenorrhea has been shown for the variants CYP2D6 and GSTM1 genotypes [for CYP2D6, odds ratio (OR) = 1.7 and 95% confidence interval (95% CI) = 0.9–3.1; for GSTM1, OR = 1.8 and 95% CI = 1.0–3.4). However, no association between these variant genotypes and occasional dysmenorrhea has been demonstrated. Taking both the CYP2D6 and GSTM1 genotypes together, the highest risk of recurrent dysmenorrhea was found among women with variant genotypes in both CYP2D6 and GSTM1 (OR = 3.1; 95% CI = 1.2–8.0) [3].

## Molecular and Systemic Pathophysiology

In primary dysmenorrhea, prostaglandin excess (produced in the endometrium after the stimulation with estrogens and progesterone) causes uterine contractions. These contractions are more frequent and prolonged compared to women that do not suffer from primary dysmenorrhea. When uterine pressure exceeds systolic blood pressure, uterine ischemia occurs, causing pain. Dysmenorrhea correlates with hormonal regulation and is usually only present after ovulation, and is therefore not seen in young girls beginning to menstruate [4].

In secondary dysmenorrhea, the pathophysiology of pain depends on the underlying disease.

## Diagnostic Principles

Diagnosis of primary dysmenorrhea is clinical. The symptoms typically occur before the age of 25. The pain starts at the onset of menstrual flow and lasts up to 72 hs. The pain is usually located in the lower abdomen and is often accompanied with nausea, vomiting and diarrhea. The pain may be controlled effectively with NSAIs. Clinical examination does not reveal any pathology; however, secondary dysmenorrhea is associated with pathologies in the reproductive system (see above). Cramping may occur at any time during the menstrual cycle, sometimes with spotting. Women with secondary dysmenorrhea often describe dyspareunia or dyschezia. NSAIs are only slightly effective for pain relief. Secondary dysmenorrhea onset usually occurs after 35 years of age [5].

## Therapeutic Principles

Oral contraceptives may provide a successful remedy for primary dysmenorrhea since they inhibit ovulation, thus diminishing the pain [1]. Another possibility is NSAI treatment for decreasing prostaglandin secretion.

Treatment of secondary dysmenorrhea always depends on the underlying pathology.

# Dysmyelopoietic Syndromes

►Myelodysplastic Syndromes

# Dyspepsia

Markus G. Donner, Dieter Häussinger
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

## Definition and Characteristics

Current definition of dyspepsia has been outlined in the ROME-III criteria of 2006. According to this consensus statement, dyspepsia is defined as the presence of one or more symptoms of gastrointestinal origin with no evidence of organic disease that may explain the symptoms [1]. Based on the prevailing symptoms and distinct pathophysiology, a pain-related and meal-related subgrouping has been introduced, termed epigastric pain syndrome and postprandial distress syndrome. The following list provides the diagnostic criteria of Rome III for dyspepsia, epigastric pain syndrome and postprandial distress syndrome. The symptoms should last for at least 3 months, with the onset at least 6 months previously [2].

A. Functional dyspepsia
   Bothersome post prandial fullness
   OR
   Early satiation
   OR
   Epigastric pain
   OR
   Epigastric pain
   AND
   No evidence of structural disease likely to explain the symptoms
B. Epigastric pain syndrome
   Pain and burning that is:
   – intermittent,
   – localized to the epigastrium of at least moderate severity, at least once per week
   And not:
   – generalized or localized the other abdominal or chest regions
   – relieved by defecation or flatulence
   – fulfilling criteria for gallbladder or sphincter of Oddi disorders
C. Postprandial distress syndrome
   Bothersome postprandial fullness
   – occurring after ordinary-sized meals
   – at least several times a week
   OR
   Early satiation
   – that prevents finishing a regular meal
   – and occurs at least several times a week

## Prevalence

The prevalence of dyspepsia in a most recent study was 15%, although figures in different studies range from 13–48% [3].

## Molecular and Systematic Pathophysiology

Development of dyspepsia is based on genetic factors, abnormal gastrointestinal motility, an altered inflammatory response of the gastrointestinal mucosa and psychosocial factors. Genetic polymorphisms may alter immunologic and neural pathways of gastrointestinal function. In some patients, IL-10 polymorphism associated with decreased levels of this antiinflammatory cytokine may perpetuate gut mucosal inflammatory response following gastrointestinal infection [4]. G-protein polymorphisms can affect gut motility and CNS perception via a blunted central alpha2-adrenoreceptor response [1].

Compared to healthy individuals, patients with dyspepsia display a greater motility response to extrinsic factors. This may lead to an increased motility of the complete gastrointestinal tract and may precipitate symptoms. Visceral hypersensitivity may be a crucial factor in patients that experience recurrent pain without evidence of a motility disorder. Patients with functional gastrointestinal disease have been shown to have a lower pain threshold to intestinal balloon distension or experience an increased sensitivity to normal gastrointestinal motility. Moreover, repetitive balloon dilatation may lead to a progressive intensity of pain compared to normal controls. This phenomenon is called stimulus hyperalgesia. Increased pain sensitivity may be due to an altered receptor sensitivity of the gut mucosa and of the myenteric plexus of the intestine. Central sensitation due to repetitive visceral stimulation may also contribute to an altered perception of visceral pain.

Following an acute gastrointestinal infection, a proportion of patients may display an increased number of mucosal inflammatory cells and increased inflammatory cytokine expression. Persistent mucosal inflammation may trigger visceral hypersensitivity. This factor may be relevant for one third of patients with dyspepsia.

Psychosocial factors may modulate the clinical outcome in patients with dyspepsia. Family studies have

shown that adopting behaviour from parents may influence the risk of developing functional gastrointestinal disease. Psychosocial factors such as stress may influence the severity of dyspepsia symptoms. Increased arousal and anxiety is associated with decreasing frequency of migrating motor complex activity in the small bowel, increasing visceral hypersensitivity and autonomic reactivity. Psychosocial factors further modify the experience of illness and illness behaviour [5].

### Diagnostic Principles

Dyspepsia by definition is a diagnosis of exclusion. Apart from gastric disorders, hepatic, biliary, pancreatic and small bowel pathology should be ruled out. In addition to gastroscopy, patients should undergo further diagnostic procedures, such as abdominal ultrasound, computed tomography, gastric emptying studies, 24-h esophageal pH measurements and magnetic resonance cholangiopancreatography. Before making the diagnosis of dyspepsia, it should be assured that the patient meets the clinical picture outlined in the above criteria.

### Therapeutic Principles

Treatment of dyspepsia is guided by the quality and severity of the symptoms. If the patient presents with mild symptoms, education should be given as to the nature of the disorder. Further, reassurance and counselling to avoid eliciting dietary substances such as coffee, alcohol and fatty meals should be provided. If presenting with moderate symptoms, medical therapy should be added. Pharmacotherapy is guided by the predominant symptom and includes prokinetics and proton pump inhibitors. Additional psychological therapy such as relaxation and behavioural therapy may aid in improving pain tolerance. In patients with severe symptoms, antidepressant treatment represents the treatment of choice. Beside tricyclic antidepressants (e.g., amitriptyline), selective serotonin reuptake inhibitors (e.g., citalopram, fluoxetine) may control symptoms by a central analgesic effect and by relieving associated depression. Further measures include psychosocial support and providing analgesic therapy in the setting of special pain treatment centres [1].

## Dystonia 5

►Dopa-responsive Dystonia

## Dystonia, Dopa-responsive

►Dopa-responsive Dystonia

## Dystonias, Primary

Norman Kock, Katja Lohmann, Christine Klein
Department of Neurology, University of Luebeck, Luebeck, Germany

### Definition and Characteristics

Primary dystonias are a group of movement disorders, characterized by involuntary twisting, repetitive movements and abnormal postures. The primary form has dystonia as the only symptom (with the exception of tremor); the cause is either unknown or genetic. The secondary form has dystonia as one of several disease manifestations; the cause is identifiable (lesion, drugs/toxins, metabolic disorders). Dystonia plus is dystonia associated with, but not secondary to other types of movement disorders.

Clinical categorization is based on age at onset, distribution of symptoms (focal, segmental, multifocal, generalized) and disease progression.

Early-onset dystonia (<20 years) starts in a limb, tends to generalize and frequently has a genetic origin. Late-onset dystonia (>20 years) spares lower extremities, frequently involves cervical or cranial muscles with a tendency to remain focal and is sporadic in most cases [1].

Familial, early-onset, generalized torsion dystonia (PTD) is the most severe form of primary dystonia. Autosomal-dominant DYT1 dystonia usually begins in childhood, starts in a limb and tends to generalize to other body parts. Penetrance is reduced to 30–40% and only about a third of the manifesting gene carriers develop the most severe phenotype [1].

In focal dystonia, clinical signs start in adulthood and usually remain focal, for example as isolated torticollis or blepharospasm. Some forms of focal dystonia are task-specific and include occupational dystonias such as writer's cramp or musician's cramp [1].

Autosomal-recessive primary dystonia was designated DYT2, showing an early limb onset and generalized or brachial segmental dystonia with prominent craniocervical involvement. Whispering dysphonia was designated DYT4, whereas DYT6 patients have a mixed phenotype with generalized and focal dystonia symptoms [1].

## Prevalence

Early-onset dystonia: 3–5 per 100,000 in different populations. Late-onset dystonia: 10–40 per 100,000 [2]. Focal dystonia is the most prevalent form of dystonia, with torticollis being the most common manifestation. DYT1 dystonia: 11 in 100,000 in the Ashkenazi-Jewish population due to a founder mutation. DYT2, 4, 6, 7 and 13 are rare diseases described in single families only.

## Genes

Currently, at least fifteen different types of dystonia can be distinguished, which are designated DYT1–15. Six of these 15 dystonias are primary forms (DYT1, 2, 4, 6, 7, and 13). With the exception of three rare forms (DYT2, 3 and 5b), all of them are inherited in an autosomal dominant fashion. Genes have been identified for six (DYT1, 3, 5, 8, 11, and 12), while the chromosomal location is known for another seven forms (DYT6, 7, 9, 10, 13, 14, and 15) (Table 1).

## Molecular and Systemic Pathophysiology

In DYT1 dystonia most cases are caused by a 3-bp deletion (904_906delGAG) in the coding region of the *DYT1* gene, which is widely expressed in human brain and encodes the protein torsin A. Most cases (about 75%) of early-onset generalized PTD are heterozygous for the GAG-deleted allele [1]. Only two other mutations have been found so far in the *DYT1* gene: An 18-bp deletion (966_983del) in one family with onset of dystonia in early adulthood and clinical features atypical of the common DYT1 dystonia and a 4-bp deletion (934_937delAGAG) in an apparently healthy blood donor. Torsin A, a 332 amino acids protein, shares homology with the AAA+ superfamily of ATPases. AAA+ proteins act as chaperones mediating conformational changes in target proteins. They are associated with diverse functions such as protein folding and degradation, cytoskeletal dynamics, membrane trafficking, vesicle fusion, and response to stress. However the function of torsin A is unknown. Recent findings point towards an interaction of torsin A with nuclear envelope proteins (Lap1) and/or in cellular trafficking (kinesin light chain 1) [3,4]. Overexpression of mutant torsin A results in the formation of intracellular inclusions in cultured cells that are likely to derive from the nuclear envelope. Neuropathological examination of four brains from GAG-deleted dystonia patients showed perinuclear inclusion bodies in the midbrain reticular formation and periaqueductal gray [5]. Prominent expression of torsin A in nigral neurons as well as colocalization of torsin A and alpha-synuclein in Lewy bodies suggests a possible dysfunction in dopamine transmission, while strong labeling of neuronal processes points to a potential role for torsin A in synaptic functioning.

In focal dystonia 25% of the patients have similarly affected relatives and several monozygotic twin pairs have been described to be concordant for focal dystonia. However, the majority of cases appear to be sporadic. Two gene loci (DYT7 and DYT13) have been associated with focal dystonia in a single German and segmental dystonia in an Italian family respectively. In a study estimating frequencies of polymorphisms in the five dopamine receptor genes and the dopamine transporter gene, cervical dystonia and blepharospasm have been shown to be associated with an allele in the D5 dopamine receptor gene [2].

## Diagnostic Principles

Involuntary twisting, repetitive movements and abnormal postures suggest dystonia. Diagnosis should be confirmed by a movement disorder specialist. Early age at onset and/or positive family history may point towards a genetic origin. Routine molecular testing is available for detection of the GAG deletion in DYT1 [6].

## Therapeutic Principles

No causative treatment is yet available in any form of dystonia, therefore relief of symptoms is the primary goal. Non-evidence-based oral medications include anticholinergics, baclofen, levodopa, benzodiazepines, carbamazepine, reserpine and tetrabenazine. Deep-brain stimulation of the globus pallidus internus (GPi) is a successful treatment option, particularly for intractable generalized primary dystonia, including DYT1 dystonia. Intrathecal baclofen may be an option in selected cases. Botulinum toxin injections into dystonic muscles are the treatment of choice for focal dystonias. Injections may also be helpful in generalized disease for symptomatic relief in specific muscle groups [6].

**Dystonias, Primary. Table 1** Monogenic forms of dystonia

| Designation | Dystonia type | Inheritance | Gene locus | Gene | OMIM number |
|---|---|---|---|---|---|
| DYT1 | Early-onset generalized torsion dystonia (TD) | Autosomal dominant | 9q | GAG deletion in *DYT1* | 128100 |

## Ebstein's Anomaly

Kei Inai
Department of Pediatric Cardiology, Tokyo Women`s Medical Univesity, Tokyo, Japan

### Synonyms

Ebstein's malformation

### Definition and Characteristics

The disorder is characterized by a displacement of the annular attachment of the leaflets of the tricuspid valve away from the atrioventricular junction. The septal and mural leaflets have a proximal attachment at a distance from the atrioventricular junction. The commissure between two leaflets is the point of

maximal displacement and is at the posterior border of the ventricular septum. The anterosuperior leaflet is not displaced but is enlarged and has a sail-like shape. The portion of the right ventricle between the anatomical valve annulus and the functional annulus created by the downwardly displaced leaflet is termed an atrialized ventricle.

## Prevalence

Ebstein's anomaly is an uncommon defect, with an estimated incidence of 5.2 per 100,000 live births [1]. It is believed to constitute fewer than 1% of all congenital heart defects.

## Genes

Several observations suggest a genetic cause but most cases of this anomaly seem to be sporadic [2]. There are reports that implicate a cytogenetic abnormality, such as mutation of the NKX2.5 gene, and chromosome17q as a possible candidate chromosome [3]. The precise genetic mechanisms involved in the disorder remain unclear.

Transformation of endocardial cells into invasive mesenchyme is a critical antecedent of cardiac cushion tissue formation. Many genes and signaling pathways are involved in this process. However, little is known about how cushions form the mesenchymal expansions that progressively project into the lumen and subsequently differentiate into mature valvular tissue [4].

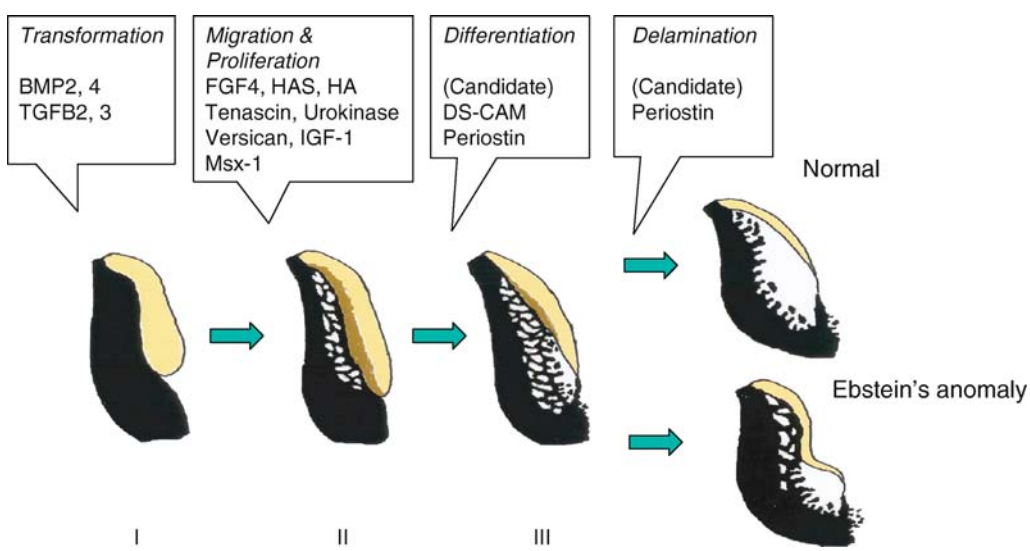
The developmental process of valvulogenesis is complex (Fig. 1).

There are currently thought to be three morphogenetic steps that sequentially serve to transform a primitive cushion pad into mature leaflet. The first consists of distal outgrowth, elongation, and spreading of cushion mesenchyme upon a substratum of ventricular myocardium. Next, multipotential cushion cells differentiate into fibroblastic tissue. Third, the leaflets delaminate from the associated ventricular myocardium, creating both free edges and a persisting, supportive, suspensory apparatus. Ebstein's anomaly has been suggested to be an abnormality in the delamination process. Although there are some candidate molecular regulators of this process, there is almost nothing known about the molecular basis of delamination.

## Molecular and Systemic Pathophysiology

The pathophysiology of this disorder depends on the degree of anatomic deformity. Because of tricuspid valve regurgitation, right ventricular volume overload is often observed, and flow into the right ventricle and pulmonary circulation are both decreased. A larger volume of blood in the right atrium contributes to right atrial enlargement. The presence of an atrial septal defect or patent foramen ovale results in right-to-left shunting at the atrial level, and patients can be *cyanotic* to some degree. During ventricular diastole, the atrialized right ventricle can act as a reservoir for blood, and true right ventricular filling can be impaired due to reduced ventricular compliance. These conditions can lead to an increasing amount of right-to-left shunting, resulting in increasing cyanosis and severe polycythemia.

Although the primary focus in patients with Ebstein's anomaly has been on right-sided structures, an increasing number of studies of left-sided abnormality have been reported. Pathologic analysis has shown increased fibrosis in the left ventricular parietal wall and ventricular septum. Interstitial fibrosis may be an



**Ebstein's Anomaly. Figure 1** Ebstein's anomaly.

acquired pathologic condition caused by arterial oxygen desaturation and/or long term right ventricular volume overload, or it may be an intrinsic congenital condition in this anomaly [5].

### Diagnostic Principles

In recent years, two-dimensional echocardiography has been the primary procedure by which Ebstein's anomaly is diagnosed. The distance between septal tricuspid and septal mitral leaflet attachment, standardized to body surface area, is known to have diagnostic power. A value greater than 8 mm/m$^2$ reliably identifies patients with this anomaly.

### Therapeutic Principles

The clinical spectrum of this disorder varies from severe heart failure to absence of symptoms. Patients with mild anatomic abnormalities, relatively normal hemodynamics, and no symptoms require only observation and precautions to prevent bacterial endocarditis. However, a certain subset of symptomatic patients need surgical intervention. The first choice is valvuloplasty or valve replacement with closure of atrial communication if it is present. If the true right ventricle is too small for biventricular repair, the Fontan operation is applied.

## Ectrodactyly, Ectodermal Dysplasia, and Clefting Syndrome

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

### Synonyms

EEC syndrome

## Definition and Characteristics

EEC syndrome is characterized by the triad of ectrodactyly (lobster claw deformity of the hands and feet), ectodermal dysplasia (defects of the hair, sweet glands, nails, and teeth) and cleft lip/palate (Fig. 1) [1].

In addition to characteristic "split-hand and foot" appearance, cutaneous or bony syndactyly may also be present [1]. Features of ectodermal dysplasia include sparse, thin blond scalp hair; sparse eyebrows and eyelashes; dry skin with inability to sweat; hyperkeratosis; hypoplastic nipples; dysplastic and pitting nails; hypodentia; microdentia; peg-shaped teeth; enamel hypoplasia; blue irides; photophobia; and blepharophimosis [1,2]. Cleft lip is always present while cleft palate is present in the majority of cases. Patients with EEC syndrome have characteristic dysmorphic facial features such as maxillary hypoplasia, short philtrum, and a broad nasal tip. Other manifestations include genitourinary anomalies such as renal agenesis/ dysplasia, hydronephrosis, duplication of the urinary collecting system, and cryptorchidism. Conductive hearing loss, hypogonadotropic hypogonadism, and neurogenic diabetes insipidus may also occur. Mental retardation is unusual.

## Prevalence

The incidence is 1 in 100,000 live births [2].

## Genes

EEC syndrome is inherited as an autosomal dominant trait with variable expression and incomplete penetrance. The disorder is caused by germline mis-sense mutations in the DNA-binding domain of the p63 gene [3]. The EEC1 gene locus has been mapped to 7q11.2–q21.3, EEC2 to chromosome 19, and EEC3 to 3q27 [4].

**Ectrodactyly, Ectodermal Dysplasia, and Clefting Syndrome. Figure 1** Clinical appearance of the split-hand (lobster claw) abnormality in a patient with EEC syndrome. Note the dry and hyperkeratotic skin.

## Molecular and Systemic Pathophysiology

The p63 gene encodes at least six different protein isotypes through the use of alternative transcription start sites and alternative splicing at the 3′ end of the gene [5]. It has been suggested that p63 is essential in tissue development as p63 −/− mice show abnormalities in the limb, palate, skin, and lacrimal glands. Ankyloblepharon-ectodermal dysplasia-clefting (AEC) syndrome, limb mammary syndrome (LMS), acro-dermato-ungual-lacrimal-tooth (ADULT) syndrome, and lacrimo-auriculo-dental-digital (LADD) syndrome, also caused by mutation of p63, have clinical features overlapping with EEC syndrome [4]. The most frequently mutated arginine codons are R204, R227, R279, R280 and R304 [4]. R280 mutations to cysteine and histidine can cause EEC syndrome and non-syndromic split hand/foot malformation whereas when arginine replaces serine it only causes EEC syndrome [4].

## Diagnostic Principles

The diagnosis is mainly clinical. The differential diagnosis includes AEC syndrome, LM syndrome, ADULT syndrome, LADD syndrome, popliteal pterygium syndrome, Rapp-Hodgkin syndrome, Zlotogora-Ogur syndrome, Hay-Wells syndrome, and non-syndromic split hand/foot malformation [4]. Prenatal diagnosis is possible by ultrasonographic detection of characteristic features or by prenatal DNA analysis [4].

## Therapeutic Principles

The management requires a multidisciplinary team comprised of a plastic surgeon, orthopedic surgeon, dentist, ophthalmologist, dermatologist, nephrologist, urologist, and speech pathologist. Genetic counseling should be offered.

## Ehlers-Danlos Syndrome

Jouni Uitto
Department of Dermatology and Cutaneous Biology, Jefferson Medical College, Philadelphia, PA, USA

### Synonyms

Cutis hyperelastica; EDS

### Definition and Characteristics

Ehlers-Danlos syndrome (EDS) comprises a group of heritable connective tissue disorders affecting primarily the skin and the skeletal system [1]. The characteristic cutaneous findings are hyperextensible and fragile skin, abnormal scar formation, and easy bruising. The joint findings consist of loose-jointedness, hypermobility, and propensity for dislocations. A number of other skeletal abnormalities, including kyphoscoliosis, can also be noted. Most importantly, some patients with EDS are at significant risk of spontaneous arterial and intestinal ruptures, and in some cases uterine rupture during labor can have catastrophic consequences [2].

### Prevalence

A relatively large number of individuals in the general population may have features suggestive of EDS, such as loose-jointedness, which are often encountered in certain ethnic backgrounds. However, more stringent diagnostic criteria that include findings in the skin and joints at the minimum limit the incidence to approximately 1:5,000.

### Genes

The clinical and genetic complexity of EDS initially led to a classification that recognized 11 distinct subtypes (EDS I-XI). More recently, a revised classification has been proposed which identifies six types [3]. Their clinical features, mode of inheritance, and the mutated gene/protein systems are shown in Table 1.

### Molecular and Systemic Pathophysiology

The molecular basis of the major subtypes of EDS are currently known. Those classical forms which

**Ehlers-Danlos Syndrome. Table 1** Classification of the Ehlers-Danlos syndrome

| EDS type[a] | Traditional[b] classification | Clinical features | Inheritance | Mutated gene/protein |
|---|---|---|---|---|
| Classical | I, II | Hyperextensible skin and joint hypermobility, atrophic scars, easy bruising | AD, AR[d] | COL5A1, COL5A2/α1- and α2-chains of type V collagen; TNX/Tenascin-X |
| Hypermobility | III | Joint hypermobility, pain, dislocations | AD | |
| Vascular | IV | Thin skin, arterial, gastrointestinal or uterine rupture, bruising, small joint hypermobility, fragility of different tissues | AD | COL3A1/α1-chain of type III collagen |
| Kyphoscoliosis | VI | Hypotonia, joint laxity, congenital scoliosis, ocular fragility | AR | PLOD/Lysyl hydroxylase |
| Arthrochalasia | VIIa, VIIb | Severe joint hypermobility with congenital dislocation, skin involvement mild, scoliosis, bruising | AD | COL1A1, COL1A2/α1- and α2-chains of type I collagen |
| Dermatosparaxis | VIIc | Severe skin fragility and hyperextensibility, bruising | AR | ADAMTS-2/Procollagen N-peptidase |
| Other[c] | V, VIII, X, XI | | | |

[a]According to The 1997 Villefranche Consensus Meeting [3].
[b]This classification has been replaced by [3].
[c]The previous EDS type IX has been reclassified as occipital horn syndrome, a disorder allelic with Menkes syndrome [5].
[d]The classical forms due to type V collagen mutations are inherited in an autosomal dominant (AD) fashion, while those caused by tenascin-X deficiency are autosomal recessive (AR).

are inherited in an autosomal dominant pattern are due to mutations in the type V collagen genes. It is now known that type V collagen plays a role in collagen fibrillogenesis primarily regulating the fibril growth, and abnormalities in this minor collagen result in fibers with compromised tensile strength. More recently, a subset of patients with the classical form have been shown to be deficient in tenascin-X, an extracellular matrix component serving as a molecular organizer of the connective tissues [4]. In fact, tenascin-X has been shown to be completely absent in both connective tissues and in serum of patients with the classic EDS inherited in an autosomal recessive pattern. Since tenascin-X can be readily determined in serum by highly sensitive ELISA or radioimmunoassays, this measurement is helpful in determining the mode of inheritance in the classical forms of EDS. A limited number of cases with hypermobility syndrome, an autosomal dominant disease, have also shown to harbor mutations in one allele of the tenascin-X gene. Most importantly, the vascular type is due to abnormalities in the type III collagen gene. As type III collagen is a relatively abundant component in the arterial vascular tissues, in the gastrointestinal tract and in uterine wall, abnormalities in this collagen explain the fragility of these tissues. Kyphoscoliosis type was the first human connective tissue disorder in which a molecular defect was identified, i.e., lysyl hydroxylase deficiency. This enzyme facilitates the conversion of selected lysyl residues to corresponding hydroxylysine residues in collagens and is dependent on ascorbic acid. Some of the mutations elevate its $K_m$ for this cofactor, and consequently, the enzyme activity can be partially restored by feeding the patients with high levels of ascorbic acid. Both arthrochalasia and dermatosparaxic subtypes are due to defects in type I procollagen-to-collagen conversion. However, the arthrochalasia type is due to heterozygous mutations in the type I procollagen genes which prevent the enzymatic conversion of the precursor to its product. Since this form of EDS is due to structural mutations, half of the abnormal collagen can have deleterious effects, and the disease is inherited in an autosomal dominant pattern. In contrast, the dermatosparaxic type is due to deficiency in procollagen N-peptidase, an enzyme that catalyzes the conversion of procollagen to collagen. Since half the amount of the enzyme is apparently sufficient to catalyze this conversion, both alleles have to be mutated, and the inheritance pattern is therefore autosomal recessive.

## Diagnostic Principles

The clinical assessment consists of skin and joint evaluation as these organ systems carry the most common, characteristic features of the syndrome. Also, genetic inquiry as to the mode of inheritance, i.e., autosomal dominant *vs.* autosomal recessive, can be helpful in appropriate subclassification and genetic counseling. Cardiovascular evaluation, particularly detection of mitral valve prolapse, aneurysms and aorta dilatation, is indicated. Mitral valve prolapse is relatively common in patients with EDS, while aorta dilatation is rare and mostly limited to the vascular type, yet

assessment of the baseline is in order. Since some forms of EDS, particularly the kyphoscoliosis type, which was previously also known as the ocular type, can affect the eyes, ophthalmologic examination should also be performed. Finally, laboratory tests for serum copper and ceruloplasmin levels are helpful in identifying the occipital horn syndrome patients in differential diagnosis of EDS. Measurement of tenascin-X levels in serum in patients with the classical form of EDS will be helpful in determining the mode of inheritance, since complete absence of tenascin-X signifies autosomal recessive mode. Finally, collagen gene analyses are available and are specifically indicated in cases where the vascular type is suspected on the basis of clinical findings. The diagnosis of the vascular type can be confirmed either by direct nucleotide sequencing of the type III collagen gene or by evaluation of the corresponding protein synthesized by fibroblast cultures established from the skin of the patient.

### Therapeutic Principles

No specific treatment, short of prevention of trauma, is currently available.

## Eisenmenger Syndrome

Gerhard-Paul Diller, Michael A. Gatzoulis
Adult Congenital Heart Centre and Centre for Pulmonary Hypertension, Royal Brompton Hospital and the National Heart and Lung Institute, Imperial College, London, UK

### Definition and Characteristics

Pulmonary arterial hypertension (PAH, i.e., an elevated mean pulmonary arterial pressure of more than 25 mmHg at rest or 30 mmHg on exercise) is commonly associated with congenital heart disease. Eisenmenger syndrome (severe PAH with right-to-left shunting and cyanosis) represents the extreme manifestation of PAH in the setting of congenital heart disease. This pathophysiologic condition may develop irrespective of the location of the shunt (atrial, ventricular or arterial communication); however onset of Eisenmenger physiology is early and occurs in the majority of patients with unrestrictive ventricular or arterial communication. In contrast, patients with even large atrial septal defects do not develop Eisenmenger syndrome and those who do, do so much later on in life.

### Prevalence

The current prevalence of Eisenmenger syndrome is estimated to be approximately 4% amongst contemporary adult congenital heart disease patients with moderate and complex lesions followed-up in tertiary centers in Europe and North America [1].

### Genes

Transforming growth factor-beta family (bone morphogenetic protein receptor type-2 [BMPR2] and activin-like kinase type-1) receptor mutations have been linked to familial PAH [2]. The prevalence of BMPR2 missense mutations in patients with idiopathic or familial PAH is approximately 26 and 50%, respectively. In contrast, only 6% of patients with PAH associated with congenital heart disease have been found to have BMPR2 missense mutations, a prevalence comparable to that reported in patients with appetite suppressant associated PAH [3]. This clearly illustrates the complex interplay between genetic susceptibility and environmental factors in the development of PAH and emphasizes the major role of increased pulmonary blood flow, pressure and potentially of cyanosis in Eisenmenger syndrome.

### Molecular and Systemic Pathophysiology

Development of PAH is a dynamic process determined by numerous pathophysiologic and genetic factors. In patients with large intracardiac defects increased pulmonary blood flow and pressure may precipitate pulmonary vascular endothelial damage, inducing a loss of endothelial barrier function, degradation of extracellular matrix and release of growth factors. These factors may induce vascular smooth muscle cell activation, hypertrophy and proliferation, resulting in vasoconstriction as well as extension of smooth muscle cells into peripheral pulmonary arteries and neointima formation. Endothelial damage precipitates thrombocyte activation and adherence favoring thrombosis. Furthermore, PAH is associated with an imbalance between endothelium derived vasodilators (such as nitric oxide and prostaglandin) and vasoconstrictors (such as endothelin and thromboxane), favoring

vasoconstriction and precipitating pulmonary vascular remodeling [4].

## Diagnostic Principles

Patients present with non-specific symptoms such as shortness of breath, cyanosis and clubbing. Eisenmenger syndrome represents a multisystem disorder complicated by hemoptysis, pulmonary thrombosis, congestive heart failure, arrhythmias and sudden cardiac death, ongoing risk of infections (bacterial endocarditis and cerebral abscess) as well as renal, hepatic and skeletal involvement.

Required investigations include regular chest radiographs (to evaluate the central pulmonary arteries [dilatation/calcification], lung parenchyma [hemorrhage or infiltrates] and signs of right atrial and right ventricular enlargement), ECG (underlying heart rhythm, signs of atrial dilatation or right ventricular strain), measurement of arterial oxygen saturations (degree of cyanosis), laboratory investigations (focusing on electrolytes, urea and creatinine, liver function tests, uric acid and full blood count. Iron deficient anemia is common in this population and transferrin saturation or serum ferritin should be assessed), objective assessment of exercise tolerance (periodically the six-minute walk test distance should be measured to guide interventions and medical therapy) and echocardiography (to investigate underlying cardiac defects, estimate pulmonary arterial pressure and assess ventricular function). High resolution chest computerized tomography and magnetic resonance imaging may be considered to further investigate pulmonary parenchyma, vasculature and the right ventricle. Cardiac catheterization is part of the initial evaluation of patients with PAH to establish the diagnosis of PAH and to assess severity of pulmonary vascular disease. Additional tests ( pulmonary function testing, overnight oximetry, ventilation-perfusion lung scintigraphy and blood screening for connective tissue disease) should be considered in selected patients.

## Therapeutic Principles

Traditional treatment options for patients with Eisenmenger syndrome were limited to palliative measures and heart-lung transplantation in selected patients. Supportive therapies include preservation of fluid balance, avoidance of iron deficiency anemia, effective contraception and avoidance of pregnancy (carrying an approximate 30–50% maternal mortality risk) as well as antiarrhythmic therapy, anticoagulation and oxygen therapy in selected patients.

Recently, specific disease targeting therapies for PAH have become available and results in patients with Eisenmenger syndrome have been encouraging. Prostacyclin analogues and phospodiesterase-5-inhibitors (such as Sildenafil) have been found to improve functional capacity, oxygen saturations and pulmonary hemodynamics in Eisenmenger patients. In addition, a recent randomized placebo controlled trial has demonstrated that oral bosentan (a dual-receptor antagonist) therapy is effective in improving functional capacity and pulmonary hemodynamics in patients with Eisenmenger syndrome [5].

John-John B. Schnog[1], Victor E.A. Gerdes[2]
[1]Department of Internal Medicine, Slotervaart Hospital, Amsterdam, The Netherlands
[2]Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands

### Definition and Characteristics

Congenital erythrocyte disorder resulting in various clinical syndromes. Patients with hereditary elliptocytosis (HE) and Southeast Asian Ovalocytosis are characterized by mostly asymptomatic altered red cell morphology whereas patients with spherocytic elliptocytosis have an incompletely compensated hemolytic anemia. In hereditary pyropoikylocytosis there is severe hemolytic anemia with poikylocytes and red cell fragmentation [1,2].

### Prevalence

Worldwide incidence estimated at 1 per 2,000 to 1 per 4,000 individuals, with higher incidence (of especially Southeast Asian Ovalocytosis) in areas where malaria is endemic [1,2].

### Genes

Mutations in genes encoding for band 4.1 (1p36.2–1p34), band 3 (17q21–q22) α (1q21) and β (14q22–q23.2), spectrin heterodimers and glycophorin C (2q14–q21) [2].

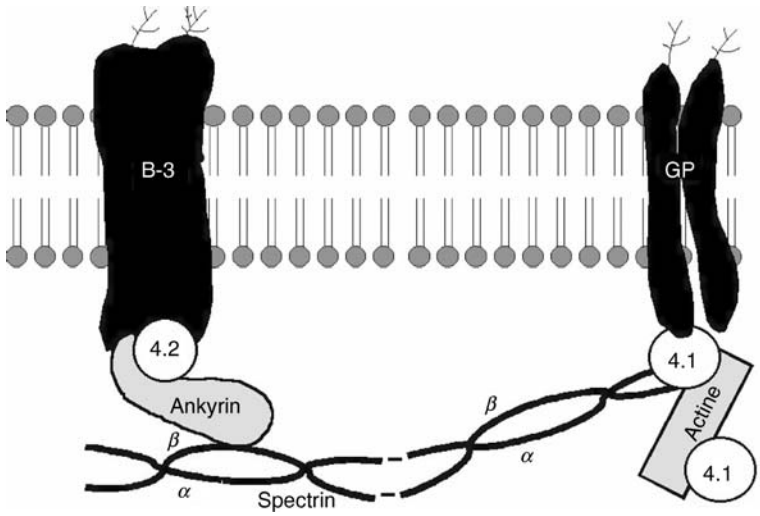
### Molecular and Systemic Pathophysiology

The lipid bilayer that forms the red cell membrane is anchored to a cytoskeleton via vertical protein interactions (see Fig. 1).

This results in the reversible deformability (as well as recoil) of red blood cells needed for traversing of the microcirculation. HE is the result of the inheritance of mutant genes, mostly via autosomal dominant pattern with the major exception of hereditary pyropoikylocytosis, a variant of HE inherited in a recessive manner. Qualitative or quantitative changes in the red cell cytoskeleton proteins result in defective horizontal interactions of the cytoskeleton with the formation of elliptically shaped red cells as a result. Self-association of αβ spectrin heterodimers results in spectrin tetramers that constitute the major building block for the red cell membrane cytoskeleton. In over 60% of patients with HE, spectrin abnormalities are found. These are mostly due to mutations in α spectrin chain that result in failure of spectrin heterodimers to form tetramers. In general, the higher the spectrin dimer membrane content, the more severe the phenotype. Reduced amount of α spectrin is usually due to the presence of low expression mutations such as α spectrin LELY (Low expression allele from Lyon). As α spectrin is produced in excess of β spectrin, low expression mutations are only of importance when co-inherited with other variants on the opposite chromosome, resulting in a relatively higher content of mutant protein. Co-inheritance of low expression mutations with α spectrin variants on the same chromosome results in amelioration of HE. Although relatively infrequent, different β spectrin mutations are described, resulting in qualitatively abnormal β spectrin dimers. Band 4.1, Band 3 as well as glycophorin C mutations can also result in HE syndromes. The clinical variability of the HE and variants results from the many mutations that can occur within these proteins, as well as from the various combinations of mutant proteins. In Southeast Asian Ovalocytosis, a mutation in band 3 results in tight binding of band 3 with ankyrin, restricting lateral mobility of the membrane and limiting invasion of these cells by malaria [1,2].

### Diagnostic Principles

Laboratory evaluation for signs of hemolysis and careful examination of the peripheral bloodsmear is



**Elliptocytosis, Hereditary and Variants. Figure 1** Schematic representation of the red blood cell lipid bilayer with its cytoskeleton, interactions of band 3 with ankyrin, ankyrin with spectrin, glycophorin C with band 4.1 and band 4.2 with band 3 are vertical interactions that anchore the cytoskeleton to the lipid bilayer. Horizontal interactions warrant lateral deformability of the cytoskeleton and these occur mainly between spectrin heterodimers and between spectrin heterodimers with actin. B-3: band 3, GP: glycoprotein-C.

essential for classification into major variants. Microcytic anemia is suggestive of cell fragmentation as seen especially in hereditary pyropoikylocytosis. Osmotic fragility (see chapter on hereditary spherocytosis) is not increased in HE, increased in spherocytic elliptocytosis and hereditary pyropoikylocytosis, but decreased in Southeast Asian Ovalocytosis. Detection of specific mutations is confined to specialized laboratories and sodium dodecyl sulfate denaturating polyacrylamide gel electrophoresis (SDS-PAGE) can be used to reveal proteins due to abnormal mobility [1,2].

## Therapeutic Principles

Management is largely supportive (folic acid supplementation, blood transfusion) and only indicated in symptomatic disease. Splenectomy ameliorates the hemolysis in severe cases [2].

# Ellis-Van Creveld Syndrome

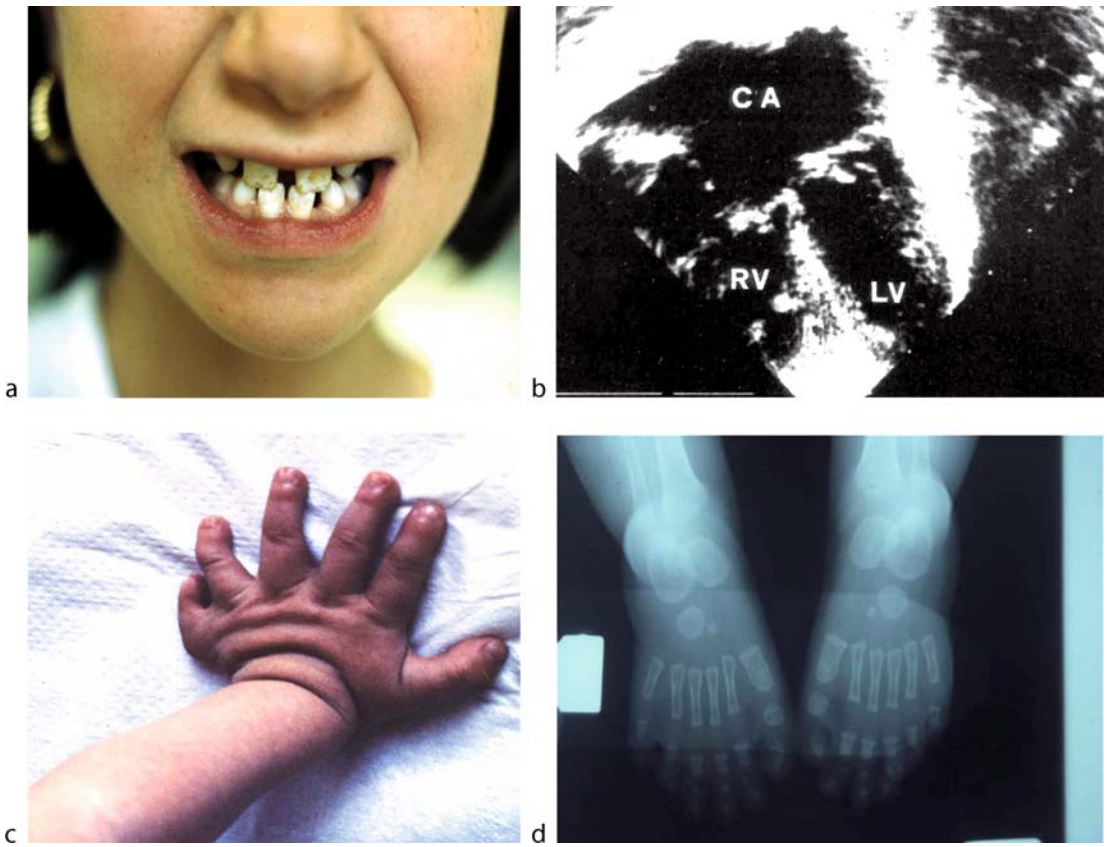
M. Cristina Digilio[1], Bruno Marino[2], Bruno Dallapiccola[3]
[1]Medical Genetics, Bambino Gesù Hospital, Rome, Italy
[2]Pediatric Cardiology, Department of Pediatrics, Sapienza University, Rome, Italy
[3]Department of Experimental Medicine, Sapienza University and CSS-Mendel Institute, Rome, Italy

## Synonyms

Chondroectodermal dysplasia; EVCS; Mesoectodermal dysplasia; Weyers acrodental dysostosis

## Definition and Characteristics

Ellis-van Creveld syndrome (EVCS) is an autosomal recessive short rib-dwarfism characterized by congenital heart defect, short stature, narrow thorax with short ribs, postaxial polydactyly of hands and feet, ectodermal defects, and oral frenula [1] (Fig. 1). Congenital heart defect occurs in 50–60% of the cases, consisting prevalently in partial atrioventricular canal defect often associated with common atrium and persistent left superior vena cava [2]. Short stature is usually disproportionate with meso/acromelic shorting of the limbs.



**Ellis-Van Creveld Syndrome. Figure 1** Ellis-van Creveld syndrome: dental anomalies (a), partial atrioventricular canal defect with common atrium (b), and postaxial polydactyly of hands (c) and feet (X-ray) (d).

Polydactyly is postaxial and often manifests with a well-formed extradigit. Oral features include cleft median upper lip, multiple oral frenula between the lip and the gum, neonatal teeth, oligodontia and enamel defects. In addition to dental anomalies, ectodermal defects include dysplastic nails. Mental development is normal.

Heterozygous mutations of the genes causing EVCS result in the allelic Weyers acrodental dysostosis [3]. This autosomal dominant syndrome is characterized by a milder phenotype, with postaxial polydactyly, cardiac defect, ectodermal anomalies, normal stature and milder skeletal chondrodysplastic signs [3,4].

## Prevalence

The exact prevalence of EVCS is unknown. The disease is rare, but an increased frequency is documented among the Amish community in Lancaster Country of Pennsylvania, US.

## Genes

*EVC*: Homozygous/compound heterozygous/heterozygous mutations in EVC (4p16.1), encoding a 992 aminoacid protein [3].

*EVC2*: Homozygous/compound heterozygous/heterozygous mutations in EVC2 (4p16.1), encoding a 1,308 aminoacid protein [5].

## Molecular and Systemic Pathophysiology

EVCS is caused by mutations in two nonhomologous genes located on chromosome 4p16 [3,5]. The first gene, EVC was previously mapped by linkage analysis to the distal short arm of chromosome 4. The majority of the EVC mutations introduce a nonsense codon directly or following a frameshift, being likely loss of function mutations. The second gene, EVC2, is adjacent to EVC arranged in a divergent configuration. The transcriptional start sites of EVC and EVC2 are separated by only 1,643 bp. It is possible that the expression of EVC and EVC2 could be coordinated by the same promoter or shared elements of overlapping promoters. The two genes encode novel proteins with no significant homology to each other or to any other protein.

In situ hybridization developmental studies in human embryonic tissues have shown that EVC gene is expressed in the bone, heart, kidney, and lung [3]. In the bone, EVC is expressed in the developing vertebral

bodies, ribs and limbs. According to clinical manifestations of the disease, EVC expression is higher in the distal limbs compared with the proximal limb. In addition, EVC is expressed in the branching epithelium and surrounding mesenchyme of the lung, metanephros and atrial and ventricular myocardium, including both atrial and interventricular septa. The partial atrioventricular canal defect with common atrium characteristic of EVCS is quite rare in the nonsyndromic patients, while is common in patients with other syndromes with postaxial polydactyly and in patients with the heterotaxia syndrome with polysplenia. A pathogenetic link among these conditions has been suggested [2]. Ciliary dysfunction has recently emerged as a major mechanism for those cardiac phenotypes overlapping heterotaxia occurring in syndromes with postaxial polydactyly.

### Diagnostic Principles

The diagnosis can be suggested in the presence of the major clinical features and following the radiological detection of short ribs, small iliac bones, shortness of limbs, fusion of carpal bones, and postaxial polydactyly. Molecular confirmation of the diagnosis can be obtained in 70% of the cases by direct sequencing of EVC and EVC2 genes [1]. About 30% of the patients with a clinical diagnosis of EVCS have mutations in EVC, while EVC2 mutations are detectable in about 40%. No differences in phenotypical manifestations have been so far detected in patients with EVC mutations compared to those with EVC2 mutations. The milder phenotype known as Weyers acrofacial dysostosis results from heterozygous mutations in both EVC and EVC2 genes.

### Therapeutic Principles

The symptomatic treatment of EVCS is involving a multidisciplinary approach with inclusion of cardiologists, orthopedics, bronchopneumologists, and dentists. In the neonatal period, respiratory distress linked to narrow chest and congenital heart defect should be monitored and treated. Cardiac malformations can be surgically repaired. Bone deformities of lower limbs can improve using prosthetic devices. Treatment for short stature with growth hormone is considered ineffective.

## Empty Sella Syndrome

Christian A. Koch
Division of Endocrinology, University of Mississippi Medical Center, Jackson, MS, USA

### Synonyms

Primary empty sella; Secondary empty sella

## Definition and Characteristics

Empty sella describes the (relative) absence of the pituitary gland on radiologic imaging by herniation or extension of the subarachnoid space into the pituitary fossa. It can be primary as an anatomic variant or congenital defect in the diaphragm sellae with secondary compression and atrophy of the pituitary gland or secondarily caused by various pituitary disorders including apoplexy, surgery, irradiation, or shrinkage of a prolactinoma on dopamine agonist therapy. Approximately 10% of patients with primary empty sella have endocrine dysfunction with partial or complete pituitary hormone deficiencies. The presentation of patients with hypopituitarism is dependent on the cell types affected, the degree of impairment, and the age and rapidity of onset. Recent studies showed growth hormone deficiency in 35–60% of adults with empty sella. Severe normovolemic hyponatremia with secondary adrenal insuffiency can occur in up to 43% of patients with empty sella. Rarely, patients with empty sella report headaches and/or visual disturbances, or present with a cerebrospinal fluid fistula/rhinorrea. If patients with empty sella have signs and symptoms of hormonal excess (i.e., acromegaly or Cushing's syndrome), a transsphenoidal exploration may be warranted [1–5].

## Prevalence

5–7% of the normal population; 6–20% of unselected autopsies; more than 80% of symptomatic patients are women.

## Genes

Unknown for primary empty sella; for patients with secondary empty sella related to a pituitary tumor or development of the pituitary, genes (for instance, PIT1, PROP1, LHX3, HESX1, MEN1, PRKAR1A, p27/KIP1, AIP) known to be involved in the pathogenesis of such adenomas or development of the pituitary.

## Molecular and Systemic Pathophysiology

*PIT-1*: Pituitary specific transcription factor in somatotrophs, lactotrophs, and thyrotrophs that binds to the GH gene promoter sequence. PIT-1 is present beginning in early fetal development and persists throughout life; mutations prevent differentiation due to impaired GH and PRL gene activation and TSH beta promoter regulation.

*PROP1*: Pituitary specific transcription factor in somatotrophs, lactotrophs, and thyrotrophs needed for subsequent PIT-1 activation and extinction of HESX1 expression; mutations prevent differentiation of anterior pituitary progenitor cells.

*HESX1*: Protein found in all precursor pituitary cell types before PROP1 and is extinguished before PIT1 appears involved in development of the pituitary and the optic nerves.

*LHX3*: Transcription factor involved in development of the pituitary and nervous system; synergistic with PIT1 in activating transcription from promoters of PRL, TSH, and PIT1.

## Diagnostic Principles

- Pituitary imaging with MRI
- In children, basal serum GH, Insulin-like growth factor-1, IGFBP-3, TSH, LH, FSH, ACTH, PRL; in adults, in addition Estradiol, Testosterone (0900), Cortisol (0900), free thyroxine levels
- Stimulation tests for presumed hypofunction or suppression tests for hyperfunction of individual hormones
- Ophthalmological evaluation

## Therapeutic Principles

For primary empty sella, usually no therapy is needed. If hormonal deficiencies are present, replacement with deficient hormones. If hormonal excess (i.e. acromegaly) is evident, transsphenoidal exploration may be necessary. If the family history is positive for a syndrome such as multiple endocrine neoplasia type 1, screening for other hormonal abnormalities (i.e. primary hyperparathyroidism) may be indicated.

# Empyema

►Pleural Effusion

# Encephalitis, Limbic, VGKC Antibody-associated

Angela Vincent
Neurosciences Group, Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK

## Definition and Characteristics

Patients present with subacute or acute onset of psychological or psychiatric disturbance, recent memory loss, and seizures. High signal in one or both mesial temporal lobes (especially the hippocampi) in T2-weighted magnetic resonance imaging (MRI), and low plasma sodium levels secondary to SIADH, are seen in 60–80% but not necessary for the diagnosis. A few patients also have peripheral symptoms (►Neuromyotonia, autoimmune and idiopathic) or peripheral and autonomic symptoms (Morvan's syndrome). Cerebrospinal fluid may be normal or show mildly elevated protein only. Oligoclonal bands, if present, are usually matched with serum bands. The patients appear to make a good recovery with immunosuppressive treatments but extensive follow-up studies have not yet been performed [1,2]. Antibodies to voltage-gated potassium channels define this syndrome. The antibodies are measured in the same manner as those in acquired neuromyotonia (►Neuromyotonia, autoimmune and idiopathic), but are typically present at higher titers (>400 pM) at least at the peak of disease [1,2]. Subsequently, they may decline spontaneously and they decline rapidly if immunosuppressive treatments are used. The antibodies may be particularly pathogenic towards Kv1.1 which is expressed strongly in the molecular layers of the hippocampus, particularly in CA1 and CA3.

## Prevalence

This is a newly-defined syndrome and the prevalence is not known. Almost all patients recognized so far are aged >30 years. The incidence of new cases is approaching 1/million/year in the UK. Cases have been recognized in many other countries but their incidence is not known.

## Molecular and Systemic Pathophysiology

The disease process is thought to be antibody mediated, unlike that in the typical paraneoplastic limbic encephalitis which is generally the result of a T cell mediated attack on the brain. The mode of action of the antibodies is not clear. VGKC antibodies associated with limbic encephalitis are likely to reduce the number or function of the Kv1.1 channels that are expressed in the molecular layer of the hippocampus but it is not yet clear whether the targeted VGKCs are on the dendritic tree of the pyramidal cells or on the interneurons. How the antibodies get into the CNS, and why they target the hippocampus specifically is also not clear.

## Diagnostic Principles

The subacute or acute onset of memory loss and seizures with high signal on MRI restricted to the temporal lobes is highly suggestive of this diagnosis but many cases do not show high signal on T2-weighted MRI sequences. A low plasma sodium is frequently observed. A VGKC antibody test of >400 pM is diagnostic, but lower levels may be difficult to interpret. Paraneoplastic causes must always be excluded, particularly thymoma and lung carcinoma, and these are sometimes associated with lower levels of VGKC antibodies (<400 pM) and a less good response to treatments.

## Therapeutic Principles

Treatment is symptomatic combined with steroids and immunosuppression. Anti-epileptics and fluid restriction may be required during the acute disease. Plasma exchange, intravenous methylprednisolone and/or intravenous immunoglobulins followed by oral steroids are probably important to ensure that the VGKC antibody levels decline as quickly as possible. In many cases it is possible to stop treatments within one year, but long term follow up is not yet available. Cases with typical presentation, clinical and radiological features but negative VGKC antibodies are sometimes treated successfully by a similar approach suggesting that other antibodies can cause a similar syndrome. The disease appears to be acute and usually monophasic but a few cases have relapsed following withdrawal or tapering of immunosuppressive treatments, so this must always be done with care.

## Synonyms

Ollier disease; Maffuci syndrome; Dyschondroplasia; Osteochondromatosis

## Definition and Characteristics

Enchondromatoses are a group of disorders with multiple benign intraosseous tumors composed of mature hyaline cartilage. Recent classifications suggest at least nine different disorders, some of which are inherited in a variable fashion [1]. Patients with Ollier disease have multiple enchondromas typically affecting short tubular, long tubular, and flat bones. Maffuci syndrome has soft tissue venous malformations in association with multiple enchondromas, and is associated with an increased risk of brain and ovarian neoplasms. Dysspondyloenchondromatosis have irregularly shaped vertebral bodies associated with enchondromas of the long tubular bones. Cheirospondyloenchondromatosis have generalized mild to moderate platyspondyly associated with enchondromas of the short and long tubular bones. Spondyloenchondrodysplasia represents two inherited disorders, transmitted in either an autosomal recessive or autosomal dominant fashion, that have enchondromas of the spine in addition to the tubular bones. Metachondromatosis have osteochondromas (exostoses) in addition to enchondromas and is inherited in an autosomal dominant pattern. Genochondromatosis, inherited in an autosomal dominant fashion, consists of distal femoral enchondromas associated with knee pain and in the more common subtype the presence of widening of the medial ends of the clavicles. Vandraager-Pena type, inherited in an autosomal recessive fashion, resembles metaphyseal dysplasia. These disorders can be phenotypically separated by the distribution of the enchondromas, the varied involvement of the hands and spine, and abnormalities of non-skeletal organ systems [1,2].

## Prevalence

Enchondromas are most commonly seen as a non-syndromic solitary lesion, representing 5–17% of all bone tumors. Enchondromatoses as a group are rare, the prevalence of which is unknown.

## Genes

Many of the enchondromatoses are rare, making mapping of loci and identification of candidate genes difficult. Ollier disease is mapped to 3p22–p21.1. An R150C mutation in the PTH/PTHrP type I receptor was identified in two of six patients with Ollier [3]. One individual had a germline mutation inherited from his father who had a mild skeletal dysplasia but with no enchondromas. The second patient likely reflected a somatic mutation as the mutation was only detected in the enchondroma. This mutation was not identified in 31 enchondromatosis patients of diverse ethnic backgrounds. Likewise immunochemistry showed no abormal expression of PTHR1 protein in these patients. Eleven patients had sequencing of the gene with no mutations identified [4]. No additional genes for the enchondromatoses have been identified.

## Molecular and Systemic Pathophysiology

Bone morphogenesis is a complex process involving, amongst many pathways, control of the rate and synchronization of chondrocyte differentiation. This is believed to be in part regulated through a feedback loop involving Indian hedgehog (Ihh) and parathyroid hormone-related peptide (PTHrP). In the growth plate, it is proposed that the presence of ectopic hypertrophic chondrocytes signals a feedback mechanism that produces Ihh which in turn stimulates PTHrP expression, which binds the PTHR1 receptor. This results in upregulation of $Bcl_2$, which delays the progression of chondroctyes to the hypertrophic zone, thus slowing their differentiation. This controls the rate of differentiation into mature bone. The R150C mutation in two patients with Ollier resulted in a mutant receptor that constitutively activated Ihh signaling. This mutant receptor in transgenic mice formed enchondroma-like lesions [3]. An activating mutation in the PTHrP receptor has also been described in a metaphyseal chondrodysplasia with abnormal formation of endochondral bone. Inactivation of the PTHR1 receptor results in advanced endochondral bone maturation. In addition to the PTHrP pathway, Ihh is believed to play an independent role in other aspects of skeletal morphogenesis such as chondrocyte proliferation and osteoblast development [5]. Further molecular studies

on the regulation of skeletal morphogenesis may provide candidate genes for the enchondromatoses.

### Diagnostic Principles

Enchondromas pathologically are composed of mature hyaline cartilage. Enchondromas appear radiographically as lytic lesions, usually situated in the medullary cavity. They have a sclerotic border with a narrow zone of transition to normal bone, and may expand the bone along with scalloping the endosteal surface of the bone. They usually contain calcification within their matrix classically described as having an "arcs and whorls" appearance. Enchondromas of short bones, typically in the hands, do not contain a calcified matrix. Magnetic resonance imaging will show typical signal changes corresponding to hyaline cartilage containing calcifications. They usually do not have a soft tissue mass component.

### Therapeutic Principles

Enchondromas may result in distortion of bone growth resulting in angular deformities in addition to bone length disturbances. These growth changes may result in functional impairment, especially in the hands and feet, or lead to pathologic fractures. Deformities may be treated by various orthopaedic procedures. Benign lesions can be curetted and bone grafted. Enchondromas situated around joints may result in a degenerative chondropathic arthropathy and these patients may be candidates for joint replacements.

Enchondromas, especially in Ollier's disease and Maffuci's syndrome, have the potential for malignant transformation into chondrosarcomas. Pain, recent growth, or radiographic evidence of cortical erosion should raise the suspicion of malignant behavior.

[2]Heart Health Institute and Department of Cardiac Science, The University of Calgary, AB, Canada
[3]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

### Definition and Characteristics

Endocarditis is defined as a localized endocardial abnormality characterized by endothelial injury and deposition of clotting elements, usually involving the cardiac valves, with or without the presence of infectious microorganisms. Nonbacterial thrombotic endocarditis (NBTE) is defined by aseptic endothelial injury in a hypercoagulable state. When endocarditis occurs in autoimmune (such as systemic lupus erythematosus) or noninfectious diseases, it is termed Libman-Sacks endocarditis or marantic endocarditis, respectively. Infective endocarditis (IE) may be classified according to sites, causes, temporal evolution or the predisposing factors of infection. Acute IE is an aggressive febrile illness that rapidly damages cardiac structures and spreads to extracardiac sites forming abscesses, and can progress to congestive heart failure and death within weeks. Subacute IE follows a much slower course, gradually damages cardiac structures and rarely causes metastatic infection, and is gradually progressive unless complicated by a major embolic event or ruptured mycotic aneurysm. IE can be classified as native valve endocarditis (NVE), or prosthetic valve endocarditis (PVE). PVE has been called early when symptoms begin within 60 days of valve surgery and late with onset thereafter. Early PVE is generally the result of intraoperative contamination, usually caused by coagulase-negative staphylococci, S. aureus, facultative gram negative bacilli, diphtheroids, and fungi. Between 2 and 12 months after valve surgery, PVE is usually due to nosocomial coagulase-negative staphylococci with a delay onset. Twelve months after surgery PVE is similar to those in community-acquired NVE. IE among IV drug abusers usually occur in man 27–37 years in age, and is

usually located on the tricuspid valve. At least 75% of non-addiction associated IE are caused by streptococci or staphylococci. Health care-associated IE is defined as an acute nosocomial IE, and includes IE arising in the community after recent hospitalization or as a direct consequence of long term indwelling devices. This IE has a high mortality rate of 27–38% [1], and may involve the tricuspid valve, transvenous pacemakers, defibrillators and prosthetic valves. Gram-positive cocci are the predominant cause of health care-associated IE. The nature of the infectious agent determines the acuity of the endocarditis. β-Haemolytic streptococci, S. aureus, Neisseria gonorrhoeae, Streptococcus pneumonie, and enterococci typically result in acute fulminant IE. Subacute IE is typically caused by S. viridans, coagulase-negative staphylococci, and the HACEK (Haemophilus aphrophilus species, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella species, Kingella kingae) group. Indolent IE can be caused by Bartonella species and C. burnetii. Symptoms of IE include fever, chills, sweats, anorexia, weight loss, malaise, myalgia, arthralgia and back pain. Clinical signs include a new or changing heart murmur, arterial emboli, splenomegaly, clubbing, petechiae, Osler's nodes, subungual hemorrhages Janeway lesions, and Roth's spots.

## Prevalence

In developed countries, the incidence of IE ranges from 1.5 to 6.2 cases per 100,000 population per year. The incidence in metropolitan areas can be as high as 11.6 cases per 100,000 population per year, and half of these are the result of self-injection drug use. The rate of PVE is 1.5–3.0% at 1 year postoperatively, and up to 3–6% at 5 years. The age-specific incidence of IE increases from 5 per 100,000 persons-year among persons younger than 50 years old to 15–30 per 100,000 persons-year in the sixth through eighth decades of life.

## Molecular and Systemic Pathophysiology

IE usually begins with NBTE secondary to initial endothelial injury and a localized hypercoagulable state which can lead to the development of an uninfected platelet-fibrin thrombus serving as a site for bacteria adhesion during transient bacteremia. Cardiac lesions most commonly resulting in NBTE are mitral regurgitation, ventricular septal defect, aortic stenosis and regurgitation. The above lesions usually result from mitral valve prolapse, rheumatic, degenerative and congenital heart disease. The pathophysiological consequence includes (i) constitutional symptoms resulting from cytokines release during destruction of cardiac structures, (ii) embolization of vegetations causing infection or infarction of remote tissues, (iii) hematogenous spreading of infections to remote sites during bacteremia, and (iv) tissue injury secondary to deposition of circulating immune complex or antibody-complement interactions with antigens deposited in tissues. The intracardiac sequelae of IE include infected vegetations, damage of cardiac valves and adjacent structures, rupture of chordae tendineae, fistula between major vessels and cardiac chambers, congestive heart failure, perivalvular abscesses, interruption of cardiac conduction system, and purulent pericarditis.

## Diagnostic Principles

Laboratory findings of IE include anemia, leukocytosis, microscopic hematuria, elevated erythrocyte sedimentation rate, positive rheumatoid factor, positive circulating immune complexes, and decreased complement. The Duke criteria are a reliable diagnostic strategy to define cases of IE [2]. The Duke criteria combine important traditional diagnostic parameters, such as persistent bacteremia, newly developed valvular insufficiency, and peripheral manifestations, with echocardiographic findings. Patients suspected of having IE may be classified as: definite, possible or rejected. Definite cases of IE are determined by clinical criteria or by pathological diagnosis at surgery or autopsy. Definite IE may be diagnosed by the presence of two major criteria, or one major and three minor criteria, or five minor criteria. The first major criterion is the isolation of microorganisms quite unique to IE: Streptococcal viridans, members of the HACEK group, as well as staphylococci and enterococci when they are community acquired or without an apparent primary focus. A second major criterion includes evidence of endocardial involvement demonstrable by echocardiography or by the development of a new valvular regurgitation. Echocardiographic criteria include: oscillating intracardiac mass, abscess, new partial dehiscence of prosthetic valve, or new valvular regurgitation. Vegetations of >2 mm in size are readily detected by transesophageal echocardiography which is superior to transthoracic echocardiography in detecting vegetations of smaller size, prosthetic valve vegetations, and perivalvular extensions of infections.

## Therapeutic Principles

The major objectives of IE therapy include eradication of infecting microorganisms and correction, if possible, of any predisposing factors. Once the infecting organism for sensitivity testing has been isolated, the antimicrobial therapy becomes straightforward. More prolonged antimicrobial therapy is often advised for PVE [3]. Indications for surgery include moderate to severe congestive heart failure, unstable prosthesis, obstruction to prosthesis orifice, uncontrolled infection despite optimal antimicrobial therapy, relapse of NVE, unavailable effective antimicrobial therapy, relapse

of PVE after optimal therapy, fistula to pericardial sack. The American Heart Association has recently issued new and dramatically restricted recommendations for the chemoprophylaxis of IE [4]. For example, cardiac conditions in which antibiotic prophylaxis with surgery and dental procedures are recommended include prosthetic cardiac valves, previous IE, various congestive heart diseases, and cardiac transplantation recipients who develop cardiac valvulopathy.

## Endomyocardial Fibrosis

Dirk Westermann, Carsten Tschöpe
Center for Cardiovascular Research, Charité, Berlin, Germany

### Definition and Characteristics

Extensive accumulation of collagen fibers in interstitial and perivascular cardiac tissue.

### Prevalence

No information available.

### Molecular and Systemic Pathophysiology

The extracellular cardiac matrix is composed mainly of collagen type 1, 3 and 4 fibers. Collagen fibers stabilize and form the cardiomyocytes into a structure and thereby coordinate contraction and relaxation of the myocardium [1]. However, extensive accumulation of collagen fibers in heart muscle worsens systolic and diastolic function due to decreased compliance of the left ventricle. Collagen fibers are produced by cardiac fibroblast and degraded by matrix metalloproteinases, balanced under physiological conditions. Certain pathophysiological conditions, associated with e.g., highly increased aldosterone, angiotensin II, pro-fibrotic cytokines, hyperglycemia, ischemia, and increased sympathotonic tonus, lead to an imbalance in cardiac collagen [2]. Cardiac myocytes and invading immunocompetent cells produce more CTGF (connective tissue growth factor), which is regulated by SMAD proteins under disease conditions. CTGF stimulates cardiac fibroblast production of collagen. Degradation of collagen by matrix metalloproteinases can be regulated under disease conditions also. Diseases leading to this kind of dysregulation resulting in cardiac fibrosis are, e.g., ischemic cardiomyopathy, dilative cardiomyopathy, valvular diseases, diabetes mellitus with diabetic cardiomyopathy, hypertensive heart disease, and also relatively rare diseases like sarcoidoses.

### Diagnostic Principles

Cardiac fibrosis can be diagnosed directly or indirectly. The only direct way is to obtain endomyocardial right or left ventricular biopsies and measure the collagen content as well as MMP and TIMP levels. The best indirect approach is documentation of cardiac fibrosis by magnetic resonance imaging.

### Therapeutic Principles

Aldosterone antagonists, ACE-inhibitors or AT1-receptor antagonists, and beta receptor blockers are the basis of pharmacological treatment next to strict control of

arterial blood pressure and blood glucose levels [3]. New therapies may include pharmacological treatment with an anti inflammatory approach or matrix metalloproteinases inhibitors.

**Endothelial Dysfunction. Figure 1** Cross-section of an artery.

## Endostosis Crani

►Hyperostosis Frontalis Interna

## Endothelial Dysfunction

Timothy Watson, Gregory Y. H. Lip
Hemostasis, Thrombosis and Vascular Biology Unit, University Department of Medicine, City Hospital, Birmingham, UK

### Definition and Characteristics

The endothelium is a single layer of cells that line the innermost surface of the entire circulatory system, from the heart to the smallest capillary. The endothelium consists of squamous cells, which act as an interface between the vessel wall and flowing blood contained within. The endothelium allows the passage of various materials and white blood cells into and out of the blood stream. The precise number and arrangement of endothelial cells varies depending on the type and site of blood vessel concerned. In larger blood vessels, (arteries and veins), the endothelium is surrounded by a thick wall of connective tissue and smooth muscle (Fig. 1). Whilst capillaries are formed solely from endothelial cells adhered to a basal lamina.

Because all endothelial cells have the capacity to regenerate, these cells play a key role in allowing the blood vessel network to remain dynamic, allowing it to remodel according to need − be it growth, or repair. Endothelial dysfunction plays a critical role in vascular disease, such as arteriosclerosis and thrombosis.

### Prevalence

Vascular lesions, such as arteriosclerosis and thrombosis are the leading cause of morbidity and mortality in most developed countries.

### Genes

A wide variety of genetic defects and gene polymorphisms cause or predispose to vascular lesions such as ►arteriosclerosis and ►thrombosis.

### Molecular and Systemic Pathophysiology

The healthy endothelium is key to maintenance of vascular homeostasis [1]. The endothelium is able to act as both a sensory and signaling organ. The former, mainly by monitoring shear stress on the vessel wall, the latter by controlling release of a variety of paracrine and autocrine substances (Table 1). It is thus able to influence vascular tone, smooth muscle proliferation, leukocyte adhesion, platelet aggregation and adhesion. Endothelial dysfunction is increasingly recognized for its key role in numerous important disease states including, atherosclerosis, hypercholesterolemia, hypertension, diabetes mellitus, thrombogenesis, whilst further evidence of endothelial dysfunction can be found with heart failure, cigarette smoking, and ageing.

**Endothelial Dysfunction. Table 1** Common substances released by endothelium

| Substance | Effect |
|---|---|
| Nitric oxide (endothelium derived relaxing factor) | Vasodilatation, antithrombotic, inhibition of leukocyte adhesion, smooth muscle growth inhibition |
| Plasminogen activator inibitor | Prothrombotic |
| Platelet derived growth factor | Angiogenesis, smooth muscle growth |
| Basic fibroblast growth factor | Smooth muscle growth, vasodilation |
| Insulin-like growth factor | Smooth muscle growth |
| Vascular endothelial growth factor | Angiogenesis |
| Heparin/heparin sulfate | Growth-inhibitory molecules, anticoagulant |
| Endothelin-1 | Vascoconstriction, smooth muscle growth |
| Angiotensin I and II | Vasoconstriction |
| Bradykinin, prostacyclin | Vasodilatation, smooth muscle growth inhibition |
| Von Willebrand factor, factor V, thromboxane | Pro-coagulant |
| Tissue plasminogen activator, prostacyclin | Anticoagulant |

For example, hypertension is a function of vascular tone. Under basal conditions, the endothelium serves to maintain the vessel in a relatively dilated state [2,3]. The ability of blood vessels to dilate in response to increased shear stress is termed flow-mediated dilatation, a process principally regulated by release of nitric oxide from the endothelium. Vasoconstriction meanwhile, occurs in response principally to angiotensin II, produced from angiotensin I by the expression of angiotensin converting enzyme by the endothelium. The activity of this enzyme varies across the circulatory system, and with age, race and circulatory volume. As a potent vasoconstrictor angiotensin II increases blood pressure [3].

There is also increasing evidence that endothelial dysfunction may be an early marker of atherosclerosis and can be detected before changes to the vessel wall are apparent on either ultrasound or angiography. Nitric Oxide, as well being a potent vasodilator, inhibits oxidation of low-density lipoprotein (LDL) cholesterol. Oxidation of LDL may be a significant contributory process to atherosclerosis, which in turn leads to further endothelial damage [4]. Thus, the process may be a vicious cycle, with endothelial damage effectively augmenting the potency of the hyperlipidemic state, accelerating further damage.

## Diagnostic Principles

Although various markers of endothelial dysfunction are measurable, their use in the clinical setting at present is somewhat limited. Various studies have established markers of endothelial perturbation, reflecting endothelial activation (e.g., soluble E-selectin), endothelial damage/dysfunction (e.g., vWf) and endothelial damage (e.g., circulating endothelial cells) [1]. Other frequently cited molecules include nitric oxide and its metabolites, high sensitivity C-reactive protein, intercellular adhesion molecule 1 and more recently endothelial progenitor cells and endothelial microparticles. Furthermore, functional assessment can be made, with, for example, flow-mediated dilatation and vasodilator stimuli.

## Therapeutic Principles

The endothelium has become of increasing interest as a target for new drug development.

The evidence for endothelial pertubation (activation/dysfunction/damage) in these disease states is well documented.

Drugs such as Angiotensin Converting Enzyme Inhibitors and Angiotensin II Receptor Blockers are ideally placed to allow effective modulation of blood pressure [3].

Several clinical trials have found that 3-hydroxy-3-methylglutaryl coenzyme-A reductase inhibitors (the "statins") appear to improve endothelial dysfunction more than could be reasonably attributed to their reduction of plasma lipids [4]. The suggestion being that statin therapy may up-regulate nitric oxide production and reduce cellular uptake of oxidated−LDL.

The endothelium thus represents an exciting potential target for several cardiovascular diseases.

### Synonyms

Gastro-enteritis; Colitis; Diarrhea; Dysentery

### Definition and Characteristics

Inflammation of the small and large bowel leading to symptoms including pain, diarrhea (>2 non-solid stools/day) and fever and possibly the sequelae of malabsorbtion (e.g. weight-loss), caused by infectious agents (bacteria, viruses, parasites, fungi), radiation, ischemia of the colon, allergic reaction or idiopathic syndromes (e.g. inflammatory bowel disease).

### Prevalence

Acute diarrhea is the leading cause of death world wide and causes an estimated yearly mortality of more than 2 million. The prevalence of chronic diarrhea is difficult to estimate.

### Genes

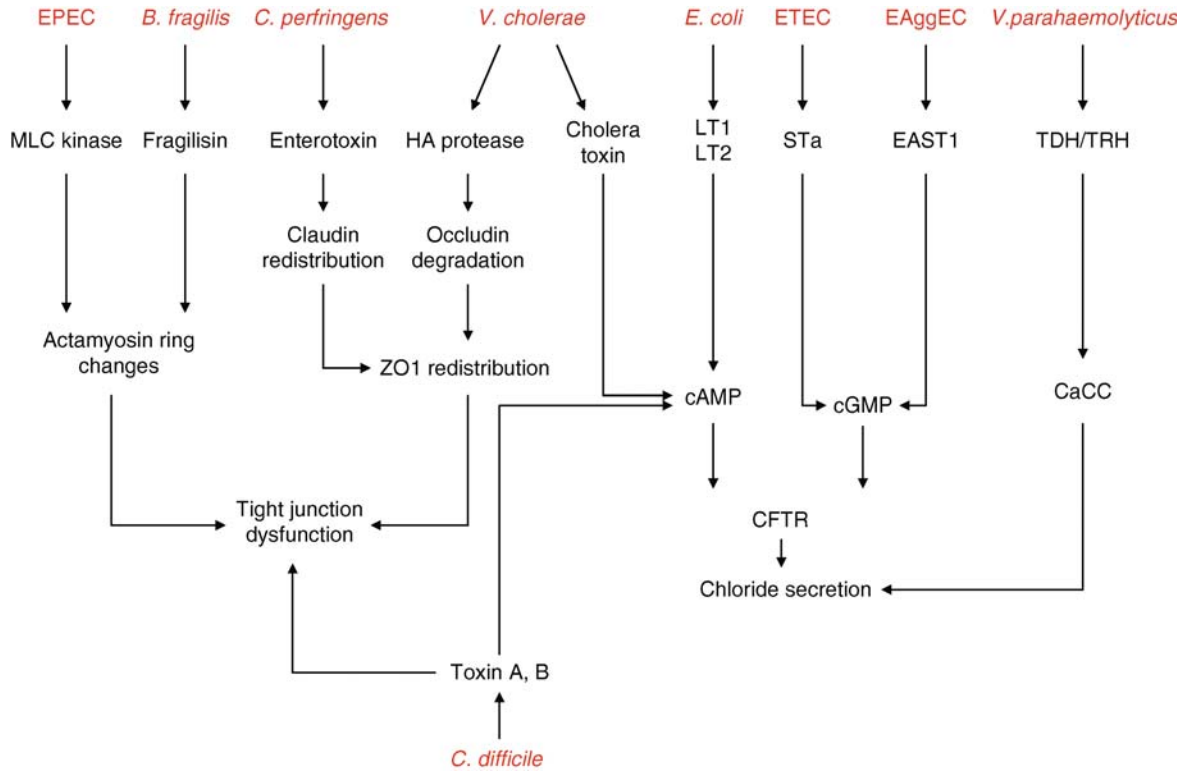
A number of genes have been implicated in chronic diarrheal syndromes. Mutation of these genes leads to malabsorbtion of ingested products and an osmotic gradient in the intestinal lumen. These genes are: DRA (chloride-bicarbonate exchange, congenital chloride diarrhea), SGLT1 (glucose stimulated sodium absorption, glucose–galactose malabsorbtion), NHE3 (sodium-hydrogen exchange, congenital sodium diarrhea), ABAT (sodium-dependent bile-acid absorption, congenital bile-acid diarrhea), LCT (lactase-phlorizin hydrolase, congenital lactase deficiency) and NEUROG3 (development of intestinal and pancreatic endocrine-cells, congenital malabsorptive diarrhea) [1].

### Molecular and Systemic Pathophysiology

The causes of secretory diarrhea are more manifold and to a large extent are infectious in nature resulting from infection with viruses, bacteria or parasites. These pathogens exert their effects on the intestinal epithelium in a number of ways of which the underlying molecular mechanisms are, for some, fairly well known.

Pathogenesis involves one or more of three mechanisms, dysfunction of the secretory system leading to sodium-chloride malabsorption; alterations of structure and function of the gut epithelial-cell tight junctions and activation of the inflammatory cascade (Fig. 1). The pathogens may invade epithelial cells via different mechanisms or remain attached to the luminal epithelial surface without invasion. Adherence and invasion strategies employed by enteric pathogens include pilus and non-pilus adhesions and secretion systems. Furthermore the secretion systems are deployed in exporting toxins into the epithelial cell e.g. V. cholerae cholera toxin via secretory system II and use of the type III secretion system by Salmonella spp., Yersinia spp., and Shigella spp. to export EspA filament, Yop proteins and IpaB and IpaC proteins respectively [2].

Toxin-initiated tight junction disruption leading to barrier dysfunction is caused by C. difficile toxins A



**Enteritis. Figure 1** Pathways and toxins leading to dysfunction of the epithelial tight junction or chloride secretory response due to activation of CFTR or CaCC. LT1, heat-labile enterotoxin 1; LT2, heat-labile enterotoxin 2; STa, heat-stable enterotoxin; EaggEC, Enteroaggregative *E. coli*; EAST1, St-like toxin produced by EAggEC; EPEC, enteropathogenic *E. coli*; ETEC, enterotoxigenic *E. coli*; TDH, thermostable direct hemolysin; TRH, TDH-related hemolysin, CaCC, calcium activated chloride channel, CFTR, cystic fibrosis transmembrane conductance regulator.

and B due to modification of the Rho family of proteins, B. fragilis toxin fragilisin and V. cholerae haemaglutinin protease due to their proteolytic action and C. perfringens enterotoxin (CPE) which causes claudin redistribution.

A chloride secretory diarrhea is caused by several organisms by cyclic AMP or GMP activation of the cystic fibrosis transmembrane conductance regulator (CFTR). Chloride secretion is the principal determinant of luminal hydration and the apically located CFTR is the major regulator of chloride secretion. Cholera toxin, LT1 and LT2 (E. coli), toxin A and B (C. difficile), STa (enterotoxigenic E. coli) and EAST1 (enteroaggregative E. coli) all activate CFTR via cAMP or cGMP resulting in chloride secretion and diarrhea. In addition the toxin TDH/TRH (thermostabile direct haemolysin/TDH related haemolysin) of V. parahaemolyticus activate the calcium chloride channel resulting in diarrhea [3]. In addition to the bacteria already mentioned Cryptosporidium, Isospora and Giardia are able to invoke an inflammatory response resulting in enteritis [4].

Activation of the inflammatory cascade results in enteritis the common final response being release of cytokines, chemokines and recruitment of inflammatory cells. A pivotal role is played by NFκB.

Osmotic diarrhea can usually be distinguished from secretory diarrhea by a reduction or cessation of stool frequency upon stopping food intake. The pathophysiology underlying this form of diarrhea is failure to digest one or more ingested products, such as lactose which results in an osmotic gradient in the intestinal lumen. The causes are listed above.

## Diagnostic Principles

Acute diarrhea is, in most cases, a self-limiting disease and therefore most often no specific diagnosis is sought. However, in order to avoid spread of a possible contagious disease or to recognize epidemiologically important and/or rare pathogens a baseline diagnostic is recommended. Traditionally bacterial pathogens have been detected using various culture methods, parasites

by microscopy and viral pathogens using ELISA techniques. However in the last decade diagnosis of pathogens causing diarrhea has been significantly advanced by the detection of pathogen-specific DNA or RNA sequences (often of the toxin genes involved in pathogenicity) using polymerase chain reaction. This technique permits, in addition, the distinction of pathogenic E. coli strains from gut commensals, can differentiate between different Clostridium difficile stains, differentiates pathogenic from a pathogenic amoebae, and has a higher specificity than ELISA techniques in the detection of viral pathogens.

## Therapeutic Principles

The most important step in the therapy of acute diarrhea is oral rehydration therapy (ORT). The standard ORT regime contains 3.5 g NaCl, 2.5 g NaHCO3, 1.5 g KCl and 20 g glucose per liter of boiled water taken ad lib. Specific antimicrobial therapy is not available in most viral and parasitic causes of diarrhea. Diarrhea mediated by amoebae or giardia is treated with metronidazole. The use of antibiotics is recommended in only a few cases of enteritis caused by shigella, campylobacter and in acute travelers diarrhea. Antibiotic treatment is always indicated for typhoid fever and bacteremic salmonellosis.

In infectious diarrhea transmission occurs most often by the faecal-oral route, and therefore the general rule: "boil it, peel it, cook it or forget it" provides the best prophylaxis. Successful vaccination is possible against a small number of pathogens causing diarrhea, for example Vibrio cholerae and Salmonella typhi. To date, no effective vaccines against parasitic infections are available. The work on vaccines against viral enteric infections is in progress. Many vaccines are based on lysates of the different pathogens or on live-attenuated microorganisms. Vaccines based on recombinant or purified antigens or toxins are presently being developed.

New targets in the therapy of enteric diseases include substances which interfere with the adherence of pathogens to the gut surface epithelium or which inhibit the adherence or signaling of toxins.

E

## Synonyms

NEC

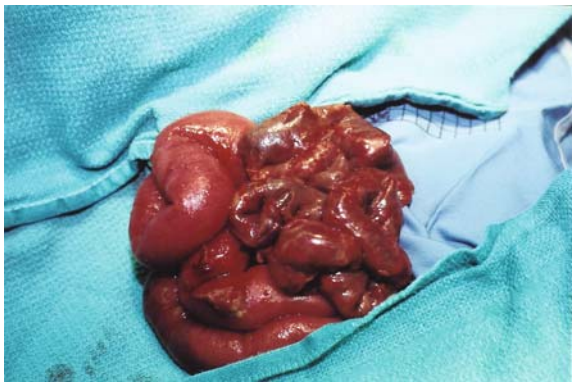
## Definition and Characteristics

Necrotizing enterocolitis (NEC), characterized by intestinal necrosis (Fig. 1), typically presents with abdominal distension, occult or fresh blood in stools, and bilious emesis [1].

Non-specific clinical features include lethargy, poor feeding, temperature instability, apnea, respiratory distress, and bradycardia [1]. Other manifestations such as abdominal wall erythema, abdominal tenderness and guarding, shock, metabolic acidosis, and disseminated intravascular coagulopathy are seen in severe cases.

## Prevalence

NEC most commonly presents in the first 2 weeks of life [1]. The incidence is estimated to be 3 per 1,000 live births and 50 to100 per 1,000 in very low birthweight infants (<1,500 g) [2]. The male to female ratio is approximately equal.



**Enterocolitis, Necrotizing. Figure 1** A neonate with necrotizing enterocolitis. Note the necrotic bowel found at laparotomy.

## Molecular and Systemic Pathophysiology

The pathophysiology remains elusive. Potential contributing factors include intestinal ischemia, colonization with pathogenic microbes, and challenge of enteral feeding with formula milk. These factors may coalesce to produce bowel injury especially in individuals with NEC-prone genotype and an immature and vulnerable gut [2,3]. Other risk factors include polycythemia, respiratory distress, hypoglycemia, congenital heart disease, exchange transfusion and medications such as vitamin E, methylxanthines and indomethacin. Once endothelial damage is initiated and propagated, endothelial cells then activate platelets and polymorphonuclear neutrophils by the release of adhesion molecules and chemokines. Activated polymorphonuclear neutrophils elaborate proteolytic enzymes causing direct tissue injury and release of cytokines. Platelet-activating factor, tumor necrosis factor, interleukin-1 (IL-1), IL-2, IL-8, IL-12, IL-18, prostaglandins and free oxygen radicals may lead to capillary leakage, increased intestinal mucosal permeability, shock and multi-organ failure. Those cytokines are involved in the final common pathway of NEC pathogenesis [3].

## Diagnostic Principles

Laboratory findings may include leukocytosis with bands and toxic granulations, anemia, thrombocytopenia, metabolic acidosis, electrolyte disturbances, hypoalbuminemia, and hypoglycemia. Severe thrombocytopenia, neutropenia, coagulopathy or acidosis may indicate an advanced disease [4]. High C-reactive protein might indicate developing complications such an abscess formation [4]. Serial abdominal films should be performed to look for signs of NEC. Suggestive radiographic findings include distended loops of bowel, portal venous air, and pneumatosis intestinalis. Radiographic signs of bowel infarction or perforation include free air in the peritoneum, free intraperitoneal fluid, fixed dilated intestinal loops, and diminished bowel gas with asymmetric loops. Abdominal ultrasonography may detect portal venous air or a gangrenous bowel. The latter is characterized by a hypoechoic rim with a central echogenic focus ("pseudo-kidney" or "target" sign).

## Therapeutic Principles

Treatment in uncomplicated cases is mainly conservative; it includes cessation of feeding, nasogastric decompression, repletion of intravascular volume with intravenous fluids, total parenteral nutrition, correction of acid-base and electrolyte imbalances, ventilatory support as indicated, appropriate blood, urine, and stool cultures, and parenteral administration of broad-spectrum antibiotics [1]. Absolute indications for surgical intervention include intestinal perforation as evidenced by pneumoperitoneum. Relative indications are erythema of the abdominal wall, a palpable abdominal mass, a persistent fixed loop on repeated abdominal radiographs, paracentesis that is positive for fluid (especially fecal material), and clinical deterioration [1]. Patients with ischemic necrosis and perforated bowel at laparotomy require bowel resection [1]. Ideally, bowel resection is performed when the intestine is gangrenous but not perforated. Resection and primary anastomosis should be considered only if the lesion is localized and the patient stable. Peritoneal drainage, "clip and drop back" technique, or exteriorization of the transected ends of the viable bowel with reanastomosis at a later date should be considered for infants with diffuse intestinal involvement or physiologic instability. Placement of a peritoneal drain or a laparotomy is usually performed for infants <1,000 grams whereas laparotomy is generally preferred for infants >1,000 grams. Feeding human milk can be protective as well as the use of probiotics and arginine supplements [2].

## Epicondylitis

Leonard O'Sullivan
Ergonomics Research Group, Manufacturing and Operations Engineering Department, University of Limerick, Limerick, Ireland

### Synonyms

Epicondylalgia; Elbow tendinosis

### Definition and Characteristics

Humeral epicondylitis is a term describing pain in the region of either the lateral or medial epicondyle, and is often exacerbated by muscle activity in the wrist extensors or flexors. Many of the forearm muscles span the elbow joint and attach to either the lateral or medial side of the humerus.

Lateral epicondylitis (tennis elbow) is tendonitis of the forearm extensor and supinator muscles at the lateral epicondyle. The tendon attaching the extensor and supinator muscles to the lateral epicondyle has a distinctly poor biomechanical design. The small size of the lateral epicondyle and large mass of the extensor and supinator muscles create high stress concentrations in the attachment site. Injury is generally regarded as occurring to the tendon but there are diverging views on whether muscle tenderness in the wrist extensors, especially the extensor carpi radialis brevis and longus, can be categorized as epicondylitis. Some studies indicate such phenomena as a separate injury of the muscle.

Medial epicondylitis primarily involves the pronator teres, flexor carpi radialis and occasionally the flexor carpi ulnaris, all of which arise from the medial epicondyle of the humerus. In addition, the ulnar nerve passes behind the medial epicondyle through the two heads of the flexor carpi ulnaris on its way to the forearm. In some instances of medial epicondylitis the ulnar nerve is also irritated. The injury is often due to repetitive wrist flexion and forearm rotation.

## Prevalence

In many epidemiological studies, prevalence rates are combined for both lateral and medial epicondylitis. However, it is estimated that medial epicondylitis is approximately 6–10 times less common than lateral. For lateral epicondylitis, prevalence rates range between 1 and 5% of the general population, with the highest reporting in the 30–55 year age group. The work relatedness of epicondylitis has not been widely studied. Data from the literature indicates increased risk for work involving repetitive contractions of the wrist extensors [1] and forearm pronation and supination [2].

## Molecular and Systemic Pathophysiology

Several pathophysiological hypotheses have been put forward but there is still little consensus on the exact nature of the anatomic structures involved. The term "epicondylitis" tends to indicate inflammation but many studies have been unsuccessful in demonstrating the presence of inflammatory cells at the chronic phases of the disease. There is a case that the term "epicondylalgia" would be a more acceptable descriptor. Alternatively "elbow tendinosis" may be favored, as this also indicates a degenerative process [3]. Angiofibroblastic tendinosis is consistent with atypical fibroblast and invasion of the vascular tissue and can be ascribed to overuse. A full or partial thickness tear in the tendon may occur as a result of overuse from repetitive microtrauma. While many tennis elbow specimens show degenerative changes the primary cause is essentially microtrauma [4].

## Diagnostic Principles

The Thomsen or Mill's test is commonly used for diagnosis of lateral epicondylitis. Lateral epicondylitis is often characterized by elbow pain and tenderness over the epicondyle, sometimes with pain radiating to the extensor aspect of the forearm, but rarely proximal to the elbow. In severe cases discomfort and pain over the epicondyle may be accompanied by oedema. Patients often report pain during contraction of the wrist and this is accompanied by reduced grip strength. It is also reported that patients may experience less pain during resisted supination. Testing of Range of Motion (ROM) of the elbow and wrist can be assessed to elicit reduced movement. A common finding is pain during restricted contraction of the wrist dorsiflexors, especially when resisting dorsiflexion of the wrist with the fingers semiflexed [4]. X ray imaging can be used to rule out other conditions.

Discomfort during medial epicondylitis is experienced along the volar aspect of the forearm. It is rarely more profound than that experienced during lateral epicondylitis. Caution is needed to differentiate medial epicondylitis from pronator outlet syndrome if symptoms are experienced distally in the median nerve distribution.

## Therapeutic Principles

Few treatment strategies have been proven to offer considerable benefit for both lateral and medial epicondylitis [3]. Conservative treatments which have been found to help alleviate symptoms include cryotherapy, NSAIDs, Cyriax manipulations, physiotherapy, and local corticosteroid injections, but these are generally accepted to provide only short-term pain relief. Many alternatives for treatment have been proposed including shock wave therapy and splinting, but these and many others have yet to gain universal scientific approval.

# Epidermal Necrolysis, Toxic

Stefan Beissert
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Lyell's syndrome, related to Stevens-Johnson syndrome

## Definition and Characteristics

Toxic epidermal necrolysis (TEN; >30% body surface area) and Stevens-Johnson syndrome (SJS; <10% body

surface area) are rare, potentially life-threatening adverse cutaneous drug reactions [1]. SJS or TEN manifest tenderness and erythema of the skin and extensive mucocutaneous exfoliation.

### Prevalence

The incidence is for SJS 1.2–6 and for TEN 0.4–1.2 per million persons. Women are more frequently affected than men with a ratio of 1.5:1.

### Molecular and Systemic Pathophysiology

The precise molecular and cellular events that lead to SJS or TEN are only partially understood. Evidence suggests that TEN is associated with an impaired capacity to detoxify reactive drug metabolites and keratinocyte cell death appears to be mediated via CD95-CD95L signaling.

### Diagnostic Principles

Diagnosis of established SJS or TEN can usually be made clinically. Biopsy and immunofluorescence can exclude differential diagnosis such as staphylococcal scalded skin syndrome or paraneoplastic pemphigus.

### Therapeutic Principles

Early diagnosis, immediate discontinuation of the causative drug(s), supportive care, specific therapy.

## Epidermodysplasia Verruciformis

►Human Papilloma Virus

## Epidermolysis Bullosa

Silke Hofmann, Leena Bruckner-Tuderman
Department of Dermatology, University Medical Center, Freiburg, Germany

### Definition and Characteristics

Epidermolysis bullosa (EB) are a group of genetic blistering diseases of the skin, which are caused by mutations in genes encoding proteins of the dermal–epidermal adhesion complex [1]. Clinical hallmarks are trauma-induced blisters and erosions of the skin and the mucous membranes; the spectrum is broad ranging from localized forms with minor blistering after physical activity to generalized forms with a lethal outcome. The main categories comprise EB simplex, junctional EB and dystrophic EB – each with several subtypes.

### Prevalence

No accurate numbers exist on the prevalence of EB, but limited data from different countries indicate a prevalence of approximately 30–60 × $10^{-6}$ (all subgroups). The disease is found all over the world, it affects all races, and women and men equally.

### Molecular and Systemic Pathophysiology

The skin layers are held together by a highly organized multiprotein aggregate, the dermal–epidermal adhesion complex (or hemidesmosomal complex). Mutated proteins of the complex are structurally abnormal, or absent, thus rendering it functionally defective [2]. External shear forces lead to separation of the dermis and the epidermis (blistering), secondary inflammation and scarring of the skin and the mucous membranes [3]. Since the same protein complex is also expressed in certain mucous membranes, extracutaneous symptoms are seen in the eyes, oral mucosa, teeth, the GI-tract and the upper respiratory tract. The various EB forms have been classified according to the ultrastructural level of blister formation, the pattern of inheritance and the mutated genes (Table 1).

### Diagnostic Principles

Skin biopsy from the periphery of a fresh blister is required for immunofluorescence analysis of marker proteins of the dermal–epidermal junction (antigen mapping). Lack of plectin, laminin 5, collagen VII or collagen XVII indicates severe EB forms. Mutation analysis is important for genetic counselling.

### Therapeutic Principles

Symptomatic treatment consists of protection from mechanical trauma, desinfection of the wounds, support of re-epithelialization in combination with dietary measures (substitution of calories, fiber, vitamins and minerals). Contractures and strictures require surgical interventions. Gene therapy (phase I) clinical trials are ongoing.

**Epidermolysis Bullosa. Table 1** Classification of EB subtypes

| EB subgroups | Pattern of inheritance | Mutated genes | Abnormal protein |
|---|---|---|---|
| EB simplex | AD, AR[a] | KRT5, KRT 14 | Keratin 5, Keratin 14 |
| EB simplex with muscular dystrophy | AR | PLEC1 | Plectin |
| Junctional EB Herlitz | AR | LAMA3, LAMB3, LAMC2; null mutations | Laminin 5 absent |
| Junctional EB non-Herlitz | AR | COL17A1, LAMA3, LAMB3, LAMC2 | Collagen XVII, laminin 5 |
| Junctional EB with pyloric atresia | AR | ITGA6, ITGB4 | Integrin α6, integrin β4 |
| Dystrophic EB Hallopeau-Siemens | AR | COL7A1; null mutations | Collagen VII absent |
| Dystrophic EB non-Hallopeau-Siemens | AR, AD | COL7A1 | Collagen VII |

[a]AD: autosomal dominant; AR: autosomal recessive.

# Epidermolysis Bullosa Acquisita

Silke Hofmann, Leena Bruckner-Tuderman
Department of Dermatology, University Medical Center, Freiburg, Germany

## Synonyms

Acquired epidermolysis bullosa; Dermolytic pemphigoid; EBA

## Definition and Characteristics

An autoimmune subepidermal blistering disease, associated with autoreactivity against collagen VII, a component of anchoring fibrils. The classical mechanobullous presentation of epidermolysis bullosa acquisita (EBA) consists of skin fragility, noninflammatory blistering and healing with scars or milia, but inflammatory disseminated forms resembling the pemphigoid diseases have been described [1].

## Prevalence

In Western Europe the annual incidence has been estimated to be 0.25 per million. The prevalence is unclear.

## Genes

Susceptibility to develop EBA appears to be increased in Caucasians, Africans and Americans with HLA class II alleles DRB1*1501 and DR5.

## Molecular and Systemic Pathophysiology

Collagen VII represents the major component of anchoring fibrils located at the dermoepidermal junction (see Fig. 1, in ►Bullous pemphigoid). The N-terminal non-collagenous NC1-domain of collagen VII associates with matrix proteins, such as laminin-5, fibronectin and collagen VII, and therefore ensures attachment between epidermis and dermis. The major target in EBA is the NC1-domain of collagen VII, and autoantibodies against this region were shown to induce leukocytic infiltration leading to dermoepidermal disruption [2]. Furthermore, the pathogenicity of collagen VII-antibodies was demonstrated by passive transfer of patients autoantibodies into adult hairless immunocompetent mice which developed all features of EBA patients [3]. Moreover, antibodies against collagen VII are also associated with blisters in a subset of lupus erythematosus patients, therefore called bullous SLE.

## Diagnostic Principles

Subepidermal blister formation in histology, linear IgG, IgA or C3 deposits at the dermoepidermal junction in direct immunofluorescence and binding of circulating autoantibodies at the dermal side of saline-separated human skin are essential diagnostic criteria. Antibodies targeting the 290 kDa-type VII collagen can be detected by western blotting with keratinocyte extracts, dermal

extracts or ELISA using recombinant NC1-domain of collagen VII.

## Therapeutic Principles

EBA is particularly refractory to immunosuppressive treatment (oral prednisone, azathioprine, cyclophosphamide, methotrexate). Recently, a combination of immunoadsorption and rituximab has been reported to have beneficial effects [4].

**Epidermolysis Bullosa Simplex with Muscular Dystrophy. Figure 1** Protein domain structure of plectin. The tripartite structure of plectin molecules comprise a central α-helical coiled rod domain flanked by large globular N-terminal and C-terminal domains. The C-terminal domain consists of six highly homologous repeat regions. Defined subdomains for binding to integrin β4, actin (ABD) and intermediate filaments (IF-BD) as well as a unique $p34^{cdc2}$ phosphorylation site are indicated. The vast majority of *Plec* 1 mutations are clustered in exons 31 and 32, which encode the entire rod and C-terminal globular domains.

# Epidermolysis Bullosa Simplex with Muscular Dystrophy

Rolf Schröder
Department of Neurology, University of Bonn, Bonn, Germany

## Synonyms

Plectin autosomal recessive

## Definition and Characteristics

Rare autosomal recessive multisystem disorder characterized by blistering of skin and mucous membranes since birth and progressive muscular dystrophy manifesting from infancy to the fourth decade of life (Figs. 1 and 2).

Additional disease related features include brain atrophy, cataracts, urethral strictures, laryngeal webs, infantile respiratory complications and a myasthenic syndrome [1–4].

## Prevalence

Until mid-year 2003, 15 cases of genetically confirmed epidermolysis bullosa simplex with muscular dystrophy (EBS-MD) have been reported.

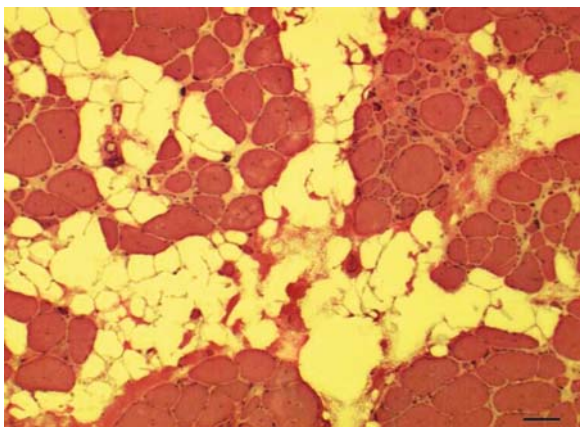
## Genes

The human plectin (PLEC 1) gene is located on chromosome 8q24 and consists of at least 42 exons including 11 alternative first coding exons. The first 30 exons encode the N-terminal globular domain, exon 31 (>3 kb) encodes the predominant part of the central

α-helical coiled rod domain and exon 32 (>6 kb) encodes the entire C-terminal globular domain [1–3].

## Molecular and Systemic Pathophysiology

The severe structural changes in skin and muscle tissue in EBS-MD patients and plectin (–/–) mice indicate that plectin, a high molecular weight cytoskeletal linker protein (530 kDa), has an essential role in cells and tissues exposed to mechanical stress [1,3,5]. Plectin is widely distributed in mammalian tissues, with highest expression in squamous stratified epithelia, muscle and brain. Apart from an actin binding domain in its amino terminal region, plectin contains a high affinity intermediate filament binding site residing in its C-terminal globular domain (Fig. 3) [3].



**Epidermolysis Bullosa Simplex with Muscular Dystrophy. Figure 2** Skin changes in a 15 months-old EBS-MD patient carrying a homozygous single guanine insertion mutation (5,588insG/5,588insG) in exon 31 of the *Plec 1* gene. Note the blisters, erosions and crusted lesions on the soles of both feet.

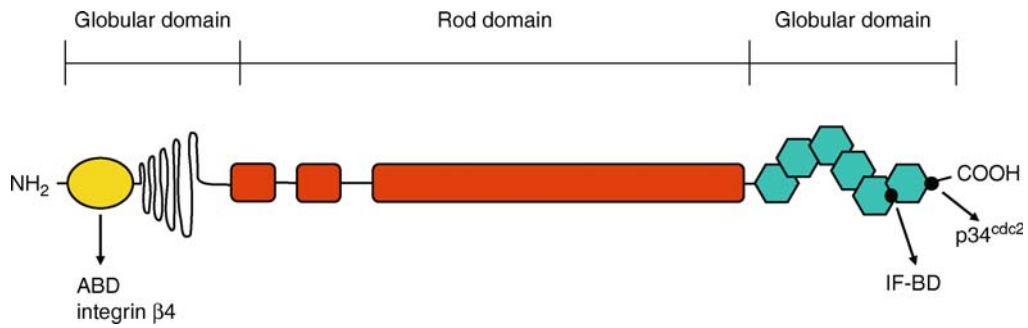
The vast majority of Plec 1 mutations are clustered in exons 31 and 32, which encode the entire rod and C-terminal globular domains. As a consequence, the plectin protein expression in EBS-MD patients is either completely abolished or a mutant, non-functional plectin protein is expressed. This in turn leads to a structural and functional disorganization of the intermediate filament cytoskeleton. While the pathological changes in the skin of EBS-MD patients seem to be the results of a faulty anchorage of cytokeratins to hemidesmosomes [1,2], the lack or expression of mutant plectin has a deleterious effect on the proper spacing, stabilization and subcellular attachment of preformed desmin filaments in striated muscle [3].

## Diagnostic Principles

Since skin blistering manifests at birth or shortly thereafter, a skin biopsy for histological, ultrastructural and antigene mapping analysis is the key diagnostic procedure to differentiate EBS-MD from other forms of hereditary epidermolytic skin diseases. The lack or abnormal plectin protein expression points towards the diagnosis of EBS-MD. Plec1 gene mutation analysis is warranted to establish the definite diagnosis of plectin-related EBS-MD.

## Therapeutic Principles

To date, no specific gene or pharmacological therapy is available. The dermatological aspect of the disease requires specific attention with regard to the prevention and treatment of blister formation in mechanically exposed skin areas. Physiotherapy is essential for those patients with beginning muscular weakness. In EBS-MD patients with severe infantile respiratory problems an early tracheostomie should be contemplated.



**Epidermolysis Bullosa Simplex with Muscular Dystrophy. Figure 3** Skeletal muscle pathology in a 25-year-olf EBS-MD carrying a homozygous 16-bp insertion mutation (13,803ins16/13,803ins16) in exon 32 of the *Plec 1* gene. Note the severe myopathic changes with marked increase of connective tissue and fat cells, fiber size variations, rounding of muscle fibers with as well as centralization and clustering of myonuclei (hematoxylin-eosin stain, bar = 50 μm).

## Synonyms

ADCME: autosomal dominant cortical myoclonus and epilepsy; BAFME: benign adult familial myoclonic epilepsy; CrtTr: cortical tremor; FAME: familial adult myoclonic epilepsy; FCMT: familial cortical myoclonic tremor; FCMTE: familial cortical myoclonic tremor with epilepsy; FCTE: familial cortical tremor with epilepsy; FEME: familial essential myoclonus and epilepsy; FMEA: amilial benign myoclonus epilepsy with adult onset; HTE: heredofamilial tremor and epilepsy

## Definition and Characteristics

The association of familial cortical tremor, myoclonus and epilepsy has been reported in several families of Japanese and European origin. Overuse of different designations and synonyms (FAME, BAFME, ADCME, FCTE, FEME, FEMEA, and HTE) may have contributed to divergent views on this syndrome. Currently, the preferred term is familial cortical myoclonic tremor with epilepsy (FCMTE) [1]. The syndrome is clinically characterized by: (i) adult-onset, irregular distal cortical myoclonus; (ii) history of generalized tonic clonic seizures (GTCSs), sometimes heralded by crescendo-like myoclonic jerks; (iii) familial occurrence. Electrophysiological studies are mandatory to confirm the diagnosis. Cortical origin of myoclonus has to be demonstrated by surface EMG recordings, jerk-locked averaging (JLA), somatosensory and flash visual evoked potentials (SEPs, VEPs), and long loop reflex I (LLRI) analysis. EEG changes are not specific. Overall, the course of the disease is rather benign and non-progressive.

## Prevalence

The prevalence is unknown. European families show ages of onset in the second and third decade, whereas in Japanese families age of onset is later. Usually seizures start later than tremor and are mostly infrequent. There is no evidence for a specific gender distribution.

## Genes

The disorder is transmitted as an autosomal dominant trait with high penetrance. A variable clinical expressivity is observed. Genetic studies mapped the disease to chromosomes 8q24 and 2p in Japanese and European families [1,2]. Exclusion of linkage to both loci in families with the identical clinical picture rises further evidence of genetic heterogeneity of this syndrome. Until today, the responsible genes are still waiting to be identified.

## Molecular and Systemic Pathophysiology

The underlying pathophysiological mechanisms remain unclear. Clinical and electrophysiological findings suggest the hypothesis of a general cortical hyperexcitability [1,2,3]. However, whether the hyperexcitability is due to enhanced rhythmic activity within the cortex or due to abnormal interactions with subcortical generators is still under discussion. Morever, loss of inhibitory cerebellar influence on cortical functions is taken into consideration [1,3]. The role of mutations in genes of ion channel subunits is well described in several monogenic epilepsy sydromes. Whether FCMTE is also a channelopathy or not, is discussed controversially [1,3,4]. Genes that are present on both chromosomes 8q24 and 2p11 or genes encoding subunits of ion channels or related structures could serve as targets for future genetic studies.

## Diagnostic Principles

Clinical and electrophysiological studies are mandatory to confirm the diagnosis of FCMTE. The clinical hallmark of the rather benign, non-progressive syndrome is the familial occurrence of cortical tremor or myoclonus, typically resembling irregular, semi-rhythmic distal jerking of the upper limbs, but the legs and face may also be affected. Emotional stress sleep deprivation and sensory stimuli may enhance the motor symptoms. Most patients experience GTCSs, which are usually not preceded by any warning. Sometimes seizures are heralded by clusters of generalized myoclonic jerks. Complex partial seizures and absences rarely occur. Seizure frequency varies from a few seizures to intractable epilepsy. In general, seizures start later than cortical myoclonus. Additional symptoms like night blindness and migraine have been reported. Patients usually show a normal cognitive function, but mild to moderate mental retardation has been described, especially in patients with poorly controlled epilepsy. Brain imaging studies are usually normal. EEG changes may range from normal background activity to generalized – or rarely focal epileptiform activities. Photomyoclonic and photoparoxysmal responses can be recorded [1–5].

The cortical origin of myoclonus has to be proven by electrophysiological studies. Surface EMG recordings reveal irregular, semi-rhythmic, high frequency (around 10/s) variable amplitude bursts lasting about 50 ms, which is consistent with cortical myoclonus. JLA discloses a typical biphasic premyoclonic potential or series of waves over the contralateral centroparietal region. SEPs exhibit enlargement of the cortical components (giant potentials) to electrical stimulation of the peripheral nerve. Moreover, also VEPs show increased amplitudes, suggesting generalized cortical hyperexcitability. LLRI is enhanced with latencies about 40–45 ms after stimulation [1–5]. Transcranial magnetic stimulation was studied in a small series of patients, indicating impaired central motor inhibitory mechanisms [2]. Interestingly, electrophysiological abnormalities have also been reported in presymptomatic patients [5]. However, it has to be pointed out, that antiepileptic drugs (AEDs) could normalize the electrophysiological findings [1].

## Therapeutic Principles

In contrast to essential tremor, cortical myoclonus does not improve with alcohol or beta blockers, but responds well to AEDs in most cases. Valproic acid, clonazepam and phenobarbital are the most commonly used effective AEDs [1,3]. Carbamazepine should be used with caution, because it may worsen myoclonus [2]. Data on the use and effectiveness of newer AEDs are lacking.

# Epilepsies, Lesion-associated Partial

Rüdiger Köhling[1], Holger Lerche[2]
[1]Institute of Physiology, University of Rostock, Rostock, Germany
[2]Neurological Clinic and Institute of Applied Physiology, University of Ulm, Zentrum Klinische Forschung, Ulm, Germany

## Synonyms

Symptomatic focal epilepsy; Symptomatic partial epilepsy

## Definition and Characteristics

Lesion-associated focal epilepsies comprise all epilepsies associated with localized aberrant brain morphology. The most common morphological alterations include cerebrovascular disease (stroke or hemorrhage), vascular and cortical malformations, head trauma, and brain tumor (endogenous or metastatic). Other common underlying reasons for partial epilepsy are cortical malformations including tuberous sclerosis, which are dealt with specifically in chapters and not further regarded here. Depending on the localization and extent of the lesion, symptoms can include, e.g., simple partial motor, sensory seizures (without loss of consciousness) or psychomotor, and other complex partial seizures

(with loss of consciousness). Commonly, seizures can secondarily generalize into tonic-clonic seizures.

## Prevalence

The risk to develop epilepsy after stroke within 5 years is 11%, with a standardized morbidity ratio (SMR: the ratio of the incidences of epilepsy in stroke patients and in the general population) of 5.9. Vascular malformations carry a risk of 7–40% to develop seizures, head trauma 2.1%, 4.2%, and 16.7% (cumulative risk, 30-year observation, mild, moderate, and severe injuries, respectively). Brain neoplasm will cause seizures in 15–95% of patients, depending on tumor type (low-grade glioma, 60–95%; meningeoma, 40%; lymphoma and malignant glioma, 17–25%). Of all epilepsies, 9% are of vascular, 4.6% of traumatic, and 5.8% of neoplastic etiology [1].

## Genes

No genes are known that predispose specifically to vascular, traumatic, or tumor-induced epilepsy. For genes that have been described to be associated with one of the underlying diseases, such as stroke or brain tumors, please refer to the respective chapters.

## Molecular and Systemic Pathophysiology

As symptomatic focal epilepsies are caused by lesions that usually develop over time, or are inflicted externally (in case of traumatic injuries), the molecular mechanisms responsible for epileptogenesis are thought to be epigenetic, i.e., to evolve from secondary changes, such as apoptosis, alterations of expression patterns of ion channels and transporters, etc., which in turn modify intrinsic cellular excitability or synaptic function.

*Ischemic Stroke*: As epileptogenic factors, a selective loss of parvalbumin-positive GABAergic interneurones and consecutive loss of inhibition with a relative increase in excitation are discussed. Further, increased axonal sprouting and recurrent excitation have been observed, and an increase in blood–brain barrier (BBB) permeability promotes neuronal excitability [2]. The latter mechanism is an intriguing one, as it applies to many pathological conditions: extravasal albumin is taken up TGFβ dependently into astrocytes and leads to a downregulation of inwardly rectifying potassium channels ($K_{IR}$). This reduces glial spatial buffering capacities leading to neuronal hyperexcitability and bursting [3]. The latter mechanism could also explain epileptogenesis after *hemorrhagic stroke*.

*Brain Trauma*: Besides breaching of the BBB (see above) as one pathomechanism, an upregulation of glutamatergic synapses, resulting in increased recurrent excitation, and functional receptor changes, resulting in increased excitatory currents, have been confirmed in undercutting experiments. Complementary to this, neuronal chloride buffering capacities are reduced due to a loss of function of the potassium-chloride co-transporter KCC2. This is likely to result in a reduced chloride driving force making GABAergic inhibition less effective.

*Brain Tumors*: In glioma models, glutamate release by glioma cells is increased due to a loss of the excitatory amino acid carrier 1 (EAAC1), which results in degeneration of neurones adjacent to the tumor, presumably via excitotoxic activation of glutamate receptors. This neuronal degeneration is thought to be crucial for tumor growth; spill-over of glutamate in addition might trigger hyperexcitability and seizures [4]. Furthermore, intrinsic excitability of neurones in the paratumoral surround is increased, inducing burst firing [5]. An additional mechanism again is speculated to rest on BBB disruption (see above). Other observations (up- and downregulations of various transmitter receptors, malignant glial cells acquiring neuronal properties, pH changes) are inconclusive.

## Diagnostic Principles

The epilepsy will be diagnosed according to standard clinical procedures including history with a detailed description of the seizure semiology, electroencephalography (EEG), and high-resolution magnetic resonance imaging (MRI) of the brain. When epilepsy surgery is considered to be due to pharmacoresistance, a detailed presurgical work-up is required with video-EEG monitoring, neuropsychological examination, and sometimes further imaging techniques, such as positron emission tomography (PET) or single photon emission computed tomography (SPECT). The goal is to determine if the lesion can be considered as the underlying reason for the epilepsy by correlating the clinical symptoms, i.e., the seizure semiology as analyzed in the video and by history, which point to the symptomatic brain area, with the localization of epilepsy typical potentials in the EEG and of the lesion detected by MRI. When the lesion is close to eloquent brain areas or when presurgical diagnostics with surface electrodes is inconclusive, invasive recordings with intracranially implanted electrodes should be considered as a second step.

## Therapeutic Principles

General principles for the treatment of partial epilepsies apply [1]. Treatment should start with an antiepileptic drug (AED) of first choice in monotherapy, such as (in alphabetical order) carbamazepine, gabapentine, lamotrigne, levetirazetam, oxcarbazepine, topiramate, or valproate, according to several guidelines. Side effects should be taken into account individually. If the first AED fails, a second overlapping medication can be started with the goal of either monotherapy or a combination of both drugs. Subsequently, other drugs

should be tried and those without a therapeutic effect discontinued. However, if two standard medications in an appropriate dosage fail, epilepsy surgery should be considered and the patient referred to an epilepsy center.

Specific aspects of associated lesions should be taken into account. For example, with brain tumors requiring chemotherapy, cytochrome P (CYP) enzyme-inducing antiepileptic drugs (AEDs) (e.g., carbamazepine or phenytoin) should be avoided, as they will reduce concentrations of chemotherapeutic anticancer agents. Valproate is discussed to increase the risk of bleeding, although statistical evidence is lacking. At the same time, it is a CYP inhibitor, and may be beneficial as it blocks histone deacetylase, and hence may help to arrest cell division and tumor growth. CYP inducing drugs should also be avoided when other medications could be influenced, such as cumarines in stroke patients.

# Epilepsies of Adulthood, Idiopathic Focal

Fabienne Picard
Department of Neurology, University Hospital of Geneva, Geneva, Switzerland

## Definition and Characteristics

Three main syndromes of familial idiopathic focal epilepsy of adulthood, following an autosomal dominant mode of inheritance, were individualized around 10 years ago. (i) Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) consists of nocturnal hypermotor seizures including either a hyperkinetic activity with frantic movements of bipedal activity, pelvic thrashing or a tonic activity or sudden and abrupt, rapidly changing dystonic postures (therefore misdiagnosed as "paroxysmal nocturnal dystonia"). Seizures may begin with a non-specific aura. Most patients remain conscious throughout the seizures. Postictal symptoms are absent or very brief. Secondarily generalized seizures are infrequent. Seizures occur frequently in clusters, with a mean of eight seizures per night. Age at onset varies but is typically during late childhood. The phenotypic expression spans from only a mild intermittent sleep disruption, often not recognized as an epileptic manifestation by the affected individuals or proxies, to a persistent, severe disability. (ii) Autosomal dominant partial epilepsy with auditory features (ADPEAF) or autosomal dominant lateral temporal epilepsy (ADLTE) is a benign syndrome with onset in the first to third decade of life (typically late adolescence) and no association with febrile seizures. The most frequent ictal symptoms correspond to auditory hallucinations such as ringing or humming, but some patients present other symptoms, alone or in association, such as visual hallucinations, olfactory symptoms or aphasic seizures. (iii) Pedigrees with familial partial epilepsy with variable foci (FPEVF) contain several members with a focal epilepsy, but without any consistency of lobar location among family members. However, the seizure semiology is constant for each individual. Onset is in the first to third decade of life.

In these three syndromes, the epilepsy may persist throughout adult life. The severity of the epilepsy may vary greatly within a family.

## Prevalence

More than one hundred ADNFLE families have been reported in literature (sporadic NFLE cases are much more numerous); several dozen ADLTE families; one dozen FPEVF families.

## Genes

*ADNFLE*: missense mutations and one small insertion in CHRNA4 (20q13.3) encoding the α4 subunit of the nicotinic acetylcholine receptor (nAChR) or missense mutations in CHRNB2 (1q21.3) encoding the β2 subunit of the nAChR. All identified ADNFLE mutations are located within the transmembrane segments contributing to the ionic pore of the receptor.
*ADLTE*: truncating and missense mutations in the LGI1 (leucine-rich glioma inactivated gene 1)/epitempin gene (10q24).
*FPEVF*: linkage to chromosome 22q11-q12, but no gene identified yet.

## Molecular and Systemic Pathophysiology

The nAChR α4 and β2 subunits, which are mutated in ADNFLE, are known to assemble, classically in a 2α3β

ratio, and form the main brain nAChR subtype in humans. Most of these receptors are located presynaptically and modulate the release of various neurotransmitters. They are present throughout the brain. In vitro electrophysiological studies of the mutant nAChRs showed for all mutations a significant increase in their sensitivity to acetylcholine (ACh), i.e. a gain of function [1]. Thalamic neurons under cholinergic control, which are part of thalamocortical loops playing a crucial role in rhythmic activities during sleep and including predominantly the frontal lobe, could be responsible for the pathophysiology [2]. Knock-in mice expressing hypersensitive mutant alpha4 nicotinic receptors were shown to be more sensitive to seizures elicited by nicotine, with seizures resembling ADNFLE. In addition, nicotine pre-treatment prevented these seizures, probably by desensitizing the receptors and thus counteracting the increased sensitivity of mutant receptors [3]. Mutations have been found in only around 10% of the ADNFLE families to date. No obvious clinical elements seem to differentiate mutation-positive from mutation-negative families.

Although the Lgi1 protein, affected in ADLTE, is not an ion channel subunit, it has very recently been shown to associate with the potassium channel Kv1.1 [4]. Lgi1 protein normally prevents inactivation of Kv1.1 by the Kvβ1 subunit. The mutant protein fails to exert this effect (loss of function), resulting in channels with rapid inactivation kinetics. By enhancing the inactivation of Kv1.1 channels, it allows a broadening of action potentials during repetitive neuronal firing and this may promote epileptic activity. Mutations have been found in half of the reported ADLTE families to date [5].

## Diagnostic Principles

The pedigrees suggest an autosomal dominant mode of inheritance. The epilepsy is non lesional, implying a normal neurological examination and a normal cerebral MRI. (An exception was the report of MRI abnormalities in the lateral cortex of the temporal lobe in one ADLTE family). The diagnosis of these syndromes is essentially clinical. In ADNFLE, nocturnal video-electroencephalogram monitoring helps by demonstrating (i) stereotyped episodes, (ii) dyskinetic or dystonic motor elements and (iii) usually numerous seizures per night during non-rapid eye movement sleep. In ADLTE, the seizure semiology has to indicate clearly a lateral temporal lobe onset in each affected member. Lastly, in FPEVF, the seizure semiology suggests a partial epilepsy of different lobar location in the different affected family members.

In all these syndromes, the interictal scalp EEG may be normal or show only mild focal abnormalities. In ADNFLE, even ictal scalp EEGs, often obscured by movement artifacts, may fail to show ictal epileptic discharges.

## Therapeutic Principles

*ADNFLE*: Carbamazepine completely suppresses seizures in about 70% of patients treated. Low dosages, around 600 mg/day in adults, are usually sufficient. Patients who are resistant to carbamazepine usually show little response to any other subsequent antiepileptic drug. Transdermal nicotine was reported to be of some help in two pharmacoresistant patients, but this treatment option needs to be further explored. Spontaneous remissions may occur, even in patients who were previously pharmacoresistant.

*ADLTE and FPEVF*: Classical antiepileptic drugs for focal epilepsies are usually effective (carbamazepine being a good choice). A good response is observed in more than 90% and 85% of the patients for ADLTE and FPEVF respectively.

# Epilepsy, Benign Childhood with Centrotemporal Spikes and other Idiopathic Partial Epilepsies of Childhood

Andreas Hahn, Bernd A. Neubauer
Department of Pediatric Neurology, Children's Medical Center, University of Giessen and Marburg, Giessen, Germany

## Definition and Characteristics

1. BECTS or rolandic epilepsy is defined by brief, simple, partial, hemifacial motor seizures, which frequently have associated somatosensory symptoms. These partial seizures have a tendency to evolve into generalized tonic–clonic seizures. Both seizure types are often related to sleep. Onset shows a peak at 6–9 years; recovery occurs before the age of

15–16 years. Characteristic features are described as follows. (i) A somatosensory onset with unilateral paresthesias involving the tongue, lips, gums and inner cheeks and (ii) unilateral, tonic, clonic or tonic–clonic convulsions involving the face, lips and tongue as well as the pharyngeal and laryngeal muscles, causing (iii) speech arrest and drooling due to sialorrhea and saliva pooling. At this stage, the seizure may end, or it may develop into a generalized major convulsion. Nocturnal seizures, the most frequent variant of this syndrome, often become generalized. The electroencephalographic hallmarks of BECTS are blunt high-voltage characteristically shaped centrotemporal spikes, often followed by slow waves. The epilepsy resolves spontaneously after 2–3 years in most cases and leaves the children unimpaired. It can be estimated that about 30% of the affected patients have only a single seizure.

2. In benign epilepsy of childhood with occipital paroxysms two subtypes exist. As a rule, children have an unremarkable development, a normal neurological status and a good prognosis. MRI is unrevealing.

Early onset benign occipital epilepsy (Panayiotopoulos syndrome) has its peak onset at 5 years. Seizures are infrequent, often single and mostly nocturnal. They usually start with a feeling of nausea, vomiting and eye deviation and later progress to unilateral or generalized convulsions. Autonomic symptoms are frequently pronounced. Seizures remit spontaneously after 1–2 years. EEG findings are strikingly variable and frequently show occipital spike complexes resembling those found in rolandic epilepsy. However, ictal EEG may show even frontal onset.

Late onset benign occipital epilepsy (Gastaut type) starts at 3–16 with a peak occurrence at 8 years. Visual hallucinations (phosphenes, colored discs etc.) sometimes followed by amaurosis and hemisensory phenomena are characteristic. Hemiclonic or generalized convulsion may follow. Postictal headache is common. Seizure frequency is high. EEG findings mostly consist of occipital bilateral spike wave paroxysms. Ictal recordings frequently show lateralized seizure onset.

3. CSWS (continuous spikes and waves during slow sleep) and ESES (electrical status epilepticus during slow sleep) may be regarded as synonymous. The majority of the affected patients also have epilepsy. Partial or generalized seizures, mostly occurring during sleep and atypical absences when awake are characteristic. EEG and seizures frequently take a benign course, but prognosis is guarded, because persistent neuropsychological and motor impairment is a sequel affecting more than 50%. Onset may occur from 2 months to 12 years. About 30–50% of affected children have identifiable brain pathology (e.g. perisylvian polymicrogyria). VP-shunts seem to pose a specific risk. Landau-Kleffner syndrome may be considered a specific course sequence of CSWS or ESES, with an "acquired epileptic aphasia" as its clinical hallmark. However, by definition there is no demonstrable brain pathology. All other features may be indistinguishable from CSWS/ESES.

## Prevalence

Rolandic epilepsy accounts for roughly 15% of all childhood epilepsies and has a prevalence of about 1/1,000.

Benign epilepsy of childhood with occipital paroxysms (Panayiotopoulos syndrome) represents about 5% of childhood epilepsy syndromes. The estimated prevalence is 1/3,000.

Benign epilepsy of childhood with occipital paroxysms (Gastaut type) represents about 1–2% of childhood epilepsy syndromes. Its estimated prevalence is 1/10,000.

CSWS/ESES and Landau-Kleffner syndrome are rare, however altogether many more than a hundred cases have been reported.

## Molecular and Systemic Pathophysiology

Rolandic epilepsy is considered an idiopathic (i.e. genetic) epilepsy syndrome. However, it has been known for a long time that the risk of siblings developing rolandic epilepsy themselves is negligible. In contrast, the epilepsy-associated EEG trait (i.e. "centrotemporal spikes"), which is invariably present in all cases with rolandic epilepsy and only in about 2% of controls, has a strong genetic component, as documented in several family studies [1]. It most probably follows a complex mode of inheritance. One possible locus for this trait resides on chromosome 15q14 as determined by linkage analysis [2]. But no gene has been identified up to now. Recently, in an international twin register analysis of 18 twin pairs (10 monozygous, eight dizygous) all were discordant for rolandic epilepsy, suggesting that non-inherited factors may play a role in this epilepsy syndrome [3]. The epilepsy associated EEG-trait is not very "epileptogenic", as only about 1/10 affected individuals show seizures. Seizure types found in sib pairs with familial centrotemporal spikes, ascertained by an index case affected with rolandic epilepsy, are variable. The majority of siblings having seizures suffer from generalized tonic–clonic seizures and febrile convulsions [1]. Cases with a more severe course ("atypical benign partial epilepsy of childhood") show a stronger genetic component than does rolandic epilepsy, as up to 40% of siblings reveal the EEG trait [4]. In siblings of children with pure rolandic epilepsy the corresponding number is only 10–15% [1].

Epilepsy of childhood with occipital paroxysms and early onset (Panayiotopoulos syndrome) and epilepsy of childhood with occipital paroxysms with late onset (Gastaut type) are also perceived as idiopathic epilepsy syndromes, implying that besides the epilepsy itself, patients show no additional neurological abnormalities and the disorder is most probably of genetic origin. However, family history in both syndromes is usually negative. Only exceptionally, are other family members affected. Siblings may show centrotemporal spikes as characteristic for rolandic epilepsy [5]. Larger family studies that include EEG recordings of the siblings are lacking. No genetic marker is available.

CSWS and ESES are symptomatic electroclinical syndromes in a significant proportion of cases (>50%?). To a large extent, the remaining portion should be considered cryptogenic, meaning that a symptomatic etiology should be suspected even though it may not always be demonstrable. Landau-Kleffner syndrome is by definition idiopathic, i.e. symptomatic cases are excluded from the diagnosis. In all three syndromes however, a certain portion of cases exists that are truly idiopathic. For practical reasons these cases will only be identifiable retrospectively (normal MRI, spontaneous remission, benign outcome etc.). These cases show major similarities and can overlap with rolandic epilepsy. One view is that they represent a spectrum with rolandic epilepsy forming the benign, common and CSWS/ESES and Landau-Kleffner syndrome representing the severe, less common ends respectively.

## Diagnostic Principles

Each reported disorder represents a specific electroclinical entity that is diagnosed in the context of etiology, seizure symptomatology and EEG findings according to criteria set by the international classification.

## Therapeutic Principles

Rolandic epilepsy will only require treatment in cases with high seizure frequency. The drug of choice is sulthiame (a carbonic anhydrase inhibitor) or gabapentin (a synthetic GABA analogue). Benign epilepsy of childhood with occipital paroxysms may be treated with carbamazepine (a blocker of voltage-dependant $Na^+$ channels) or sulthiame. Treatment of these three syndromes does not usually represent a major challenge. In contrast CSWS/ESES, and Landau-Kleffner syndrome are, as a rule, extremely difficult to treat and no concise treatment algorithm is established. Valproic acid (a blocker of voltage-dependant $Na^+$ and T-type $Ca^{2+}$ channels with additional GABA-ergic properties), benzodiazepines (GABA-ergic), ethosuximide (a T-type $Ca^{2+}$ channel blocker) or even corticosteroids are frequently used.

## Synonyms

IGE

## Definition and Characteristics

The four classical subtypes of IGE are (i) childhood absence epilepsy (CAE) or pyknolepsy, (ii) juvenile absence epilepsy (JAE), (iii) juvenile myoclonic epilepsy (JME) or impulsive petit mal or Janz syndrome, and (iv) epilepsy with generalized tonic-clonic seizures (grand mal) on awakening (EGMA). These syndromes are defined by distinct clinical features and characteristic epilepsy-typical potentials in the electroencephalogram (EEG) without structural brain lesions and with normal development. Absence seizures in CAE manifest from the fourth to the tenth year of life. The short losses of consciousness with behavioural arrest last about 10 s and occur in clusters

of up to 100 seizures per day. The ictal EEG shows 3–4 Hz generalized spike and wave discharges. JAE manifests around puberty. Absences occur at a lower frequency and not in clusters. Generalized myoclonic seizures on awakening with bilateral myoclonic jerks of arms and shoulders and preserved consciousness are the hallmark of JME starting in puberty. The EEG shows generalized polyspikes. About 10% of patients with IGE present with febrile convulsions, preceding the onset of absences or of myoclonic jerks. Generalized tonic-clonic seizures on awakening can develop in all three forms in adolescence, most frequently in JME. If these seizures develop without preceding absence or myoclonic seizures, the syndrome is called EGMA. Seizures in JME and EGMA are often provoked by sleep deprivation and alcohol. The different IGE subtypes can overlap between individual patients and families, with CAE/JAE and JME/EGMA being most closely associated. The concordance rate in twins is up to 95%. The risk for a first-degree relative to develop any IGE syndrome is 5–8% [1].

## Prevalence

IGE has a prevalence of roughly 0.4% in the general population. CAE and JME are most common [1].

## Genes

The inheritance of IGE is polygenic probably involving at least several genes in most cases. Genetic defects have been identified in a few patients or families as follows.

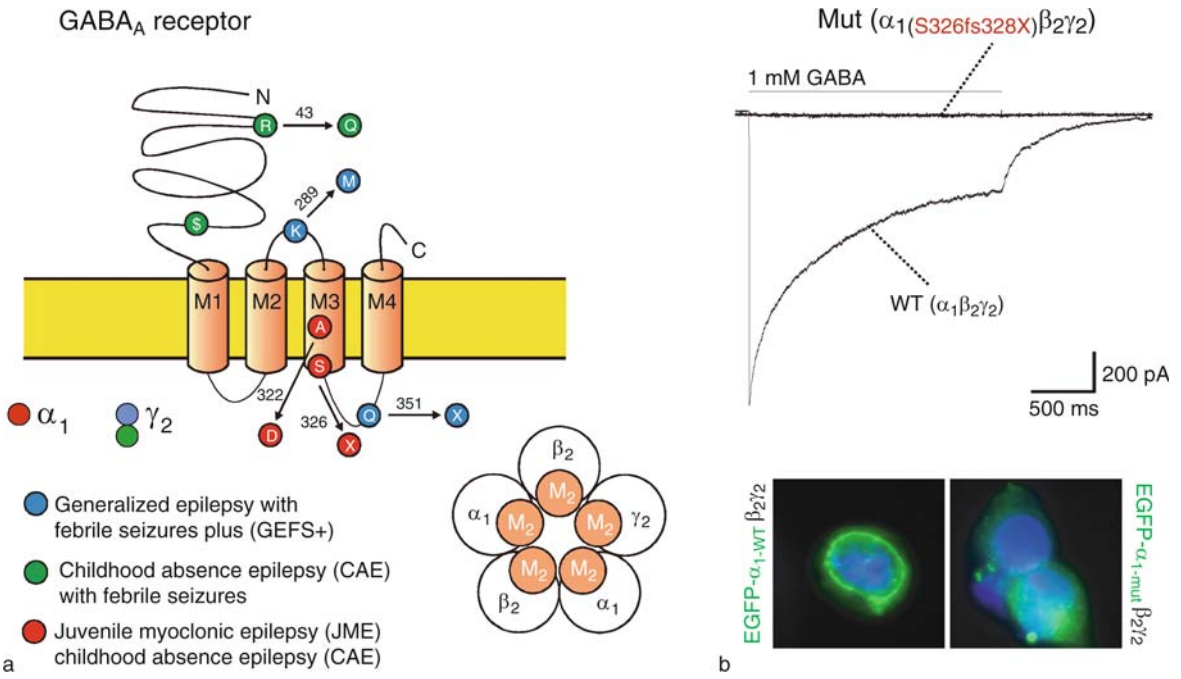
## Molecular and Systemic Pathophysiology

As shown in the Table 1, an increasing number of mutations associated with IGE syndromes were identified in genes encoding subunits of voltage- or ligand-gated ion channels. These encouraging results provide a plausible pathophysiological concept, since ion channels form the basis for neuronal excitability and are the major targets for anticonvulsive pharmacotherapy. Functional electrophysiological studies characterizing the molecular defects of the mutant channels in heterologous expression systems in vitro point to an important role of GABAergic synaptic inhibition in the pathophysiology of IGE. The mutations in GABRG2 and GABRA1 clearly lead to a more or less complete loss-of-function of the respective receptors (Fig. 1) so that only half of the receptors should be available in a heterozygous condition.

This should reduce GABAergic transmission, which could well explain the generation of seizures. Furthermore, mutations in CLCN2 should indirectly affect GABAergic inhibition, since ClC-2 is one of the proteins responsible for the neuronal transmembrane $Cl^-$ gradient that is necessary for an inhibitory GABA response. On a systemic level, it is well established that thalamocortical loops play a major role for the generation of synchronized rhythmic discharges as observed in generalized seizures [2]. GABAergic inhibition in the nucleus reticularis thalami (NRT), in which $GABA_A$ receptors and ClC-2 are expressed, might link these molecular and systemic pathophysiological observations. Some of the variants in CACNA1H (T-type $Ca^{2+}$ channel) found in Chinese CAE patients increase channel activity, which could enhance burst firing in thalamic neurons involving the same neuronal circuits. The mutations/variants described in CACNA1A and CACNB4 are allelic to some mouse models of absence epilepsy with ataxia and could also involve T-type channels by compensatory mechanisms.

**Epilepsy, Idiopathic Generalized. Table 1** Overview of genes and loci that have been associated with IEG

| Gene | Locus | Protein | Diseases | MIM # |
|---|---|---|---|---|
| GABRG2 | 5q31–33 | $GABA_A$ receptor $\gamma_2$-subunit | CAE with febrile or other seizures | 607681, 137164 |
| GABRA1 | 5q34–35 | $GABA_A$ receptor $\alpha_1$-subunit | JME, CAE | 606904, 137160 |
| CLCN2 | 3q26 | ClC-2 voltage-gated $Cl^-$ channel | CAE, JAE, JME, EGMA | 607682, 607631, 600570 |
| EFHC1 | 6p11–12 | Myoclonin1 | JME | 254770, 608815 |
| CACNA1H | 16p13.3 | T-type $Ca^{2+}$ channel $\alpha_{1H}$-subunit | CAE | 607904 |
| CACNB4 | 2q22–23 | $Ca^{2+}$ channel $\beta_4$-subunit | JME, JAE | 606904, 601949 |
| CACNA1A | 19p13 | P/Q-type $Ca^{2+}$ channel $\alpha_{1A}$-subunit | CAE with ataxia | 601011 |
| – | 6p21, 8q24, 9q32–33, 10q25–26, 14q23, 15q14, 18q21 | – | IGE, CAE, JME | 600669, 600131, 606904 |



**Epilepsy, Idiopathic Generalized. Figure 1** GABA$_A$ receptor mutations in IGE (and GEFS+). (a) Proposed transmembrane structure of the GABA$_A$ receptor including the mutations identified up to now. The GABA$_A$ receptor is a pentamer and its most abundant form in the brain contains homologous $\alpha_1$-, $\beta_2$-, and $\gamma_2$-subunits. (b) The S326fs328X mutation of the GABA$_A$ receptor $\alpha_1$-subunit abolishes the GABA-induced $Cl^-$ current (top) by impairing the surface expression of the GABA$_A$ receptor harboring the S326fs328X mutant ($\alpha_1$-mut) subunit (bottom) in transfected mammalian (HEK293) cells (modified after [5]). $: splice site mutation.

How the other mutations, variants and loci mentioned in the Table could promote epileptic seizures is less well understood. Myoclonin1 was described to interact with synaptic R-type $Ca^{2+}$ channels [4]. Genetic association studies revealed polymorphisms possibly related to IGE in CACNA1A, in BRD2/RING3 on 6p21 encoding a nuclear transcription factor (MIM 601540), and in ME2 on 18q21 encoding malic enzyme 2 which could be involved in GABA synthesis (MIM 154270). See [1–4] for other references and further reading.

## Diagnostic Principles

The diagnosis is based on the characteristic descriptions of the seizures by the affected person themselves and their relatives and on the typical EEG abnormalities, as described above.

## Therapeutic Principles

The treatment of choice is with one of the orally taken anticonvulsant drugs, valproate, ethosuximide (good for absences but less good for other seizure types), lamotrigine (can aggravate seizures, in particular in JME), topiramate, levetiracetam and zonisamide. Three of these drugs, valproate, ethosuximide and zonisamide block T-type $Ca^{2+}$ channels (see pathophysiology). About 90% of all patients become seizure-free with one of these drugs or a combination without having side effects. Due to their worse side effect profile, phenobarbital and primidone should only be given if the other drugs fail. All other known anticonvulsants, in particular carbamazepine, should not be given, due to frequently observed seizure aggravation.

## Synonyms

Limbic epilepsy; Epilepsy with mesial temporal lobe sclerosis; Temporal lobe epilepsy with hippocampal sclerosis (HS)/Ammon's horn sclerosis; MTLE

## Definition and Characteristics

The hallmarks of mesial temporal lobe epilepsy (MTLE) are typical simple partial (aura) and complex partial (with a loss of consciousness) seizures, which can develop into secondary generalized tonic–clonic seizures. The first habitual seizures usually occur in late childhood or early adolescence. The most common aura is described by the patients as a rising epigastric sensation (epigastric aura), others include emotional disturbances such as fear, autonomic symptoms, olfactory or gustatory sensations. Auras typically occur in isolation and can precede complex partial seizures. The latter commonly begins with a motionless stare and oroalimentary automatisms (e.g., lip smacking, chewing), during which the patient may be unresponsive. Gestural and reactive automatisms of the limbs or sometimes the whole body are also common. Dystonia of one extremity is usually contralateral to the side of ictal onset. Seizures typically last for 1–2 min. The neurological examination is usually normal. Most patients have deficits in episodic memory. Verbal memory is mostly affected with left MTLE, whereas visuo-spatial memory more with right MTLE. The interictal electroencephalogram (EEG) of patients with MTLE typically shows unilateral or bilateral independent mesial temporal spikes, best seen with basal (sphenoidal, inferior temporal) derivations. Ictal EEG patterns commonly consist of rhythmic 5 to 7-Hz discharges seen in the mesial temporal region of the side of onset. High-resolution MRI often demonstrates unilateral and sometimes bilateral hippocampal atrophy associated with an hypertintense T2 signal in one or both hippocampi, which is highly specific for HS. Most patients are sporadic, but familial aggregation can sometimes be observed [1].

## Prevalence

About 40% of all epilepsies, the prevalence of epilepsy being 0.5–1% of the world's population.

## Molecular and Systemic Pathophysiology

Structural correlates of MTLE include HS, glial tumors, vascular malformations, and neurodevelopmental lesions. Gliotic lesions due to trauma or infections can also give rise to MTLE. HS is the major neuropathological substrate in patients with MTLE, and it is present in 60–70% of patients with MTLE who undergo surgery for treatment of medically refractory seizures. HS most likely has different causes and results from complex interactions among genetic and environmental factors. Histopathological hallmarks include segmental loss of pyramidal neurons, granule cell dispersion, reactive gliosis, and axonal sprouting of surviving neurons. The pathogenetic mechanisms underlying the development of MTLE remain undetermined. Hypotheses that have been put forward hold that developmental malformations or precipitating events in early development, such as febrile seizures, may initiate a lasting and progressive change that leads to a propensity of the hippocampus to generate seizures in later life. Animal models of febrile seizures suggest that, indeed, early life febrile seizures cause lasting changes in the excitability of hippocampal neurons that rely on lasting changes in certain ion channel species expressed in their cell membrane [2,3].

Apart from the process of epileptogenesis, a larger number of studies have focused on the mechanisms underlying seizure generation in chronic stages of epilepsy. Such studies have in some cases been undertaken in parallel on human tissue obtained during surgery from MTLE patients and animal models of MTLE. They have yielded a plethora of changes, some of which are likely pathogenetically relevant. Changes in neurons can be categorized into changes on the level of synaptic communication between neurons and changes in their intrinsic excitability. Synaptic changes include changes in the expression and subunit composition of postsynaptic neurotransmitter receptors, changes in the frequency-dependent properties of synapses and their ability to display long-term changes in synaptic strength. The GABAergic system has been at the center of attention with regard to synaptic

changes. Changes in GABAergic neurotransmission appear to be region specific, including loss of certain subtypes of GABAergic interneurons, change in subunit composition of GABA receptors that lead to enhanced susceptibility to block extracellular $Zn^{2+}$ that is released during neuronal activity, and the emergence of depolarizing GABA responses due to changes in the chloride gradient. Changes in the GABAergic system are complex, and cannot easily be summarized as an altered balance between excitation and inhibition. Nevertheless, many of the reported changes in GABAergic function may contribute to hyperexcitability. In addition to synaptic changes, multiple changes in the intrinsic properties of hippocampal neurons occur. Intrinsic changes have been shown to be caused by transcriptional and posttranslational changes in ion channels. The resultant changes in properties of specific ion channels lead to changes in the intrinsic membrane properties of neurons that in turn alter how synaptic input is integrated and converted to an output signal. In addition to neurons, increasing evidence suggests that properties of glial cells are profoundly altered in MTLE. For instance, astroglial cells may lose part of their capability to regulate extracellular potassium levels. Immune cells may also play a role in some MTLE syndromes.

### Diagnostic Principles

The diagnosis is based on history by the patient and by persons who have observed seizures, on the EEG and on high-resolution MRI. For epilepsy surgery, simultaneous Video-EEG monitoring with recording of seizures is necessary, and it is sometimes also useful to confirm the diagnosis. Additional diagnostic procedures include neuropsychological investigation and more imaging techniques such as interictal glucose positron emission tomography (FDG-PET), which can show a hypometabolism of the affected temporal lobe.

### Therapeutic Principles

Treatment starts with a first-line antiepileptic drug in monotherapy, the dose of which is increased until seizure freedom or the occurrence of side effects such as tiredness, dizziness, diplopia, or gait disturbance. There is no data available to show superiority of one antiepileptic drug over another, so that those drugs with lesser side effects should be preferred. When monotherapy fails, combinations can be useful, but interactions and side effects should be considered and monitored carefully. Seizures are often refractory to pharmacological treatment in MTLE [4], that is, when at least two standard medications in an appropriate dosage fail. In this case, patients should be referred to an epilepsy center and epilepsy surgery should be considered, since with a long duration of uncontrolled seizures, increasing memory problems and other behavioral disturbances are reported. Patients with MTLE and unilateral HS are excellent candidates for surgical treatment, with a 60–80% chance to become free of disabling seizures [5].

# Episodic Ataxia Type 1 and Type 2

Tracey D. Graves, Michael G. Hanna
Centre for Neuromuscular Disease, National Hospital for Neurology and Neurosurgery, Department of Molecular Neuroscience, Institute of Neurology, London, UK

## Synonyms

Familial periodic ataxia; Periodic vestibulocerebellar ataxia; Acetazolamide-responsive episodic ataxia; EA1; EA2

## Definition and Characteristics

These two autosomal dominant types of paroxysmal ataxia are distinguished by attack duration and associated clinical features. EA1 attacks are brief and frequent whereas those in EA2 are prolonged (maybe up to several days) and much less frequent. Patients with EA1 have neuromyotonia in between attacks, whereas EA2 patients have interictal nystagmus. Patients with EA2 often have migraine. Independent of attack frequency, or severity, patients with EA2 may develop a progressive cerebellar ataxia. There is an increased risk of epilepsy in both EA1 and EA2. Certain triggers may be identified by individuals (see Table 1).

## Prevalence

This is estimated to be approximately 1:200,000 in EA2 and 1:1,000,000 in EA1.

## Genes

*EA1*: point mutations in KCNA1 (12p13) encoding Kv1.1, a delayed-rectifier voltage-gated potassium channel. 16 mutations have been reported to date, all apart from one lead to amino acid substitutions.

*EA2*: point mutations and small insertions/deletions in CACNA1A (19p13), encoding Cav2.1, the presynaptic voltage-gated P/Q-type calcium channel. There have been 52 mutations reported, which are spread throughout the gene.

## Molecular and Systemic Pathophysiology

EA1 is caused by point mutations in KCNA1. This potassium channel is located in the CNS and at Nodes of Ranvier in the PNS and is involved in depolarization of neurons following depolarization. Mutations are located throughout the gene, although there is one residue where multiple mutations have been found (T226). Mutant channels show loss of function in addition to some which show a dominant negative effect on wild-type channel function. Some mutations cause reduced trafficking of the channel to the cell membrane.

EA2 is caused by mutations in the P/Q-type calcium channel, Cav2.1. This is a presynaptic protein present in both the CNS and PNS. It provides the calcium influx required for neurotransmitter release. Mutations are spread throughout the gene and are usually distinct between families. When heterogeneously expressed, these channels show loss of function and a variable dominant negative effect on wild type channel function. Some mutant subunits are retained in the endoplasmic reticulum and therefore are unable to support calcium currents.

## Diagnostic Principles

Diagnosis is based on a thorough clinical history and examination findings. Witness accounts and video recordings of attacks are very helpful. Key features include length of attack, precipitants, response

**Episodic Ataxia Type 1 and Type 2. Table 1** Clinical features of EA1 and EA2

| | Episodic ataxia type 1 | Episodic ataxia type 2 |
|---|---|---|
| Age of onset | Early childhood | Before age 20 |
| Features of attacks | Ataxia | Ataxia, truncal instability which may persist between attacks, dysarthria, nystagmus |
| | Dizziness often without vertigo | May be associated with vertigo, nausea, vomiting and headache. Weakness may occur during spells and can precede onset of episodic ataxia |
| | Visual blurring | |
| | No nystagmus | |
| Precipitating factors | Abrupt postural change, emotion, startle, vestibular stimulation, intercurrent infection | Physical or emotional stress e.g. intercurrent infection |
| Duration | Minutes | 30 min to h/days |
| Frequency | Many per day | Not usually more than one per day |

to medication and associated features (see Table 1). Clinical examination should reveal myokymia in EA1 patients. This is a reflection of continuous peripheral nerve hyperexcitability, most easily demonstrated around the eyes as twitching and in the fingers, as small amplitude side to side movements. Patients may develop contractures due to continuous muscle activity. An EMG should reveal myokymia. EA2 patients will usually have interictal nystagmus, classically in the downbeat direction. They may also develop interictal cerebellar signs related to disease duration. MRI in EA2 cases often shows cerebellar atrophy. A family history compatible with autosomal dominant transmission provides supportive evidence, however, the absence of a positive family history does not exclude the diagnosis, as new mutations occur and there is reduced penetrance in some pedigrees. CACNA1A is a large gene and as there are no mutation hotspots, mutation detection requires sequencing of the entire gene, which in many countries is only available on a research basis. Some patients with an EA2 phenotype do not have mutations in known exons. This may reflect genetic heterogeneity or mutations in regions of the gene not covered by sequencing i.e. promoter, introns or other undescribed exons. KCNA1 is much smaller and can easily be sequenced to detect mutations.

## Therapeutic Principles

As in all rare diseases, there is no randomized control trial data. Therefore treatments are empirical.

*EA1*: Sodium channel blockers such as phenytoin may be used to treat the myokymia. Carbamazepine is effective against both myokymia and ataxia. Acetazolamide has been used, but is less effective than in EA2. As attacks are brief, many patients will not require treatment or will discontinue medications as side-effects may be worse than the symptoms. Attack frequency tends to decrease with age, such that patients may be able to discontinue treatment as they get older.

*EA2*: Acetazolamide is the mainstay of treatment and may completely ameliorate attacks in some individuals. Renal function should be monitored and annual screening for renal calculi undertaken. In those who are unresponsive or unable to tolerate the side-effects, several options exist although these are not licensed or produced in many countries. Paradoxically, the calcium-channel blocker flunarizine can be effective. The carbonic anhydrase inhibitor dichlorphenamide can also be used. 4-aminopyridine and 3,4-diaminopyridine have also been shown to be effective in case reports.

# Epistaxis

Werner J. Heppt[1], Rainer Weber[2]
[1]Department of Otorhinolaryngology, Klinikum Karlsruhe, Karlsruhe, Germany
[2]Städtisches Klinikum Karlsruhe, Karlsruhe, Germany

## Definition and Characteristics

Epistaxis means any bleeding from the nose, which originates in 90% of the cases from smaller vessels in the anterior part of the nasal septum (= locus Kiesselbachii) and in 10% from the posterior nasal cavity.

## Prevalence

Two-third of the population experience epistaxis during their life. More than 50% of children between 6 and 10 years had at least one episode of epistaxis. Some diseases with epistaxis as the leading symptom are hereditary hemorrhagic telangiectasia (HHT, Rendu-Osler-Weber syndrome) and juvenile nasopharyngeal angiofibroma (JNA).

## Genes

HHT is an autosomal dominant disease. Two genes have been identified: Endoglin on chromosome

9q33–q34 and activin receptor-like kinase 1 on chromosome 12q13 [2].

JNA occurs mainly in adolescent males and has a locally aggressive growth pattern. Common known genetic abnormalities are β-catenin-mutations, chromosomal gains on chromosome 4q, 6q, and 8q and complete loss of chromosome Y [3]. Alterations of the IFG-II/H19 imprinted region occur in JNA [4]. IGF-II might be a potential growth regulator of nasopharyngeal angiofibromas. The high frequency of beta-catenin mutations in sporadic JNA and the presence of identical beta-catenin gene mutations in recurrent tumors indicate that activating beta-catenin gene mutations are important in the pathogenesis of JNA [5].

### Molecular and Systemic Pathophysiology

Local factors for epistaxis are digital manipulation, trauma and acute or chronic rhinitis. Systemic factors are coagulation disorders due to medication (e.g., aspirin or coumarin) or hereditary coagulopathies (e.g., hemophilia), insufficiently treated hypertension or HHT. JNA or malignant tumors may also lead to severe epistaxis. HHT: More than 90% of patients suffer from recurrent nosebleeding and epistaxis is most often the first symptom of HHT. Blood vessels form AV-shunts, which lead to the typical red color, whereas the capillary bed is reduced.

### Diagnostic Principles

Nasal endoscopy is the diagnostic tool of choice. Isolated, multiple, or diffuse lesions of the mucosa, tumors or malformations can be localized precisely in the entire nasal cavity and nasopharynx. In the case of tumor growth, additional CT and MRI are necessary to diagnose the whole size of the tumor. In some cases, particularly in JNA, angiography is mandatory.

### Therapeutic Principles

Electrocoagulation, nasal packing, endonasal coagulation or clipping of the sphenopalatine or ethmoidal artery, laser coagulation, and embolization via an angiography are recent therapeutic measures, which have to be applied individually. Operations via an external approach (skin incision) are seldom indicated nowadays. For tumor surgery, various techniques have been developed, e.g., endonasal, sublabial, and midfacial degloving.

## Epithelial Basement Membrane Dystrophy

Walter Lisch[1], Andreas Janecke[2], Berthold Seitz[3]
[1]Department of Ophthalmology, Klinikum Hanau, Hanau, Germany
[2]Division of Clinical Genetics, Innsbruck Medical University, Innsbruck, Austria
[3]Department of Ophthalmology, University of Saarland, Homburg/Saar, Germany

### Synonyms

Map-dot-fingerprint-bleb dystrophy; Cogan microcystic epithelial dystrophy; EBMD

### Definition and Characteristics

EBMD is a bilateral epithelial disorder and can present four different components of corneal opacities:

1. Maps demonstrating irregular islands of thickened grey hazy epithelium with scalloped circumscribed borders predominantly localising to the central cornea.
2. Dots or Cogan's microcysts demonstrating irregular round, oval or comma-shaped putty-grey opacities above all in the central cornea.
3. Fingerprint lines demonstrating parallel concentric lines above all paracentral, best seen in retroillumination.
4. Bleb pattern (Bron) demonstrating pebbled glass, only seen in retroillumination.

These four corneal opacity units can change location, size, and shape over time with no signs of progression. The alterations can be asymptomatic or may also cause reduced vision, mainly through mild irregular astigmatism. EBMD is often combined with pain attacks, red eye, and epiphora due to recurrent epithelial erosion. The history of nocturnal or waking pain is almost pathognomonic for EBMD.

### Prevalence

EBMD is the most common anterior corneal dystrophy usually presenting sporadic cases but sometimes

inherited as a dominant trait [1,2]. It most commonly appears in the fourth decade of life or later. In the general population, less than 2% of individuals manifest some signs of this dystrophy. In about 10% of EBMD cases recurrent erosions occur with the consequence of pain attacks. Conversely, 30% of patients with recurrent corneal erosions show some signs of EBMD [3].

## Genes

Boutboul and associates [4] described two novel heterozygous mutations, Leu503Arg and Arg666Ser in the transforming growth factor beta-induced (TGFBI) gene (formerly BIGH3 gene) in two families with autosomal dominant inheritance and one sporadic case of EBMD in their series of 30 patients. Pathogenicity of the identified mutations was assumed due to their absence among 96 healthy controls and among more than 200 patients with other corneal dystrophies. Leu509Arg was also found to co-segregate with the disease in four patients in two generations. Leu509 is a highly conserved residue, and localizes to the fourth fasciclin-like domain of the TGFBI protein. The majority of previously described mutations causing distinct corneal dystrophies cluster in this domain. The Arg666Ser mutation, present in two affected sibs as well as in their unaffected father, and in the sporadic patient, localizes more C-terminal in a domain with unknown function. The Arg666Ser mutation is suggested to be incompletely penetrant with regard to EBMD. Distinct mutations in the TGFBI gene which are all predicted to cause an altered protein, keratoepithelin, are associated with a growing number of corneal dystrophies. Molecular analysis of both large pedigrees in which EBMD segregates in a Mendelian fashion, as well as TGFBI screening of further simplex cases will help to further eludicate the pathogenesis of this corneal dystrophy.

## Molecular and Systemic Pathophysiology

In the normal cornea there is a turnover of epithelial cells. Stem cells residing at the limbus divide and produce a progeny of daughter cells which migrate centropetally along the basal lamina. In EBMD this forward migration is impeded by the intra-epithelial sheets. The migrating cells remain trapped behind the basal laminar barrier of the map lesions presenting the dots. The bleb pattern is due to the presence of a neutral mucopolysaccharide-protein complex, forming a continuous layer between the basal lamina and Bowman's layer. The predisposition of EBMD to epithelial erosions is due to a disturbance of the normal mechanism of epithelial attachment to Bowman's layer, induced by the presence of the aberrant basal laminar material. Biochemical studies suggest that TGFBI is a component of the extracellular matrix, where it binds to fibrinogen and various forms of collagen to support cell adhesion and spreading. Mutant TGFBI protein has been detected in corneal deposits, and a majority of TGFBI mutations are thought to lead to increased protein stability causing accumulation of protein.

## Diagnostic Principles

The diagnosis of EBMD is based on slit lamp examination in direct and indirect illumination, fluorescein staining, best seen by dilated pupil. The four types of opacities, maps, dots, fingerprints, and bleb patterns of EBMD can each occur in isolation or in any combination. This dystrophy may be associated with recurrent corneal erosions either spontaneously, or in response to mild trauma. If a macro-erosion occurs, the clinical features of the disorder on the side of the erosion may be lost with the epithelium, so that after healing, only a few features of the disorder may persist at the site of the erosion, whereas they remain recognizable in the fellow eye [5]. For this reason, it is essential to examine both corneas in any patient who presents with corneal erosions in mydriasis regardless of whether it appears to be traumatic. In this situation, the features of EBMD are often found in the patient's eye without complains, while the eye with the erosion shows few, or no typical changes [5].

## Therapeutic Principles

EBMD may be an entirely asymptomatic disorder that is discovered by chance and requires no treatment. Where maps or fingerprint lines occur in the visual axis they may disturb vision and can be treated effectively by debridement. A typical EBMD induced recurrent erosion attack is heralded by severe pain occurring in the early hours of the morning or on opening the eyes on waking. Patients may adapt manoeuvres to minimize or prevent pain on lid opening, such as light manipulations of the closed lids, or deliberate movements of the eyes prior to lid opening. Recurrent erosion due to EBMD may be treated medically in the first instance, with topical antibiotics and mydriatics in the acute phase and topical lubricants at night in the chronic phase. The use of contact lenses, including gas permeable silicone hydrogel soft lenses, can be very useful and helpful. However, where recurrences persist, the recommended treatment is phototherapeutic keratoplasty (PTK) after epithelial debridement with a success rate in the region of 85%. Another less attractive but effective approach for recurrent corneal erosion is anterior stromal micropuncture, which is contraindicated in the central region of the cornea.

## Synonyms

(Streptococcal) cellulitis

## Definition and Characteristics

Acute bacterial infection of the dermis and hypodermis involving the lymphatic vessels by hemolytic streptococci, usually group A, but also group C or G and in newborns group B. It is a specific clinical type of superficial cellulitis.

## Prevalence

Frequent.

## Molecular and Systemic Pathophysiology

There needs to be (i) minor trauma of the skin as port of entry (e.g., mycosis at toe webs) and (ii) presence of Streptococci pyogenes. Erysipelas is usually caused by streptococci Lancefield group A or less commonly by group C, G, or B. It is dubious if the classical picture of erysipelas is also caused by other bacteria such as Streptococcus pneumoniae, Staphylococcus aureus, or Hemophilus influenzae, as their presence at possible sites of entry is no proof and as isolation of the causative agent from within the infected tissue cannot be easily performed.

Streptococcal enzymes and perhaps also toxins are involved in spread of bacteria in the tissue. They, however, are not capable of breaking the skin barrier; so bacteria need a preexisting lesion to come by the epidermis. M proteins or proteins binding to fibronectin, collagen, or laminin, as well as streptococcal hyaluronidase, facilitate spread of streptococci within the tissue. Their effect is increased by the action of streptococcal proteins, which bind to plasminogen (streptokinase and cystein protease SpeB), as they activate human proteases in a way that impairs inactivation by their natural inhibitors (alpha1 antiplasmin). On histology tissue spaces and lymphatic channels are found to be infected with streptococci. There is marked edema, vasodilation, and infiltration of neutrophils and mononuclear cells along infected sites. There is usually a marked, often systemic inflammatory reaction caused by mediators of inflammation and perhaps toxins. It includes fever, chills, raised CRP, and neutrophilia.

## Diagnostic Principles

Clinical hallmarks are erythema with shiny surface and well-defined margins, often with characteristic fingerlike protrusions due to extensions along lymphatic vessels or clefts. Interdigital mycosis is the most common portal of entry for the disease. Other local risk factors include lymphoedema.

## Therapeutic Principles

Penicillin G is the drug of choice as all Streptococci pyogenes are sensitive [1,2]. Amoxicillin and macrolides are also effective. Bed rest with the leg elevated is important. Anticoagulants are indicated in patients at risk of venous thromboembolism. Treating the portal of entry represents a causative prophylaxis of recurrence. For patients with recurrences, a long-term antibacterial therapy (e.g., intramuscular benzathine penicillin) is advised.

## Synonyms

Erythema contusiformis; Dermatitis contusiformis

## Definition and Characteristics

A self-limiting cutaneous reaction consisting of inflammatory, tender, nodular lesions usually located on the anterior aspects of the lower extremities.

## Prevalence

Erythema nodosum (EN) is the most common type of panniculitis with a reported prevalence in England of 2.4 per 1,000 population. However, the exact prevalence differs in each country according to the prevalence of the etiological factors. EN occurs at any age with a peak between 20 and 30 years. In adult life, it is 3–6 times more common in females than in males.

## Molecular and Systemic Pathophysiology

The exact pathophysiology of EN is unknown. Currently, it is recognized as a delayed hypersensitivity reaction that can be triggered by a wide variety of antigenic stimuli including bacterial, viral, fungal and protozoal infections; drugs; benign and malignant systemic diseases. Streptococcal infection and sarcoidosis are the most commonly reported triggering factors, however failure to identify a provoking agent occurs in many cases. Histopathological features and immunfluoresence studies supports the delayed hypersensitivity mechanism, the latter have shown deposits of immunocomplexes in and around the venules of the connective tissue septa of the subcutaneous fat. Circulating immunocomplexes and complement activation have been reported in some patients with EN. Recent studies suggest that reactive oxidative intermediates (ROI) produced by activated neutrophils with their tissue damaging effect, together with certain pro-inflammatory cytokines such as interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α) (with or without a TNF-α promotor polymorphism) may play a role in the pathogenesis of EN.

## Diagnostic Principles

Clinical features are characteristic and consist of sudden onset of ill-defined, tender, erythematous nodules and/or raised plaques usually bilaterally located on the anterior aspects of the legs (Fig. 1). In late stages the lesions appear as a bruise and eventually heal without scarring. Associated fever, chills, malaise, hilar adenopathy, or arthralgia are usually attributed to the underlying provocating factor. Histopathological features shown in a deep skin biopsy confirms the diagnosis. Elevated erythrocyte sedimentation rate (ESR) usually correlating with disease activity, is evident in most cases. Other laboratory and radiological investigations beside full history taking may help to identify an underlying cause.

**Erythema Nodosum. Figure 1** Erythema nodosum showing erythematous nodules and plaques on the anterior aspect of the leg.

## Therapeutic Principles

The treatment of erythema nodosum should be directed to the underlying provoking cause, if identified. In most cases, spontaneous regression of EN occurs within few weeks. Bed rest, aspirin, nonsteroidal anti-inflammatory drugs (indomethacin or naproxen) and hydroxychloroquine may help to relief pain and enhance resolution. Potassium iodide can be used in persisting lesions. Systemic corticosteroids are restricted to severe cases after excluding an underlying infectious cause.

# Erythema Papulatum of the Newborn

►Erythema Toxicum

# Erythema Toxicum

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Erythema toxicum neonatorum; Toxic erythema of the newborn; Erythema neonatorum allergicum; Urticaria neonatorum; Flea-bite dermatitis; Erythema papulatum of the newborn

## Definition and Characteristics

Erythema toxicum is a transient neonatal dermatosis characterized by large blotchy areas of erythema studded with erythematous or yellowish papules and sometimes pustules (Fig. 1) [1].

The papules and pustules usually measure 1–3 mm in diameter, while the surrounding erythema 1–3 cm in diameter. In the majority of cases, the lesions develop between 24 and 48 h of age, but they may appear as late as 3 weeks. Rarely, the eruption is present at birth [2]. Although individual lesions may last for a few hours, the eruption persists for several days, or rarely, several weeks. There is no residual pigmentary change or scarring. The trunk is the site of predilection. The face and extremities may also be involved but the palms and soles are almost always spared. The papules and pustules are usually discrete and scattered. The number may vary from a few to dozens.

## Prevalence

Erythema toxicum develops in approximately 50% of all healthy term infants [3]. The condition occurs less frequently in preterm infants. Erythema toxicum is more common during the summer or autumn months. No sexual or racial predisposition has been noted. Erythema toxicum has not been reported in stillborn infants [2].

**Erythema Toxicum. Figure 1** Florid lesions of erythema toxicum on the face, body, and limbs of a newborn infant.

## Molecular and Systemic Pathophysiology

There is a positive correlation between the severity of the lesions and the duration of vaginal delivery implying prolonged contact with vaginal secretion might be possible [4]. Commensal microorganisms gain entry into the skin, possibly through hair follicles [3]. This triggers the local immune system and a systemic acute phase response, including an increase in body temperature [3]. Histologically, there is an accumulation of activated immune cells near the hair follicle, in particular dendritic cells, eosinophils, macrophages, and neutrophils [3,5]. It has been shown that water channel proteins aquaporin-1 (AQP1), AQP3, psoriasin, nitric oxide synthase (NOS) enzymes, interleukin (IL)-1, IL-8, eotaxin, and adhesion molecule E-selectin are involved in the activation of the skin immune system [5].

## Diagnostic Principles

The diagnosis is mainly a clinical one and in the majority of cases is a spot diagnosis, provided one is familiar with this condition. Erythema toxicum should be differentiated from transient neonatal pustular melanosis. The latter is very common in black infants. The lesions of transient neonatal pustular melanosis are present at birth and consist of vesiculopustules without surrounding erythema. The pustules fade within 24 h, leaving a hyperpigmented macule surrounded by a collarette scale. Other differential diagnosis includes miliaria rubra, infantile acropustulosis, and folliculitis. If necessary, the diagnosis can be confirmed by Wright or Giemsa stain of a pustule which reveals numerous eosinophils with few or no polymorphonuclear cells and no microorganisms.

## Therapeutic Principles

Erythema toxicum is a self-limited disorder and no treatment is required. Parents should be reassured of the benign nature of this condition.

## Erythrokeratodermia Variabilis

Sonja Ständer, Heiko Traupe
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

EKV

### Definition and Characteristics

Autosomal dominant genodermatosis with genetic heterogeneity, high penetrance, and intra- and interfamilial variability that belongs to a genetically heterogeneous group of erythrokeratodermias. Patients with erythrokeratodermia variabilis (EKV) develop transient, scaling, figurate erythemas as well as localized hyperkeratotic plaques on the extremities and trunk already present at birth or during infancy persisting throughout life. The skin lesions can be triggered by several factors such as stress, sudden temperature changes, mechanical friction, and sun exposure [1,2].

### Prevalence

Not determined, rare disease (C1 : 1,000,000).

### Genes

GJB3 gene encoding connexin (Cx) 31, localized on chromosome 1p35.1; GJB4 gene encoding Cx 30.3, localized on chromosome 1p34-p35.

### Molecular and Systemic Pathophysiology

The epidermal intercellular communication is mediated by different channel systems including gap junctions built by connexins including Cx30.3 and Cx31 that are preferentially expressed in the upper differentiating layers of the epidermis [1]. Since connexin channels are multifunctional contributing to tissue homeostasis, synchronization of stimuli response, control of growth, and development, faulty Cx30.3 and Cx31 structure may alter intercellular interaction leading to disturbed differentiation of keratinocytes [1,3]. This idea is supported by the observation that HeLa cells, which were transfected with mutant hCx31 protein, died within 5 days possibly due to defect opening and closure mechanisms of the mutated Cx31 channels [4]. However, the exact pathomechanisms of Cx 30.3 defects remain to be determined.

Up to now, several distinct heterozygous missense mutations have been identified in the GJB3 gene. These mutations involve the cytoplasmic amino-terminal and transmembrane domains and are predicted to

interfere with assembly of Cx31 channels [1,2]. However, not all families showed heterozygous mutations in Cx31. One homozygous Cx 31 mutation was found in a family with recessive inheritance of EKV [3]. Other mutations related to development of EKV were detected recently in the GJB4 encoding Cx30.3 (1p34-p35) [2,5].

### Diagnostic Principles

The hallmark of EKV is the continuous occurrence of transient erythemas that fade within a few hours or days. The histological investigation reveals acanthosis and orthohyperkeratosis of the epidermis with variable lymphocytic perivascular infiltrate in the upper dermis.

### Therapeutic Principles

Oral treatment with retinoids has been described to be effective in adults and children. In addition, also topical application of tretinoin cream has shown benefit. No gene or dietary therapy is available as of yet.

## Erythromelalgia

William Jeffcoate
Foot Ulcer Trials Unit, Department of Diabetes and Endocrinology, City Hospital, Nottingham, UK

### Synonyms

Erythrothermalgia; Erythermalgia

### Definition and Characteristics

The diagnosis is clinical and rests on the association of inflammation and severe pain in one or more limbs (usually the foot). Symptoms are typically episodic, rarely constant. Crises are typically triggered by warming above 32 and by the limb being dependent. Cases fall into one of three groups: (i) an autosomal dominant form (primary erythromelalgia), which appears in childhood, (ii) erythromelalgia secondary to myeloproliferative disorders, (iii) other causes. In the inherited form symptoms usually start in childhood. The condition otherwise presents in middle-age; sex incidence is equal [1].

### Prevalence

Rare.

### Genes

The inherited form has been linked to mutations in SCN9A on chromosome 2q, which encodes a sodium channel alpha subunit [2].

### Molecular and Systemic Pathophysiology

Whatever the primary cause, it is thought that the clinical presentation is the consequence of abnormal microvascular flow with a resultant increase in vasoconstrictor tone. Disordered vasodilatation occurs during crises with arteriovenous shunting and decreased flow in the distal capillary bed. This effect is most marked on the plantar aspect of the foot which has a higher density of capillary anastomoses. The pain may result from decreased nutritive flow to the tissues, or from the involvement of C-fibers – which are known to be reduced in number and to exhibit impaired conduction velocity [3,4]. It is possible that hyperexcitability of C-fibers mediates both pain sensation and the exaggerated inflammatory response. In those cases which are associated with myeloproliferative disorders (with thrombocythaemia), there is evidence of an associated platelet-dependent change in microvascular flow [5]. Platelet expression of CD62P and CD63 antigens and sVCAM are higher in cases of erythromelalgia complicating thrombocythaemia. In primary (inherited) erythromelalgia, there is histological evidence of mild intra- and peri-vascular inflammation of unknown cause. There is some syndromic overlap with complex regional pain syndrome type 1 (CRPS-1), with which it may share common pathological features, and some of the pathological processes may be similar to those in chilblains and in Raynaud's phenomenon.

### Diagnostic Principles

The diagnosis is clinical.

### Therapeutic Principles

Cases which are secondary to thrombocythaemia respond well to the administration of aspirin. A wide

variety of other agents have been used, with benefit being reported in 20–30% following the use, for example, of non-steroidal anti-inflammatory agents, <b>blockers, anticonvulsants, psychotropic agents (phenothiazines; tricyclic antidepressants) and prostaglandin analogues, as well as physical methods (sympathectomy, transcutaneous electrical nerve stimulation) and treatments directed at any underlying myeloproliferative disorder. Infusions of sodium nitroprusside are effective in primary erythromelalgia.

# Erythrothermalgia

►Erythromelalgia

# Esophageal Diverticula

Marcus Schmitt
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

Esophageal diverticulum; Zenker diverticulum; Zenker's diverticulum; Pharyngoesophageal diverticula; Congenital esophageal diverticulum

## Definition and Characteristics

- Esophageal diverticula are protrusions of the esophageal wall. Depending on the herniating layers of the esophageal wall "true" and "false" diverticula can be distinguished: whereas true diverticula consist of all layers of the intestinal wall, so called "false" diverticula or pseudodiverticula contain only mucosa and submucosa. Esophageal "intramural" pseudodiverticulosis is confined to the submucosa. These very rare pseudodiverticula are formed by dilatation of the esophageal submucosal glands that communicate with the esophageal lumen.
- Esophageal diverticula can be classified depending on their location:
  - Diverticula above the upper esophageal sphincter (Zenker's diverticulum)
  - Diverticula near the middle of the esophagus (traction diverticulum)
  - Diverticula nearly above the lower esophageal sphincter (epiphrenic diverticulum).
- Symptoms of esophagal diverticula may be dysphagia, chest pain, nocturnal cough, aspiration pneumonia or regurgitation and halitosis [1].

## Prevalence

Epidemiologic data is rare because most esophageal diverticula are symptomless. The true prevalence is unknown but may range from 0.015 to 2% of the population. For Zenker's diverticulum a prevalence of 2.3% was found in radiographic studies. The prevalence of Zenker's diverticula among the general population is thought to be 0.01–0.11% [2]. Most esophageal diverticula occur in middle-aged adults. Zenker diverticula are typically seen in male patients older than 50 years.

## Genes

Molecular causes of esophageal diverticula have not been detected so far. In patients with Ehlers-Danlos syndrome esophageal diverticula occur due to disorders that affect connective tissues.

## Molecular and Systemic Pathophysiology

Two main pathogenetic factors are discussed for the development of esophageal diverticula: Zenker diverticulum and epiphrenic diverticula are caused by motor abnormalities of the esophagus and an increased intraluminal pressure. Traction diverticula are thought to be the result of extraluminal inflammatory processes (e.g. tuberculosis) and fibrotic changes near the esophageal wall leading to "true" diverticula.

Zenker's diverticula emerge from a defect in the muscular wall of the hypopharynx in a natural area of weakness known as "Killian's triangle" which is formed by the oblique fibers of the inferior pharyngeal constrictor muscle and the cricopharyngeal sphincter. Due to the prevalence of Zenker diverticula in older people aging and degeneration of these muscle fibers is discussed as a cause of this diverticula.

## Diagnostic Principles

Diagnosis is based on barium contrast radiography or endoscopy.

Barium radiography is the diagnostic procedure of choice. Diagnosis can also be made by upper endoscopy, but requires an experienced endoscopist. An esophagogastroduodenoscopy should be performed if symptoms like dysphagia or odynophagia exist in order to exclude other diseases especially malignancies.

## Therapeutic Principles

Major goals of therapy are decreasing symptoms and avoiding complications. Asymptomatic and minimally symptomatic esophageal diverticula do not require treatment.

Because symptoms like dysphagia in patients with mid esophageal and epiphrenic diverticula often are the result of the underlying dysmotility, the motility disorder should be treated as a first choice. Younger patients (<50–60 years) with Zenker diverticula are treated by open surgery. For older patients with comorbidities endoscopic intraluminal treatment (stapler, needleknife, or Argon-Plasma-Coagulation) will be an option due to the resources and skills available in the local situation.

# Esophageal Dystonia

►Achalasia

# Esophageal Spasm

Thomas Frieling
Medical Clinic II, Helios Klinikum Krefeld, Krefeld, Germany

## Synonyms

Esophageal spasm: Diffuse esophageal spasm; Distal esophageal spasm

## Definition and Characteristics

Esophageal spasms are frequently suspected to be the cause of retrosternal chest cramps in patients with noncardiac chest pain (NCCP). This entity was first described in 1892 in hypochondriac patients with unexplained chest pain [1]. The concept that NCCP might be caused by esophageal spasms is suggested by the patients symptoms describing retrosternal cramp or spasm. However, recent studies indicate that esophageal motility is normal in most patients with NCCP and esophageal spasm accounts for only 3% of motility abnormalities seen in these patients. The most common motility disorder that can be detected is the hypercontractile or nutcracker esophagus that differentiate to esophageal spasm by peristaltic contractions with high-amplitudes (>180 mmHg), whereas esophageal spasm (DES) is characterized by simultaneous contractions of high amplitude (>180 mmHg) and normal relaxing lower esophageal sphincter (LES). However, gastroesophageal reflux disease (GERD) is a more common cause of NCCP [2].

## Prevalence

DES is a relative rare manometric abnormality, accounting for 3–7% of abnormalities in patients referred for esophageal manometry and can be found in 3% of patients with NCCP and/or dysphagia. It is seen in any age, but most commonly in patients older than 50 years; family cluster have been reported [3].

## Molecular and Systemic Pathophysiology

Similar to achalasia, the current concept about the pathophysiology of DES is an altered endogenous nitric oxide (NO) synthesis and/or degradation. There have been cases of DES and non-specific that progress to achalasia. However, the putative link between DES and achalasia is not established and needs further elucidation.

## Diagnostic Principles

Barium swallow illustrates sudden distortions in the lower half of the esophagus with puckering into a series of pockets, giving a beaded appearance (Fig. 1).

However, these findings are neither specific nor sensitive in diagnosing DES. DES is preferably diagnosed by esophageal manometry. Characteristics are simultaneous contractions with high amplitudes and prolonged durations (Fig. 2).

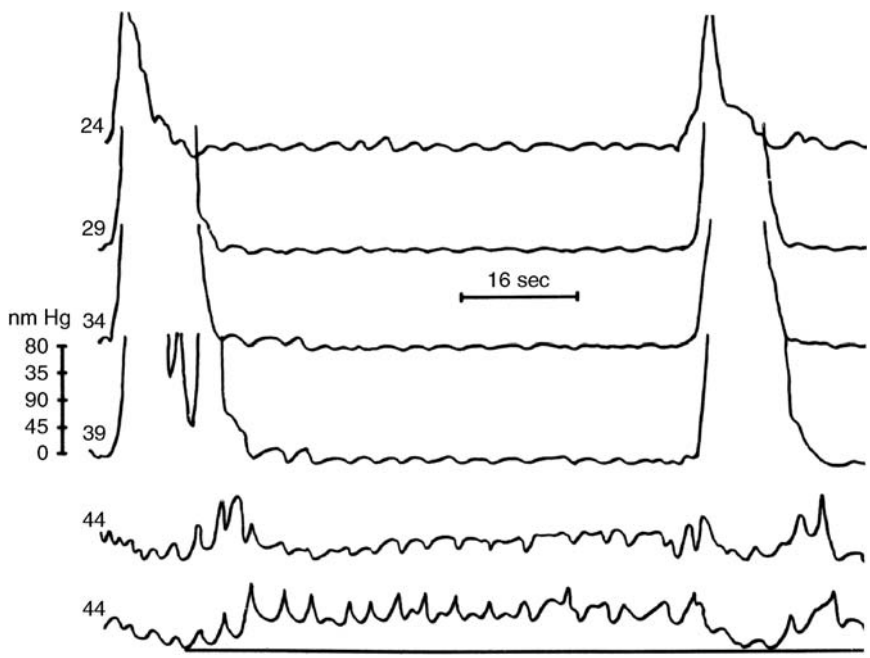
Spastic contractions are usually above 180 mmHg. The manometric features proposed for a diagnosis of DES are the presence of at least 10% of swallows having simultaneous contractions in the distal esophagus, and mean simultaneous contraction amplitude >30 mmHg [4]. Combined multichannel intraluminal impedance and manometry suggests that in DES

**Esophageal Spasm. Figure 1** Barium swallow illustrates sudden distortions in the lower half of the esophagus with puckering into a series of pockets, giving a beaded appearance.

approximately half of the patients have normal bolus transit, and the remaining half abnormal bolus transit for both liquid and viscous or either liquid or viscous.

## Therapeutic Principles

Treatment of DES is rarely easy. As simultaneous esophageal contractions can be the result of GERD and NCCP is frequently caused by GERD, initial treatment with proton-pump inhibitors (PPI) is recommended. Patients not improving with PPI therapy may be treated by smooth muscle relaxants such as nitrates, calcium-channel blockers, phosphdiesterase inhibitors, or peppermint oil. However, data supporting this concept are spare. Injection of botulinum toxin at several levels in the esophagus can be an effective treatment for symptoms caused by DES [5]. In patients with dysphagia and regurgitation esophageal dilation by rigid dilators or balloon distension of LES may be helpful. In addition, long surgical esophageal myotomy may be a valid treatment strategy in appropriately selected patients with DES. An alternative therapeutic principle is to modulate sensory perception by application of visceral analgetics (tricyclic antidepressants, serotonin reuptake inhibitors). The rational for this is the concept that patients might develop decreased perceptions thresholds ("irritable esophagus") and that some patients with DES had higher anxiety and depression scores.



**Esophageal Spasm. Figure 2** Esophageal manometry (24, 29, 34, and 39 cm inc. reveals simultaneous contractions with high amplitudes (>500 mmHg) and prolonged duration. The LES (44 cm inc.) relaxes completely to gastric pressure (line) upon swallowing.

# Esophagitis

Marcus Schmitt
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

## Definition and Characteristics

Esophagitis summarizes several entities leading to an inflammation of the esophageal wall. Many underlaying disorders can be distinguished, the most common cause is ►gastroesophageal reflux diseases.

Less common causes are infections, medications, radiation therapy, systemic diseases, eosinophilic esophagitis and trauma.

## Prevalence

Epidemiologic data is rare. For gastroesophageal reflux disease (GERD), see there.

## Genes

So far affected gene(s) are unknown.

## Molecular and Systemic Pathophysiology

Characteristic symptoms are heartburn, retrosternal discomfort or pain, dysphagia, odynophagia, and malnutrition in severe esophagitis. Bleeding and hematemesis rarely occur.

Systemic pathophysiology of esophagitis depends on its etiology. Reflux of gastric acid or bile acids into the esophagus occur most frequently. Abnormalities in host defense may predispose to infections, such as neutropenia, impaired chemotaxis and phagocytosis, alteration in humoral immunity and impaired T-cell lymphocyte function. Steroids, cytotoxic agents, radiation, and immune modulators can also contribute to impaired host immune function. Disruption of mucosal protective barriers and clearance functions as well as antibiotics that suppress the normal bacterial flora may contribute to the invasive ability of microorganisms.

Local injury by topical damage (hyperosmolarity) may be the leading mechanisms in pill esophagitis.

Among many causes most common are infectious causes (candida species, noncandidal fungi, herpes simplex virus (HSV), cytomegalovirus (CMV), varicella-zoster virus (VZV), Epstein-Barr virus (EBV), mycobacterium avium-intracellulare).

Parasitic infections (e.g., chagas disease, trypanosoma cruzi, cryptosporidium, pneumocystis, leishmania donovani), however, are rare.

Systemic illnesses include skin disorders (epidermolysis bullosa, pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid), eosinophilic esophagitis, Behçet disease, Graft versus host disease (GVHD), inflammatory bowel disease, sarcoidosis and metastatic cancer.

Moreover drugs (NSAIDs), chemotherapy (e.g. cytarabine, daunorubicin, 5-fluorouracil, methotrexate) and radiation therapy may cause esophagitis.

## Diagnostic Principles

Diagnosis is mainly based on endoscopy which shows inflammation and erosions of the esophageal mucosa, the ability to take samples for pathological and cytological examination, viral and bacterial cultures. Radiological contrast media studies e.g. barium studies are less accurate for mucosal details.

## Therapeutic Principles

Therapy is directed to the underlying cause.

Drug therapy with proton pump inhibitors (PPI) is applied in patients with gastroesophageal reflux disease. For bile acid reflux induced esophagitis sucralfate is recommended. Antibiotic and antiviral treatment is restricted to microbiologically induced inflammation and infection, corticosteroids are recommended for special indications e.g. eosinophilic esophagitis.

# Esophagitis, Eosinophilic

Nirmal S. Mann
School of Medicine, University of California, Sacramento, CA, USA

## Synonyms

Feline esophagus; Ringed esophagus corrugated esophagus; Stiff esophagus

## Definition and Characteristics

Unlike hypereosinophilic syndrome, where multiple organs outside the gut may be involved, in eosinophilic esophagitis (EE) esophagus is the mainly involved organ although other parts of the gastrointestinal tract may be involved. There is absence of parasitic infestation and other known causes of tissue eosinophilia. The squamous epithelium of esophagus is normally devoid of eosinphils. Some cases of gastroesophageal reflux may have significant tissue eosinophilia in the esophagus. The primary EE may be allergic (secondary to ingested or inhaled allergen) or idiopathic. In EE, the eosinophils may infiltrate the mucosa, submucosa and the serosa although the serosal involvement is rare. The patient may present with food impaction, chest pain or a history of heart burn. In fact gastroesophageal reflux has been mentioned as a potential etiology of EE. It is possible that in some cases aeroallergens may be responsible; a case has been described where exacerbations of EE with esophageal biopsy showing tissue eosinophilia occurred during the pollen season with remission during winter months.

## Prevalence

75% of patients with EE are males. The mean age is between 36 and 42 years. A personal history of atopy and allergies occurs in a significant number of cases. The disease seems to be more common in USA, Europe, Australia and Japan. EE also is quite common in school age children. Food allergies are seen in many EE patients. The prevalence has been reported as being from 15 per 100,000 in Switzerland to 100 new cases per year now being diagnosed in children at Pittsburg.

## Genes

Like allergies in general, EE clusters in families and an autosomal dominant pattern of inheritance has been proposed because there is 10% rate of familial clustering especially in first degree relations of EE patients.

## Molecular and Systemic Pathophysiology

After exposure of food or aeroallergens, eosinophils migrate to the esophageal mucosa and submucosa in response to chemotactic factor. However in idiopathic EE, no specific allergen may be identified. The eosinophils release many chemical mediators which have injurious effect on the esophageal mucosa and submucosa. The eosinophils liberate cationic proteins such as major basic protein, eosinophilic cationic protein, eosionphil derived neurotoxin and eosinophil per oxidase. The other chemical mediators released from eosinophils are macrophage colony stimulating factor and tumor necrosis factor alpha. In sensitized persons after exposure to allergens, the IgE may degranulate mast cells resulting in the release of platelet activating factor, eosionphil chemothactic factor, histamine and leukotrience B4.

The main cells involved in the pathogenesis of EE are the eosinophils and the mast cells. The most important effect of eosinophils is to degranulate the mast cells which produce various injurious toxins and proteins. These toxic factors cause damage to the esophageal tissue via inflammation. However eosinophils may directly damage the esophageal wall. The eosinophil chemotactic factor produced in the esophageal mucosa and submucosa recruits more eosinophils into the esophageal tissue thus setting up a vicious cycle.

As already mentioned the tissue damage and inflammation produced by eosinophil medicated and mast cell mediated liberation of injurious tissue toxins produces the various clinical esophageal symptoms and signs of EE. The patients may develop dysphagia with food impaction, chest pain and heartburn. The esophagus may become stiff and non-compliant. These manifestations are aggravated by massive infiltration of eosinophils and mast cells in various layers of the esophagus but particularly in the esophageal mucosa.

## Diagnostic Principles

The diagnosis is made by the presence of clinical features such as dysphagia usually with food impaction, heartburn and abnormal esophageal PH. On endoscopy the esophagus may show fine mucosal rings (hence the synonym feline esophagus or corrugated esophagus). The fine mucosal rings result from contraction of the muscularis mucosae due to the effect of histamine and acetylcholine. Initially these rings are probably reversible but continuous contraction of mucularis mucosae may result in scarring, rigid and mildly narrowed esophagus. Multiple esophageal biopsies should be taken and to make the histalogic diagnosis of EE sheets of eosinophils infiltrating the epithelium should be seen. Other conditions with eosinophilic infiltration of mucosa such as gastroesophageal reflux disease, parasitic or fungal infections, peripheral hypereosionphilic syndrome, inflammatory bowel disease, allergic vasculitis,

periarteritis and drug injury etc. should be excluded by appropriate tests.

### Therapeutic Principles

Based on the observation that some cases of EE are due to food allergens, elemental diets have been tried with variable results. Systemic corticosteroids have an excellent initial effect but relapses are common when steroids are stopped. Corticosteroids are effective anti-inflammatory agents and also inhibit eosinophil growth factors. However long term systemic steroids have undesirable side effects. Inhaled topical steroids such as fluticasone have been found to be useful. In the author's experience antihistamines (H1 receptor antagonists) are effective. Various combinations of antihistamines should be tried since there is individual variation in response to antihistamines. Ketotifen which is a potent antihistamine also has mast-cell stabilizer effect and may be very effective in relieving the symptoms of EE. When heartburn and chest pain are dominant symptoms then proton pump inhibitor may be used. When dysphagia is present careful esophageal dilation should be carried out; over dilation should be avoided as there is risk of esophageal laceration and perforation because the esophagus is stiff with low compliance.

### Synonyms

Estrogen insensitivity

## Definition and Characteristics

The disorder is characterized by total or partial lack of response of target tissues to physiological estrogen (E) levels. Inheritance is autosomal recessive. Despite it has long been thought that mutation of E receptors (ER) would have been lethal by affecting embryo implantation, Smith et al. [1] described a 28–year-old-man with E resistance due to homozygous cytosine-to-thymine transition at codon 157 of the ERα gene, resulting in a premature stop codon and consequent absence of protein. The patient showed osteoporosis, incomplete epiphyseal closure, with a history of continuing linear growth in adulthood despite otherwise normal pubertal development. He was normally masculinized and serum E and gonadotropin levels were elevated but T was normal. Although the patient had normal genitalia, his semen analysis revealed a low number of sperms with very poor viability. Glucose tolerance was impaired and both bilateral axillary acanthosis nigricans and hyperinsulinemia were present. Bone mineral density of the lumbar spine was 3.1 SD below the mean for age-matched normal women; there was no biochemical evidence of increased bone turnover. Both parents were heterozygous carriers of the mutation and were second cousins. Three sisters were also heterozygous. Further clinical and laboratory analysis found evidence of early atherosclerosis in the left anterior descending coronary artery and endothelial dysfunctional associated with abnormal serum lipid concentrations reflecting E insensitivity. The absence of a functional ER was suggested as a possible novel risk factor for coronary artery disease [2].

## Prevalence

E deficiency is such an extremely rare condition that, to date, only one case of complete resistance has been reported in humans [1], maybe for problems in implantation of the affected embryos or for a suspected impaired fertility of heterozygous women. Till now, no mutation in the human ERβ gene has been described, leaving the issue of their existence and their phenotypic correlates unknown.

## Genes

The affected genes are ERα (ERS1): locus 6q25.1 and ERβ (ERS2): locus 14q23.2.

## Molecular and Systemic Pathophysiology

The reduced or absent response to E is due to a defect in the E receptor (ER) intracellular signaling cascade initiated by ligand binding to ER. E exert their action at cellular levels through different signaling pathways involving different isoforms of ER, namely the main classic intracellular receptor ERα, ERβ (iER), or the alternative truncated form, ER46, or a putative membrane isoform (mER) (Fig. 1a).

Two different genes generate two proteins of about 66 kDa (ERα) and 55 kDa (ERβ) with distinct tissue and cell patterns of expression. The receptors belong to the family of nuclear steroid receptors and are similarly organized in functional domains (Fig. 1b). Additional ER isoforms have been characterized in several tissues and seem to play a role in tumorigenesis and in modulating E response.

ES binding induces iER release from inhibiting chaperons, the receptor dimerization, nuclear translocation, and binding to the responsive elements (ERE) of target genes, finally leading to modulation of gene expression. Modulation and rate of gene transcription depend on the ability of the activated ER to recruit co-activator or co-repressor molecules as well as by ER homo- and hetero-dimerization (Fig. 1a). Non-genomic effects may be mediated by alternative isoforms of ER and rapidly activate intracellular second messengers [3].

Besides alteration of the ER, defects at any level of the signaling cascade activated by E may lead to a decreased sensitivity and consequently to a cell/tissue resistance to the hormone. A stop codon mutation in the ERα gene resulting in the absence of the receptor has been described as the only cause of total E resistance known [1]. Additional mutations in ER resulting in a partial E resistance might be difficult to diagnose due to the absence of a suggestive phenotype.

Data obtained in the mouse models of selective knocking out ERα (ERKO), ERβ (βERKO), or double KO have been pivotal for characterizing the role of different receptors in mediating E effects. These animals represent unique models of selective E resistance and present phenotypic changes in both sexes associated with the gonads, mammary glands, reproductive tracts, skeletal tissues, and cardiovascular system depending on the type of KO receptor [4].

## Diagnostic Principles

ER defect screening might be included in the differential diagnosis of apparently disparate entities as tall stature, unfused epiphyses, osteoporosis, abnormal gonadotropin secretion, and infertility [1,5]. Differential diagnosis from aromatase deficiency, which is characterized by absent E production due to a defect in the aromatase gene [5], should be taken in account. Thus, diagnosis should be confirmed by the genetic screening for mutation of both the ERα and the aromatase genes.

## Therapeutic Principles

Different from what happens in aromatase deficiency, E treatment was ineffective in the man with E resistance [5]. Currently, E replacement treatment is not recommended in men with E resistance due to *ERα* mutation even though it is not known if E may be beneficial through their action involving other different

# Ethanol-induced Liver Cirrhosis

►Liver Cirrhosis, Alcoholic

# Ethylmalonic Encephalopathy and Acrocyanosis

Rossana Mineri, Valeria Tiranti
Unit of Molecular Neurogenetics, Pierfranco and Luisa Mariani Center for the Study of Children's Mitochondrial Disorders, IRCCS Foundation Neurological Institute "C, Besta", Milan, Italy

## Definition and Characteristics

Ethylmalonic encephalopathy (EE, OMIM#602473) is a fatal metabolic disorder of infancy, characterized by mental retardation and regression. The main neuropathological features of the disease are symmetrical necrotic lesions in the basal ganglia and brainstem (Fig. 1a), resembling Leigh syndrome (LS, OMIM# 256000). Other clinical features are: showers of petechiae and orthostatic acrocyanosis (Fig. 1b), hyperlactic acidemia and chronic mucoid diarrhea. High levels of ethylmalonic acid (EMA) in the urine (Fig. 1c) and high levels of C4 and C5 acylcarnitines in blood are invariably present in the disease. In addition, an isolated defect of cytochrome c oxidase was consistently present in the skeletal muscle of affected patients.

## Prevalence

EE is a rare autosomal recessive disorder, mainly affecting children from the Mediterranean basin and the Arabian peninsula.

## Genes

Ethylmalonic Encephalopathy is caused by mutations in the ETHE1 gene (19q13.32) that codes for a mitochondrial protein located into the matrix of the organelle. We have been collecting more than 50 patients from 40 families, presenting a fairly homogeneous clinical and biochemical presentation, in spite of a wide spectrum of ETHE1 mutations including missense, non-sense, frameshift and deletion of single exons or of the entire gene (Fig. 1d). No correlation between type of mutation and severity of the clinical phenotype was observed.

## Molecular and Systemic Pathophysiology

The disease is characterized by an unusual association of biochemical findings in particular elevated concentration of C4 and C5 acylcarnitine in plasma and high levels of EMA in the urine. These findings could be theoretically produced by deficiency in two enzymes: the short chain acylcoenzyme A dehydrogenase (SCAD) [1] and the 2-methyl-branched chain acylcoenzyme A dehydrogenase (2M-BCAD) [2]. However, the in vitro activities of these two enzymes in EE fibroblasts have been reported to be perfectly normal. Another hypothesized co-factor in the etiology of EE, was the 625G>A

the plasma membrane associated with caveolae (B1) or associating on the inner part of plasma membrane with growth factor receptor (GFR) and second messengers such as Src in multi-protein complex (B2) or associating to the mitochondrial matrix (B3), or through unusual membrane receptor (mER, B4). These latter mechanisms mainly involve rapid activation of second intracellular messengers (such PI3K, MAPKs, Src, tyrosine kinases, phosphatases) instead of direct activation of nuclear gene transcription. : classic intracellular ER; : mRNA synthesizing ribosome; : heat shock protein associated to ER: : novel membrane ER: : ER co-activators; : ER co-repressors; : mitochondria; : caveolae. (b) On T2 MRI images of a transverse section of the brain, symmetrical, patchy, high-intensity signals are present in the head of nucleus caudatus and in the putamen (*arrows*). (c) Gas-chromatographic profile of urinary organic acids in EE. The abnormal peak of EMA is indicated in red. Asterisks indicate internal standards. (d) ETHE1 mutations identified in our patients. Missense (*in light blue*) and loss of function (*in orange*) mutations are indicated along the schematic representation of the ETHE1 cDNA. The genomic organization of human ETHE1 is represented below the cDNA. (e) Structural comparison between the 3D model of the human ETHE1 protein (*in light blue*) and the crystal structure of the Arabidopsis ETHE1 protein (*in orange*). The structural overlapping is almost complete except for a shift of one alpha helix in the C-terminus part of the proteins.

SNP in the gene encoding the mitochondrial short-chain acylCoA dehydrogenase (SCAD) [3]. However, no difference in the frequency of the 625G vs. the 625A SCAD alleles was found in 50 ETHE1 mutants and in 53 control individuals. On the contrary, the 625A allele was significantly over-represented in 28 patients with non-EE EMA aciduria ($P < 0.01$). This data rules out a pathogenetic role of SCAD variants in EE, indicating that mutations of ETHE1 are responsible for the high level of excretion of ethylmalonic acid in this condition [4]. The ETHE1 gene product is a cysteine-rich metallo-protein located in the mitochondrial matrix, and is structurally homologous to, but functionally different from, glyoxalase II (GlyII), a cytosolic thioesterase involved in glutathione recycling. *In silico* modeling and crystallographic analysis suggested that the ETHE1 protein may also be a thioesterase, acting on a still unknown substrate [4]. The comparison between a 3D-structure of the human ETHE1 protein obtained by homology modeling and the crystal structure of the Arabidopsis ETHE1 protein [5] indicates that the two proteins are structurally similar with an RMSD (Root Mean Square Deviation) of 3.5A. By native gel electrophoresis and atomic-spectrometric analysis we could show that human ETHE1 works as a homodimer coordinating two atoms of iron, as also reported for Arabidopsis ETHE1 [5]. Although the specific role of the ETHE1 protein is still to be completely clarified, this data corroborate the hypothesis that Ethe1p, like hGlyII, is a thioesterase enzyme, which is part of a novel metabolic pathway specific to mitochondria.

## Diagnostic Principles

Diagnosis is made by clinical observation and laboratory tests. Molecular genetics study in affected patients is performed by analyzing the seven exons of the

ETHE1 gene, using both PCR and sequencing. Quantitative real-time PCR is also available to identify deletions that are present in compound heterozygous.

Western-blot analysis with specific antibody can be performed in selected cases, for immuno-detection of the ETHE1 protein.

The identification of ETHE1 as the gene responsible for EE, is the basis for a rational genetic counseling and offers the unique possibilities to prevent the transmission of the disease by performing prenatal genetic testing.

## Therapeutic Principles

Although no efficient therapeutic treatment is available for this disorder, and in general for mitochondrial disorders, an antioxidant cocktail seems to slightly improve the clinical condition in some cases. This pharmacological approaches stem from the notion that one of the consequences of impairment of respiratory chain function is the generation of excess reactive oxygen species.

# Euthyroid Sick Syndrome

Seda Sancak[1], Ralf Paschke[2]
[1]Marmara University Medical School, Istanbul, Turkey
[2]III Medical Department, University of Leipzig, Leipzig, Germany

## Synonyms

Nonthyroidal illness syndrome; Low $T_3$ syndrome [1–4]; ESS

## Definition and Characteristics

Euthyroid sick syndrome (ESS) is characterized by low triiodothyronine ($T_3$), high reverse serum triiodothyronine ($rT_3$) and normal or reduced thyroid stimulating hormone (TSH) concentrations [1–4].

ESS is seen in a variety of nonthyroidal illnesses including severe infections, trauma, myocardial infarction, major surgery, malignancy, inflammatory conditions, sepsis, coronary artery bypass surgery, bone marrow transplantation, burns and starvation [1–4]. With recovery from the underlying illness, these abnormalities of thyroid function disappear [1,2].

## Prevalence

The prevalence depends on which groups of patients are evaluated. Among patients admitted to hospital medical services, the prevalence of a low serum $T_3$ concentration is ~50%, that of a low serum $T_4$ concentration is ~15–20%, and that of an abnormal serum TSH concentration is ~10% [4].

## Molecular and Systemic Pathophysiology

The changes in endocrine function during severe illnesses occur in a biphasic pattern: The initial adaptive response consists of proteolysis, lipolysis and gluconeogenesis. These processes provide the essential substrates for vital organs. The second phase is a maladaptive response which is associated with suppression of thyroid hormone and other pituitary hormones [3,5].

Acute illness induces alterations in thyroid hormone equilibrium within hours which occur in a dual presentation. Within 2 h after onset of the disease, serum levels of $T_3$ decreases and $T_4$ and TSH rise. Subsequently, TSH and $T_4$ levels often return to normal and $T_3$ levels remain low [5].

Serum $T_4$ levels are reduced in ESS in proportion to the severity and probably length of the illness. In acute, short term of illness, there is no drop in serum $T_4$. However, with increasing severity of illness, the drop in $T_4$ reaching a value below 4 μg/dL is usually associated with the risk of death [2,3]. Serum $T_4$ is reduced in part because of a reduction in thyroxine-binding globulin (TGB) [1–3].

Serum levels of $T_3$ decrease due to decreased conversion of $T_4$ to $T_3$ and/or increased turnover of thyroid hormones. The fall in $T_3$ values within 24 hours shows the severity of illness. Serum levels of $rT_3$ increase due to reduced $rT_3$ degradation. The number and occupancy of hepatic nuclear $T_3$ receptors were shown to decrease in animal models [1–5].

The low $T_3$ syndrome at the tissue level can be due to inhibition of uptake of $T_4$ into hepatocytes [1–4]. This can be due to the presence of binding inhibitors such as elevated nonesterified fatty acids and bilirubin and

reduced albumin [2–5]. But another study invalidated this argument by showing return of serum levels to normal values when $T_4$ is replaced in patients with ESS [3].

The alteration of the thyroid axis during the prolonged phase appears to be different. TSH values are low-normal with low $T_4$ and $T_3$ serum concentrations. Essentially, pulsatile TSH secretion is diminished and this can be related to low serum levels of $T_3$. Recent studies have shown that, after chronic illness, hypothalamic messenger RNA for thyrotropin-releasing hormone (TRH) is reduced [3,5]. Van den Berghe and co-workers showed that administration of TRH to patients with ESS leads directly to increased TSH, $T_4$ and $T_3$ levels [3]. All these findings show that the impairment of hypothalamic stimulation can be the cause [3,5]. A further evidence of diminished hypothalamic function in these patients is the drop of serum testosterone, FSH and LH [3].

Cytokines or other inflammatory mediators such as tumor necrosis factor-α, interleukins (e.g., IL-1, and IL-6), interferon-δ [1–3] which are administered to man or experimental animals, have caused changes in thyroid function tests that resemble ESS [1–5].

Besides the factors mentioned above endogenous dopamine, prolonged hypercortisolism [3, 5], decrease in leptin levels [3] may play a role to suppress the hypothalamic function.

### Diagnostic Principles

With few exceptions, serum $T_3$ and free $T_3$ levels are low and reverse $T_3$ ($rT_3$) are high [3]. Serum TSH is typically normal or reduced and may be markedly low, although it is usually not less than 0.05 μU/mL [3].

Serum TSH is typically undetectable in hyperthyroidism with high serum free $T_4$ concentration. It is also undetectable in less than 7% patients with ESS who have usually been treated with dopamine or corticosteroids [1,4].

An elevated TSH probably suggests the presence of primary hypothyroidism; accompanying findings of goiter, low free $T_4$ and positive antithyroid antibodies supports this diagnosis. An elevated serum concentration of $rT_3$ argues against hypothyroidism [3].

### Therapeutic Principles

There is no clear evidence that $T_4$ and $T_3$ treatment of ESS in animals or man is disadvantageous, and no certain proof that it is advantageous and only in some studies it appears to be beneficial [3]. High doses of $T_3$ given directly after cardiac surgery may have some clinical benefits [1,3,4].

A recent study has shown that low thyroid hormone levels in prolonged illnesses do not reflect an adaptive, protective mechanism against hypercatabolism because restoring physiological levels of thyroid hormones by continuously infusing TRH was found to reduce hypercatabolism [4,5]. Coinfusion of TRH and growth hormone releasing peptide (GHRP) appear to be an even better strategy because the combination also seems necessary to increase the pulsatile fraction of TSH release [4,5].

Serum cortisol should be measured if thyroid hormone is to be given [3].

Cortisol should be above 20 μg/dL. If below 20 μg/dL, ACTH should be drawn and the patient should be given supportive cortisol therapy [3].

Ongoing studies document the beneficial effects of hormone therapy such as GHRP, TRH, GNRH, insulin, adrenal steroids and leptin [3].

# Extrasystoles

Eric A. Sobie, Hena R. Ramay
Pharmacology and Systems Therapeutics, Mount Sinai School of Medicine, New York, NY, USA

## Synonyms

Premature ventricular contractions; PVCs; Ectopic beats; Delayed afterdepolarizations; DADs

## Definition and Characteristics

Extrasystole refers to an additional heartbeat, or systole. As the name implies, an extrasystole occurs outside the regular sequence of heartbeats and is therefore an arrhythmia. PVC is a synonymous term. An extrasystole can arise supraventricularly and propagate through the heart's specialized conduction system, activating the ventricles in the normal sequence, or it can be initiated by a spontaneous action potential (AP) in the ventricles or the Purkinje network. In the latter case, since the sequence of ventricular activation is altered, these extrasystoles are considered ectopic beats. At the cellular level, extrasystoles are apparent as spontaneous depolarizations of the cell membrane. As these most often occur after the previous AP has repolarized, they are termed DADs.

A single extrasystole is generally harmless, as the normal pattern of activation will reassert itself on subsequent beats. The patient may experience a sensation of the heart "skipping a beat," but this quickly passes. If extrasystoles are initiated periodically from a single location at a rate greater than the heart's intrinsic beating frequency, they can cause monomorphic ventricular tachycardia. In rare cases, a single extrasystole can trigger a reentrant loop which leads to sustained ventricular tachycardia (monomorphic or polymorphic), which can then degenerate into ventricular fibrillation. This can cause death if electrical defibrillation is not performed within minutes.

## Prevalence

Extrasystoles are one of the most common forms of arrhythmia. Upon 24-h Holter ECG monitoring, they can appear in nearly 40% of the apparently healthy population [1]. The presence of extrasystoles, by itself, is therefore not considered a clinically important arrhythmia. Frequent extrasystoles can, however, indicate a more serious underlying problem.

## Genes

Extrasystoles are generally not caused by mutations in specific genes. Catecholaminergic polymorphic ventricular tachycardia (CPVT) is an inherited disease characterized by frequent extrasystoles. This disease is caused by mutations in RYR2 (encoding the cardiac ryanodine receptor) or CASQ (encoding calsequestrin).

## Molecular and Systemic Pathophysiology

Extrasystoles are usually caused by premature APs initiated in ventricular myocytes or Purkinje cells. These premature APs result from spontaneous positive deflections in the cellular transmembrane potential known as DADs. The mechanism underlying DADs is illustrated in Fig. 1.

Electrical excitation in cardiac myocytes is coupled to contraction through increases in intracellular calcium ($[Ca^{2+}]_i$) that occur with each AP. Most of the increase in $[Ca^{2+}]_i$ results from release of $Ca^{2+}$ from the sarcoplasmic reticulum (SR) through release channels called ryanodine receptors (RyRs). This release is triggered by $Ca^{2+}$ entry through L-type channels in the cell membrane [2]. This process of $Ca^{2+}$-induced $Ca^{2+}$ release (CICR) involves positive feedback and is potentially unstable. The cell controls this potential instability by grouping RyRs into spatially segregated clusters (Fig. 1, top diagrams). In a resting myocyte, spontaneous release of SR $Ca^{2+}$ from a cluster of RyRs will appear as a spatially restricted (~2 μm) $Ca^{2+}$ spark (middle left image) that will not spread to neighboring regions.

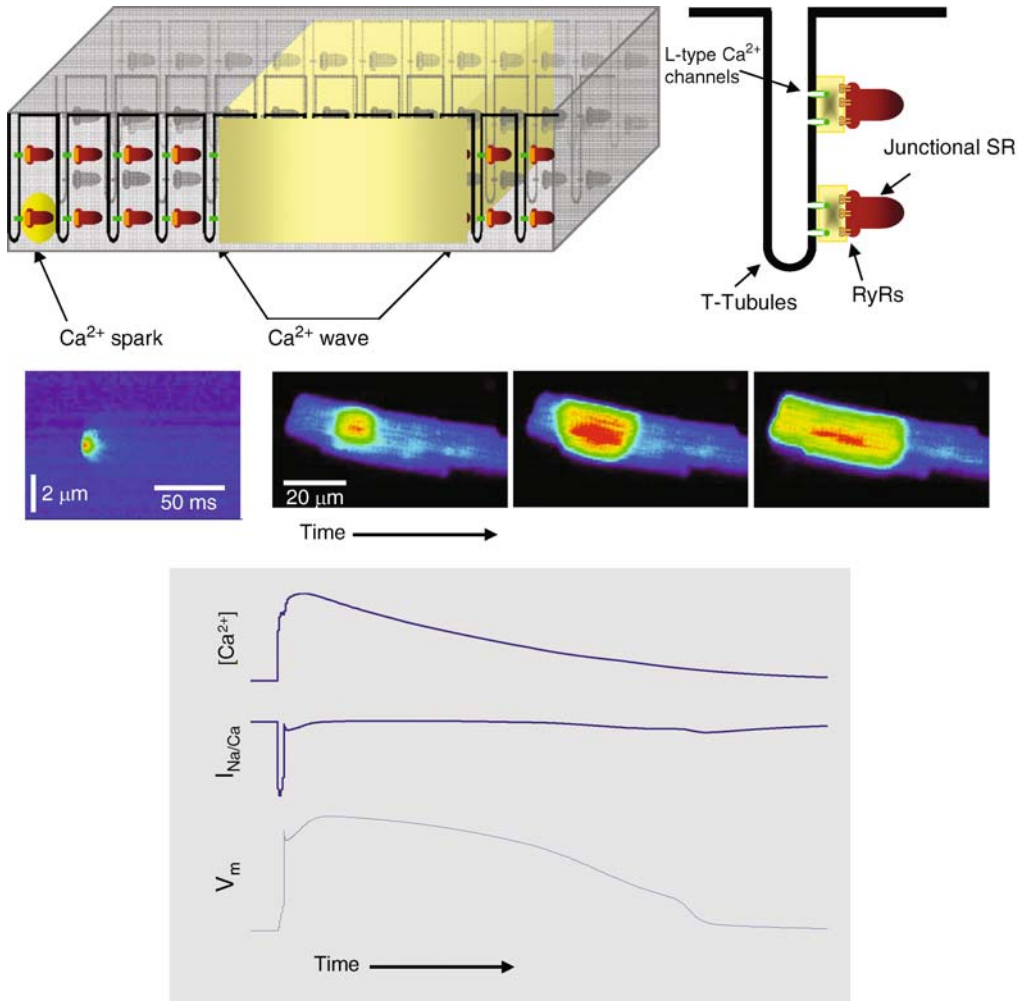
Under pathological conditions such as $Ca^{2+}$ overload, RyRs can become more sensitive to increases in $[Ca^{2+}]_i$. Then a spontaneous $Ca^{2+}$ spark can trigger release from neighboring clusters of RyRs, and a regenerative $Ca^{2+}$ wave can result (Fig. 1, middle images). This wave, propagating at roughly 100 μm/s, will increase cellular $[Ca^{2+}]_i$ from ~100 nM to about 1 μM. Some of this $Ca^{2+}$ will be exported from the cell via the electrogenic $Na^+$-$Ca^{2+}$ exchanger, which imports three $Na^+$ ions for each $Ca^{2+}$ ion that exits. $Na^+$–$Ca^{2+}$ exchange therefore supplies inward membrane current which depolarizes the cell membrane as it lowers $[Ca^{2+}]_i$. This results in a DAD, which, if large enough, can cause an ectopic action potential (Fig. 1, bottom).

## Diagnostic Principles

Extrasystoles are detected using standard ECG or 24-h Holter monitor ECG recordings. Since a significant percentage of healthy patients will exhibit some extrasystoles, diagnosis relies on more specific information, such as the frequency of ectopic beats, the region from which they originate, or the conditions under which they become more frequent [3].

## Therapeutic Principles

The presence of extrasystoles is, by itself, not considered a condition to be treated aggressively. However,



**Extrasystoles. Figure 1** Schematic of the cardiac myocyte illustrating the spatial arrangement of RyR clusters (*top left*). Clusters are located in the junctional SR and in apposition to L-type $Ca^{2+}$ channels in the T-tubular (cell) membrane (*top right*). Spontaneous $Ca^{2+}$ release from a cluster of RyRs is visualized as a localized $Ca^{2+}$ spark (*middle left*). Under pathological conditions, a spark can trigger release from neighboring RyR clusters and a regenerative $Ca^{2+}$ will result (*middle right*). Some of the $Ca^{2+}$ released during the wave will be exported from the cell via the $Na^{+}$-$Ca^{2+}$ exchanger, leading to a DAD or an ectopic beat depending on the extent of the depolarization (*bottom plots*).

when a patient presents with frequent ectopic beats along with other symptoms such as decreased ejection fraction, implantation of a cardioverter-defibrillator may be indicated. The Cardiac Arrhythmia Suppression Trial (CAST) found increased mortality, compared with placebo, in patients receiving drugs meant to inhibit ectopic beats [4]. Since this trial, the use of antiarrhythmic agents to suppress extrasystoles is not recommended.

# Extrinsic Allergic Alveolitis

►Hypersensitivity Pneumonitis

# Fabry Disease

Robert J. Desnick
Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine of New York University, New York, NY, USA

## Synonyms

Anderson-Fabry disease; α-Galactosidase A (α-Gal A) deficiency; Ceramide trihexosidase deficiency; Hereditary dystopic lipidosis; Angiokeratoma corporis diffusum universale

## Definition and Characteristics

X-linked lysosomal storage disease caused by deficient activity of the enzyme α-galactosidase A (α-Gal A) which leads to the progressive accumulation throughout the body of neutral glycosphingolipids with terminal α-linked galactosyl moieties, predominately globotriaosylceramide (GL-3). Affected males typically die in their 40s or 50s due to complications of renal failure, cardiac involvement, or cerebrovascular disease [1].

## Prevalence

The disease is panethnic with an estimated incidence of ~1 in 50,000 males. Over 400 α-Gal A mutations have been identified in families with Fabry disease [1,2].

## Genes

The α-Gal A gene, localized to Xq22.1, is translated into an ~1.4 kb mRNA that is unique since it does not have a 3′ untranslated region. The mRNA encodes a 429 residue glycopeptide containing a 31 residue leader sequence. The mature 398 residue glycopeptide dimerizes to form the homodimeric enzyme.

## Molecular and Systemic Pathophysiology

In classically affected males who have little, if any, α-Gal A activity, the disease-causing glycosphingolipid deposition occurs primarily in the lysososomes of microvascular endothelial cells leading to ischemia and infarction. The resulting early clinical manifestations include the angiokeratomas, acroparesthesias, hypohidrosis, corneal and lenticular changes, and postprandial abdominal cramping and diarrhea [1]. Gradual deterioration of renal function to end-stage renal disease (ESRD) usually occurs in the third to fifth decades. Heterozygous females may remain relatively asymptomatic throughout a normal life span; however, with increasing age, many may manifest disease symptoms, which are usually less severe than in males. A few heterozygous females (~1–2%) have been described with clinical manifestations as severe as those observed in affected males with the classic phenotype.

Affected males with residual (>1%) α-Gal A activity have the later-onset phenotype which typically presents in the fifth to eighth decades with left ventricular hypertrophy, mitral insufficiency, cardiomyopathy, proteinuria and/or renal insufficiency [1]. They have no vascular endothelial GL-3 deposition, and do not have vascular involvement including angiokeratomas, acroparesthesias, hypohidrosis, cerebrovascular disease or renal failure.

## Diagnostic Principles

Fabry disease should be considered in males and females with angiokeratomas, acroparesthesias, hypohidrosis, characteristic corneal and lenticular opacities, stroke, left ventricular hypertrophy, or renal insufficiency of unknown etiology. In males, demonstration of deficient α-Gal A activity in plasma, leukocytes, or cultured cells is diagnostic. Heterozygous females, due to random X-chromosome inactivation, may have normal or deficient α-Gal A activity. Therefore, demonstration of a mutation is required for accurate carrier diagnosis.

## Therapeutic Principles

Phenytoin, carbamazepine, carbamazine, and gabapentin are effective for pain prophylaxis. Dialysis and renal transplantation are recommended for renal failure. Enzyme replacement therapy (ERT) using recombinant human α-Gal A has been shown to safely reverse the pathogenesis of the major clinical manifestations, to decrease pain, and stabilize renal function [2–5]. ERT has been approved in the United States, Europe and 45 other countries. A group of physicians expert in Fabry

disease recommended that all males with Fabry disease (including those with end-stage renal disease) and heterozygous females with substantial disease manifestations should be treated with ERT and the treatment should be initiated as early as possible, particularly in boys with the classic phenotype.

# Facial Paralysis

Orlando Guntinas-Lichius
Department of Otorhinolaryngology, Friedrich-Schiller-University, Jena, Germany

## Synonyms

Peripheral facial paralysis; Bell's palsy; Idiopathic facial palsy

## Definition and Characteristics

Facial paralysis (palsy, FP) is an acute, monosymptomatic, peripheral facial nerve paresis of unknown etiology. The characteristic unilateral symptoms are a paralysis of the mimic muscles, initial postauricular pain, tear flow, taste disorder and phonophobia. Hereditary congenital facial palsy (HCFP) belongs to the congenital cranial dysinnervation disorders [1]. HCFP1 presents as asymmetric, mostly bilateral weakness of some or all facial muscles HCFP2 is unilateral or bilateral and often combined with hearing loss or congenital deafness.

## Prevalence

The lifetime prevalence is reported for Western Europe and the USA to reach 0.6%. The incidence has been estimated to be 10–50 cases per 100,000 of population.

## Genes

A family history is present in 2–28% of all cases [2]. Recurrence in familial FP is frequent, especially if the first episode occurs during childhood. The mode of inheritance in idiopathic familial FP is possibly of autosomal dominance with low penetrance. The genetic factors that possibly lead to neuropathy of the intratemporal facial nerve or increase the individual's susceptibility to FP are unknown. Inheritance of HCFP is autosomal dominant with a penetrance of 95% in HCFP1 and of 60% in HCFP2. Two loci have been identified, one on chromosome 3q21.2–q22.1 (HCFP1) and one on chromosome 10q21.3–q22.1 (HCFP2). To date, no causative mutations have been identified.

## Molecular and Systemic Pathophysiology

Although the cause remains unknown, recent evidence suggests a possible association in some cases with a reactivation of an infection by herpes simplex virus, which has been shown to be latent in a high proportion of seventh nerve ganglia. Probably, the infection leads to a viral inflammation and edema of the nerve. Due to its complicated course through a narrow bone channel within the temporal bone, the edema causes a reduction in the nerve's vascular supply, particularly in the labyrinthine segment. The prevailing notion is that the inflammation is variably accompanied by autoimmune processes related to herpes simplex virus [3]. The result is nerve damage of various degrees with or without nerve degeneration and regeneration. HCFP is probably caused by maldevelopment of the facial nucleus and/or the facial nerve.

## Diagnostic Principles

FP is a diagnosis of exclusion. A congenital, central, traumatic, neurological, infectious, metabolic, neoplastic or iatrogenic cause has to be ruled out by the patient's history, physical examination, ultrasonography of the neck, hearing tests and special radiographic and laboratory examinations related to the patient's symptoms [4]. Electromyography at rest and with volitional motion of the mimic muscles gives information about the severity and prognosis of the nerve lesion.

## Therapeutic Principles

Because of its unknown etiology, optimal patient selection and optimal treatment are still unknown. There may be significant morbidity or incomplete recovery associated with severe disease. Corticosteroids with or without an antiviral agent, acyclovir, are often tried [5], although the available evidence from randomized controlled trials does not show significant benefit. The paralyzed eyelid is protected with drops during the day and a moisture chamber at night.

# Facioscapulohumeral Disease

►Facioscapulohumeral Muscular Dystrophy

# Facioscapulohumeral Muscular Dystrophy

George W. Padberg
Department of Neurology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands

## Synonyms

Facioscapulohumeral disease; FSHD; Muscular dystrophy type Landouzy-Dejerine

## Definition and Characteristics

FSHD is the third most common muscular dystrophy. Its inheritance pattern is autosomal dominant with a high mutation frequency: 10% of gene carriers in a population are new mutations. Approximately 30% of all gene carriers are asymptomatic; a large number of these do not realise the mild signs of the disease [1].

FSHD most likely manifests itself first in an – often asymmetrical (50%) – facial weakness, which frequently goes unrecognised. Initial complaints are usually of shoulder muscle weakness (80%) while foot-extensor (10%), pelvic girdle (5%) and facial (5%) muscle weakness are less common presentations. On clinical examination almost invariably shoulder girdle weakness is present, often asymmetrically with an unexplained preference for the right side. A number of gene carriers do not progress beyond shoulder weakness; in our experience at age 60 approximately two third of all gene carriers have developed foot-extensor weakness and 50% pelvic girdle weakness. At this age 20% of patients are wheelchair dependent outdoors.

Dysphagia and dysarthria are rare symptoms; lingual hypoplasia and facial immobility have been reported in severe cases. Respiratory function diminishes somewhat, relative to the severity of the disease but in our experience less than 1% of patients are on ventilatory support at night. Cardiac muscle involvement has been debated for a long time; conduction defects occur slightly more frequently than in the normal population. Muscle pain (50–80%) and fatigue (35–60%) are neglected symptoms in the older literature. Contractures are rare, with exception of ankle contractures. Pectus excavatum occurs more frequently (5%) than expected and must have a molecular explanation related to the genetic mechanisms of FSHD.

A subclinical high tone hearing loss (75%) and a retinal vasculopathy with teleangiectasis (60%), only rarely lead to deafness or visual loss, with exception of the infantile from of FSHD (onset before age 10). This latter form represents the more severe end of the clinical spectrum with often marked facial weakness and early wheelchair dependency. In Japan this form appears associated with mental retardation and epilepsy. Recently other studies were published suggesting central nervous system involvement in FSHD [2].

While the mean age at onset of symptoms is in the second decade most authors stress the extreme variability of the disease even within single families where members have an identical deletion (see below). There appears to be a consistent gender difference in all populations studied. Females tend to be more often asymptomatic, have a later onset of first symptoms and possibly a slower rate of progression. Also, male mosaics are more often symptomatic than females and at lower percentages of mutated cells.

## Prevalence

The most cited prevalence is 1:21.000 for the European (Caucasian) population. It is debated if this figure applies to all populations [1].

## Genes

In 1990 linkage was found to 4q35 and in 1992 the genetic defect was identified as a reduction in size of a polymorphic EcoRI fragment which hybridises with

probe p13E-11. In controls this fragment contains 11 to 100 KpnI units each 3.3 kb in size, and collectively called D4Z4. This EcoRI fragment is reduced in size by a partial deletion of an integral number of KpnI units resulting in fragments of 10–38 kb (1–10 units) [3].

An almost identical repeat resides on 10q26. In 10% of the population repeat exchanges between chromosomes 4 and 10 can be found, and occasionally hybrid repeats are present. Although the chromosomal origin of the repeats can be recognized by different restriction enzymes, the correct allele constitution for all chromosomes can be difficult to determine. After a long search it was concluded that only small fragments on chromosome 4 are causally related to FSHD. Subsequently we demonstrated that the 4q telomere presents two variant alleles, termed A and B, and that only shortened 4qA alleles are seen in FSHD.

While each unit of the D4Z4 repeat contains a double homeobox sequence and an open reading frame repeated attempts failed to demonstrate a transcript. Early on attention had shifted to a possible position effect and this concept was strengthened when a D4Z4 binding complex consisting of HMG2B, YY1 and nucleolin was identified. It was suggested that this complex acts as a repressor on the transcription of nearby genes so that a D4Z4 deletion results in less repressor binding and transcriptionally upregulation of the known genes FRG2 (FSHD related gene 2 at 37 kb), FRG1 (at 120 kb) and ANT1 (at 3 Mb). This upregulation appeared distance and deletion size dependent. Additional studies suggested FRG1, and not the others, as the gene for FSHD since mice overexpressing FRG1 in muscle develop a myopathy with a severity proportional to the overexpression. However previous studies using various techniques had failed to demonstrate overexpression of FRG1 in FSHD muscle. Similarly, controversies remained over ANT1 involvement [3].

Recently it was demonstrated that the ORF in the D4Z4 repeat is evolutionary conserved and that its gene DUX4 appears expressed in mice and primary FSHD myoblast and acts as a pro-apoptotic protein [4].

## Molecular and Systemic Pathophysiology

After the initial failure to demonstrate a transcript from D4Z4, theories focussed on the altered chromatin structure in 4q35 which could lead to a position effect (upregulation of neighbouring genes through loss of a silencer complex), a change in cis-looping (allowing long distance activation), or an altered nuclear lamina binding (leading to a redistribution of transfactors). Lack of confirming studies and contradictory results has left the FSHD community without a leading hypothesis.

In the search for epigenetic mechanisms D4Z4 was shown to be significantly hypomethylated compared to controls. Interestingly, hypomethylation of D4Z4 was also demonstrated in the rare cases of phenotypic FSHD without a D4Z4 deletion.

RNA profiling of FSHD muscles repeatedly demonstrated a pattern distinct from other muscular dystrophies, but mostly resembling the nuclear envelope diseases. The various studies however did not reveal identical profiles which led to somewhat different interpretations of the most relevant pathogenic pathways involved: altered muscle cell (myoblast) differentiation, oxidative stress handling and endothelial cell function [5].

## Diagnostic Principles

The diagnosis of FSHD is based on clinical examination and family history supported by the demonstration of a 4qA specific D4Z4 deletion. If DNA diagnostics are negative and clinical suspicion is still high EMG and muscle biopsy are indicated to rule out the differential diagnosis. In these cases D4Z4 methylation studies might be warranted.

## Therapeutic Principles

At present no causally related therapies are available for FSHD. Prednisone, Albuterol and Creatine have been studied without clear positive results. Calcium-entry blockers and folic acid have been tested in pilot studies. Aerobic training appears to have a moderate effect. Uncertainty about the duration of the effects warrants additional studies [1,3].

## Familial Hypobetalipoproteinemia

Gustav Schonfeld[1], Xiaobo Lin[1], Maurizio Averna[2], Pin Yue[1]
[1]Washington University in St. Louis School of Medicine, St. Louis, MI, USA
[2]University of Palermo, Palermo, Italy

### Synonyms

FHBL due to apolipoprotein-B (apoB) deficiency; FHBL due to defective PCSK9; FHBL

### Definition and Characteristics

Historically, hypobetalipoproteinemia (HBL) was arbitrarily defined an LDL-cholesterol and/or apoB plasma level of ≤5th percentile corrected for age, race and gender. The term familial HBL (FHBL) was applied to individuals in families in whom low LDL-C/apoB levels appear to be inherited.

### Prevalence

For apoB defects, 1–2 per thousand Caucasians; for PCSK9 4% in Blacks and <1% in Caucasians.

### Genes

The first associated molecular defect was a truncation-producing mutation of apoB [1]. Since then over fifty different truncation-producing mutations, and two missense mutations have been published [2,3]. The apoB defects are associated with susceptibility to steatohepatosis [4]. Another genetic cause of FHBL is a set of loss of function mutations in proprotein convertase, subtilisin/kexin9 (PCSK9) [5]. Both of theses genetic causes of FHBL segregate as autosomal dominant traits. Linkage studies have identified additional possible loci for FHBL on chromosomes 1, 3, and 10 in other families. At the present time, the corresponding genes are unknown.

FHBL is distinct from both abetalipoproteinemia (ABL, due to MTP deficiency), and chylomicron retention disease (due to Sar1b deficiency), both inherited as autosomal recessive traits. The latter two syndromes are usually recognizable in infancy due to early signs of dietary fat malabsorption, malnutrition, failure to thrive and vanishingly low levels of apoB100 and/or apoB48 in plasma. Severe cases of FHBL and mild cases of abetalipoproteinemia can overlap symptomatically.

Modest lowering of LDL-C levels, e.g. ~20–30th percentile, have been linked to several loci, and relevant mutations in three genes have been identified: the intestinal cholesterol transport er, Niemann-Pick1-Like1 (NPC1L1) in enterocytes, and the cholesterol ester transfer protein

(CETP) and apolipoprotein E isoform E2, in plasma. Thus, there are a variety of genetic defects along the cholesterol/lipoprotein pathway that produce a range of symptoms, from none to severe, and a wide array of cholesterol lowering. It is likely that more genetic variations, which affect the levels of LDL-C in a downward direction will be found in future.

## Molecular and Systemic Pathophysiology

ApoB contains several functional domains: four domains interact with glycoproteins, including glycoproteins in arteries. These regions are thought to be involved in atherogenesis. One apoB domain, located near the C-terminus, interacts with the LDL receptor. Missense mutations in this region, produce familial apoB-defective hypercholesterolemia. Truncation-producing mutations of apoB produce low apoB levels, by two mechanisms: (i) apoB100, the product of the normal allele, is produced in liver by lower than expected rates because apoB100 is degraded at unusually high rates within liver, (ii) the truncated form for apoB has a restricted capacity for exporting lipids from liver, and truncation-bearing lipoproteins are cleared very rapidly from plasma mostly by the kidney. These defects result in a restricted capacity for hepatic VLDL production, which reduces the amount of precursor for intravascular LDL production, and predisposes toward steatohepatosis.

Pcsk9, an endopeptidase, is present in a secreted form in plasma. It degrades LDL receptors on the surfaces of cell. Gain of function mutations result in LDL accumulation in plasma, i.e. hypercholesterolemia. Conversely, loss of function mutations result in excessive LDL receptor function and hypobetalipoproteinemia.

## Diagnostic Principles

FHBL is the most likely diagnosis in patients presenting with low levels of apoB and/or LDL-C in the absence of secondary causes (e.g. celiac disease, hepatitis C, liver failure, metastatic cancer), and with minimal symptoms (e.g. high dietary fat intolerance). Relatives with similar findings help to confirm the presumptive diagnosis. Confirmation on the molecular level requires genetic analyses of APOB and PCSK9. Since milder cases of ABL may mimic FHBL, it may be necessary to search for MTP defects in cases where APOB and PCSK9 defects are not found.

## Therapeutic Principles

For symptomatic fat malabsorption, fat intake should be limited to tolerated levels and fat-soluble vitamins may need to be replaced. In those with steatohepatosis, caloric intake, and exercise may be helpful. No data are available on drug therapy for these syndromes.

## Fanconi Anemia

John-John B. Schnog[1], Victor E. A. Gerdes[2]
[1]Department of Internal Medicine, Slotervaart Hospital, Amsterdam, The Netherlands
[2]Amsterdam Vascular Medicine Group, Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands

### Definition and Characteristics

Autosomal recessive disorder which usually presents in childhood with progressive bone marrow failure. Typical birth defects are present in about 60% of patients. Short stature is common and patients have a predisposition for malignancy, especially acute myeloid leukemia.

### Prevalence

Most common type of congenital aplasia. The prevalence is similar among all races and ethnic groups, although slightly higher frequencies have been observed in Ashkenazi Jews and Afrikaners of South Africa due to founder mutations. The heterozygote frequency is estimated 1:300.

### Genes

Multiple genes may be involved: Fanconi anemia complementation group A (FANC-A) located at 16q24.3, FANC-B at Xp22.31, FANC-C at 9q22.3, FANC-D1 at 13q12.3, FANC-D2 at 3p25.3, FANC-E at 6p22-p21, FANC-F at 11p15, FANC-G at 9p13, FANC-J at 17q22, FANC-L at 2p16.1 and FANC-M at 14q21.3 (online mutation database: www.rockefeller.edu/fanconi/mutate/).

### Molecular and Systemic Pathophysiology

The precise pathophysiology is unknown. However, in the last decade considerable progress has been made in the understanding of the disorder. Involvement of at least 11 complementation groups (proteins) has been shown in experiments: A, B, C, D1, D2, E, F, G, J, L and M. The genes have been cloned and defects of A (±65%), C (±10%) and G (±15%) account for the majority of patients. Spontaneous chromosome breakage and hypersensivity to agents which produce inter-strand DNA cross-links has been observed

consistently in Fanconi anemia cells. Another phenomenon is a prolonged duration of the G2 phase of the cell cycle. The complementation groups have a function in DNA repair. Interactions between different FA proteins in a common pathway have also been suggested. A complex of A, C, E, F, G and L is formed in the nucleus, the so-called FA nuclear complex. B is probably required for the formation or stabilization of the complex. The complex is constitutively present and after inter-strand cross-link production part of the complex localizes to chromatin and the nuclear matrix. D2 is mono-ubiquitinated (activated) in case of DNA damage, only in the presence of a functioning FA nuclear complex. D1 and J function probably downstream of D2 in the pathway, and M is probably involved in the assembly of the FA nuclear complex and M may act as an engine that translocates this complex along DNA. Although it is likely that the FA proteins have a function in DNA repair, the mechanism has not been elucidated. There are indications that the proteins have either a direct or indirect influence on DNA repair.

### Diagnostic Principles

Patients do not always have physical abnormalities and may present solely with cytopenias. In vitro enhancement of chromosome breakage by diepoxybutane and mitomycin C in lymphocytes is the diagnostic standard. Serum alpha-fetoprotein is usually elevated and may be used to differentiate Fanconi anemia from other types of anemia or cytopenia.

### Therapeutic Principles

Allogeneic stem cell transplantation is the only therapy able to restore bone marrow function. It is indicated for patients with severe cytopenias. The results with unrelated donor transplants are poor, compared to the results with HLA-identical siblings. Hematopoietic growth factors can be used for patients with neutropenias without an HLA-matched sibling. Gene therapy is under investigation.

## Fanconi Renotubular Syndrome

►Fanconi Syndrome

## Fanconi Syndrome

Pedro R. Cutillas[1], Robert J. Unwin[2]
[1]Luwig Institute for Cancer Research, London, UK
[2]Centre for Nephrology and Department of Physiology, Royal Free and University College Medical School, University College London, London, UK

### Synonyms

Renal Fanconi syndrome; Fanconi renotubular syndrome; Lignac-de Toni-Debré-Fanconi syndrome

### Definition and Characteristics

There are many causes of this syndrome, both genetic and toxic. It is characterized by a generalized defect in proximal tubular reabsorption of filtered solutes, such as glucose, amino acids, phosphate, as well as low molecular weight proteins (e.g., retinol binding protein and vitamin D binding protein). Clinical features can include a metabolic acidosis (due to bicarbonate losses and impaired ammonium generation), rickets and growth retardation in children and osteomalacia in adults (reduced vitamin D synthesis), and renal stone disease related in part to increased urinary calcium excretion. Progressive renal failure can also be a feature of this syndrome.

### Prevalence

No overall figure for its prevalence can be given, because there are several different genetic and toxic causes. Various drugs and toxins can cause the renal Fanconi syndrome, especially heavy metals (cadmium, uranium, lead and mercury), aminoglycoside antibiotics, some antiretroviral drugs (e.g., azidothymidine [AZT]) and certain cytotoxic drugs (e.g., ifosafamide, cisplatin), many of which seem to affect mitochondrial

**Fanconi Syndrome. Table 1** Genetic causes of Fanconi syndrome

| Disorder | Defective gene | Encoded protein | Inheritance |
|---|---|---|---|
| ADIF | Unknown | Unknown | Autosomal dominant |
| Cystinosis | *CTNS* | Lysozyme cystine transporter | Autosomal recessive |
| Cytochrome c oxidase deficiency | *COX* | Cytochrome c oxidase | Autosomal recessive |
| Dent's disease | *CLCN5* | Chloride channel 5 | Autosomal recessive |
| Fructose intolerance | *ALDOB* | Fructose-bisphosphate aldolase B | Autosomal recessive |
| Galactosaemia | *GALT* | Galactose-1-phosphate uridylyltransferase | Autosomal recessive |
| Glycogen storage disease type I (von Gierke disease) | *G6PC* | Glucose-6-phosphatase | Autosomal recessive |
| Lowe syndrome | *OCRL* | Inositol polyphosphate 5-phosphatase | X-linked recessive |
| Tyrosinaemia | *fahA* | Fumarylacetoacetase | Autosomal recessive |
| Wilson disease | *ATP7B* | Copper-transporting ATPase 2 | Autosomal recessive |

function, which might explain their predilection for the proximal tubule. Inherited forms of the renal Fanconi syndrome include X-linked recessive disorders like Dent's disease and Lowe oculocerebrorenal syndrome; autosomal recessive diseases like cystinosis, tyrosinaemia, fructose intolerance, galactosaemia, glycogen storage disease type I, and cytochrome c oxidase deficiency; and an autosomal dominant idiopathic form. Therefore, prevalence is difficult to estimate, though most inherited cases are rare; even for the more common cystinosis has wide ranging estimates (from 0.03 to 0.4 per 10,000 live births), depending on the population studied.

## Genes

Several causative genes have been identified. These gene products can be broadly classified as being involved in cellular energy metabolism (e.g., cytochrome c oxidase and glucose 6-phosphatase), in membrane trafficking or in ion and solute transport (e.g., lysosomal cystine transporter and the chloride channel 5). Known genetic causes are listed in Table 1.

## Molecular and Systemic Pathophysiology

There are at least two molecular mechanisms that may explain how mutations in genes that cause the renal Fanconi syndrome may affect proximal tubular function: (i) impaired energy metabolism and reduced ATP generation that directly or indirectly supports intracellular and plasma membrane transport processes, as well as any association with free radical generation and oxidative injury; (ii) disrupted receptor mediated endocytosis and related control of apical membrane transport proteins, e.g. NaPT2a and NHE3. Phosphaturia can also be explained by the action of filtered parathyroid hormone, but hypercalciuria is less easy to account for. Why progressive renal failure occurs in many cases of this syndrome, especially when inherited, is not well understood. Possible explanations are increased proteinuria per se (as has been proposed for other renal diseases associated with significant proteinuria) or the uncontrolled actions within the tubule of filtered bioactive peptides, including some inflammatory cytokines.

## Diagnostic Principles

The diagnosis is often made in childhood when clinical features of the syndrome may be obvious with the signs of a metabolic acidosis, vitamin D deficiency, hypophosphataemia and hypokalaemia. However, if there is multi-system involvement, as in the glycogen storage diseases, detection may be prompted by the primary disorder. In adults, a high index of suspicion is often necessary in the setting of unexplained renal impairment, drug therapy, renal stone disease or unexplained hypokalaemia and other fluid and electrolyte disorders.

## Therapeutic Principles

Pharmacological therapy is available, depending on the underlying cause, e.g., penicillamine (Wilson's disease), cysteamine (cystinosis). Dietary therapy is available for fructose intolerance only by avoiding fructose containing foods. Other treatments are available but therapy is oral replacement only and includes bicarbonate, sodium and potassium supplements, and active forms of vitamin D and/or calcium supplements. End-stage renal failure can be managed by renal replacement therapy (dialysis and renal transplantation).

### Synonyms

Farber lipogranulomatosis; Acid ceramidase deficiency

### Definition and Characteristics

Autosomal recessive defect in the lysosomal acid ceramidase leads to accumulation of ceramide in various tissues (Fig. 1).

### Prevalence

To date at least 78 cases of Farber's disease have been reported. No data of heterozygote frequency among general population are known.

### Genes

ASAH1 (N-acylsphingosine amidohydrolase) was mapped to the chromosomal region 8p21.3–p22. At least ten mutations are known [1].

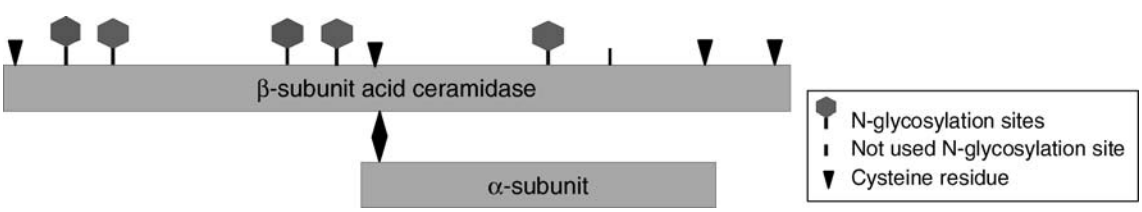
### Molecular and Systemic Pathophysiology

Typical clinical phenotype of Farber's disease is painful swelling and deformation of joints, subcutaneous nodules in relation to the affected joints and over pressure points and progressive hoarseness due to laryngeal involvement. Seven subtypes exhibit differences in the age of onset and the severity of the disease. Usually symptoms appear during the first few months after birth. The severe form of the disease is progressive and leads to death in early childhood. The mild form of Farber's disease is characterized by later onset and a longer lifespan. A fatal neonatal form with hepatosplenomegaly has also been described [2].

Accumulation of ceramide in subcutaneous nodules and in the kidney. In severely affected patients, ceramide also accumulates in the liver, lung, and neuronal cells. Ultrastructural studies show cytoplasmic vacuoles, probably arisen from lysosomes. Those Farber bodies that contain tubular structures presumably contain ceramide.

### Diagnostic Principles

Diagnosis may be made by demonstration of ceramide accumulation in tissue or cultured cells and also by determination of residual acid ceramidase activity in tissue samples. Diagnosis can also be made by loading studies with labeled precursor in cultured cells. Ultrastructural studies of biopsy samples show characteristic "Farber bodies."



**Farber's Disease. Figure 1** Domain structure of human acid ceramidase.

### Therapeutic Principles

Only supportive treatment is available to date.

## Fasciitis, Eosinophilic

Jean-François Pellissier[1],
Georges Serratrice[2],
Dominique Figarella-Branger[1]
[1]Laboratoire de Biopathologie Nerveuse et Musculaire, Faculté de Médecine de Marseille, Marseille, France
[2]Service de Neurologie et Maladies Neuromusculaires, Marseille, France

### Synonyms

Shulman's syndrome [1]; Eosinophilic perimyositis [2]

### Definition and Characteristics

Eosinophilic fasciitis (EF) is a scleroderma-like syndrome with hypereosinophilia and increased ESR.

EF occurs between 30 and 60 years of age. Infantile cases are observed. A short prodromal phase includes fatigue, myalgia and arthralgia associated with low grade fever. Autumn and winter are prevalent seasons. Swelling and stiffness of arms and legs due to oedema and thickening of skin and subcutaneous tissues appear rapidly resulting in a "peau d'orange" effect.

Other parts of the body may be affected, but the face is usually spared. Raynaud phenomenon is rare. Muscle weakness is present only in rare patients with polymyositis. Small joint involvement mimicking rheumatoid arthritis can be observed. Carpal tunnel syndrome is reported in 25% of cases.

### Prevalence

EF is a rare disease. The sex ratio indicates a male predominance (2:1). There is no report on the association of certain HLA haplotypes with EF.

### Molecular and Systemic Pathophysiology

Pathogenic mechanisms and pattern of immunity of EF are unknown. Isolated reports indicate an increased concentration of TGF-β1 and IL-l in fibroblasts of fascia. An abnormal expression of fibronectin and types I, III and IV collagen genes was reported [3]. Increased levels of IL-5 inducing hypereosinophilia was noted in one patient. Studies of adhesion molecules displayed heterogeneous results, but they could be a support for eosinophil recruitment [4].

### Diagnostics Principles

They are based upon clinicopathological features, which are different from those of scleroderma. Other conditions such as eosinophilia-myalgia syndrome, eosinophilic nodular myositis and eosinophilic polymyositis belong to differential diagnosis.

*Laboratory Investigations*: Eosinophilia can be intermittent and requires repeated examinations. ESR is elevated. Serum CK is usually normal. Hypergammaglobulinemia is frequent (75%). Other abnormal tests have been reported such as circulating immune complexes in acute forms and antinuclear antibody reaction. EMG is normal or shows non specific changes.

*Pathology*: One piece biopsy including skin and subcutaneous tissue, fascia and muscle has to be performed [5]. The skin is normal or exhibits dermal changes with small perivascular cuffs of lymphocytes. The polymorphous inflammatory infiltrates are responsible for thickened fascia and consist of lymphocytes, plasma cells, macrophages and more or less eosinophils.

Inflammatory cells can be observed in the interstitial space of muscle. Eosinophils are numerous in perimyositis.

Muscle fibers are normal. Necrotic fibers are present in cases with polymyositis. By immunohistochemistry, class I MHC antigens are expressed on cell membranes of perifascicular fibers.

Mononuclear cells phenotype shows polyclonal inflammatory cell subtypes.

## Therapeutic Principles

Spontaneous remission is common, but relapses are frequent. Signs and symptoms usually respond to steroids. Haematological complications can appear such as anemia, thrombocytopenia, leukaemia and lymphoproliferative disorders.

# Fasciitis, Necrotizing

Cord Sunderkötter
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Flesh-eating syndrome; In some nomenclatures overlap with Fournier-gangrene

## Definition and Characteristics

Necrotizing fasciitis is a life-threatening soft-tissue infection usually due to beta-hemolytic streptococci group A, characterized by necrosis of skin and of subcutaneous tissue involving the superficial fascia often resulting in toxic shock.

## Genes

The severity of invasive streptococcal infections is influenced by the genetically determined susceptibility of the host to release large amounts of inflammatory cytokines in response to streptococcal superantigens. Some HLA class II haplotypes (e.g., DRB1*1501/DQB1*0602) confer strong protection, whereas others increase the risk of severe disease via cytokine responses [1].

## Molecular and Systemic Pathophysiology

There needs to be entry of group A Streptococci pyogenes, or, less frequently, by other aggressive microbial organisms (enterobacteriaceae, pneumococci, Vibrio spp.) into skin. Invasive and destructive potential of certain strains of β-hemolytic streptococci depends on expression of a certain array of toxins and enzymes as well as probably on a genetic predisposition of the host to respond to certain bacterial superantigens. Also some degree of immune dysfunction (including diabetes mellitus) appears to be a prerequisite in patients, especially when bacteria other than β-hemolytic streptococcus group A are the causative organisms.

Invasive streptococci evade PMN-mediated killing by expressing several protective gene products after phagocytosis [2]. Required, though not sufficient for tissue destruction and invasion, is expression of streptolysin S, a β-hemolysin that injures cell membranes including those of lymphocytes, neutrophils, and endothelial cells by an unknown mechanism distinct from that of streptolysin O and phospholipases. Marked recruitment of neutrophils together with neutrophil-derived oxygen radicals or proteases and streptolysin-induced lysis of neutrophils is another factor in soft tissue necrosis. Other virulence factors shared by beta-hemolytic streptococci and necessary for invasion are antiphagoctyic surface M or M-like proteins, proteins binding to fibronectin, collagen or laminin, streptokinase, as well as streptococcal hyaluronidase. Strains most frequently associated with invasive infections and necrotizing fasciitis are serotype M1 and M3 [3]. The high virulence among certain contemporary serotype M3 strains is closely linked to expression of a unique combination of phage-encoded virulence factor such as a SpeA3 variant of the streptococcal superantigen pyrogenic exotoxin A (50% more mitogenic than the SpeA1 variant) and other toxins not present in less aggressive M3 strains. Another component of necrotizing fasciitis is streptococcus-induced dysregulation of the anticoagulation pathways [4] as reduced tissue perfusion contributes to tissue necrosis.

## Diagnostic Principles

A high index of suspicion is important as necrotizing soft tissue infections have no pathognomonic

signs. Patients present with cellulitis (phlegmona), red-violaceous erythema, edema, bullae, crepitus, and fever. The pain may seem out of proportion to the physical findings. Magnetic resonance imaging is able to identify the extent of fasciitis and soft tissue edema. High CRP, elevated white blood cell count, anemia, electrolyte abnormalities, coagulopathy, and acidosis provide clues to the diagnosis.

### Therapeutic Principles

Rapid and aggressive surgical debridement of infected tissue is essential. Antimicrobial therapy is secondary, but remains important. Parenterally applied penicillin G is the drug of choice against Streptococci pyogenes. Addition of clindamycine is recommended as it has good penetration in the tissue and as it interferes with production of the toxin by inhibition of protein synthesis [5]. Intravenous immunoglobulin has been shown to reduce mortality if the necrotizing fasciitis is associated with the toxic shock syndrome by decreasing the superantigen activity on cytokine release by T cells. Neutralization of toxins may become another valuable therapeutic goal.

[2]Cátedra de Gastroenterología y Enzimología Clínica – Departamento de Bioquímica Clínica, Facultad de Farmacia y Bioquímica, Universidad de Buenos Aires, Buenos Aires, Argentina

### Synonyms

Panniculitis; Necrosis of the adipocytes

### Definition and Characteristics

Cell death can either involve a regulated and programmed process known as apoptosis, or be the result of stressful exogenous stimuli comprehending membrane disruption, cell swelling, release of lytic enzymes from zymogens and lysosomes leading to enzymatic digestion, denaturation and coagulation of cytoplasmatic proteins, or breakdown of cell organelles, and is referred to as necrosis.

Regarding structure and function, the widely distributed fat tissue can be considered as an organ. Adipocytes or fat cells are integrated in lobules separated by a thin septa of connective tissue, which gives rise to subcutaneous fat. The septa carries nerves and lymphatic and blood vessels as each lobule receives an arteriole, which will form capillaries into the lobule while a capillary network surrounds each cell. Adipocytes are responsible for fat synthesis and storage, being part of the reticuloendothelial system.

Fat necrosis is a sterile, inflammatory process, which is probably caused by blood, tissue and pancreatic lipase. Other enzymes, such as phopholipase $A_2$ and trypsin, may also participate in liquefying fat cell membranes and splitting trygliceride esters with the consequent release of fatty acids leading to the aseptic saponification of the adipocyte lipid content. These lipids may later combine with calcium forming deposits that are then surrounded by inflammatory cells. The possible deficiency or absence of a protease inhibitor must also be considered as a factor involved in this process. Necrotic adipocytes may appear as anucleated cells or foci of necrotic fat tissue with shadowy outlines due to disintegration of the cellular structure exhibiting a granular cytoplasm and basophilic calcium deposits that may or may not be surrounded by inflammatory infiltrate. Furthermore, necrotic adipocytes, in some cases, may only be recognized by the absence of the nuclei [1].

Fat necrosis can acquire different histologic patterns. (i) Lipophagic necrosis corresponds to macrophages

containing the lipid products from dead fat cells. (ii) Liquefactive fat necrosis exhibits granular wisps of amphophilic detritus. (iii) Hyalinizing fat necrosis presents proteic substances embedding the adipocytes. (iv) Membranous fat necrosis shows disrupted cellular organelles with an eosinophilic of amphophilic rim seen at a late-stage instance; if the lesion is extensive, fat microcysts lacking any structure are found. (v) Ischemic fat necrosis is localized at the center of the lobule involving smaller anucleated adipocytes; at late stages it can associate with lipophagic necrosis [2].

## Prevalence

Breast fat necrosis has an incidence of 6:1,000. Amongst congenital lung diseases, $\alpha_1$-Antitrypsin (AAT) deficiency is second in prevalence to cystic fibrosis. The ZZ variant has an incidence of 1:2,800. Amongst Americans with chronic obstructive pulmonary disease and emphysema, the incidence is 1:2 [3]. Pancreatitis occurs in 1:10,000 inhabitants.

## Genes

AAT deficiency is an autosomal, recessive, inherited disease resulting from a mutation in the AAT gene at locus 14, known as the protease inhibitor locus ($PI^*$) where, under normal conditions, the allele is PI*MM. The allele variants S and Z are associated with the disorder due to the change in amino acid composition [3]. The principal gene mutations associated with pancreatitis are: cationic trypsinogen (PRSS1), pancreatic secretory trypsin inhibitor (SPINK1), cystic fibrosis transmembrane conductance regulator, alcohol metabolizing enzymes and human leukocyte antigen locus.

## Molecular and Systemic Pathophysiology

Breast fat necrosis is a benign non-suppurative inflammatory condition that can mimic breast cancer. It is mostly seen in peri-menopausal women with a wide range of presentations although its commonest form is that of a lump. It is usually associated with a history of previous breast trauma, surgery or biopsy of the breast [1].

AAT deficiency principally involves pulmonary and hepatic disorders. This potent protease inhibitor neutralizes trypsin and neutrophil elastase. Panniculitis is a rare complication observed in this disease, where fat necrosis is associated with acute inflammatory infiltrate. Nodules are generally found in lower limbs although they can appear anywhere in the body. AAT is synthesized in the liver parenchymal cells and then found in the bloodstream as a monomer. The mutated AAT cleaves forming polymers, which have pro-inflammatory properties and accumulate in the heptacocyte being unable to reach the blood [3].

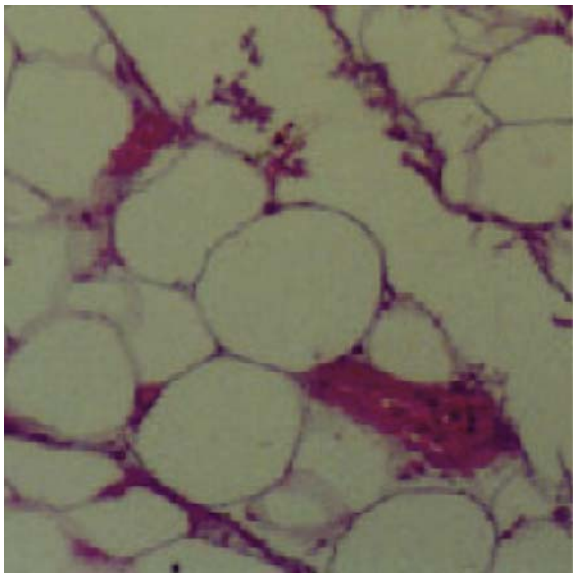
Pancreatic fat necrosis is associated with both acute and chronic pancreatitis that can range from mild to severe when large and confluent areas of necrosis and hemorrhage are involved. Type 1 necrosis is observed in mild pancreatitis involving edema and fat necrotic spots on the surface of the gland as well as small veins and venules. In type 2 necrosis disseminated ductal and periductal necroses outnumber the foci of fat necroses, which may even be absent. Although there is an important inflammatory process, the acinar tissue remains relatively unaffected. If fat necrosis becomes infected, this takes place in the early stage of the pseudocyst development.

Dispersed fat necrosis associated with pancreatitis may present as multiple nodules in distal upper and lower extremities, which can evolve to a nodular eruption complicated with a purulent-looking discharge leaking from the nodules. It is interesting that gram staining of the content from skin nodules may not confirm the presence of microorganisms. This milky fluid is rich in fatty acids, necrotic adipocytes and neutrophilic inflammatory infiltrate [4] (see Fig. 1).

## Diagnostic Principles

Breast fat necrosis can be assessed by mammography, ultrasound and magnetic resonance imaging. Tissue diagnosis is performed by fine needle aspiration cytology or core biopsy of breast lesions.

AAT deficiency is suspected when AAT serum levels are below 104 mg/dL (normal range is 104–276 mg/dL).



**Fat Necrosis. Figure 1** Fat necrosis in acute pancreatitis. Acute pancreatitis was induced in male inbred adult Wistar rats by the Bilio-Pancreatic-Duct-Outlet-Exclusion Closed-Duodenal-Loops Model (BPDOE-CDLs) [5]. Histology of the pancreatic tissue shows peri-pancreatic fat with edema, leukocyte infiltrate and fat necrosis.

The phenotype identification is done by electrophoresis. If panniculitis is suspected the diagnosis is confirmed by tissue biopsy.

Fat necrosis associated with pancreatitis is diagnosed by biochemical profile (mainly leukocytosis, amylasemia and lipasemia), computed tomography scan and skin biopsy.

### Therapeutic Principles

Panniculitis secondary to AAT deficiency can be treated by intravenous infusion of AAT and, if necessary, liver transplantation. If required AAT can also be administered in the case of pancreatitis.

## Fatigue Syndrome

►Chronic Fatigue Syndrome

## Fatty Liver Disease, Nonalcoholic

Matthias Wettstein
Internal Medicine I, Passau Hospital, Passau, Germany

### Synonyms

Nonalcoholic steatohepatitis; NASH; NAFL

### Definition and Characteristics

Nonalcoholic fatty liver disease (NAFL) is an increasingly recognized condition that includes steatosis and nonalcoholic steatohepatitis (NASH) and may progress to fibrosis and cirrhosis. Obesity, type 2 diabetes mellitus or hyperlipidemia are associated with NAFL in more than 80% of the cases. Other causes of liver disease should be excluded, but exact differentiation is often not possible because steatosis and steatohepatitis can sensitize the liver for other pathogens.

### Prevalence

It is estimated that 20–30% of adults in Western countries have excess fat accumulation in the liver and that approximately 10% of these meet the diagnostic criteria of NASH [1]. The prevalence of NAFL is 57–74% in obese persons. Many cases with pure steatosis have a benign course, but progression to steatohepatitis, advanced fibrosis and cirrhosis is possible. NASH has been recognized as the major cause of cryptogenic liver cirrhosis. In NASH-associated cirrhosis, the rate of liver-related complications and mortality are similar to hepatitis C-associated cirrhosis, but hepatocellular carcinoma is less common. However, there are also non-obese, non-diabetic patients with elevated transaminases showing the histological features of NASH.

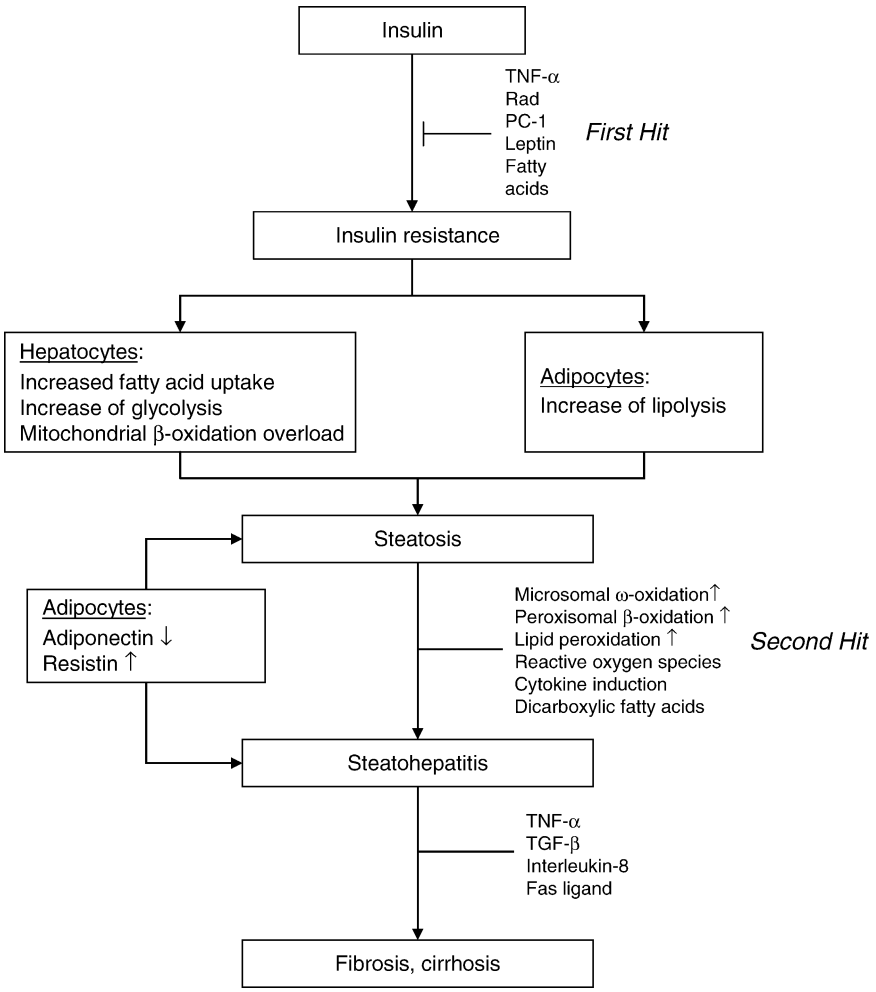
### Molecular and Systemic Pathophysiology

Histological findings in NAFL include steatosis, inflammatory-cell infiltration, hepatocyte ballooning, Mallory bodies and fibrosis, and are indistinguishable from the liver damage resulting from alcohol abuse. NASH is characterized by infiltration of polymorphonuclear cells and mononuclear cells in the presence of steatosis and some degree of fibrosis in most cases.

The pathogenesis of NAFL is not completely understood and it may reflect a heterogenous group of diseases. According to the “two hit hypothesis” the primary step is the development of insulin resistance with subsequent lipid accumulation in the hepatic parenchymal cells (Fig. 1).

The pathogenesis of insulin resistance is multifactorial and involves Rad activation (ras associated with diabetes) and cytokines such as tumor necrosis factor α. Insulin resistance also leads to hyperinsulinemia which increases the synthesis of fatty acids, stimulates glycolysis and decreases the production of apolipoprotein B-100 in hepatocytes. A consequence of insulin resistance and hyperinsulinemia are peripheral lipolysis, increase of circulating fatty acids and an overload of hepatic mitochondrial β-oxidation. Defectice β-oxidation increases microsomal ω-oxidation with formation of cytotoxic dicarboxylic acids.

In the progression of steatosis to steatohepatitis (“second hit”) reactive oxygen species derived from defective mitochondria play a major role [2,3]. In patients with NASH, activity of the mitochondrial respiratory chain is impaired which correlates with serum TNF alpha, insulin resistance and body mass index. Increased intrahepatic levels of fatty acids provide



**Fatty Liver Disease, Nonalcoholic. Figure 1** The "two hit hypothesis" of the pathogenesis of nonalcoholic fatty liver disease. Hypoadiponectinemia may promote liver steatosis and steatohepatitis independent of insulin resistance.

a source of oxidative stress. Reactive oxygen species promote inflammation and fibrosis by lipid peroxidation, cytokine and Fas ligand induction.

Recent studies have pointed out the role of adipokines in NASH. Adipokines such as adioponectin, leptin and resistin are peptides produced in adipose tissue and are involved in regulation of lipid metabolism. Adiponectin enhances lipid clearance from plasma and β-oxidation of lipids in muscle. Overexpression of resisting leads to glucose intolerance and increases free fatty acid levels in animal models. In a study in non-obese, non-diabetic patients with biopsy-proven nonalcoholic steatohepatitis circulating adiponectin levels were lower and postprandial lipemia was higher in NASH patients than in controls [4]. Hypoadiponectinemia may be a pathomechanism independent of insulin resistance in NASH [5].

The steatotic liver is also more vulnerable to other liver pathogens such as alcohol, hepatitis C virus and the presence of heterocygeous mutations of hereditary disorders may also play a role.

## Diagnostic Principles

The diagnosis of NAFL is suspected in patients with asymptomatic elevation of serum aminotransferases and the sonographic aspect of a fatty liver. However, the latter is not a mandatory finding. In most cases, there is a moderate transaminase elevation not higher than 100 U/l and a minor elevation of alkaline phosphatase and γ-glutamyltransferase. The ratio of aspartate aminotransferase to alanine aminotransferase is usually less than 1, but it increases with advanced fibrosis. NAFL diagnosis and staging require liver biopsy, which is recommended in patients with persisting more than twofold elevation of transaminases. In most studies, an alcohol intake of less than 20 g/day in women and 30 g/day in men is used to separate between alcoholic and nonalcoholic fatty liver disease. Other causes of

liver disease such as drug-induced liver injury, viral hepatitis, autoimmune disease, metabolic or hereditary disorders must be excluded by laboratory testing.

### Therapeutic Principles

Primary target of treatment in NAFL are associated conditions. Weight reduction often results in improvement of liver-test results. However, rapid weight loss may worsen inflammation, so that a maximum weight reduction of 500 g/week in children and 1,500 g/week in adults are recommended. Good metabolic control of diabetes and hyperlipidemia is important, but not always reverses NAFL. Medical treatment should be considered in patients with histologically proven steatohepatitis and fibrosis. There is no generally accepted medical treatment available, but improvement of histology and/or laboratory values in NASH patients has been shown in pilot studies for gemfibrozil, vitamin E, metformin, losartan, betaine and the peroxisome proliferation activator receptor (PPAR)-gamma agonist rosiglitazone. Ursodeoxycholic acid was of no benefit. Liver transplantation must be considered in patients with end-stage liver disease resulting from NASH.

### Synonyms

Sweet's syndrome

### Definition and Characteristics

Acute onset of painful erythematous skin plaques histologically rich of neutrophils *without* vasculitis with fever and potential multiorgan involvement including liver, kidney, lung, joints, oral mucosa, central nervous system, and others. In 30% of the cases association to a prior unspecific infection. In 30% of the cases parainflammatory (rheumatoid arthritis, chronic inflammatory bowel disease, lupus erythematodes, sarcoidosis, yersiniosis, tuberculosis, focal infections), in 10% of the cases paraneoplastic (myelodysplasia, leukemia, gammopathy, lymphoma, solid malignant tumours) occurrence [1,2].

### Prevalence

Overall estimated to be 1 in 300,000. Highly changing annual incidence of Sweet's syndrome, possibly caused by infection waves, was reported [2].

### Genes

Only poor data are available on predisposing genes. Studies of a limited number of patients pointed to a higher risk of western European patients expressing the HLA-A1-B8-DR3 haplotype as well as to a higher frequency of HLA-B54 and HLA-Cw1 in Japanese patients [2,3].

### Molecular and Systemic Pathophysiology

Main pathological feature is the acute neutrophil and mononuclear cell infiltration of the upper dermis *without* evidence for vasculitis. Vasculitis-like damage of some vessels may be present and is suggested to be caused secondarily by the enormous transit of neutophils through the vessel walls. This interpretation is substantiated by the negative results of direct immunofluorescence with anti IgG, IgM, IgA, C3, and C4 antibodies. Presence of a neutrophil activating local cytokine milieu involving interleukin-8 and TNF-alpha is suggested. The latter is confirmed by the rapid therapeutical response of the disease to infliximab in single cases. Activated T-cells are present and cytokine expression profiling points to a helper cell type 1 reaction [2,4].

### Diagnostic Principles

*Major Criteria*:

1. Abrupt onset of tender or painful erythematous plaques or nodules occasionally with vesicles, pustules or bullae
2. Predominantly neutrophilic infiltration in the dermis without obvious vasculitis

*Minor Criteria*:

1. Preceded by a non-specific respiratory or gastrointestinal tract infection or by vaccination or associated with inflammatory diseases, hemoproliferative disorders, solid malignant tumors or pregnancy
2. Accompanied by periods of general malaise and fever
3. Laboratory values during onset: ESR > 20 mm; C reactive protein elevated, segmented-nuclear neutrophils and stabs >70% in peripheral blood smear, leukocytosis >80% (three out of four necessary)
4. Excellent response to treatment with systemic corticosteroids

Both major and two minor criteria are needed for diagnosis [2].

### Therapeutic Principles

The persistence of Sweet's syndrome is limited in more than 80% of the cases. Thus corticosteroids, potassium iodide or even indomethacine normally quickly resolve clinical signs and symptoms. Cessation of the therapy after about two weeks is recommended. Alternatives especially in chronically relapsing cases are colchicine, dapsone, cyclosporin A, and thalidomide. The latter as

F

well as biological TNF-alpha blocking drugs such as eternacept or infliximab should be considered only in the rare severe relapsing cases. Each patient should be evaluated for the presence of severe associated diseases. In relapsing patients, reevaluation for the presence of neoplastic disease, for example after another 6 months, should be done since Sweet's syndrome occurs early in these associated diseases.

## Synonyms

Febrile convulsions

## Definition and Characteristics

Febrile seizures (FS) are defined as "an event in infancy or childhood, associated with fever but without evidence of intracranial infection or other definable cause." FS occur between 6 months and 6 years of age with a median age of onset of 18 months. Fever is usually high, greater than 38.5°C. FS are typically brief, generalized tonic or tonic clonic, although 4–16% exhibit focal features and seizures longer than 20 min are reported in 5% of children. Thirty per cent of children have recurrent FS during subsequent illness. Risk factors for recurrence include (i) onset before 18 months, (ii) a first FS at low fever (close to 38°C), (iii) a family history of FS. FS are classified as "simple" or "complex." Complex FS make up less than 25% of attacks and are defined by: duration longer than 15 min, focal ictal features or focal post-ictal defect, or recurrence within 24 h. A higher risk of later epilepsy is reported in complex FS, but the vast majority of children with FS does not develop epilepsy and show a normal intellect and behavioral outcome. The FS+ syndrome was described as FS persisting after the age of 6 years or FS combined with non febrile seizures within families in which FS, FS+ and IGE are combined in an autosomal dominant trait called GEFS+ (►Generalized Epilepsy with Febrile Seizures plus Severe Myoclonic Epilepsy of Infancy).

## Prevalence

3–8% in children up to 7 years of age.

## Genes

Eight FS loci have been identified on chromosome 8q13–21(FEB1, #609800), 19p13.3 (FEB2,#602477), 2q24 (FEB3, #604403), 5q14 (FEB4, #604352), 6q22–24 (FEB5, #609255), 18p11.2 (FEB6, #609253), 21q22 (FEB7, % 611515) and 3P23-24.2 (FEB9, % 611643) but the respective genes remain to be identified. A genotype-phenotype correlation was suggested with FEB5 related to simple FS, FEB2 to complex FS and the other loci to FS associated with later afebrile seizures or epilepsy [1]. In a family with autosomal dominant FS, amissense mutation has been detected in the genes SCN1A, encoding the $Na_v1.1$ alpha subunit of voltage-gated sodium channels [2], and GABRG2, encoding the gamma2-subunit of the GABA (A) receptor [3]. These genes are also affected in more severe epileptic disorders such as GEFS+ and ►Dravet Syndrome.

## Molecular and Systemic Pathophysiology

Risk factors for a first febrile seizure (FS) have been identified in population based studies and in studies comparing children with FS with controls exhibiting only fever. These risk factors include high body temperatures during an infectious illness, parental report of slow development, day care attendance and a positive history of febrile seizures in the immediate family. FS have traditionally been considered to be predominantly an exogeneously mediated seizure disorder provoked by an intercurrent febrile illness. However, family studies have documented that relatives of FS probands

have a higher risk of developing a FS than the general population. The risk for siblings of affected children is reported as 10–20%. These studies as well as other data strongly suggest that FS are inherited as a genetically complex disorder influenced by variations in several susceptibility genes.

For the FS mutation in SCN1A, a partial loss-of-function of $Na_V1.1$ has been shown by electrophysiological methods [2]. $Na_v1.1$ loss of function causes hypoexcitability of inhibitory neurons in the hippocampus and the neocortex of gene targeted mice, thus a predicted decrease of inhibition in neuronal circuits [4,5]. This selective effect could be due to a particularly high expression of $Na_v1.1$ in a subpopulation of GABAergic neurons, as shown in the developing neocortex of the mouse [4]. These evidences are consistent with the effect reported for a GABA (A) receptor FS mutation, which also predicts a loss of neuronal inhibition [3]. Interestingly, similar pathogenic mechanisms have been also proposed for GEFS+, SMEI, and IGE, showing a possibly close relationship among these clinically distinct epilepsy syndromes.

## Diagnostic Principles

FS are diagnosed on a clinical basis. The occurrence of a seizure associated to fever in the age range of 6 months to 6 years must raise this diagnosis. An intracerebral infection should be ruled out. Lumbar puncture should be considered in children aged <12 months and when the clinical history or examination suggest meningitis. EEG and neuroimaging should only be considered for complex FS. The investigations done should be directed by the degree of illness and the suspected underlying infection.

## Therapeutic Principles

FS are usually a benign disorder, although a first febrile seizure often appears to be life-threatening to parents. Reassurance and education (of the families) about the causes and prognosis of this disorder is a leading point in the management of FS. On the basis of risk/benefit analysis, neither long-term nor intermittent anticonvulsant therapy is indicated for children who have experienced one or more simple febrile seizures, and no evidence suggests that any therapy administered after a first simple seizure will reduce the risk of a subsequent febrile seizure or the risk of recurrent afebrile seizures (i.e. epilepsy). Acute treatment such as rectal diazepam and buccal or intranasal midazolam are effective and can be administered at home for FS lasting >5 min. For FS resistant to this treatment, medical assistance is sought. Although it does not prevent simple febrile seizures, antipyretic therapy is desirable during an infectious illness. No evidence exists that continuous antiepileptic drugs reduce the risk of epilepsy whereas considerable potential side effects exist. However, for complex FS the risk of status epilepticus and later pharmacoresistant epilepsy (i.e. Dravet syndrome or temporal lobe epilepsy) is such that continuous treatment is advised. For children with recurrent FS which are geographically isolated, intermittent treatment with diazepam can be considered.

## Ferritinopathy

Johann Michael Schröder
University Hospital, RWTH Aachen, Aachen, Germany

### Synonyms

Neuroferritinopathy; Granular nuclear inclusion body disease; Basal ganglia disease, Adult onset (MIM 606159)

### Definition and Characteristics

Autosomal dominant, adult-onset, slowly progressive multisystem disease mainly affecting the central motor system. Ferritinopathy is clinically characterized by presentations of a distinct movement disorder ("neuroferritinopathy") with chorea, dystonia and an akinetic-rigid parkinsonian-like syndrome, with variable expression in different family members [1,2]. Tremor, cerebellar ataxia, parkinsonism, pyramidal signs, behavioral disturbances, cognitive decline and episodic psychosis were noted in some families.

### Prevalence

Thus far only a few cases and families have been described in different countries, although it is suggested that cases remain undetected among those with Parkinson's disease or other, related movement disorders.

### Genes

Mutations have been detected exon 4 of the gene encoding ferritin light chain (FTL) on chromosome 19 [1,2]. They affect protein folding and stability, increasing iron availability and oxidative stress.

### Molecular and Systemic Pathophysiology

Pathologically, intranuclear and intracytoplasmic bodies were found in astrocytes, microglial and oligodendroglial cells, subsets of neurons in the central nervous system, the choroid plexus and cerebral blood vessels, numerous fibroblasts in the skin and the epithelium of renal tubules [1]. Biochemical analyses revealed that these bodies, isolated from the striatum and cerebellar cortex, were mainly composed of ferritin light polypeptide (FTL) and ferritin heavy polypeptide (FTH1) [2]. The bodies were immunolabeled by anti-ferritin and anti-ubiquitin antibodies and were stained by methods for ferric iron. Their fine structure and ferric iron component are obviously identical to those previously described in the perivascular cells of the muscle and nerve biopsy from a 32-year-old woman with slowly progressive motor disturbances in a multisystem disease named "granular nuclear inclusion body disease" at the time of its description [3].

The cellular pathophysiology of the FTL mutation is not yet elucidated. The mutant FTL protein could disrupt maintenance of the iron cores of ferritin polymers, possibly with the mutant L chain C terminus directed outwards from the ferritin shell. This might then lead to chronic iron leakage from ferritin polymers, thus increasing free cytoplasmic iron and ferritin. Accumulation of iron causes cell death through oxidative stress, which finally leads to the clinical phenotype of a movement disorder.

### Diagnostic Principles

It is of interest that this disease can be identified not only by autopsy or by molecular genetic analysis of the FTL gene, but also by a muscle, nerve or skin biopsy. Such biopsies may be easier to perform than molecular genetic screening of the considerable variety of movement disorders that may cause similar clinical symptoms. A positive iron reaction in addition to the immunohistochemical demonstration of the ferritin heavy polypeptide in the intranuclear inclusions or extracellular deposits and the electron microscopic identification of their characteristic granular fine structure confirm the diagnosis. Yet a conformational change of the ferritin light-chain may cause failure to immunostain the abnormal ferritin deposits [4]. Energy dispersive microanalysis may confirm the light microscopic identification of iron within the granular deposits [5]. Using these methods ferritinopathy can be clearly distinguished from diseases with filamentous nuclear inclusions seen in "neuronal intranuclear hyaline inclusion disease," spinocerebellar atrophy types 1–3, and 6 and other trinucleotide repeat diseases or sporadic and hereditary inclusion body myopathy, inclusion body myositis (IBM) and oculopharyngeal muscular dystrophy.

### Therapeutic Principles

Iron depletion treatment has been performed in a small number of neuroferritinopathy patients [1]. Imaging techniques might be helpful markers for successful brain iron depletion in presymptomatic patients. But it is too early to comment on its efficacy.

## Fever

Ho Sung Kang
Department of Molecular Biology, College of Natural Sciences, Pusan National University, Pusan, Korea

### Synonyms

Pyrexia

### Definition and Characteristics

Fever is a medical symptom that shows a temporary elevation in the body's thermoregulatory set-point and a concomitant rise in internal body temperature (core temperature) usually by about 1–2°C.

### Prevalence

Fever frequently results from infection, inflammation, tissue distruction, metabolic disorder, and chemotherapeutics causing tumor necrosis. The prevalence is similar in males and females at all ages.

### Genes

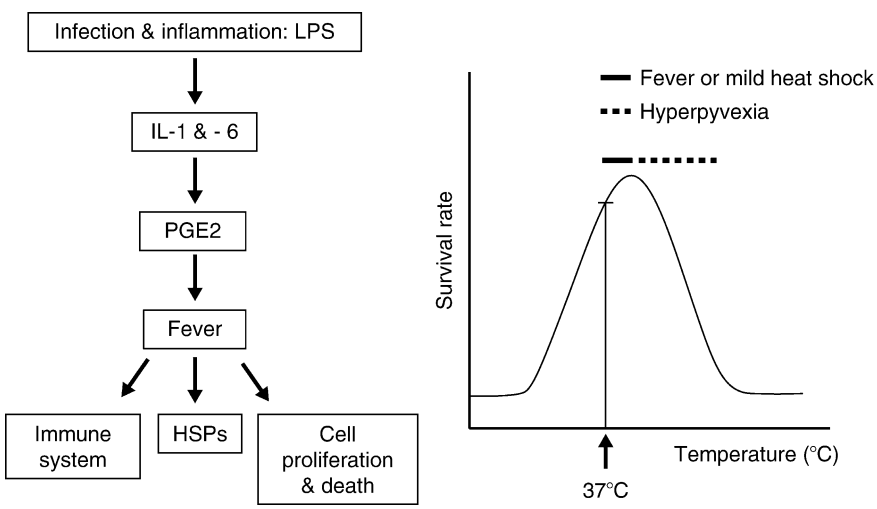
A number of genes is involved in a febrile response; pyrogenic cytokines (as interleukin 1 (IL-1) and IL-6), the phospholipase A2 (PLA2), cyclooxygenase-2 (COX-2), and microsomal PGE2 synthase (mPGES-1), the heat shock proteins, and cyclin D and p21.

### Molecular and Systemic Pathophysiology

Fever is a coordinated endocrine and systemic response that is controlled by the brain and is generally polyphasic, and different mechanisms underlie different febrile phases [1,2]. The mechanism of fever has been well demonstrated for the pyrogen bacterial lipopolysaccharide

(LPS). LPS is recognized by several receptors, including the toll-like receptor (TLR) 4, on various cells including macrophage, resulting in the synthesis and release of various cytokines, such as in IL-1, IL-6, and the tumor necrosis factor-alpha (TNF-alpha) (Fig. 1). There are two types of cytokines responsible for the generation of fever: endogenous pyrogenic cytokines including IL-1, IL-6, and IL-8 and endogenous antipyretics such as IL-10. TNF-alpha has been shown to have pyrogenic and antipyretic properties, depending on the physiological conditions. The interactions of pyrogenic and antipyretic cytokines determine the height and duration of the febrile response. These cytokines migrate to the circumventricular organs of the brain and cross the blood-brain barrier (BBB). The BBB is thought to be not a barrier preventing the signal transduction of the cytokines, but rather the transducer itself. In the endothelial and perivascular cells of the BBB, the cytokines activate the PLA2, COX-2, and microsomal PGE2 synthase (mPGES-1) that induce synthesis of prostaglandin E2 (PGE2), the ultimate mediator of the febrile response. There are multiple PGE2 receptors; EP3 among these receptors are thought to be a primary receptor to recognize fever. EP3-bearing preoptic neurons project to the raphe pallidus in which premotor symphathetic neurons that could drive thermogenesis in the brown fat and skin vasoconsteiction are localized.

The febrile response has been associated with improved survival during infection [3]. The assumption is supported by *in vivo* studies in diverse animal species including warm blooded vertebrates and humans. Many possible mechanisms by which fever might confer protection have been proposed. First, fever-range thermal stress influences multiple parameters of the immune response including lymphocyte proliferation and cytotoxic activity, production or bioactivity of proinflammatory cytokines, lymphocyte trafficking to secondary lymphoid organs that are major sites for launching effective immune responses during infection or inflammation, and lymphocyte-endothelial adhesion, a critical checkpoint controlling lymphocyte extravasation [3,4]. In addition, fever may protect organisms from harmful stresses through heat shock factor 1-dependent induction of the heat shock proteins that function as molecular chaperone and exert cell cycle regulatory and anti-apoptotic activities [3]. Furthermore, fever-ranged mild heat stress does some beneficial roles in organisms via regulating cell proliferation and cell death [5]. In most cases, severe thermal stress is thought to act as a proteotoxic stress that causes protein denaturation and exerts a variety of anti-proliferative effects in *in vitro* mammalian cell culture system. For instance, acute exposure to heat shock leads to a transient arrest of cell cycle through inducing p21 CDK inhibitor and other regulatory proteins and more severe heat shock induces the programmed cell death known as apoptosis. In contrast, fever-ranged mild heat stress is known to



**Fever. Figure 1** Scheme of molecular mechanism of fever. Fever can result from infection and inflammation. One model for the mechanism of fever has been described for bacterial LPS, the most common pyrogen. LPS is recognized by various cells including macrophage, resulting in the synthesis and release of pyrogenic cytokines such as IL-1and IL-6. The cytokines bind with endothelial receptors on vessel walls, or interact with local microglial cells and induce synthesis of PGE2, the ultimate mediator of the febrile response, by the PLA2, COX-2, and mPGES-1. The febrile response has been associated with improved survival during infection, while hyperpyrexia decreases survival rate. Physiologic fever is proposed to do some beneficial roles in organisms (i) by influencing multiple parameters of the immune response including lymphocyte proliferation and cytotoxic activity, neutrophil and dendritic cell migration, and production or bioactivity of proinflammatory cytokines, (ii) by heat shock factor 1-dependent induction of the heat shock proteins, or (iii) by regulating cell proliferation and death.

promote cell viability and proliferation. Mild heat stress induces the synthesis of cyclin D1 that plays a critical role(s) in G1 progression of the cell cycle through multiple Ras signal pathways involving Rac1, extracellular regulated kinase (ERK), and PI3-kinase. The mild heat shock-activated signal cascade is likely to be activated by the thermal changes in the fluidity of membrane lipids. It is very difficult to define the terms "mild" and "severe," since the effects of heat stress are determined by both heat temperature and exposure time: as temperature increases by 1°C, the time required for the same extent of the heat shock response is reduced by twofold. Furthermore, heat shock sensitivity varies depending on biological factors including cell types, tissue origin, developmental stage, and cell cycle phase of the cell line analyzed and the cellular events measured. Thus, the criteria for grading heat stress should be considered in both arithmetic and biological aspects. The heat shock response may be evolved at the early stage of evolution to protect organisms from environmental thermal and other proteotoxic stresses before the febrile response is established; a more recently evolved febrile responses is likely to empty some of molecular mechanisms of an evolutionally conserved heat shock response [3,5].

### Diagnostic Principles

When rectal/otic, oral, and axillar temperature is higher than 38, 37.5, and 37.2°C, respectively, a patient is diagnosed to get a fever.

### Therapeutic Principles

Since fever is a signal for infection or inflammation but is beneficial in human, it must be treated in situations when the core temperature increases to harmful hyperpyrexia. Medication such as selective inhibitors of COX-2 is frequently used to lower the thermoregulatory set-point.

## Fiber Type Disproportion, Congenital

Johann Michael Schröder
University Hospital, RWTH Aachen, Aachen, Germany

### Definition and Characteristics

Muscle fiber type disproportion (FTD), according to Brooke's [1] definition, is characterized by (i) hypertrophy

of type 2 muscle fibers, (ii) predominance of type 1 fibers with normal or slightly reduced diameters and (iii) a difference between the mean diameter of these main fiber types of more than 12%. Although FTD was first regarded as a congenital myopathy (CFTD), our data and those of others indicate that it is a heterogeneous syndrome caused by a variety of disorders, including peripheral neuropathy [2].

## Prevalence

Computer retrieval of our cases classified as FTD from a data file of more than 12,000 muscle biopsies (from the years 1966–2003) revealed 331 cases. Thus FTD represents a relatively frequent histopathological feature although less frequent than the reverse histochemical pattern, i.e. selective type 2 muscle fiber atrophy (642 cases). The clinical appearance depends on the type of the underlying disease. The children studied by Brooke [1] appeared to be hypotonic ("floppy babies"). The disease presented shortly after birth. In other cases there was only slight hypotonia in the legs; in yet another case there was severe retardation of the motor and mental development together with disturbances of growth, deformity of the head and scoliosis. Some cases were unusually severe or fatal.

## Genes

Half of the patients studied by Brooke [1] had relatives with similar symptoms. CFTD was also recorded in concordant twins. In another case, a balanced chromosomal translocation t(10;17) (p 11.2;q25) and arthrogryposis multiplex congenita was described and the translocation breakpoints considered as candidate regions for a myopathy gene [3]. Mutations in ACTA 1 (actin myopathy) [4] and in SEPN1 (selenopathy) [5] are other molecular genetically defined causes of CFTD.

## Molecular and Systemic Pathophysiology

Although FTD as a histopathological syndrome is heterogeneous and seen in a variety of disorders, the final pathway of its pathogenesis and histochemical manifestations could be similar. Muscle weakness in these disorders might be more or less well compensated by hyperactivity and overload of the remaining fibers. It is remarkable in this context that 65% of the patients in our series are male and only 35% female. If the type of overload causing hyperactivity is generally of short duration, it would mimic training conditions such as weight lifting in which selective hypertrophy of type 2 muscle fibers is known to occur. But other causes, such as undefined neurogenic disturbances of the peripheral reflex arc, should also be taken into consideration.

## Diagnostic Principles

It is important to distinguish patients with congenital fiber type disproportion (CFTD) from those with Werdnig–Hoffmann disease because the prognosis of FTD is significantly better. The disease should also be distinguished from the various forms of congenital muscle dystrophy. Facioscapulohumeral muscular dystrophy, which may show large type 2 fibers, should also be considered. Fiber type disproportion is also seen in myotonic dystrophy, spinocerebellar disorders, fetal alcohol syndrome, globoid cell leukodystrophy, infantile acid maltase deficiency, rigid spine syndrome, Marden-Walker syndrome, Lowe's or Mobius' syndrome, hypothyroidism and hydrocephalus. Small type 1 fibers may be encountered in many congenital myopathies, including nemaline myopathy, actinopathy and selenopathy as mentioned above, centronuclear myopathies and fingerprint myopathy. Several patients initially reported as having CFTD showed rods in their initial or later muscle biopsies. Myotubular myopathy was observed in one member and fiber type disproportion in another in the same family (for references see [2]). In one of our patients, who died because of nocturnal apnea at the age of 19 years several months after the muscle biopsy had been performed, we noted microscopic hydromyelia at the thoracic level. His brother, who later developed neurofibromatosis, also died of nocturnal apnea and had similar fiber type disproportion. Thus FTD should be regarded as a histopathological feature that is nonspecific and may be associated with a variety of congenital and noncongenital muscle disorders.

## Therapeutic Principles

Due to the great variety of causes of CFTD, there is no specific therapy available.

### Synonyms

Type II fibrinogen deficiencies; Congenital dysfibrinogenemia; Hypodysfibrinogenemia; Dysfibrinogenemia of liver disease; Acquired dysfibrinogenemia

### Definition and Characteristics

Dysfibrinogenemia is a coagulation disorder caused by a variety of structural abnormalities in the fibrinogen molecule that result in abnormal fibrinogen function. The antigen level of fibrinogen may be normal or reduced and is associated with abnormal coagulant activity. Dysfibrinogenemia can be associated with both bleeding and thrombotic manifestations. It can be inherited or acquired. Dysfibrinogenemia, generally inherited as an autosomal dominant trait [1,2].

### Prevalence

The prevalence of inherited dysfibrinogenemia among the general population is rare, and the determination of the true incidence is difficult because many patients are asymptomatic. Only 200–300 families are reported to have congenital dysfibrinogenemia. Approximately 50% of patients with severe liver disease exhibit bleeding secondary to abnormal fibrinogen molecules. The prevalence of dysfibrinogenemia in patients with a history of venous thrombosis is low, i.e. 0.8%.

### Genes

The fibrinogen molecule is a hexamer, consisting of three paired polypeptide chains: A-a, B-b, and g; A and B refer to specific polypeptides on two of the chains. The synthesis of the protein in hepatocytes is under the control of three paralogous genes (one for each chain, i.e. FGA, FGB, and FGG) located within 50 kb on chromosome 4 (4q31.3). To date more than 80 different gene mutations variously distributed in the three genes coding for fibrinogen (FGA, FGB, FGG) on chromosome 4 have been described. Each is named for the city where it was first discovered. With only rare exceptions, the congenital dysfibrinogenemias are inherited in an autosomal dominant or codominant fashion [3].

### Molecular and Systemic Pathophysiology

Fibrinogen plays an important role in the coagulation cascade by representing the substrate for fibrin clot formation. Upon vascular injury, thrombin cleavage of fibrinopeptides A and B from the Aa and Bb chains of fibrinogen, respectively, leads to the formation of the so called fibrin monomer. A loose fibrin clot develops as fibrin monomers spontaneously polymerize. The formation of a firm insoluble fibrin gel depends upon cross-linking of the polymer by the transglutaminase activity of factor XIIIa. The fibrin clot has an essential role in limiting bleeding at sites of blood vessel injury, and in addition, it also provides the structure for assembly and activation of the fibrinolytic proteins. Depending on the fibrinogen abnormality, defects may occur in one or more of the steps during fibrin clot formation. Gene mutations in any of the three genes affecting anyone of the functional properties of fibrinogen have been described, including absence or delayed release of fibrinopeptide A and B, delayed or enhanced polymerization, defective crosslinking, decreased thrombin binding, and delayed plasmin digestion. The most common defect involves polymerization of the fibrin monomer. Bleeding tends to be relatively mild or even absent; it's not life threatening. Patients diagnosed with fibrinogen Oslo I have an abnormal fibrinogen that forms a fibrin clot that is resistant to fibrinolysis by plasmin, and is associated with thromboembolic complications that are often relatively mild. Acquired dysfibrinogenemia occurs most often in patients with severe liver disease. The impairment of the fibrinogen, which is synthesized in the

liver, is due to a structural defect caused by an increased carbohydrate content impairing the polymerization of the fibrin, depending on the degree of abnormality of the fibrinogen molecule. Rarely, dysfibrinogenemia may be associated with malignancies.

## Diagnostic Principles

*Clinical Findings*: Bleeding occurs in ~50% of the patients and is usually mild and may not manifest until after a surgical procedure, 40% of patients are asymptomatic, and the remaining 10% have a thrombotic disorder or combined thrombotic and bleeding tendencies. Bleeding manifestations include: menorrhagia, postoperative bleeding, epistaxis, postoperative wound dehiscence, defective wound healing, bruising, mild soft tissue hemorrhage, and intraoperative bleeding. Severe hemorrhage is very rare. Patients with severe liver disease may experience extreme bleeding.

*Laboratory Findings*: Dysfibrinogenemia is diagnosed by abnormal tests of fibrin clot formation. The thrombin time (TT) and reptilase time are the screening tests, and the fibrinogen clotting activity–antigen ratio is the confirmatory test. The fibrinogen antigen level may be low, normal, or high. For this reason, it's important to assess both the activity of fibrinogen, which should be decreased, and the antigen level, which should be within the reference range. Shortened TT may occur in patients prone to thrombosis (fibrinogen Oslo I). The inherited form is diagnosed by demonstrating similar laboratory test abnormalities in family members, and if necessary by analysis of the fibrinogen protein or fibrinogen genes in the patient. Definitive characterization of the abnormal fibrinogen can be performed in a research laboratory. Euglobulin clot lysis time may aid in the diagnosis. The acquired form is diagnosed by demonstrating abnormal liver function tests and by ruling out dysfibrinogenemia in family members.

## Therapeutic Principles

Medical treatment is not indicated in the majority of patients. Fresh frozen plasma (FFP) or cryoprecipitate may be transfused depending on the severity of the bleeding. Patients with recurrent thrombotic events may require long-term anticoagulation with coumadin or subcutaneous heparin. Administration of prophylactic cryoprecipitate may prevent recurrent miscarriages.

# Fibrinogen: Quantitative Mutations

Marina Marchetti, Hugo ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, University of Maastricht, Maastricht, The Netherlands

## Synonyms

Type I fibrinogen deficiencies; Congenital hypofibrinogenemia; Congenital afibrinogenemia

## Definition and Characteristics

Congenital afibrinogenemia and hypofibrinogenemia are autosomal recessive bleeding disorders characterized by the complete absence or reduced amount of immunoreactive fibrinogen, respectively. These abnormalities lead to a clinical spectrum ranging from the complete lack of symptoms to severe bleeding [1].

## Prevalence

The frequency of afibrinogenemia is 1–2 cases per million people; a high rate of consanguinity has been reported. The male-to-female ratio is 1:1.

## Genes

Afibrinogenemia and hypofibrinogenemia represent the same disorder, being the phenotypic expression of the homozygous and heterozygous condition for mutations in the genes encoding the molecule of fibrinogen. The fibrinogen molecule is a hexamer, consisting of three paired polypeptide chains: A-a, B-b, and g; A and B refer to specific polypeptides on two of the chains. The synthesis of the protein in hepatocytes is under the control of three paralogous genes (one for each chain, i.e. FGA, FGB, and FGG) located within 50 kb on chromosome 4 (4q31.3) [2].

## Molecular and Systemic Pathophysiology

Fibrinogen is a 340-kD glycoprotein that circulates in plasma at a concentration of 2–4g/L, with a half-life of 4 days. Fibrinogen is the substrate for fibrin clot formation. In normal fibrin clot formation, a fibrin monomer forms after thrombin cleaves fibrinopeptide A and B from the alpha and beta chains of the

fibrinogen molecule. Factor XIIIa then catalyzes the cross-linkage between different fibrin chains, forming a stabilized fibrin polymer or clot. Several different types of genetic lesions and pathogenetic mechanisms have been described in affected individuals including gross deletions, point mutations causing premature terminations codons, missense mutations affecting fibrinogen assembly/secretion, and uniparental isodisomy associated with a large deletion. A total of 63 point mutations (20 missense, 17 nonsense, 13 ins/del, and 13 splicing mutations) and three large deletions leading to quantitative fibrinogen deficiency have been described. The majority of mutations (70%) is truncating and distributed over the three genes, whereas all the 20 missense mutations affect only the Bb and c chains. With the exception of the 11-kb deletion and the IVS4 + 1G>T mutation, which seem to be relatively frequent, most mutations are unique to an individual or a family. Heterozygosity for these mutations causes hypofibrinogenemia, while afibrinogenemia is due to a homozygous or combined heterozygous state of these mutations [3].

### Diagnostic Principles

*Clinical Findings*: The coagulation defect in afibrinogenemia is no more severe than hemophilia. Afibrinogenemia is usually detected at birth, when it causes uncontrolled bleeding from the umbilical cord. Spontaneous intracerebral bleeding and splenic rupture can occur throughout life, while other bleeding episodes such as gum bleeding, epistaxis and gastrointestinal bleeding are common. Other relatively frequent symptoms are hemorrhages from mucosal tracts, hemarthroses, and hematomas. Hypofibrinogenemia shows a milder bleeding pattern, with trauma- and surgery-related hemorrhages largely exceeding spontaneous events (80 vs. 20%). Both afibrinogenemia and hypofibrinogenemia are associated with recurrent miscarriage and peripartum hemorrhages.

*Laboratory Findings*: Prolongation of prothrombin time (PT) and activated partial thromboplastin time (aPTT), thrombin time (TT) and reptilase time. These two last tests are more sensitive to abnormalities of fibrinogen than the PT or aPTT. In afibrinogenemia, fibrinogen concentrations are usually less than 0.1 g/L in symptomatic individuals. Genotyping still provides a valuable tool for diagnosis confirmation, identification of relatives who might be potential carriers, and prenatal diagnosis [1,3].

### Therapeutic Principles

For patients with clinical bleeding associated with afibrinogenemia replacement of fibrinogen to a level of 0.5–0.8 g/L is usually adequate to maintain hemostasis, although levels greater than 1 g/L have been recommended for central nervous system hemorrhage. The adult dose is 1–2 g IV. The pediatric dose is 20–30 mg/kg IV. Cryoprecipitate has been used as a source of fibrinogen.

## Fibrinolytic Defects

►Fibrinolytic Disorders

## Fibrinolytic Disorders

Lev I. Patrushev
Department of Biotechnology, Shemyakin-Ovchinnikov Institute of Bioorganic Chemistry RAS, Moscow, Russia

### Synonyms

Fibrinolytic defects; Abnormalities of the fibrinolytic system; Disfibrinolysis

### Definition and Characteristics

Congenital or acquired abnormalities of the fibrinolytic system leading to hypo- or hyperfibrinolysis due to impaired activity of plasmin, its inhibitors, or plasminogen (PLG) activators.

### Prevalence

Primary genetic disorders of fibrinolysis are uncommon, acquired fibrinolytic disorders are frequent, and secondary to other primary disorders or therapeutic interventions.

### Genes

PLG coding for the plasminogen, localized or chromosome 6q26-6q27; SERPINF2 – alpha-2-plasmin inhibitor, 17p13; SERPINE1 – plasminogen activator inhibitor

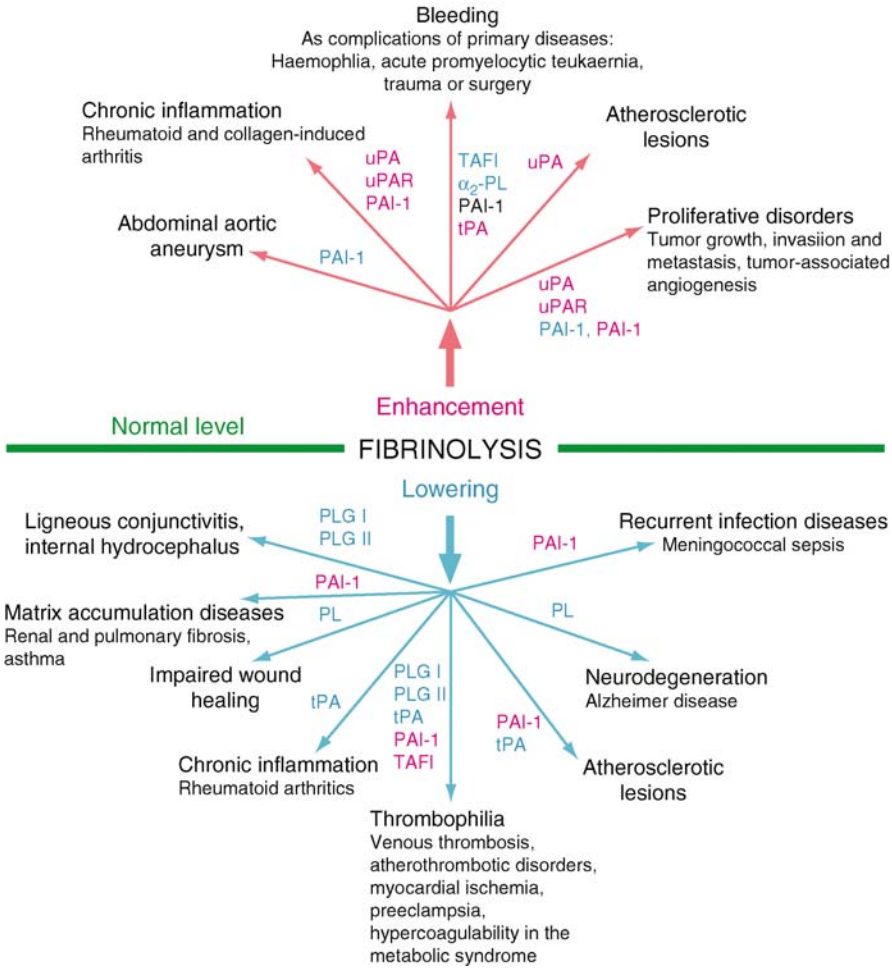
type 1, 7q21.3; PLAT – tissue plasminogen activator, 8p12-8p11; PLAU – urokinase-type plasminogen activator, 10q24; CPB2 – carboxypeptidase B2 (plasma) (thrombin-activatable fibrinolysis inhibitor), 13q14.1; UPAR – plasminogen activator receptor, urokinase-type (urokinase receptor), 19q13.2.

## Molecular and Systemic Pathophysiology

According to plasmin primary fibrinolytic function, PLG-deficient patients exhibit thrombophilia (OMIM 173350). On the contrary, enhanced fibrinolysis because of congenital or acquired loss of fibrinolytic inhibitor (i.g. alpha-2-antiplasmin (OMIM 262850)) activity is often associated with bleeding ([1], see however [2]) (Fig. 1).

Ligneous conjunctivitis as a consequence of impaired clearing by the cornea of fibrin deposits is a serious complication of PLG deficiency. The same pathophysiological effects on vascular homoeostasis can be associated with increased concentration of plasminogen activator inhibitor-1 (PAI-1) (OMIM 173360) or defects in tissue plasminogen activator (tPA) (OMIM 173370), urokinase-type plasminogen activator (uPA) (OMIM 191840) release from the vessel wall, as well as high plasma levels of the thrombin-activatable fibrinolysis inhibitor (TAFI) (OMIM 603101) [1,3–5].

Literature about the thrombogenic effects of the 4G-675/5G polymorphism in the PAI-1 gene promoter (as a consequence of increased gene transcription and significantly higher PAI-1 level) in relation to myocardial infarction and venous thrombosis is inconsistent. Children with the 4G/4G genotype may have an increased risk of meningococcal septic shock. The same effect of 4G/4G genotype was observed in the preeclampsia patients, which is associated with



**Fibrinolytic Disorders. Figure 1** The disorders associated with impairment of fibrinolytic system. Components with lowered or enhanced activity are marked by blue or red color correspondingly. PLG, plasminogen; PL, plasmin; tPA, tissue plasminogen activator; uPA, urokinase; uPAR, urokinase receptor; PAI-1, plasminogen activator inhibitor-1; TAFI, thrombin-activatable fibrinolysis inhibitor.

thrombosis of the intervillous or spiral artery of the placenta. In contrast, an association of the 5G homozygous genotype with familial abdominal aortic aneurysm was observed, which appeared to be the consequence of increased activation of matrix metalloproteinases (MMPs) by plasmin. The pathophysiological importance of the plasmin/PLG system in inflammatory diseases such as arthritis or atherosclerosis as well as tumor cell invasiveness and metastasis has been well established. The failure of TAFI activation with subsequent excessive fibrinolysis as well as a failure of clot formation has been associated with recurrent respiratory infections, vulvovaginitis, and impaired wound healing [3]. Plasmin plays the multifaceted role in the vessel wall. Local plasmin generation is required for the activation of several MMPs, which convert procytokines to active forms [3]. These and other (see Fig. 1) examples implicate a significant role of the plasmin system in a variety of human disorders. In most cases, the detailed mechanisms of the plasmin-mediated effects still remain to be elucidated.

### Diagnostic Principles

The analysis of protein components of the plasmin/PLG system by current molecular biology techniques. Detection of mutations in the corresponding genes may confirm the congenital nature of fibrinolytic disorder.

### Therapeutic Principles

Replacement therapy with lysine-conjugated PLG. Fibrinolysis inhibitors, including ε-aminocaproic acid and tranexamic acid, are effective in treating and preventing bleeding episodes [2,4].

### Synonyms

Albright syndrome; Mazabraud syndrome; McCune-Albright syndrome

### Definition and Characteristics

Fibrous dysplasia (FD) is a focal bone lesion composed of fibrous connective tissue, immature bone spicules, with occasional islands of cartilaginous tissue. In most cases FD occurs as a single lesion (monostotic FD; MOFD) but can also occur at multiple sites (polyostotic FD; POFD). McCune-Albright syndrome (MAS) is classically defined by the triad of POFD, café-au-lait skin lesions, and sexual precocity. However, MAS patients may also develop hyperplasia or adenomas of other endocrine glands with associated endocrinopathies (hypercortisolism, hyperthyroidism, acromegaly), hypophosphatemia, or other nonendocrine manifestations. MAS patients may also present with only POFD and one other clinical manifestation. Mazabraud syndrome is the co-occurrence of POFD and intramuscular myxomas [1–3].

## Prevalence

MOFD is fairly common and is often a clinically silent lesion that is an incidental radiological finding. POFD is somewhat less common, and MAS is much less common than POFD.

## Genes

GNAS coding for the stimulatory G protein α-subunit (Gs α) on chromosome 20q13 [4].

## Molecular and Systemic Pathophysiology

The underlying molecular defect is mutation of Gsα codon Arg201 resulting in constitutive activation of the protein. Gsα is a ubiquitously expressed protein that couples receptors for many hormones and other extracellular signals to adenylyl cyclase, the enzyme that catalyzes the production of intracellular cyclic AMP (cAMP). Activating Gsα mutations in FD/MAS are somatic, rather than germline. Patients with POFD and MAS have multiple sites of disease due to somatic mutations occurring during early development leading to a widespread distribution of cells harboring the mutation. FD results from increased proliferation and abnormal differentiation of osteoblastic precursor cells (bone marrow stromal cells) resulting from inappropriately high levels of intracellular cAMP. In several endocrine glands (thyroid, adrenal cortex, gonads, pituitary somatotrophs) both growth and hormone secretion are normally stimulated by hormones which raise intracellular cAMP. Constitutively active Gsα within these endocrine glands in MAS patients leads to endocrine activation even in the absence of the respective stimulating hormones. The café-au-lait skin lesions are hyperpigmented lesions which result from increased intracellular cAMP levels in melanocytes, which leads to excess pigment production.

## Diagnostic Principles

FD is generally diagnosed by its characteristic ground glass (although occasionally sclerotic) appearance on standard radiographs. The diagnosis of MAS is usually obvious based upon its characteristic clinical presentation. Hormonal measurements will confirm that abnormal endocrine glands are hypersecreting in an autonomous manner. Because the GNAS mutations are somatic, genetic analysis of blood is often not diagnostic, although a mutation can usually be identified in clinically affected tissues.

## Therapeutic Principles

Fractures associated with FD heal well with conservative management. Occasionally surgery is required for nonhealing fractures, severe pain or deformity, or imminent nerve compression. Radiotherapy is contraindicated as it is generally ineffective and may lead to malignant degeneration. Bisphosphonates are also effective in some patients. Endocrine manifestations are treated by surgical removal of affected endocrine glands or specific medical therapy (e.g. antithyroid drugs, somatostatin analogs for acromegaly). There is no specific treatment for the café-au-lait skin lesions.

# Fifth Disease

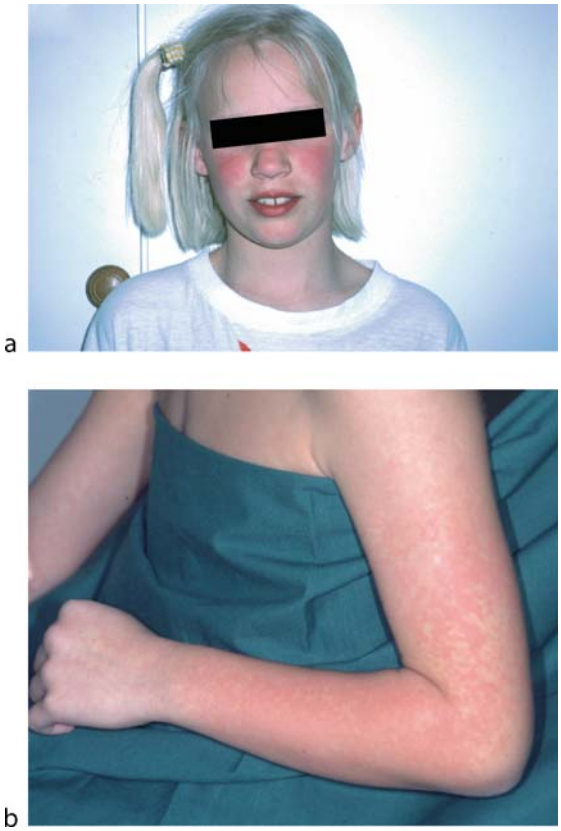
Adiba Isa
Department of Clinical Immunology, Center for Stem Cell Treatment, Odense University Hospital, University of Southern Denmark, Odense, Denmark

## Synonyms

Erythema infectiosum; Slapped cheek disease; Stickers disease

## Definition and Characteristics

Erytheme infectiosum is a mild and common childhood disease. The disease generally affects children of 4–10 years of age. Human parvovirus B19 (B19) is known as the only causative agent of this disease. B19 infection in children can be asymptomatic (in 25% of the cases), but it can also cause a mild self-limiting disease. The infection starts by an asymptomatic phase for 1 week, which is often followed by a characteristic symptom of facial erythema on the cheeks, often called as “slapped cheeks disease” with circumoral pallor, in combination with fever, malaise, headache, nausea, coryza, itching, and excretion of virus in respiratory droplets. The third phase occurs about 1–4 days after the second phase and includes exanthema such as maculopapular rash on the trunk, back, and extremities, and in some cases causes arthralgia (Fig. 1) [1].



**Fifth Disease. Figure 1** Erythema infectiosum (fifth disease). (a) Typical cutaneous eruption, rash appears on the cheeks: "slapped cheek." (b) Stage two symptoms present as maculopapular erythema of the extremities due to the appearance of the antiviral–antibody complex formation.

## Prevalence

B19 is a ubiquitous virus and causes a sporadic and common infection worldwide, which most often occurs in the late winter and early spring. The virus is transmitted via respiratory droplets and through infected blood products and vertically from mother to the fetus. The seroprevalence is high and raises with age; by the age of 15, most of the individuals contracted with the virus are infected, and about 85% in adults. The seroprevalence is about 15% in preschool children to 50% in youths [1,2].

## Molecular and Systemic Pathophysiology

As mentioned, B19 is the only causative agent of fifth disease and the only known host cell for B19 is the human erythroid progenitor cell. B19 is a small virus with single-stranded DNA and contains only three small genes, which are translated to nonstructural protein 1 (NS1) and capsid proteins 1 and 2 (VP1 and VP2). The virus targets rapidly growing erythroid progenitor cells by using three cellular receptors for complete infection. The virus binds to the cellular receptor blood group P antigen, a glycolipid globoside, expressed in a variety of cells such as hematopoetic stem cells, fetal liver cells, and megakaryocyte. Persons who lack P antigen on their erythrocyte are not susceptible to B19 infection. The second coreceptor is the integrin α5β1, and the last identified coreceptor is the ku 80, an autoantigen, which allows the entry to the cell. NS1 is cytotoxic and mediates apoptosis in erythroid progenitor cells, resulting in a temporary suppressed erythropoiesis, followed by a drop of reticulocyte numbers to undetectable levels about 7–10 days postinfection. A temporary drop in hemoglobin is also shown in previously healthy individuals. Lymphopenia, neutropenia, and thrombocytopenia may also occur 6–10 days after infection. Transient aplastic crisis can also occur in patients with underlying hematological disorder. Cessation of erythropoiesis in this group causes severe anemia, because of the higher requirements for red blood cells [3].

B19 infection mediates a high antibody response, as well as a high and long-time activation of the $CD8^+$ T-cell response has also been shown [4]. $I_gM$ antibody production is correlated with the decline in the viral load in peripheral blood, and $I_gG$ antibodies directed to the VP1 appear to confer lifelong protection against a secondary infection. In fact, most of the symptoms such as the typical rash, joint symptoms, or both, occur secondary to the appearance of the antiviral complex.

## Diagnostic Principles

Beside the characteristic symptom, erythema infectiosum can easily be laboratory-diagnosed by serological tests. Anti-B19-specific $I_gM$ antibodies against the VP2 can be detected about 10–12 days after the initial infection and persist for up to 3 months. Specific $I_gGs$ appear about 2 weeks postinfection and are present in the peripheral blood lifelong. The serological tests can be confirmed by direct detection of the B19-specific DNA in the peripheral blood by PCR methods. B19 DNA can be detected in high titres (about $10^{12}$ copies/ml in serum) shortly after the infection. However, B19 DNA is detectable several years postinfection in lower titres by quantitative PCR in serum [2,3].

Direct detection of B19 DNA is important for diagnosis of immunosuppressed individuals, since the antibodies are difficult to detect. In immunocompromised patients, a positive PCR result indicates an ongoing infection.

## Therapeutic Principles

Still, there is no antiviral treatment for B19 infection. The infection, however, is mild and self-limiting, and in immunocompetent individuals, there is no need for medical treatment. Intravenous immunoglobulin (IVIG) against the virus exists and can be used in immunocompromised patients. A week of IVIG

treatment has shown a decrease of the virus and higher levels of reticulocytes in peripheral blood. Blood transfusion can also be needed sometimes. There is no available vaccine against B19 infection yet, but there is one in phase two trial, based on the humoral immune responses [5].

However, B19 infection has shown to give high and activated T-cell responses, which indicates that T-cells are important for the clearance of the virus, and it might be useful to include these responses in a future vaccine [4].

## Flatulence

Fernando Azpiroz
Digestive System Research Unit, Hospital General Vall d'Hebron, Barcelona, Spain

### Synonyms

Meteorism

### Definition and Characteristics

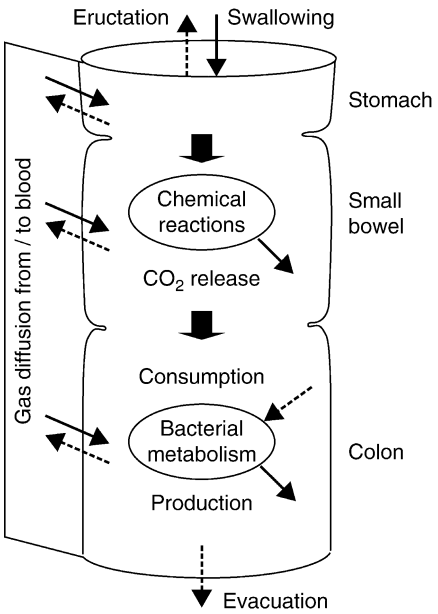
The clinical definition of flatulence is imprecise. In a broad sense, flatulence refers to symptoms produced by intestinal gas, and includes excessive flatus, belching, impaired anal gas evacuation, and abdominal bloating.

### Prevalence

Ten to thirty percent of the population and 90% of patients with irritable bowel syndrome report abdominal bloating and gas related symptoms.

### Molecular and Systemic Pathophysiology

Four clinical conditions with different pathophysiological mechanisms can be defined (Fig. 1).



**Flatulence. Figure 1** Intestinal gas metabolism. Gas input results from swallowing, chemical reactions, diffusion from blood, and bacterial fermentation. Gas output is achieved by eructation, absorption, bacterial consumption, and anal evacuation.

*Excessive and/or bad smelling flatus*: Some patients complain of odoriferous gas evacuation, which may become socially disabling. Odour depends on trace elements, such as sulfur-containing gases ($H_2S$, methanethiol, and dimethyl sulphide) that are produced by sulphate-reducing bacteria in the colon [1]. Other patients complain of excessive passage of gas per anus. The frequency of anal gas evacuation in healthy subjects varies depending on the diet, but is usually around twenty evacuations per day, and the volume of daily gas evacuated ranges between 200 and 700 ml. The volume and smell of gas evacuated is determined by-and-large by the action of colonic microflora on unabsorbed, fermentable food residues entering the colon. Gas-producing substrates include some types of fiber, starch, oligosaccharides, and sugars. Excessive or odoriferous anal gas evacuation depend both on the composition of colonic flora and on the diet. Excessive gas production on a normal diet is usually due to a highly flatulogenic colonic flora. Excessive gas production may be also the consequence of diseases that affect the normal absorption of nutrients within the small bowel (i.e. intestinal malabsorption), but due to their clinical manifestations, these cases are readily recognized and accordingly treated.

*Impaired anal gas evacuation*: In contrast to the patients with excessive flatus, some patients complain of impaired anal evacuation and abdominal gas retention. Normally, rectal evacuation is achieved by a mild abdominal compression coupled to anal relaxation. Some patients have an incoordination with inadequate anal relaxation during straining and impaired evacuation [2]. This type of functional outlet obstruction may produce sensation of difficult gas evacuation and gas retention, which is frequently associated to constipation. Fecal retention in these patients would prolong the process of colonic fermentation of residues and increase gas production.

*Belching*: Some patients complain of excessive belching as if the gastric production of gas were unlimited. These patients inadvertently swallow air (aerophagia), and the process is frequently triggered by a basal dyspeptic-type symptom of epigastric fullness, that the patients misinterpret as excessive gas in the stomach. During repetitive and ineffective attempts of belching, air is introduced into the stomach with increasing discomfort. The patient's misconception is reinforced by the partial relief experienced when eructation finally occurs.

*Bloating and abdominal symptoms*: Patients with functional gut disorders, irritable bowel and related syndromes, frequently attribute their abdominal symptoms to intestinal gas. Bloating, for instance, is one the most common and bothersome complaints in a large proportion of patients with various functional gut disorders. Probably these patients represent a heterogeneous group in which the symptoms are produced by different combinations of pathophysiological mechanism, that in most cases are subtle and undetectable by conventional methods. Recent studies have consistently shown that IBS patients, who attribute their symptoms to intestinal gas, have impaired handling of intestinal contents, due to abnormal gut reflexes, which may result in segmental pooling and focal gut distension. Additional evidence indicates that these patients also have intestinal hypersensitivity with increased perception of intraluminal stimuli. Gas symptoms may be associated to abdomino-phrenic incoordination. In these patients segmental pooling within the gut releases abnormal viscerosomatic reflexes leading to paradoxical diaphragmatic contraction, relaxation of the anterior abdominal wall and distension [3]. However, this does not imply that gas is necessarily the offending element. Other intraluminal component could trigger the abnormal responses, and thus be responsible for abdominal symptoms, that the patients erroneously attribute to intestinal gas.

## Diagnostic Principles

Diagnosis is largely based on a careful clinical history.

## Therapeutic Principles

Treatment depends on the pathophysiological mechanisms involved.

F

1. Patients complaining of *excessive and/or odoriferous gas evacuation* may benefit from a low-flatulogenic diet, that includes: meat, fowl, fish and eggs; among carbohydrates, gluten-free bread, rice bread, and rice; some vegetables, such as lettuce and tomatoes; and some fruits, such as cherries and grapes. On the contrary, high-flatulogenic foodstuffs include: beans, Brussels sprouts, onions, celery, carrots, raisins, bananas, wheat germ, and fermentable fiber [4]. After a one week gas-free diet, these patients usually experience frank symptom relief. By an orderly reintroduction of other foodstuffs, they should learn to identify their offending meal components.
2. In patients with *gas retention due to impaired anal evacuation*, anal incoordination can be resolved with biofeedback treatment [2], which also resolves fecal retention, and thereby, the time for fermentation and gas production are also reduced.
3. *Aerophagia* usually resolves, or at least improves, with a clear pathophysiological explanation of the symptoms. Some patients present psychological problems that may require specific therapy [4,5].
4. *Bloating and abdominal symptoms* may improve with the treatment of the underlying functional gut disorder [5].

## Fluorosis

Guang-Sheng Li, Ling Jing, Hui Xu
Institute of Endemic Diseases, Norman Bethune College of Medical Sciences, Jilin University, Changchun, China

### Synonyms

Fluoride excess; Fluorine intoxication; Endemic and occupational fluorosis; Dental fluorosis and skeletal fluorosis

### Definition and Characteristics

Fluorosis is a condition due to long-term intakes of excessive amount of fluoride through drinking water, or foodstuffs containing large amounts of fluoride, or inhalation of gases containing fluoride. It is characterized by skeletal changes, consisting of osteosclerosis, osteomalacia, osteoporosis and extraperiosteal ossification, and by mottling of the enamel of the teeth when exposure occurs during enamel formation. Simultaneously, fluorosis is also associated with some damages in other organs or tissues.

### Prevalence

The occurrence of endemic fluorosis has been reported in more than 50 nations and regions of the world. Prevalence is higher in Asia, Africa and South America. For example, in 15 villages of Rajasthan in India, the prevalence of skeletal fluorosis among adults ranged from 4.4% at a water fluoride level of 1.4 mg/l to 63.0% at the level of 6.0 mg/l [1]; In villages in Guizhou, China (coal burning-born fluorosis area), the prevalence of dental fluorosis in children was 82.52% [2]. Occupational skeletal fluorosis has been reported mainly in aluminum smelter workers, cryolite workers and workers from magnesium foundries, fluorspar processing, and superphosphate manufacture.

### Molecular and Systemic Pathophysiology

The nature of human dental fluorosis belongs to enamel maturation defect, probably resulting from delayed removal of amelogenins of enamel that affected the enamel maturation, caused enamel hypomineralization and porosity. Up to now, there is no direct evidence to show that fluoride at micromolar levels affects proliferation and differentiation of enamel organ cells [3]. The exact mechanism of fluoride interfering metabolism of enamel matrix proteins remains obscure.

Skeletal fluorosis is mainly characterized by a high bone turnover state based on accelerated osteogenetic action. The mechanisms involved in the activation of osteoblasts by fluoride are not completely clear, but include increased secretion of parathyroid hormone (PTH), enhanced expression of transcriptional factors such as AP-1(activator protein-1) and cbfa1 (core binding factor a1), as well as upregulation of cytokines or growth factors such as bFGF (basic fibroblast growth factor), BMP2 (bone morphogenetic protein 2), IGF (insulin-like growth factor), TGF-β (transforming growth factor beta), PDGF (platelet derived growth factor) and OPGL (osteoprotegerin ligand), etc. Several signal transduction ways, such as G-protein and $[Ca^{2+}]i$, may mediate the action of fluoride on bone cells; oxidative stress may participate in the activation of osteoblasts by fluoride [4,5].

### Diagnostic Principles

The diagnosis of fluorosis is based on clinical features and radiographic findings; characteristic clinical features include mottled enamel (chalky white appearance, brown stain and pitting), big joints pain, and restricted motion. Radiographic findings consist of osteosclerosis, osteopenia, calcification and ossification of ligamentous attachments.

### Therapeutic Principles

Exposure to fluoride needs to be reduced. As dietary calcium deficiency is a main provoking and aggravating factor of endemic fluorosis, improvement of nutritional calcium supply to residents living in endemic areas is very important. In view of the role of oxidative stress in the pathophysiology of fluororsis, residents in endemic areas should receive appropriate, antioxidant-rich food.

## Folate Deficiency

Anne M. Molloy, John M. Scott
Department of Biochemistry, Trinity College Dublin, Dublin, Ireland

### Synonyms

Folic acid deficiency

### Definition and Characteristics

Folic acid deficiency (more correctly termed folate deficiency) can be defined as blood or tissue levels of folate that are insufficient to maintain adequate function of the enzymes that utilize this vitamin as a cofactor. The earliest effects of deficiency are in rapidly dividing cells such as those of the blood and digestive system. Clinically, folate deficiency causes a characteristic macrocytic anemia in peripheral cells, which may be mirrored by megaloblastic changes in the bone marrow. Biochemical characteristics of deficiency include low serum and red cell folate concentrations and raised plasma homocysteine. The definition above allows for the newer nutritional concept of inadequate (rather than clinically deficient) folate status as a risk factor for a number of chronic conditions causing morbidity and mortality in later life, including cardiovascular disease, colon cancer and aspects of neuropsychiatric dysfunction such as depression and Alzheimer's disease. The chemically stable, commercially available form of the vitamin is folic acid. This compound is a synthetic precursor of biologically active folates, which exist as tetrahydrofolate (THF) derivatives. Folic acid is readily absorbed in the small intestine and converted to THF by the enzyme dihydrofolate reductase.

### Prevalence

Folate deficiency is a significant nutritional problem, considered to be the most important cause of anemia after iron deficiency [1]. Low dietary intake is the most common reason although alcohol abuse, smoking, and oral contraceptives contribute to low status in otherwise healthy individuals. In unfortified populations some 10% of people may have blood folate levels less than 3 ng/ml. The prevalence is higher (about 15%) in

women between 20–45 years old. Pregnancy puts a stress on maternal folate stores. It has been estimated that some 30–50% of pregnant women in underdeveloped countries are folate deficient [2]. Lower than normal maternal blood levels of folate are associated with risk of neural tube defects and periconceptional folic acid supplementation prevents at least 50–70% of these birth defects. Up to 40% of chronic alcoholics are folate deficient, based on blood and bone marrow abnormalities.

## Genes

Severe inborn errors have been described; most commonly in the 5,10-methylenetetrahydrofolate reductase (MTHFR) gene. A polymorphism in this gene (677C→T) is also the most common known genetic cause of mild folate deficiency worldwide.

## Molecular and Systemic Pathophysiology

The folate cofactors accept one-carbon units from several sources (principally serine and formate) and donate them to other molecules in a variety of enzyme reactions. THF is the biologically active parent unit and folates exist as formyl-, methylene-, methenyl-, methyl- and formimino-derivatives. These derivatives are required for the production of purines and pyrimidines for DNA synthesis and to maintain a supply of methyl groups through S-adenosylmethionine (SAM) for the methylation of DNA, proteins, neurotransmitters, etc. The overall system is divided into two metabolic cycles; a DNA synthesis cycle and a methylation cycle. The sulfur amino acid, homocysteine, is an essential intermediate at the junction of these two cycles. Two key enzymes control this metabolic junction; MTHFR and methionine synthase. MTHFR irreversibly converts 5,10-methyleneTHF to 5-methylTHF, thereby channeling one-carbon units away from DNA synthesis and into the regeneration of methionine from homocysteine, via methionine synthase, to be used for SAM mediated methylation reactions. Inadequate folate status has numerous cellular consequences including abnormalities of DNA synthesis and repair and inadequate methylation of essential biological components [3]. Megaloblastic abnormalities in severe folate deficiency result from reduction in the de novo synthesis of purines and thymidylate and a build-up of associated precursors in the rapidly dividing cells of the bone marrow. Deoxyuridine monophosphate (dUMP), the substrate for thymidylate synthase, accumulates and is inappropriately incorporated into DNA, leading to replication abnormalities and strand breaks. The effects of folate deficiency on the methylation cycle are less clearly defined although hypomethylation of DNA has been observed. It is likely that neuropsychiatric symptoms and depression are related to abnormal methylation function in the brain, due to raised homocysteine and S-adenosylhomocysteine, the SAM derived product of methyltransferase reactions. In pregnancy, increased folate catabolism is an important cause of low folate status, while alcohol ingestion inhibits the absorption and renal handling of folates. Risk of chronic disease has been associated with elevated plasma homocysteine, which is highly reactive and toxic. The relatively unstable 677C→T variant of MTHFR results in a diminished supply of methyl groups to the methylation cycle. This variant is associated with elevated plasma homocysteine. It is an accepted risk factor for neural tube defects. There is evidence that it is also a risk factor for cardiovascular disease, probably via elevated homocysteine [3].

## Diagnostic Principles

A serum folate concentration less than 2 ng/ml (4.5 pmol/ml) or red cell folate less than 100 ng/ml (226 pmol/ml) indicate clinical deficiency. However, 11–30% of patients with clear megaloblastic anemia due to folate deficiency have blood levels above these cutoffs. Many population surveys use a cutoff of 3 ng/ml (6.8 pmol/ml) to indicate deficiency. Elevated plasma homocysteine (variously defined as greater than 2.5–3 SD above the mean of laboratory controls) is a highly sensitive, but not specific, functional test for folate deficiency. Abnormal hematological findings include increased MCV, hypersegmented neutrophils and macrocytosis. Patients with severe deficiency have megaloblastic bone marrow morphology. These hematological changes also occur in cobalamin deficiency [1]. Diagnosis is based on blood folate estimations. Elevated homocysteine supports the presence of inadequate status. The diagnosis is confirmed by a clinical response to therapy with folic acid and exclusion of cobalamin deficiency as the underlying problem [4].

## Therapeutic Principles

Folic acid, alone and in multivitamin preparations, is the predominant pharmacological therapy for folate deficiency. Green leafy vegetables are a natural source of dietary folates but the average absorption of food folates is about 50%, ranging from 25% to 75% depending on the food source [5]. Cereal products, breads, milk and other foods that have been fortified with folic acid are a more important source of folate in modern diets. A number of countries have introduced mandatory fortification of specific food vehicles with folic acid (such as cereal grains in the USA and Canada), primarily to increase the folate status of women of child-bearing age, and thereby reduce the incidence of neural tube defects.

►Thyroid Cancer

# Folliculitis

Cord Sunderkötter
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

In sensu latu: abscess; Superficial folliculitis; Follicular impetigo; Ostiofolliculitis

## Definition and Characteristics

Inflammation of hair follicles usually due to infection with bacteria, but also to infection with yeast, dermatophytes or primarily due to physical trauma or due to complex and less well defined etiology.

## Prevalence

Bacterial folliculitis: Frequent, no exact indices, more frequent (i) in warm or hot regions with high humidity (ii) under bad socioeconomic conditions with poor hygiene and insufficient nourishment, and (iii) in cases of predisposing conditions such as diabetes mellitus, immunosuppression, immunodeficiency, or perfusion deficits due to arterial occlusive disease or due to venous insufficiency.

## Molecular and Systemic Pathophysiology

Bacterial folliculitis: Hair follicles are colonized with commensal bacteria and yeast. It offers a special habitat characterized by secretions of eccrine and sebaceous glands and by reduced oxygen tensions. In superficial parts of follicles around the ostium the microflora is composed of bacterial flora of the skin (Staph epidermidis, micrococci, transiently Staph aureus). The acroinfundibular part contains the yeast Malassezia furfur. The mostly anaerobic conditions of the infrainfundibulum foster growth of Propionibacterium acnes.

Growth of gramnegative bacteria (Pseudomonas aeruginosa) is possible under special conditions such as antibiotic therapy, immunosuppression or microinjuries in contaminated surroundings such as in hot whirlpools. Microbes not belonging to the usual habitat can also invade the follicle and cause primary infection. Common pathogens are zoophilic dermatophytes such as Micorsproum canis, Trichophyton tonsurans, Trichophyton verrucosum.

Microbial colonization or contamination leads to overt infection and inflammation when the balance which limits microbial growth is disturbed. Such disturbances take place when (i) more aggressive bacteria equipped with more degrading enzymes gain entry into follicles and colonize it (Staph aureus, Pseudomonas aeruginosa), (ii) when increased proliferation of commensal microbes is induced as can be caused by several factors. A frequent one is occlusion of follicles due to occlusive clothes or dressings, occluding fatty ointments, marked hydration of epidermis in humid climate, or friction. Another cause can be decrease in the immune response by poor hygiene or nutrition, diabetes mellitus, immunosuppression, immunodeficiency or perfusion deficits. Apparently minor occlusion or physical trauma is sufficient to elicit inflammation, but on the other hand these inflammations subside rapidly.

Proliferation of microbes leads to release of degrading enzymes and mediators of inflammation with subsequent recruitment of granulocytes, monocytes and lymphocytes (inflammatory infiltrate). The accumulation and degradation of granulocytes in the limited space of follicles results in formation of small abscesses clinically visible as pustules.

Superficial folliculitis can extend to deeper parts of the follicle and the deep perifollicular tissue (furuncle), form abscesses with neighboring follicles (carbuncle) or form phlegmones or cellulitis.

Special forms with more complex pathophysiology are perifolliculitis capitis abscedens et suffodiens, folliculitis decalvans, and folliculitis as part of acne vulgaris.

### Diagnostic Principles

Clinical hallmark is a red papule with transition into a pustule around a follicle of vellus or terminal hair. Although diagnosis can often be made clinically, microbiological analysis should be performed when infection spreads into radially or into deeper parts of the follicle (furuncle). It will yield additional information as to the eliciting pathogen. Care must be taken to obtain material from within the pustules and not from their surface containing the cutaneous mircroflora. Mere detection of commensals such as Malassezia furfur or Demodex mites is not a proof for so-called Pityrosporum or Demodex folliculitis so this diagnosis needs to be completed by quantitative determination and other clinical parameters such as predilection sites.

### Therapeutic Principles

(i) Elimination or avoidance of eliciting factors; (ii) antimicrobial treatment depending on the extent of folliculitis; usually local antiseptics are sufficient (local antibiotics must not be used); systemic antibiotics are required when there is spread into deeper parts of follicles in the face (lack of lymphnodes) or when there are systemic signs of infection. In case of folliculitis due to tinea capitis systemic and local antimycotics are required.

However, superficial folliculitis often is self limited and does not need special treatment as the eliciting causes often are transient [1,2].

## Fong Disease

►Nail-Patella-Syndrome

## Food Allergy

Axel Lorentz, Stephan C. Bischoff
Department of Nutritional Medicine, University of Hohenheim, Stuttgart, Germany

### Definition and Characteristics

"Food allergy" describes adverse reactions to food based on immune pathogenesis. The symptoms range from slight inconveniences to life-threatening shock reactions. Food allergy can involve different organ systems such as the oral cavity and digestive tract, the skin, the respiratory tract, and the cardiovascular system. Gastrointestinal symptoms occur in one third of the cases.

### Prevalence

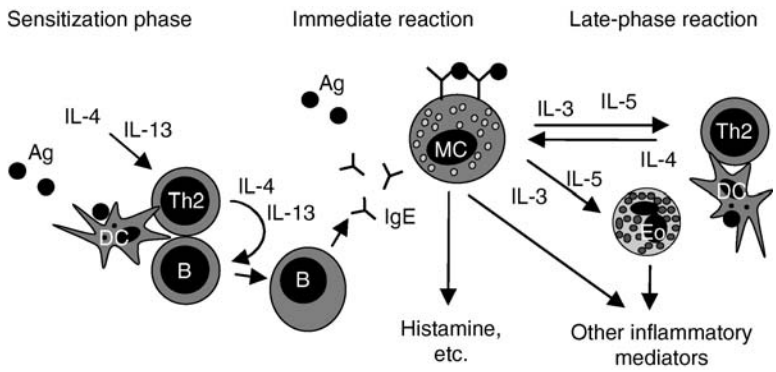
Food allergy is responsible for about one quarter of children and one tenth of adults suffering from food incompatibilities, which affect approximately 20% of the general population in Western countries, i.e., food allergies affect up to 6–8% of children younger than 10 years of age and 1–4% of the adult population [1].

### Genes

During the last years it became clear that allergy has a genetic background. Recent studies reported associations with HLA class II genotypes, mutations in the genes encoding for IgE, and the β-chain of its high-affinity receptor FcεRI. Cytokines as well as their receptors and signalling molecules have also been examined regarding polymorphisms associated with allergy. Most noteworthy is the linkage of atopy with distinct mutations in the genes encoding for the β-chain of the IL-4 receptor and STAT6 gene. The genes for the cytokines IL-13, IL-10, and TGF-β have been examined and associated with allergy as well [1].

### Molecular and Systemic Pathophysiology

Immunologic hypersensitivity reactions are divided into types I, II, III, and IV based on antigen-revealing molecule (IgE, IgG, immune complexes, T cell receptor). The best characterized food based allergic reaction is the IgE mediated type I reaction. During an allergic reaction, naïve lymphocytes give rise to the



**Food Allergy. Figure 1** Phases of allergic reaction. Ag–antigen, B–B cell, DC–dendritic cell, eo–eosinophilic granulocyte, IgE–immune globulin E, IL–interleukin, MC–mast cell, Th2–T helper cell type 2.

production of Th2 cytokines, namely IL-4 and IL-13, which are responsible for the development of IgE-producing plasma cells (Fig. 1).

The immediate phase of allergic reaction occurs through crosslinking of mast cell and basophil surface IgE receptor-bound IgE by allergens leading to the release of vasoactive amines such as histamine, lipid mediators such as leukotrienes and prostaglandins, chemokines and cytokines such as IL-3, IL-5, IL-8, IL-13. The allergic inflammation or late phase of allergic reaction is a consequence of colonization and activation of inflammatory cells such as mast cells and eosinophilic granulocytes. Inflammatory mediators derived from mast cells and eosinophils are primarily responsible for the clinical symptoms of patients with food allergies. These patients have increased levels of histamine, tryptase, eosinophilc cationic protein, IL-5 and TNF-α in serum, urine, intestinal lavage and stool [1,2].

## Diagnostic Principles

Evaluation of food allergy is primarily based on the clinical history correlating symptoms with specific foods. Identified foods as possible origins should be eliminated from the diet and symptoms should be monitored. If specific foods are not identified by the clinical history or by a diet diary, a hypoallergenic diet may be tried for several weeks. Then, if a benefit is seen, new foods may be gradually introduced in an attempt to identify specific food proteins responsible for the adverse reaction. Skin prick testing provides a relatively easily available and practicable method to assess a panel of food allergens. An alternative or complementary technique to skin testing is the measurement of specific IgE in the serum. If possible, a double-blinded placebo-control food challenge should be performed. To diagnose food allergy manifesting in the gastrointestinal tract we developed the colonic mucosal allergen challenge by injecting a panel of antigens into the mucosa and observing for a wheal-and-flare response by endoscopy [3].

## Therapeutic Principles

The best therapeutic principle of food allergy is avoidance of the responsible allergen. So far, there is no clear evidence that oral desensitization, injection immunotherapy, prophylactic medication, or similar techniques are beneficial in prevention or modulation of food allergy. Antihistamines, ketotifen, oral cromolyn, and corticosteroids may modify symptoms to food allergens, but their efficacy is unclear. If an elimination diet cannot be adhered to or when one is unable to identify specific foods, antiallergic medications should be tried. In more severe cases of food allergy, therapy with corticosteroids may become necessary. Novel immunomodulatory therapeutic approaches include modified allergens, novel adjuvants, or neutralizing antibodies or receptor antagonists of Th2 cytokines [1,4].

# FPAH

►Pulmonary Hypertension

# Fragile X Syndrome A

Filippo Tamanini
Department of Cell Biology and Genetics, Center for Biomedical Genetics, Erasmus University Medical Center, Rotterdam, The Netherlands

## Synonyms

Fragile X syndrome; FRAXA

## Definition and Characteristics

X-linked form of mental retardation associated with a fragile site at Xq27.3.

## Prevalence

The fragile X syndrome is one of the most common inherited causes of mental retardation with a prevalence of 1:4,000 males. It accounts for ~30% of all X-linked mental retardation (XLMR).

## Genes

The FMR1 gene codes for FMRP (FragileX Mental Retardation Protein) and is localized on chromosome Xq27.3. In the vast majority of fragile X patients the coding region of the gene is not mutated. However, an unstable CGG repeat is present in the 5′ untranslated region of the FMR1 gene and this repeat is abnormally expanded in fragile X patients (full mutation). The CGG expansion leads to hypermethylation of the FMR1 promoter and thus to transcription silencing and no FMRP production.

## Molecular and Systemic Pathophysiology

FMRP (Molecular Weight 70–80 kDa) is an RNA binding protein highly expressed in neurons and consequently the brain is the tissue mainly affected in FRAXA patients. FMRP contains several RNA binding domains, two K-homology (KH) motifs and one arginine-glycine-glycine rich region (RGG box). Specific binding was demonstrated to its own mRNA (FMR1), as well as to other brain mRNAs (MAP1, BC1, ecc). FMRP is localized in the cytoplasm and has been found to be associated with actively translating polyribosomes where it may function as an inhibitor of translation. Therefore, an alteration in the stability and/or translation of FMRP target mRNAs in the neuronal cell body and at the synapses may explain the mental retardation seen in fragile X patients.

## Diagnostic Principles

A typical adult male patient has long face, prominent ears, and large testicles (or macroorchidism), which are considered the triad of clinical involvement in the fragile X syndrome. The mental retardation is often associated to a number of autistic-like behaviors (poor eye contact, sensitivity to touch, hand flapping). Molecular diagnosis of the CGG amplification, which constitutes >95% of the fragile X mutations, relies on Southern blot analysis of blood DNA (using both the enzymes EcoRI and EagI). A rapid method based on antibody detection of the FMRP protein in cells of blood smears has been validated.

## Therapeutic Principles

There is no cure at present for the fragile X syndrome. However, the demethylation of the FMR1 promoter by treatment with 5-azadeoxycytidine results in reactivation of the gene and synthesis of FMRP in cultured cells derived from FRAXA patients.

# Fragile X Syndrome E

Filippo Tamanini
Department of Cell Biology and Genetics, Erasmus University Medical Center, Rotterdam,
The Netherlands

## Synonyms

FRAXE syndrome

## Definition and Characteristics

Mild form of X-linked mental retardation associated with a fragile site in Xq28, 600 kb distal to FRAXA.

## Prevalence

FRAXE is quite rare, with an incidence estimated to be <1:50,000.

### Genes

The FMR2 gene consists of 22 exons that span ~500 kb in Xq28. The expression of FMR2 is high in hippocampus and Purkinje cells of the cerebellum. Expansion and methylation of a CGG repeat in the 5′ untranslated region of FMR2 is the most common mutation and it results in reduction of FMR2 expression.

### Molecular and Systemic Pathophysiology

The FMR2 protein has a molecular mass of 141 kDa and is localized in the nucleus. FMR2 is very rich in proline and serine. It is similar to two other proteins, AF4 and LAF-4. It has been hypothesized that FMR2 may be a brain-specific transcriptional activator, however, its function remains elusive. Impaired conditional fear and enhanced long-term potentiation has been described in an FMR2 knock-out mouse model.

### Diagnostic Principles

The mental status of male FRAXE patients range from mildly retarded to a mild mental handicap. Delays in language development are particularly prominent. In general, the mental functions of FRAXE patients are better than those of fragile X syndrome (FRAXA) patients. In many respects, the FRAXE site behaves similarly with that at FRAXA. FRAXE is mainly caused by expansion of an unstable CGG repeat associated with abnormal methylation and promoter silencing. Southern blot on DNA from blood cells (digested with EcoRI) is used for diagnosis.

### Therapeutic Principles

No therapy is available for FRAXE patients.

## FRDA

►Friedreich's Ataxia

## Friedreich's Ataxia

Thomas Klockgether
Department of Neurology, University Hospital Bonn, Bonn, Germany

### Synonyms

FRDA

### Definition and Characteristics

Friedreich's ataxia (FRDA) is characterized by progressive ataxia that begins around puberty. However, approximately 20% of FRDA patients have a late disease onset after the age of 25 years. Apart from ataxia, FRDA patients present with areflexia, pyramidal signs, weakness, sensory disturbances, ataxic speech and eye movement abnormalities. The majority of FRDA patients have a hypertrophic cardiomyopathy that often remains subclinical. Diabetes mellitus occurs in 10–30% of all patients [2].

### Prevalence

The prevalence of FRDA has been found to range between 1.7 and 4.7:100,000.

### Genes

FRDA is an autosomal recessively inherited disorder. In the vast majority of patients, the causative mutation is a homozygous GAA repeat expansion in the first intron of a gene coding for a mitochondrial protein named

frataxin. A few FRDA patients are compound heterozygotes with one allele carrying the GAA repeat expansion and the second a point mutation.

### Molecular and Systemic Pathophysiology

The intronic GAA repeat expansion impedes normal transcription of the frataxin gene resulting in a reduction of frataxin tissue levels, the extent of which depends on the length of the shorter GAA expansion. Frataxin acts as an iron chaperone protein that is involved in the biosynthesis of iron–sulfur clusters [1]. Consequently, frataxin deficiency results in decreased levels of iron–sulfur cluster containing proteins, such as subunits of complexes I, II and III of the mitochondrial respiratory chain and aconitase. Decreased activity of respiratory chain complexes then causes reduced cellular energy production and impaired defense to toxic free radicals. The mitochondrial iron accumulation that has been observed in yeast with a targeted disruption of the frataxin homologue YFH1p appears to be secondary to impaired respiratory chain function. The knockout of the frataxin gene in mice causes embryonic lethality. Conditional models with selective disruption of frataxin in either cardiac or neuronal tissue mimic important features of the human disease [3].

### Diagnostic Principles

A diagnosis of FRDA is clinically highly probable in patients with an early onset of ataxia and a typical phenotype including progressive course, ataxic speech, areflexia, Babinski sign and cardiac hypertrophy. A definite diagnosis is made by demonstration of a homozygous GAA repeat expansion in the frataxin gene. In ataxia patients who are heterozygous for the expansion, sequencing of the other frataxin allele to search for a point mutation is required.

### Therapeutic Principles

Since frataxin deficiency leads to increased production of free radicals, free radical scavengers are currently being investigated in FRDA. Trials using idebenone, a short-chain analogue of coenzyme Q10 demonstrated a beneficial effect on cardiac hypertrophy and neurological functions. Physiotherapy and speech therapy are generally recommended. Patients with clinically relevant cardiomyopathy and diabetes mellitus should receive standard medical treatment.

### Synonyms

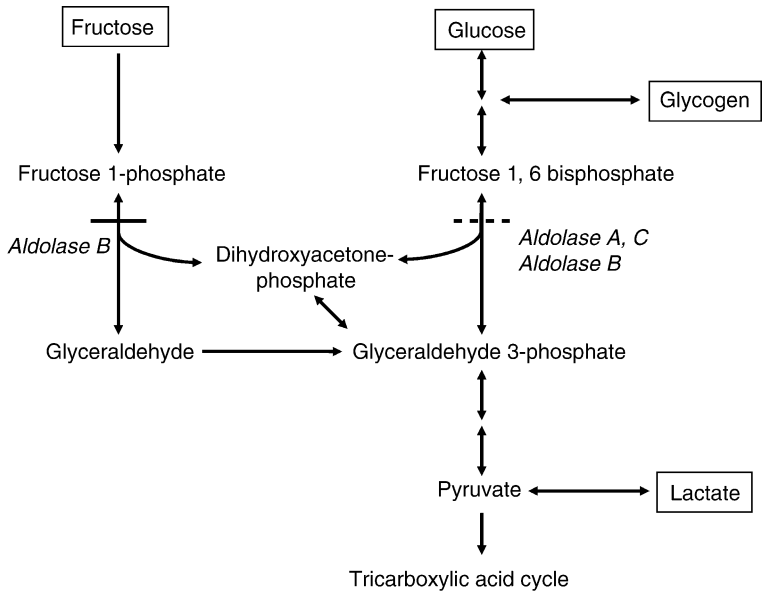
Fructosemia; Aldolase B Deficiency

### Definition and Characteristics

Autosomal recessive inborn error of fructose metabolism leading to fructose avoidance, liver failure, hypoglycemia, and metabolic acidosis.

### Prevalence

The prevalence of HFI is roughly 1 in 20,000 in Switzerland and in the U.K.



**Fructose Intolerance, Hereditary. Figure 1** Hepatic fructose metabolism in hereditary fructose intolerance (modified from ref [2]).

## Genes

Mutations in ALDOB (9q22.3), coding for aldolase B, cause HF1. Three common mutations account for 84% of the aldolase B mutations in Europe: A149P (which is the most common), A174D, and N334K.

## Molecular and Systemic Pathophysiology

Aldolase B is an isoenzyme expressed mainly in the liver and kidney, induced by the presence of fructose. Ingested or infused fructose is rapidly phosphorylated to fructose 1-phosphate. Aldolase B cleaves the six carbon molecule fructose 1-phosphate into two, three-carbon compounds, dihydroxyacetone-phosphate (DHAP) and glyceraldehyde (Fig. 1). These products can subsequently enter glycolysis, gluconeogenesis, or glycogen synthesis. The latter two processes require aldolase B to catalyze the conversion of excess DHAP and glyceraldehyde-3-phosphate to fructose 1,6-bisphosphate. There is controversy as to whether aldolase B is necessary for gluconeogenesis in the absence of fructose.

HFI mutations lead to reduced aldolase B activity, sometimes through disruption of either the enzyme's tetrameric structure or its active site. Ingestion of fructose in HFI patients leads to accumulation of fructose 1-phosphate, which in turn causes inhibition of glycogenolysis and gluconeogenesis and results in hypoglycemia. Hepatic fructose 1-phosphate stimulates pyruvate kinase and results in increased lactate and metabolic acidosis. Reduced intestinal fructose 1-phosphate causes nausea. Deficiency of inorganic phosphate results in hypophosphatemia, decreased ATP, and inhibition of adenosine deaminase, which in turn cause hyperuricemia. Decreased hepatic ATP is probably responsible for abnormal coagulation and liver failure. Reduced renal ATP causes a proximal renal tubular dysfunction, leading to wasting of amino acids and worsening of hypophosphatemia and acidosis.

## Diagnostic Principles

The combination of postprandial vomiting, shock, liver failure, and hypoglycemia in young children or fructose aversion, nausea, growth failure, and hepatomegaly in older children are consistent with the disease. Diagnosis is confirmed by either biochemical assay of liver tissue or by ALDOB molecular analysis.

## Therapeutic Principles

Supportive care for acute metabolic decompensation, combined with elimination of all fructose, sucrose, and sorbitol from the diet.

F

### Synonyms

Alpha-fucosidase deficiency

### Definition and Characteristics

Fucosidosis is an autosomal recessive disorder which is often grouped according to severity of the phenotype: The severe early-onset phenotype (type I) is characterized by psychomotor retardation, coarse facies, growth retardation, dysostosis multiplex, neurologic symptoms, an increase in sweat sodium chloride concentration, and early death. The symptoms develop within the first year of life. Patients of the milder type II show later onset of the disease and often survive to adulthood. The major distinguishing features of the type II phenotype are the presence of angiokeratoma and a more normal sweat sodium chloride value. Clinical features of the disease are reviewed in [1].

### Prevalence

About 100 patients reported in the literature to date.

### Genes

Defective FUCA1 gene coding for alpha-fucosidase localized on chromosome 1p34.

### Molecular and Systemic Pathophysiology

Deficiency of a lysosomal fucosidase impairs degradation of fucosylated glycoproteins and glycolipids resulting in excessive accumulation of fucose-containing oligosaccharides and glycolipids in most tissues. Intracellular storage of these compounds progressively affects cellular functions. To date 26 mutations in the FUCA1 gene have been described that include base changes resulting in premature stop codons, single base shift deletions, two-base deletions resulting in a frameshift, large deletions, base substitutions resulting in defective splicing, base substitutions resulting in amino acid substitutions, and homozygous insertions [1,2].

### Diagnostic Principles

The clinical symptoms are indicative but not sufficient for definitive diagnosis of the disease, therefore complementary laboratory diagnosis is necessary. The presence of storage granules in lymphocytes in a conventionally stained blood smear is a simple indicator for many lysosomal disorders. Urine samples from type I or type II fucosidosis patients contain large amounts of fucosyl glycoconjugates that can easily be detected by thin-layer chromatography [3]. Enzymatic assay of alpha-fucosidase in white blood cells or cultured fibroblasts is the most direct and precise means of diagnosis and, therefore, should always be applied [2]. For prenatal diagnosis, cultured amniotic cells or chorionic villus cells are used. Fucosidase activity can also be assayed in plasma or serum samples, but is complicated by the fact that some normal individuals have extremely low levels of this enzyme in serum or plasma. DNA analysis should be considered for genetic counseling, but this can only be achieved when the molecular lesion has been characterized in the specific family at risk or when linkage analysis is informative.

### Therapeutic Principles

Allogeneic stem cell transplantation appears to become a possible therapeutic option for some lysosomal disorders, including fucosidosis [4].

### Synonyms

Galactosemia type II; Galk deficiency

### Definition and Characteristics

Autosomal recessive inborn error in galactose metabolism leading to hypergalactosemia and cataract formation.

### Prevalence

Overall estimates of homozygotes range from 1:100,000 to 1:1,000,000. Some mutations, however, have higher frequencies in particular populations such as the A198V mutation in Japanese, Korean and Chinese populations [1] and the P28T mutation in Roma and Bosnian populations [2,3].

### Genes

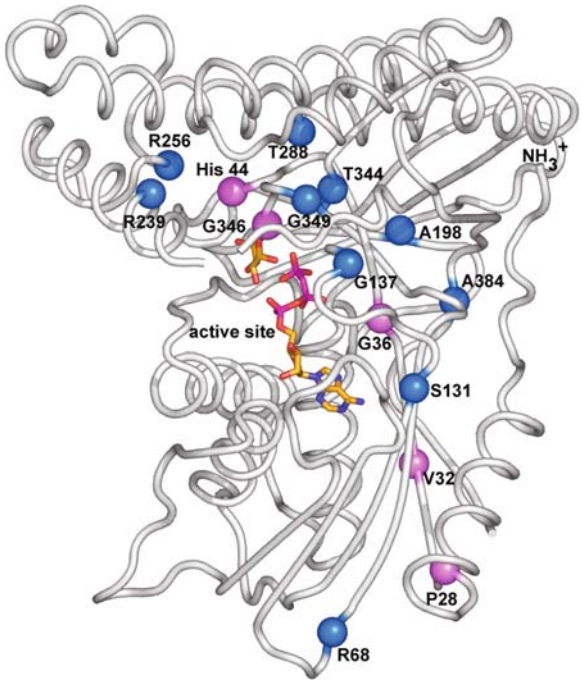
GALK1 coding for galactokinase, localized on chromosome 17q24 [4].

### Molecular and Systemic Pathophysiology

Galactokinase functions in normal galactose metabolism by catalyzing the MgATP-dependent phosphorylation of the C-1 hydroxyl group of α-D-galactose. Approximately 25 mutations (including base substitutions, base deletions, and larger deletions) have been reported in human galactokinase, which give rise to Type II galactosemia (MIM#230200). The main clinical manifestation of galactokinase deficiency is the early onset of cataracts. Formation of cataracts is most likely due to galactose accumulation in the lens of the eye where the enzyme aldose reductase catalyzes its conversion to galactitol [5]. The increased concentration of galactitol, which cannot be transported across the cellular membrane, results in water uptake ultimately leading to the formation of cataracts. Shown in Fig. 1 are the locations of some of the known mutations in human galactokinase. Those sites of mutations indicated by the pink spheres give rise to very low or no detectable blood enzyme activity (P28T, V32M, G36R, H44Y, and G346S) whereas those positions indicated by the blue spheres demonstrate reduced blood activity (R68C, S131I, G137C, A198V, R239Q, R256W, T288M, T344M, G349S, and A384P). Point mutations located near the active site of the enzyme include H44Y, G346S, and G349S. These mutant proteins demonstrate reduced catalytic efficiencies in vitro. Interestingly, the enzyme bearing the A198V mutation has kinetic parameters which are essentially indistinguishable from the wild-type protein. In contrast with the other mutations, where cataract formation is near certainty within the first few years of life, this mutation merely results in a higher incidence of cataracts in later life [1].

### Diagnostic Principles

Symptoms include the formation of cataracts during the first months of life, increased blood galactose levels,



**Galactokinase Deficiency. Figure 1** The structure of human galactokinase and location of point mutations in the enzyme that give rise to Type II galactosemia. Galactose and ATP are shown as stick models within the structure.

and the absence or a reduced level of galactokinase activity in the red blood cells.

## Therapeutic Principles

A diet restricted in lactose and galactose is the main course of therapy. Surgical removal of cataracts may be required in some cases.

# Galactorrhea

Andrea L. Utz, Beverly M. K. Biller
Neuroendocrine Unit, Massachusetts General Hospital, Boston, MA, USA

## Definition and Characteristics

The secretion of milk substance from the breast nipple that is not associated with recent pregnancy or breastfeeding.

## Prevalence

Galactorrhea is most common in parous pre-menopausal women; however, rare cases occur in nulliparous and post-menopausal women and men.

## Genes

Prolactin-secreting tumors (prolactinomas) are a common cause of galactorrhea. Most prolactinomas arise sporadically; however, rarely they are a component of a genetic syndrome: ►Multiple Endocrine Neoplasia-1 (MEN1) and Familial Isolated Pituitary Adenoma (FIPA). In MEN1 syndrome mutations in the MEN1 gene cause menin protein disruption. The genetic basis of FIPA is currently unknown. Carney Complex results frequently from an inactivating mutation of the protein kinase A type 1A regulatory subunit (PRKAR1A) gene, and can be associated with hyperplasia of pituitary lactotroph cells and subsequent hyperprolactinemia [1].

## Molecular and Systemic Pathophysiology

Milk production is a complex process that requires estrogen and progesterone for mammary duct development and alveolar maturation. Only breast tissue that has been primed by these hormones can produce milk. The action of lactogenic hormones (human placental lactogen and/or pituitary prolactin), glucocorticoids, growth hormone, thyroxine, and insulin are also required for lactation [2]. During the normal process of pregnancy and parturition, placental lactogen and prolactin activate the lactation process. In the pathologic situation of galactorrhea, lactation is predominantly caused by excess prolactin. Other causes of galactorrhea, including mechanical nipple stimulation, may be due to transient prolactin elevations [3]. Most common causes of galactorrhea:

- Hyperprolactinemia
  - Pregnancy/breastfeeding
  - Pituitary/hypothalamic pathology
    - Prolactinomas
    - Other pituitary or hypothalamic tumors/infiltration/inflammation

- Infundibular disruption (e.g., stalk transection, radiation damage)
- Most common medications
  - Antipsychotics: typical and atypical, particularly risperidone
  - Anxiolytics: buspirone
  - Antihypertensive medications: verapamil, reserpine, methyldopa, atenolol
  - GI motility drugs: metoclopramide, domperidone
  - Histamine antagonists
  - Pain medications/drugs of abuse: opiates, marijuana, cocaine
  - Anesthetics
- Primary hypothyroidism
- Chronic renal failure
- Cirrhosis
- Ectopic human placental lactogen or prolactin production
  - Hydatidiform moles, choriocarcinoma
  - Bronchogenic carcinoma, renal adenocarcinoma, lymphoma
- Nipple/chest wall stimulation
  - Manual manipulation
  - Suckling
  - Herpes zoster reactivation
  - Chest surgery or tumors
  - Burns
  - Cervical spine lesions
- Idiopathic

Prolactin is primarily secreted from lactotroph cells in the anterior pituitary; signaling from the hypothalamus regulates its release. Tuberoinfundibular dopaminergic neurons of the hypothalamic arcuate nucleus release dopamine into the hypophyseal portal venous circulation. Dopamine binds to dopamine D2 receptors, producing an inhibitory signal that suppresses release of prolactin from lactotrophs [4,5]. A disruption of this inhibitory signal can lead to elevated prolactin levels. This is usually a result of infundibular damage due to transection by trauma, compression by a parasellar mass, or infiltration by inflammatory or neoplastic cells. Additionally, drugs that suppress hypothalamic dopamine secretion or antagonize lactotroph dopamine receptors can cause hyperprolactinemia by diminishing the inhibitory signal.

Estrogen increases prolactin secretion via a decrease in the inhibitory dopamine signal and by direct stimulation of the pituitary lactotroph. High estrogen levels are likely the cause of lactotroph hypertrophy and hyperprolactinemia of pregnancy. A common pathologic cause of increased prolactin is secretion by tumors derived from pituitary lactotrophs, referred to as prolactinomas. Thyrotropin releasing hormone (TRH) is a stimulus for prolactin secretion and excess TRH secretion, usually as a result of severe primary hypothyroidism, can result in elevated prolactin. Serum prolactin is excreted via the kidney and liver; therefore renal insufficiency or severe liver disease may result in elevated levels.

Hyperprolactinemia is often associated with menstrual irregularity and hypoestrogenemia in pre-menopausal women, and testosterone deficiency in men, due to the suppression of pituitary gonadotropins by prolactin. Decreased gonadal steroid production can have detrimental effects on bone mineral density in both women and men. Hyperprolactinemia can also lead to female and male infertility.

## Diagnostic Principles

Galactorrhea is often bilateral and clear, white, or yellow in appearance. Galactorrhea can be distinguished from other liquid breast discharge by the presence of microscopic fat globules. The following blood tests should be obtained in an individual with galactorrhea: β-human chorionic gonadotropin (β-HCG) in pre-menopausal women, prolactin, thyroid stimulating hormone (TSH), creatinine, and liver function tests. A careful history of medication use and chest wall stimulation should be elicited. The majority of cases will be associated with an elevated prolactin level and a brain MRI with pituitary focus is indicated, unless the patient is pregnant or has another cause of prolactin elevation, such has primary hypothyroidism or neuroleptic medications.

## Therapeutic Principles

While galactorrhea itself is not a medical concern, treatment is indicated if galactorrhea is troublesome or accompanied by gonadal dysfunction or infertility. Additionally, the presence of a large (>1 cm) or enlarging prolactinoma warrants treatment. If chest wall or nipple stimulation is the etiology of galactorrhea, this should be avoided. Medications that are associated with galactorrhea/hyperprolactinemia can be discontinued or substituted if medically feasible. This is often not possible in patients taking medications for psychiatric illness; reassurance about the benign nature of galactorrhea can be helpful. If the prolactin-stimulating medications must be continued, gonadal steroid replacement is recommended if deficient; however, this will not diminish the galactorrhea.

The standard therapy for galactorrhea is with dopamine agonist medications (such as bromocriptine, cabergoline, or quinagolide [not available in the U.S.]). Most prolactinomas respond to treatment with dopamine agonist medical therapy, resulting in a decline in serum prolactin level and a reduction in tumor volume. Rarely, surgical tumor resection is indicated, particularly if the individual does not tolerate, or has

inadequate response, to medical therapy. Additionally, surgery may be indicated to resect non-prolactinoma sellar lesions that disrupt the infundibular dopamine inhibitory signal and result in hyperprolactinemia. Very rarely, radiation therapy is used for large or neurologically-compromising tumors that are unresponsive to medication and not surgically resectable.

# Galactosemia Type II

►Galactokinase Deficiency

# Galactosialidosis

Eugen-Matthias Strehle
Neuromuscular Genetics, International Centre for Life, Newcastle upon Tyne, UK

## Synonyms

Neuraminidase (sialidase) deficiency with β-galactosidase deficiency; Protective protein/cathepsin A deficiency; Goldberg syndrome [1]; PPCA deficiency

## Definition and Characteristics

The lysosomal storage disease galactosialidosis (OMIM 256540) is closely related to sialidosis (OMIM 256550). In galactosialidosis both the enzymes β-galactosidase and α-neuraminidase are malfunctioning whereas in sialidosis only sialidase is defective. These enzyme deficiencies lead to the accumulation of oligosaccharides, glycoproteins and glycolipids in the lysosomes in different organ systems. Galactosialidosis can be divided clinically into three types: infants affected by the early infantile form present with dysmorphic features, telangiectasias, hydrops fetalis, hypotonia, hepatosplenomegaly and heart failure. Death ensues within the first 2 years of life. The late infantile form (beyond 3 months) is characterized by coarse facial features, corneal opacities, cardiac valve disease, dysostosis multiplex and mild developmental delay. Patients with the adult/juvenile form are predominantly of Japanese origin and show a coarse facies, angiokeratomas, macular cherry-red spots, hearing loss, epilepsy, ataxia, cardiomyopathy, vertebral anomalies and learning difficulties [2].

## Prevalence

Epidemiological data on this rare autosomal recessive disorder are scarce and vary geographically. Less than 100 patients with galactosialidosis have been described worldwide. The estimated prevalence is <1/1,000,000 (www.mannosidosis.org).

## Genes

Galactosialidosis is caused by a deficiency of the protective protein/cathepsin A (PPCA) which is part of a lysosomal multi-enzyme complex including sialidase, β-galactosidase and *N*-acetylgalactosamine-6-sulfate sulfatase [3]. PPCA belongs to the family of serine carboxypeptidases. The gene encoding the human PPCA precursor has been mapped to chromosome 20q13.12 (PPGB). The 54.5 kDa precursor protein consists of a signal peptide, a 32-kDa chain and a 20-kDa chain. Processing of the precursor results in the 2-domain PPCA. Several different mutations of PPGB have been identified in the three types of galactosialidosis, the commonest being SpDEx7, Y395C and Y249N (www.ihop-net.org).

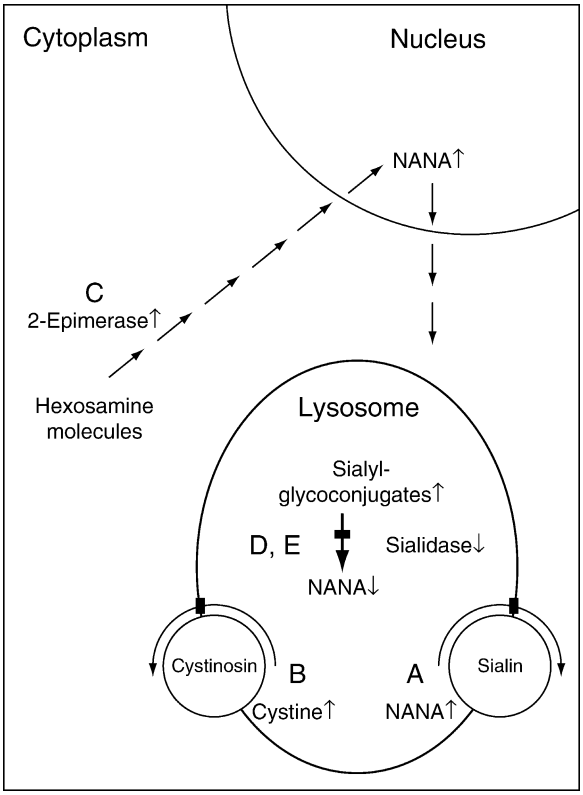
## Molecular and Systemic Pathophysiology

The underlying pathomechanisms of galactosialidosis are not fully understood but most clinical features can be attributed to the excessive storage and excretion of sialylconjugates. Bound sialic acids can be found on outer cell membranes of many living organisms where they act as biological masks. Their catabolism takes place in the lysosome and requires the above mentioned multi-enzyme complex. PPCA, which is deficient in galactosialidosis, facilitates the aggregation of β-galactosidase molecules thus protecting them from degradation. It also controls the intracellular transport and the activation of α-neuraminidase. The catalytic function of the protective protein/cathepsin A is separate from its stabilizing effect. PPCA acts

as carboxypeptidase, deamidase or esterase. Among others it cleaves the lysosomal receptor protein LAMP2a and hydrolyzes neuropeptides and drugs against human immunodeficiency virus. A second, similar multi-enzyme complex has been located at the cell surface where β-galactosidase is replaced by a variant, the elastin-binding protein (EBP). EBP serves as transport protein for tropoelastin, an essential component of elastic fibers [4].

## Diagnostic Principles

Patients with galactosialidosis show increased levels of sialyloligosaccharides in the urine and other body fluids. These substances can be determined by thin layer chromatography, high performance liquid chromatography (HPLC) or gas chromatography/mass spectrometry (GC/MS). Inclusion bodies (vacuoles, fibrogranular material) have been demonstrated in blood lymphocytes, bone marrow macrophages, glomerulocytes, hepatocytes, neurons and other cell types. Although the enzymatic activity of PPCA can be measured directly, the standard diagnostic test is a combined assay of α-neuraminidase and β-galactosidase in leukocytes and/or cultured skin fibroblasts. Prenatal diagnosis is performed on amniotic fluid or placental cells. Enzyme activity is reduced to ~10% compared to controls. Sialidosis, mucolipidosis and gangliosidosis should be considered as differential diagnoses.



**Galactosialidosis. Figure 1** Schematic representation of the metabolic pathways in (A) sialic acid storage disease; (B) cystinosis; (C) sialuria; (D) sialidosis; and (E) galactosialidosis (NANA, *N*-accetylneuraminic acid; 2-epimerase, uridine diphosphate *N*-acetylglucosamine 2-epimerase. (Reprinted from [2] with kind permission of Mary Ann Liebert, Inc., publishers).

## Therapeutic Principles

To date only supportive treatment is available for galactosialidosis. Affected children should be managed by a multidisciplinary team including a pediatrician, geneticist, metabolic specialist and allied health professionals. In a PPCA-deficient mouse model bone marrow transplant (BMT) corrected the phenotypical characteristics of galactosialidosis. Human GS fibroblasts have been transformed in vitro with the recombinant PPCA gene (PPGB). As a result the activity of α-neuraminidase and β-galactosidase was restored and the accumulated sialyloligosaccharides were metabolized further [5]. In lysosomal storage disorders with CNS involvement enzyme replacement therapy (ERT) and gene therapy are of limited value due to difficulties of the enzyme/gene in crossing the blood-brain barrier. (Fig. 1).

►Cholecystolithiasis

# GAMT

►Guanidinoacetate Methyltransferase Deficiency

# Gardner's Syndrome

Markus Böhm, Thomas A. Luger
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Definition and Characteristics

Gardner's syndrome (GS) is an autosomal dominant genodermatosis and considered a phenotypic variant of familial polyposis coli (FAP). It is characterized by polyposis coli and numerous mesenchymal tumors on and under the skin and in the bones.

## Prevalence

The exact prevalence is unknown.

## Genes

GS is caused by truncating mutations of the adenomatous polyposis coli (APC) gene (codons 1,403 and 1,578). This gene is also affected in FAP [1].

## Molecular and Systemic Pathophysiology

Patients with identical APC mutations may have different phenotypic expression. The APC gene functions as a tumor suppressor gene by means of its crucial involvement in wnt-signaling. Unidentified modifier genes are thought to contribute to the wide range of extracolonic manifestations.

## Diagnostic Principles

Extracolonic mesenchymal lesions including epidermal inclusion cysts, lipomas, fibromas, desmoid fibromatoses and osteomas are the hallmark of GS [2]. They are the first manifestation of GS and occur in early childhood before the development of intestinal polyps. The extracolonic tumors typically occur at multiple sites but appearance of only few lesions has been reported. In addition to skin lesions multiple unerupted teeth may alert the physician to possible underlying GS [3].

## Therapeutic Principles

If undetected patients with GS inevitably develop colorectal carcinoma at a much younger age than those with sporadic intestinal cancer. Prophylactic total colectomy or proctocolectomy is generally advised. However, there are several reports indicating a beneficial effect of non-steroidal anti-inflammatory drugs such as indomethacin or sulindac on gastrointestinal polyps in patients with GS [4]. In addition to the 100% risk of malignancy of colonic polyps if left untreated patients with GS are at high risk for development of adenomas of the stomach, duodenum, small intestine, tumors of various endocrine tissues and malignant neoplasms of the central nervous system. Lifelong surveillance and genetic counseling are necessary.

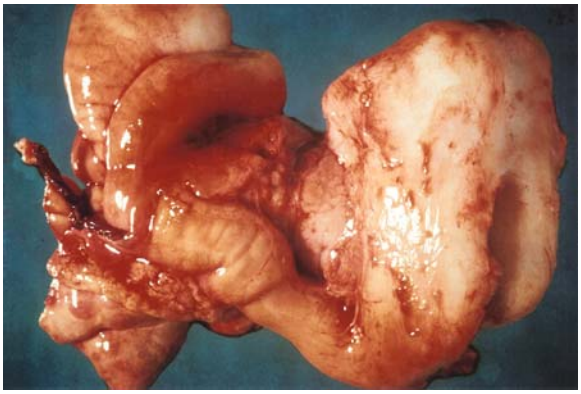
# Gastric Duplication

Alexander K. C. Leung[1], Andrew L. Wong[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Department of Surgery, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Gastric duplication is classified into two types: cystic and tubular, with the cystic type more common [1]. The structure is lined by typical gastric mucosa, often accompanied by patches of ectopic intestinal epithelium, contains a smooth muscle coat fusing with the muscularis propria of the stomach, is contiguous with



**Gastric Duplication. Figure 1** Gross pathology. Note the gastric duplication on the greater curvature of the stomach.

the wall of the stomach, and shares a common blood supply [2,3]. Most duplications do not communicate with the stomach and are located along the greater curvature of the stomach or the posterior wall of the antrum (Fig. 1) [2].

The clinical presentation depends on the size and location of the duplication and whether there is a communication with the rest of the alimentary tract [2]. Patients may be asymptomatic or present with an abdominal mass and symptoms of upper gastrointestinal tract obstruction, such as non-bilious vomiting. Other presenting symptoms include failure to thrive, abdominal pain, and anemia. Associated anomalies, which occur in about 50% of cases, include duplications of the oesophagus, ileum, and colon; oesophageal atresia; congenital heart disease; vertebral anomalies; diaphragmatic hernia; omphalocele; and malrotation of the bowel [2]. Complications include pancreatitis, erosion into adjacent structures, and perforation. When an intraluminal communication exists between the duplication and the normal stomach, peptic ulceration and hemorrhage may result.

## Prevalence

Gastric duplications are rare and account for less than 4% of alimentary tract duplications [2]. The female to male ratio is approximately 2:1 [2].

## Molecular and Systemic Pathophysiology

Presumably, a gastric duplication arises during the fourth week of gestation from faulty separation of the endoderm and notochord [2,3]. A band between these two structures may cause a traction diverticulum leading to gastric duplication. Alternatively, it may result from faulty splitting of the notochord, allowing the endodermal stomach to herniate through the gap [4]. The herniated structure may interfere with anterior fusion of the vertebrae mesoderm with resultant vertebral anomalies.

## Diagnostic Principles

The differential diagnosis includes pancreatic cyst and pseudocyst, pancreatic cystic tumor, choledochal cyst, and intramural tumor of the stomach. Ultrasonography and computed tomography are helpful in the diagnosis. However, neither procedure can tell whether the mucosa is gastric or not. The most useful method for diagnosing gastric duplication is scintigraphy with Tc-99m pertechnectate [1].

## Therapeutic Principles

Surgical excision is the treatment of choice for a gastric duplication cyst because it is non-functional and malignant transformation has been reported [5]. A non-communicating gastric duplication can be treated either by complete resection of the duplication or by excision of the wall shared by the normal stomach and the duplication [1,4]. An asymptomatic communicating gastric duplication usually does not require any treatment [1].

# Gastric Ulcer

►Peptic Ulcer

# Gastrinoma

►Zollinger-Ellison Syndrome

# Gastritis

Markus G. Donner, Dieter Häussinger
Department of Gastroenterology, Hepatology and Infectious Diseases, Heinrich-Heine-University, Duesseldorf, Germany

## Definition and Characteristics

Gastritis is defined as an inflammatory process confined to the gastric mucosa. Endoscopically, gastritis is defined by the appearance of edema, erythema, exsudate, coarsening or atrophy of the gastric mucosa or mucosal hemorrhage. According to the Sydney system, different forms can be endoscopically described as erythematous-exsudative, erosive, atrophic, hemorrhagic, hyperplastic or enterogastric gastritis [1]. Histopathological investigation serves to determine the topography, severity and etiology of gastritis. The updated Sydney System has been accepted as the standard classification of gastritis (Table 1) [1]. Often, there is not a good correlation between the endoscopic and histologic appearance.

## Prevalence

Autoimmune gastritis (type A gastritis): 1.4–2.7% (persons > 60 years), H. pylori-positive gastritis (type B gastritis): 20–50%, chemically induced gastritis (type C gastritis): 3%.

## Molecular and Systemic Pathophysiology

The most common etiologic factors are autoimmune disease (type A), H. pylori infection (type B) and chemical irritation of the gastric mucosa (type C). In autoimmune gastritis there is autoantibody formation against parietal cell $H^+/K^+$-ATPase, which secretes hydrogen ions into the gastric lumen. H. pylori infection has been assumed to trigger antibody formation crossreacting with antigens of parietal cells. Some patients also develop antibodies against intrinsic factor. Interferon-γ-secreting CD4 T-cells appear to be crucial mediators of the immune response. Histopathology shows an atrophic gastritis with infiltrates of lymphocytes and plasma cells containing parietal cell antigens. Autoimmune gastritis leads to a progressive destruction of parietal cells and chief cells of the gastric mucosa with subsequent pyloric-type glands and intestinal metaplasia [2]. Atrophy of the gastric glands eventually leads to achlorhydria and vitamin $B_{12}$ deficiency. Enterochromaffine-like cell hyperplasia develops and may progress to carcinoid tumor formation.

Infection with H. pylori usually occurs in childhood. H. pylori secretes urease, which cleaves urea to bicarbonate and ammonium ions and thus permits survival in an acidic environment. H. pylori binds to the epithelium by adhesion molecules, mainly by BabA, but rarely envades the mucosa. Translocation of the bacterial protein CagA to epithelial cells induces cytokine production by the host cells and subsequent cell damage. Vigorous immune response with neutrophil activation and subsequent production of reactive oxygen species induces epithelial cell damage. The infection consists of an initial acute phase with erosions and hemorrhages. Subsequently, a chronic infection with lymphocytic infiltrates in the lamina propria develops [3]. In most patients, the infection predominantly occurs in the antrum, although some individuals may develop pangastritis with glandular atrophy and intestinal metaplasia. This condition may progress to dysplasia and adenocarcinoma and may explain the increased risk of malignancy in Type A and B gastritis [4]. Type B gastritis is also a risk factor for MALT lymphoma and gastric cancer.

Type C gastritis is provoked by chemical irritation of the gastric mucosa, usually by alcohol, various drugs and refluxing bile salts. Non-steroidal anti-inflammatory drugs (ASAIDs) are known as very common agents to provoke type C gastritis. Most NSAIDs inhibit cyclooxygenase (COX) of the gastrointestinal mucosa, particularly COX-1, which catalyzes prostaglandin synthesis from arachidonic acid [5]. Prostaglandins are essential constituents of the gastric juice and protect the mucosal layer from chemical injury. Further, diffusion of NSAIDs into the epithelial cells of the gastric mucosa may interfere with mitochondrial oxidative phosphorylation and induce mucosal damage.

## Diagnostic Principles

Clinically, acute gastritis is usually associated with upper abdominal pain and nausea. Chronic forms may be accompanied by anorexia or bloatedness but may often be free of symptoms. Diagnosis is made by gastroscopy and subsequent histopathological investigation of mucosal specimen. Biopsies should include samples for h. pylori urease testing, which may help to decide on antibiotic therapy. Special forms of gastritis may require additional microbiological investigations such as PCR for cytomegalovirus or tuberculosis. In case of a recurrent H. pylori infection microbiological culture and resistance profiling should be carried out. Following antibiotic therapy determination of h. pylori antigen in stool or $^{13}C$ urea breath test can be used to verify successful treatment.

## Therapeutic Principles

Acute gastritis is usually self-limiting and rarely requires specific treatment. Therapy of type A gastritis

**Gastritis. Table 1** The updated Sydney system for the classification of gastritis and gastropathy [1]

| Type of gastritis | Etiologic factor | Other designations |
|---|---|---|
| **Non-atrophic** | Helicobacter pylori | Superficial |
| | | Diffuse antral gastritis |

| | Fungi | |
| | Parasites | |

is limited to substituting vitamin $B_{12}$ deficiency. Yearly gastroscopy and biopsy is required to detect pre-malignant lesions of the gastric mucosa. Symptomatic type B gastritis is treated by proton pump inhibitors (PPI) and antibiotic treatment of h. pylori. H. pylori treatment usually consist of PPI, clarithromycin and amoxicillin for 7 days. Alternately, metronidazol can be used instead of amoxicillin. Recurrent infection is treated following resistance profiling. Type C gastritis is treated by stopping the causative agent, and applying prokinetics, sucralfate and cholestyramin.

# Gastro-Enteritis

►Enteritis

# Gastroenteritis, Esoinophilic

Nirmal S. Mann
School of Medicine, University of California, Folsom, CA, USA

## Definition and Characteristics

It may involve any part of the GI tract from the esophagus to the rectum. There is extensive tissue eosinophilia occurring in any layer or layers of the gut wall. It may also result in eosinophilic ascites.

## Prevalence

It is a rare disease but increasing numbers of cases are being recognized. The disease can affect any age group but typically occurs in the third to fifth decades of life. Slight male preponderance has been reported.

## Genes

Genetic studies have not been performed in eosinophilic gastroenteritis (EG).

## Molecular and Systemic Pathophysiology

After exposure to allergen, in response to chemotactic factor, eosinophils migrate to the GI tract and may get localized to any layer of the GI tract. The eosinophils liberate cationic proteins e.g. major basic protein, eosinophilic cationic protein, eosinophil derived neurotoxin and eosinophil peroxidase. Eosinophils also release interleukin-3 and -5, tumor necrosis factor alpha and granulocyte – macrophage colony stimulating factor. In response to allergens, in sensitized persons, IgE may degranulate mast cells, releasing platelet activating factor, histamine, eosinophil chemotactic factor and leukotriene B4.

The cells involved in the pathogenesis are the eosinophils and the mast cells. Eosinophils may directly damage the gut layers but most importantly they degranulate the mast cells producing various injurious toxins and proteins which cause the histologic damage via tissue inflammation. The eosinophilic chemotactic factor recruits more eosinophils to the affected site thus setting up a vicious cycle.

The inflammation and damage produced by eosinophil-mediated and mast–cell mediated release of injurious proteins is responsible for the various manifestations in this condition. The patients may develop dysphagia, esophageal chest pain, gastrointestinal bleeding, gastric outlet obstruction, small bowel obstruction or diarrhea and protein-losing enteropathy. Thes manifestations are due to massive infiltration of the various layers of the gut with eosinophils. When eosinophils infiltrate the serosal layer of the gut then eosinophilic ascites may result.

## Diagnostic Principles

The diagnosis is made by the characteristic clinical features and presence of numerous eosinophils seen on biopsy specimens of the gut wall. Peripheral eosinophilia is present in many but not in all the cases. Eosinophils are not present in large numbers in other organ systems. Laboratory studies are done to exclude other causes of eosinophilia such as parasitic infestations and hypereosinophilic syndrome. Endoscopy of the esophagus may show characteristic mucosal rings (Corrugated Esophagus) which result from the contraction of the muscularis mucosae mediated by histamine–anticholine interaction. Eosinophilic ascites can be diagnosed by demonstrating large numbers of eosinophils in the ascetic fluid.

## Therapeutic Principles

There are no prospective controlled studies to guide the management of EG. There is a strong association of EG with food allergies and restrictive-elemental diets have been tried with variable results.

In the author's experience antihistamines (H1 receptor antagonists) are effective and should be the initial treatment. Various combinations should be tried for maximum benefit. Ketotifen which in addition to being an antihistamine also is a mast cell stabilizer has improved symptoms and intestinal eosinophilia in EG patients. Gluicocorticoids are an effective treatment for EG. They are potent anti-inflammatory agents and also inhibit eosinophilic growth factors. However long term treatment with systemic steroids is undesirable because of their side effects. Topical steroids such as fluticasone have been used successfully. Non-enteric coated budesonide has helped patients affecting the ileum and right colon. Leukotriene receptor antagonists such as Montelukast and Suplatast Tosilate may be tried. Anti-interleukin-5 (Mepolizumab) is being evaluated. Some patients with EG may develop obstruction requiring surgical resection of the obstructing segment.

# Gastroesophageal Reflux Disease

Marcus Schmitt
Gastroenterology, Hepatology and Infectiology, UKD, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

GERD

## Definition and Characteristics

GERD is a disease with symptoms suggestive of reflux or its complications. The cardinal symptoms associated with GERD are heartburn, dysphagia and regurgitation.

## Prevalence

Epidemiologic data is rare because of the more general definition of GERD. Most prevalence data are based upon the symptoms heartburn and/or regurgitation. Only 15 epidemiological studies of GERD that fulfilled strict quality criteria are shown so far. GERD prevalence (as defined by at least weekly heartburn and/or acid regurgitation) is 10–20% in the Western world and about 5% in Asia. Incidence is 5 per 1,000 person years.

## Molecular and Systemic Pathophysiology

The main pathogenetic factor of GERD is the reflux of gastric juice from the stomach into the distal esophagus. The lower esophageal sphincter is the main antireflux barrier at the gastroesophageal junction. There are three pathophysiologic mechanisms for a failing of this antireflux barrier: (i) transient lower esophageal sphincter relaxations (tLESRs), (ii) hypotensive lower esophageal sphincter (LES), (iii) the anatomic disruption of the gastroesophageal junction in association with a hiatal hernia.

Esophageal clearance is important for normal esophageal function. Physiologically esophageal acid clearance begins with emptying the refluxed fluid from the esophagus by peristalsis and is completed by titration of the residual acid by swallowed saliva. Disturbed peristalsis and impaired salivary function are the factors leading to GERD. Not only acid reflux and a decreased esophageal clearance are essential factors resulting in GERD but pepsin and in some extent bile acids, trypsin and hyperosmolality may increase mucosal susceptibility of the esophagus to acid injury. Furthermore esophageal epithelial defense mechanisms (preepithelial, epithelial, and postepithelial factors) may also be disturbed e.g., due to cellular acidification.

Genetic disorders or molecular causes of a reflux disease have not been detected so far. But twin studies with monozygotic twins suggest a heritability for GERD up to 31%.

## Diagnostic Principles

Diagnosis is based on history with the report of the cardinal symptoms: classical symptoms are dysphagia, heartburn and regurgitation. Endoscopically GERD leads to macrosopic mucosal lesions due to inflammation. Extraesophageal presentations include chest pain, asthma, cough, ear-nose-throat syndromes and others.

For patients who require diagnostic evaluation, useful tests are endoscopy and ambulatory pH monitoring.

An index esophagoscopy provides a help for detecting, stratifying, and managing of GERD. However, the absence of endoscopic features of GERD does not exclude the diagnosis. If there are no endoscopically detectable lesions but still symptoms the term non erosive reflux disease NERD is used.

Ambulatory pH monitoring confirms gastroesophageal reflux disease in patients with persistent symptoms who do not have endoscopyical evidence for mucosal damage.

The so called Bernstein test is useful to determine symptom correlation with esophageal acidification in patients with NERD. The test is done by alternately infusing saline or 0.1N HCl into the mid-esophagus via a nasogastric tube. A positive test is defined as reproduction of the patient's symptoms with acid perfusion but not with saline. This test is ideal for determining acid sensitivity.

Even though the esophagus may appear endoscopically normal, it is not necessarily histologically normal: nonerosive esophageal reflux disease NERD. Two-thirds of patients who have symptoms of GERD but have no visible endoscopic findings have histologic evidence of esophageal lesions that respond to acid suppression.

## Therapeutic Principles

Major goals of therapy in GERD are healing of lesions and alleviation of symptoms. Therefore medical drug therapy with proton pump inhibitors (PPI) is recommend e.g., esomeprazole or pantoprazole. Lifestyle modifications and H2 receptorantagonists lost their importance since acid suppressive therapy with PPI became available and had healing rates more than 80%.

Surgery is an effective therapy but healing rates are <100%. Furthermore new symptoms like gas bloating, dysphagia, inability to belch may arise. Sophisticated diagnostic examinations should be performed to select the patients who will have a benefit of this invasive therapy. Endoscopic treatment has not proven any superiority to drug therapy or selected surgery so far.

# Gastroschisis

Alexander K. C. Leung[1], William Lane M. Robson[2], Andrew L. Wong[3]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]The Childrens' Clinic, Calgary, AB, Canada
[3]Department of Surgery, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Gastroschisis is a congenital malformation characterized by a full-thickness abdominal wall defect that results in visceral herniation, almost always to the right of the umbilical cord (Fig. 1) [1].

The rectus muscles are normally formed and the defect is usually small. There is no sac that covers the exposed viscera. The extra-abdominal intestine can look normal but more commonly the gut appears to be thickened, foreshortened, edematous, and discolored. A variably developed serosal peel might be present on the surface, which results from in utero exposure of the intestine to amniotic fluid [1]. Approximately 10–20% of affected infants have associated anomalies [2]. Malrotation, shortening, stenosis, or atresia of the small intestine is common [1]. Cryptorchidism might be present but other extra-abdominal abnormalities are rare. Infants born with gastroschisis are more likely to be premature and to have a history of poor fetal growth.

**Gastroschisis. Figure 1** Note that the defect is to the right side of the umbilical cord.

## Prevalence

The incidence ranges between 0.4 and 4.6 live births and appears to be increasing [2,3]. Gastroschisis is reported to be associated with young maternal age (<20 years) and maternal exposure to cigarette smoking, alcohol, illicit drugs, acetaminophen, and vasoactive medications [2,3].

## Molecular and Systemic Pathophysiology

Gastroschisis is likely caused by premature regression of the right omphalomesenteric artery or right umbilical vein, which leads to a failure of normal development of the mesodermal components of the abdominal wall [4]. Gastroschisis might also result from a vascular accident that affects the right omphalomesenteric artery or right umbilical vein. The condition develops by the fifth or sixth gestational week and is more common on the right side because the right umbilical vein involutes, which makes this side more vulnerable to insufficient blood supply.

## Diagnostic Principles

Gastroschisis is usually diagnosed during prenatal ultrasonography. The classical findings include free-floating loops of bowel outside the abdominal cavity and the presence of the abdominal defect on the right side of the umbilical cord [3]. The maternal serum α feto-protein is usually very high with an average elevation of more than nine multiples of the normal mean [2]. Severe cases are associated with high levels of amniotic β-endorphin.

## Therapeutic Principles

Available data do not support routine caesarean section for infants with gastroschisis [4]. In the neonatal period, the exposed intestine should be covered with a warm, moist saline gauze and the infant should be placed under a radiant warmer [1]. Most infants with gastroschisis are dehydrated at birth and require intravenous hydration. A nasogastric tube should be placed to decompress the gastrointestinal tract. Prophylactic parenteral broad-spectrum antibiotics are indicated to prevent sepsis [1].

Gastroschisis can usually be treated with primary closure of the fascia after the abdominal wall is stretched such that the viscera can be reduced into the abdominal cavity. Occasionally, a staged repair is necessary, with application of a Silastic silo and gradual reduction of the protruding viscera, with delayed closure of the defect as the overlying abdominal wall expands [3]. Postoperative ventilatory support is often required for a few days. Most infants require parenteral nutrition for 2–3 weeks until the bowel begins to function normally.

# Gaucher Activator Deficiency

►SAP-C Deficiency

# Gaucher Disease

Manisha Balwani, Ainu Prakash-Cheng*, Robert J. Desnick
Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine of New York University, New York, NY, USA

## Synonyms

Gaucher disease; Acid β–glucosidase deficiency; Glucocerebrosidase deficiency

## Definition and Characteristics

Autosomal recessive lysosomal storage disease with three major subtypes all resulting from deficient of acid β-glucosidase (glucocerebrosidase) activity and accumulation of glucocerebroside (glucosylceramide; GL-1): type 1, non-neuronopathic disease; type 2, acute neuronopathic disease of infancy; type 3, subacute or chronic neuronopathic disease, intermediate phenotype. Clinical manifestations common to all three subtypes include hepatosplenomegaly and pancytopenia. Types 1 and 3 have significant skeletal involvement due to progressive marrow infiltration. Neurological involvement occurs in types 2 and 3 disease [1].

## Prevalence

All types are panethnic. However, type 1 disease is prevalent in the Ashkenazi Jewish population with a heterozygote frequency of about 1 in 16. Type 2 is rare with an incidence of $1\times10^{-6}$, while type 3 is prevalent in the Norbottnian Swedish population [1].

## Genes

The 7.5 kb gene encoding acid β-glucosidase (GBA) is located on chromosome 1q21, and contains 11 exons. A 5 kb pseudogene is about 16 kb downstream from GBA, and unequal cross-overs or gene conversions result in GBA mutations causing Gaucher disease. Approximately 200 different mutations have been described with at least four being relatively common (N370S, L444P, IVS2$^{+1}$G->A, c84insG [or 84GG]), especially in the Ashkenazi Jewish population [1].

## Molecular and Systemic Pathophysiology

Subtypes correlate with amount of residual acid β-glucosidase activity due to different mutations. The deficient or absent enzymatic activity results in the progressive accumulation of glucosylceramide in cell lysosomes throughout the body, but predominantly in monocytes and fixed macrophages ("Gaucher cells") in the liver, spleen, and bone marrow [1]. Progressive bone marrow infiltration causes osteopenia, Erlenmeyer flask deformity, osteonecrosis, bone pain and crises, and pathologic fractures.

## Diagnostic Principles

Clinical manifestations, including fatigue, easy bruisability, frequent nosebleeds, hepatosplenomegaly, and bone pain, may suggest the diagnosis of type 1 disease. Type 2 infants fail to thrive, have brainstem and cranial nerve involvement, and a rapidly progressive neurodegenerative course with death by 2 years of age. Type 3 patients present in childhood with horizontal supranuclear gaze palsy and neurological abnormalities, and other systemic signs of type 1 disease. Diagnosis of patients with all three subtypes is made by demonstration of deficient acid β-glucosidase in peripheral leukocytes. Affected individuals and carriers can be identified by mutation analysis. Common mutations have been found facilitating molecular testing. Genotype/phenotype correlations include: (i) the presence

*deceased

of even one N370S allele is neuroprotective, resulting in Type 1 disease; (ii) homozygosity for the L444P allele may result in either type 2 or 3 disease; (iii) the D409H allele is seen in a select group of patients with cardiac and neurological involvement.

### Therapeutic Principles

Intravenous enzyme replacement therapy (ERT) with mannose-terminated acid β-glucosidase has been shown to be safe and effective in improving the symptoms of type 1 Gaucher disease [2,3]. Following adequate doses (30–60 IU/kg every 2 weeks), patients experience reductions in liver and splenic volumes, increases in hemoglobin and platelet counts, increase in energy levels and amelioration of bone pain and bone involvement [2]. ERT is dose-dependent, particularly to treat or prevent the debilitating bone involvement [3,4]. Patients should be evaluated annually to assess disease progression and response to therapy [5].

GEFS+; SMEI; ICEGTC

### Definition and Characteristics

GEFS$^+$ is a familial epilepsy syndrome characterized by a spectrum of epilepsy phenotypes that occur within a family. The phenotypes are heterogeneous but typically begin in childhood with febrile seizures; a variety of afebrile epileptic seizure types may also occur. The most common phenotype is classical febrile seizures (FS). The next most frequent phenotype is Febrile Seizures Plus (FS$^+$) which may have a number of presentations: febrile seizures persisting after the sixth year of life, afebrile generalized tonic-clonic seizures, or both. Other phenotypes characterized by additional seizure types include FS$^+$ with absences, FS$^+$ with myoclonic seizures, FS$^+$ with atonic seizures and FS$^+$ with partial seizures. The severe end of the GEFS$^+$ spectrum includes the following epileptic encephalopathies: myoclonic-astatic epilepsy (MAE, Doose syndrome), and Dravet syndrome and related disorders (see below). The penetrance in the large families through which GEFS$^+$ was recognized was about 60%; however, it is likely that GEFS$^+$ usually follows complex inheritance [1,2].

SMEI/Dravet syndrome is characterized by hemiclonic and generalized seizures that typically begin at 6 months, but the range of onset is within the first year of life. The infant usually presents with febrile status epilepticus. Further convulsive attacks occur in the ensuing months with and without fever. Hemiclonic attacks may involve either side. Between 1 and 4 years, other seizure types commence, including myoclonic, partial, absence and sometimes atonic seizures. Developmental stagnation, sometimes with regression, occurs after the first 1 to 2 years of life. SMEI mostly occurs in "sporadic" cases (due to de novo mutations in SCN1A, see below) but some patients have a family history of febrile or afebrile seizures consistent with milder GEFS$^+$ phenotypes. In about 5% of SMEI cases, they have a familial SCN1A mutation that is also found in their relatives with milder GEFS$^+$ phenotypes [1,2].

SMEB (Borderline SMEI) refers to children with a SMEI phenotype, who do not have all the key features such as myoclonus or generalized spike wave activity. A subset of SMEB is called ICEGTC and has a similar course to SMEI, but only convulsive seizures occur. Familial cases of ICEGTC, where other family members have GEFS$^+$ have been described [1,2].

Since the identification of SCN1A mutations as the main cause of SMEI, other severe childhood epilepsies have been characterized and identified to be allelic disorders, such as severe infantile multifocal epilepsy (SIMFE) and cryptogenic focal or generalized epilepsies [1]. Of particular interest is a study demystifying the enigma of vaccine-related epileptic encephalopathies [3]. The identification of SCN1A mutations in 11 of 14 such patients clearly revealed that so-called "vaccine encephalopathy" usually has the phenotype of SMEI or SMEB with an identifiable genetic cause and that the onset just coincided with vaccination. Thus, the GEFS$^+$/SMEI spectrum extends from benign simple febrile seizures to a variety of severe epilepsy syndromes of childhood, including ICEGTC, MAE, SMEI and also focal epilepsies [1,2].

### Prevalence

There is no good data on the prevalence of GEFS+ and related disorders.

## Genes

Table 1 gives an overview of the genes in which mutations have been identified in GEFS$^+$, SMEI, and related diseases.

## Molecular and Systemic Pathophysiology

Functional studies of mutations identified in GEFS$^+$ and other syndromes revealed both gain- and loss-of-function mechanisms. Gain-of-function alterations so far described include an acceleration of recovery from fast inactivation shortening the refractory period after an action potential, increased persistent $Na^+$ currents predicting membrane depolarization due to an inward flow of $Na^+$, hyperpolarizing shift in window current increasing a permanent inward flow of $Na^+$ at potentials near to the resting membrane potential, and resistance to the decrease in channel activity upon high frequency depolarizations. However, loss-of-function mechanisms were described in part for the same as well as for other mutations such as enhanced fast and slow inactivation or a depolarizing shift of the steady-state activation curve, all of which reduce the amount of available $Na^+$ channels. Even a complete loss-of-function has been described for some GEFS$^+$ mutations. Hence, loss-of-function mechanisms seem to predominate for GEFS$^+$, which is in agreement with the genetic findings in SMEI, as outlined below. In contrast to the missense mutations found in GEFS$^+$ families, about 40% of the SMEI patients carry nonsense mutations predicting truncated proteins without function, and about 40% have missense mutations. SMEI point mutations also yielded non-functional channels [2].

Interestingly, the $Na^+$ channel blocker lamotrigine, the only drug of this class which is in use in patients with idiopathic generalized epilepsies, may deteriorate the clinical situation in SMEI patients; in particular, it can lead to an increased number of myoclonic seizures.

These observations confirm that SMEI is a loss-of-function $Na^+$ channel disorder caused by haploinsufficiency of SCN1A and from a genetic and clinical point of view – like ICEGTC – a severe allelic variant of GEFS$^+$. The percentage of SMEI patients carrying $Na^+$ channel mutations is high, probably about 80% overall, although early reports varied from 35 to 100%. The mutation rate is slightly lower in SMEB and related phenotypes. $Na^+$ channel mutations are relatively rare in GEFS$^+$ families.

Since the voltage-gated $Na^+$ channel generates and propagates action potentials, a loss-of-function of this channel is predicted to decrease membrane excitability. It therefore seems paradoxical that such mutations can cause epilepsy. However, when acting predominantly on inhibitory neurons, this effect could well be responsible for the occurrence of hyperexcitability in neuronal circuits, inducing epileptic seizures. Indeed, two recent models of SCN1A-targeted mice showed that Nav1.1, encoded by SCN1A, is the major $Na^+$ channel of inhibitory neurons. These mice develop a severe epilepsy resembling SMEI in humans; they show a decreased $Na^+$ current density in inhibitory neurons, and these neurons are less excitable than those from WT mice [4].

The loss of excitability of inhibitory neurons very nicely corresponds to the effects seen with $GABA_A$ receptor mutations, since functional studies of the GABRG2 mutations revealed a more or less pronounced loss-of-function as a common pathogenic mechanism, which directly reduces inhibitory GABAergic transmission. This mainly occurred due to nonsense mutations or transport defects to the membrane [2]. A knock-in mouse model of one mutation, found in a family with childhood absence epilepsy and febrile seizures, reveals that the phenotype, in particular absence seizures, can be reproduced in mice and that the reduction in GABAergic inhibition occurs in the cortex [5].

## Diagnostic Principles

The diagnosis is based on the clinical characteristics described above, i.e., age of onset, seizure semiology, trigger factors such as fever, developmental course, and other history obtained from the family. EEG and MRI further characterize the epilepsy syndrome and exclude symptomatic causes.

## Therapeutic Principles

Many patients with the mild phenotypes of the GEFS$^+$ spectrum do not require treatment. GEFS$^+$ patients

**Generalized (Genetic) Epilepsy with Febrile Seizures Plus, Severe Myoclonic Epilepsy of Infancy. Table 1**
Genes, Locus, affected proteins, resulting phenotypes, and OMIM numbers for GEFS$^+$ and related syndromes

| Gene | Locus | Protein | Number of mutations | Diseases/phenotypes | MIM number |
|---|---|---|---|---|---|
| *SCN1A* | 2q23–24.3 | $Na^+$ channel α-subunit $Na_v1.1$ | >200 | FS, GEFS$^+$, SMEI, SMEB, ICEGTC, SIMFE | 604233, 607208 |
| *SCN1B* | 19q13.1 | $Na^+$ channel $\beta_1$-subunit | 4 | GEFS$^+$ | 604233 |
| *GABRG2* | $5_q31.1–33.1$ | $GABA_A$ receptor $\gamma_2$-subunit | 5 | FS, GEFS$^+$, CAE with febrile or other seizures of the GEFS$^+$ spectrum, SMEI | 604233, 607208 |

presenting with afebrile seizures are treated with standard anticonvulsant medications and usually achieve seizure freedom. In contrast, SMEI and related forms are highly resistant to pharmacotherapy. Valproate, topiramate and clobazam can be useful, and bromide may have positive effects in some patients. A new promising option is stiripentol, which is being used increasingly early on during the course of the disease by specialized epilepsy centers. Lamotrigine may aggravate seizures in SMEI. A molecular diagnosis initiated after the first prolonged/complicated febrile seizure revealing mutations in SCN1A may help to stratify treatment options early on and avoid the need for other invasive investigations.

## Synonyms

GDM

## Definition and Characteristics

The first manifestation of reduced glucose tolerance of variable degrees that appears during pregnancy, with or without insulin requirement, which comprises the clinical manifestation of previously undiagnosed typ-1 and type-2 diabetes or, in most cases, of impaired glucose tolerance in individuals with genetic predisposition for type-2 diabetes or reduced glucose tolerance, and manifestation of ►MODY (maturity onset diabetes in the young).

## Prevalence

Depending on the current definition, the prevalence of gestational diabetes is 2–6% of all pregnancies. In Germany, 10–15% of all women with GDM are positive for islet cell antibodies and insulin antibodies. Only 4% of GDM remain insulin- dependent after delivery. 40% of GDM develop type-2 diabetes mellitus in their remaining lifetime, current opinion estimates up to 90%.

## Genes

Type-1 diabetes exhibits allelic associations with certain HLA-Class II genes. HLA susceptibility genes for T1DM are DRB1*0401, DRB1*0404, DQB1*0302, DRB1*0301, DQB1*0201. The DRB1*04/DRB1*03 heterozygous state also confers increased susceptibility. HLA genes known to confer "resistance" to T1DM are DRB1*1501, DQB1*0602-DQA1*0102. HLA specificities were defined according to the WHO nomenclature committee in 1999. HLA-class I genes "do" not confer convincing susceptibility; increased and decreased associations have been attributed to linkage disequilibrium. Susceptibility haplotypes and genotypes are dependent on the population screened and show major divergences among countries. HLA-DR3(16) was increased in Chinese GDM. MHC genes are encoded on chromosome 6p21.

The genetic basis of type-2 diabetes is polygenetic and not well defined. Type-2 diabetes is associated with polymorphism of the following genes: CAPN10, APM1, PPAR-g, E48K in Kir6.2, AV98 in HNF1a. In type-2 diabetes, susceptibility genes confer increased risk of manifestation in a situation of predisposing surrounding factors, not the disease itself.

- The inheritance of MODY-forms is monogenic and transferred in an autosomal dominant manner. Therefore, the presence of a MODY mutation causes the manifestation of the disease.
- MODY 1 is due to a mutation of the hepatic nuclear factor 4 alpha (HNF-4alpha)-gene, located on chromosome 20q.
- MODY 2 is attributed to a mutation of the glucokinase (GK)-gene on chromosome 7p.
- MODY 3 is attributed to a mutation of the hepatic nuclear factor 1 alpha (HNF-1alpha)-gene, located on chromosome 12q.
- MODY 4 is attributed to both a mutation of insulin promoter factor-1 (IPF-1) and pancreatic homebox-1 (PDX-1), both located on chromosome 13q.
- MODY 5 is attributed to a mutation of hepatic nuclear factor 1 beta (HNF-1beta)-gene, located on chromosome 17q.
- MODY 6 is attributed to a mutation of the neuro-D1/beta2 (NeuroD1)-gene located on chromosome 2q.

Of these, MODY 2 and MODY 3 are most often found in GDM.

A mitochondrial mutation at position 3243 nucleotide pair (A-to-G) present in a cohort of 84 type-1 diabetic patients was reported in a Chinese type-1 diabetic patient who manifested as GDM.

No clear evidence was found for prohormone convertase 1, insulin receptor substrate 2 (IRS-2), or mitochondrial gene mutations.

## Molecular and Systemic Pathophysiology

In the most common form of GDM, miellitus; confounding factors are overweight, carbohydrate rich diet, sedentary life-style and presence of anti-insulinemic hormones during pregnancy. This results in insulin

resistance, reactive hyperinsulinemia and secretion and relative insulin deficiency with subsequently elevated blood glucose levels, possibly due to alterations of insulin secretion. The missence mutations A98V and P447L in HNF1alpha or Phe199Ser in ngn3 (neurogenin 3-gene) are associated with a reduced insulin secretion by up to 30%. Genetic variants of CAPN10 with increased expression of CAPN10-mRNA are associated with insulin resistance. Impaired conversion of pro-insulin to insulin is also discussed as a mechanism for reduced insulin secretion reserve. Genetic variants of CAPN10 may be present in 18% of GDM.

In the course of GDM, by week 24 of gestation, insulin resistance is implied by counter-regulatory hormones and results in elevated insulin requirements. In healthy subjects, the pancreatic beta cells respond with increased insulin output and succeed in maintaining glucose homeostasis. In GMD, glucose tolerance is impaired.

In GDN on the basis of type-1 diabetes mellitus, an autoimmune attack with subsequent inflammation and destruction of pancreatic beta cells leads to a reduced secretion reserve. Elevted blood glucose levels normally occur when about 90% of beta cells are destroyed. In the pregnancy with its physiological insulin resistance, insulin defiency may scome apparent. This sub-population is characterised by the presence of antibodies and persistent insulin deficiency after delivery.

In GDM, pronounced insulin resistance occurs in the course of the second and third trimester of pregnancy, beginning in week 22 of gestation. The insulin resistance is also the factor for the manifestation of type-2 diabetes mellitus and relative insulin deficiency in pregnant women.

In the 9th to 12th week of gestational age, the fetus is not able to synthesise insulin. Maternal insulin is not passing the placental barrier. So, hyperglycaemia of the mother implies hyperglycaemia to the foetus. In the early gestational age, hyperglycaemia leads to increased risk of foetal malformation. From the 12th week of gestational age onwards, the foetus is able to synthesise its own insulin and regulate the foetal blood glucose level. With glucose passing the placental barrrier, hyperglycemia of the mother induces fetal hyperinsulinemia, supported by hypertrophy and hyperplasia of pancreatic beta-cells. This results in macrosomia or large-for-date babies with premature birth and increased risk to develop respiratory distress syndrome.

In MODY, low birth weight is more common, when the fetus is carrier of a MODY mutation resulting in reduced insulin secretion capacity.

Macrosomia in infants of GMD women is influenced by inheritence, e.g. in Cree of James Bay, Canada, the prevalence of macrosomia was 34.3% in Cree versus 11.1% in non-native Canadians.

## Diagnostic Principles

Screening via blood glucose levels, the 50 g oral glucose challenge test is administered as a screening method in the 24th week of pregnancy, and the 75 g oral glucose challenge test in 24th to 28th week of pregnancy as a confirming test. HbA1c-values are too insensitive to diagnose GDM in time. HbA1c is still of value for monitoring therapeutic goals. HbA1c goal is <6.5% in the 1st and <5.5% in the second and third trimester. Insulin antibodies are present in women with type-1 diabetes, but also in a proportion of typ-2 diabetes, and are not helpful for diagnosis. The therapy for GDM is not different on the basis of MODY. So, a general screening for MODY genes is not helpful. With low birth weight and positive family history for MODY, GK (glucokinase)-gene and HNF-1alpha -gene analysis may be useful.

## Therapeutic Principles

In 75% of GDM, diet alone is sufficient to achieve the therapeutic goals. In 15% of GDM, insulin therapy is required.

## Gilbert Syndrome

Peter L. M. Jansen
Department of Gastroenterology and Hepatology, Academic Medical Center, Amsterdam, The Netherlands

### Synonyms

Gilbert's syndrome; Meulengracht syndrome; Mild unconjugated hyperbilirubinemia

### Definition and Characteristics

Autosomal recessive abnormality characterized by mild unconjugated hyperbilirubinemia with serum bilirubin levels that increase on fasting and intercurrent illnesses.

### Prevalence

Approximately 6% of Caucasian population, more in males than in females. In Japan the prevalence is approximately 2–3%.

### Genes

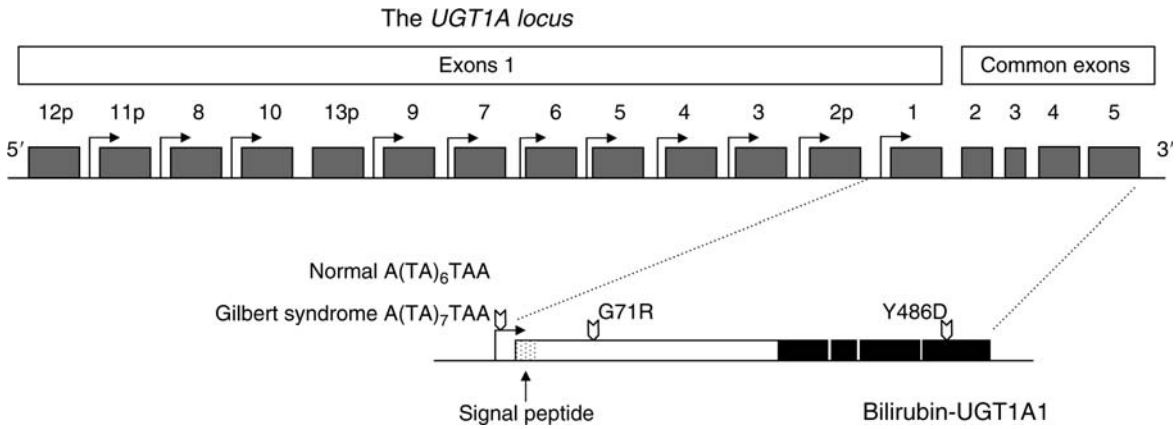
UGT1A1 is encoded by the UGT1 gene on chromosome 2q37.

### Molecular and Systemic Pathophysiology

Bilirubin is conjugated to bilirubin mono- and diglucuronide in the endoplasmic reticulum of the hepatocytes in the liver. This is mediated by the enzyme bilirubin-uridinediphosphoglucuronate glucuronosyltransferase, bilirubin UDPglucuronosyltransferase or UGT1A1. The UGT gene encodes a number of UGT's catalyzing the glucuronidation of bilirubin, quinols, and phenols. Two members of the UGT1A family accept bilirubin as substrate UGT1A1 and UGT1A4 but only UGT1A1 contributes significantly to bilirubin glucuronidation. Gilbert syndrome was first described by Gilbert and Lereboullet in 1901. The syndrome is characterized by mildly elevated serum bilirubin levels (30–80 μmol/l) caused by a reduced UGT1A1 activity to 20–30% of normal. Figure 1 shows the organization of the UGT1 gene.

Among Caucasians the frequency of the UGT1A1*28 allele is approximately 35–40% [1,2]. Thus, homozygosity for UGT1A1*28 among Caucasians may be in the order of 12–16%, in Asians it is in the order of 2–3%. Not all of these persons have Gilbert syndrome. Additional factors, such as increased erythrocyte turnover (but not necessarily overt hemolysis) or impaired hepatic uptake play a role in the expression of the syndrome.

In Asian populations the prevalence of UGT1A1*28 is low, Asian patients with Gilbert syndrome often have



**Gilbert Syndrome. Figure 1** Four exons (exons 2–5) at the 3′ end encode the common carboxyterminal domain of all UGT isoforms encoded by this locus. This carboxyterminal domain contains the membrane spanning region and the UDP-glucuronic acid binding site. Upstream of these four exons are a number of exons that encode the substrate binding site. Each unique exon 1 is spliced to exon 2 and the intervening mRNA segment is spliced out. Each of the exon 1's is preceded by a different promotor allowing differential regulation of the various UGT1 enzymes. The promotors contain a TATAA box that is important for the transcription by RNA polymerase II. Bilirubin UGT1A1 contains a TATAA box with six TA dinucleotide repeats. A prolonged TATAA box is associated with a decreased transcription rate and decreased UGT1A1 activity. Caucasian patients with Gilbert syndrome almost invariably are homozygous for a TATAA box with seven instead of six TA repeats. The prolonged TATAA box with seven TA repeats has been named UGT1A1*28 allele. In Japanese patients Gilbert syndrome may be caused by structural gene mutations.

missense mutations of the UGT1A1 coding region, like the G71R and the Y486D mutation [3].

The serum bilirubin level is the result of bilirubin synthesis and removal. A combination of UGT1A1*28 homozygosity and overt hemolysis will cause increased serum bilirubin levels. This is particularly seen in the Mediterranean area where glucose-6-phosphate dehydrogenase and beta-thalassemia is prevalent. The same applies to African Americans among whom sickle cell anemia is prevalent. In neonates a combination of Gilbert syndrome and hemolysis may lead to kernicterus and/or prolonged neonatal jaundice. Also, without the mentioned hemolytic syndromes, Gilbert syndrome may cause prolonged neonatal jaundice. Hypersplenism and congenital spherocytose in combination with UGT1A1*28 will also lead to increased serum bilirubin levels. In patients with congenital spherocytosis and Gilbert syndrome there is a high incidence of gallstones.

Patients with Gilbert syndrome more often experience side effects such as diarrhea upon administration of the topomerase I inhibitor irinotecan (CPT-11) [4]. There appears to be a linkage between UGT1A1*28 and a variant UGT1A6 (UGT1A6*2) with reduced enzymatic activity. Therefore, patients with Gilbert syndrome may have reduced glucuronidation of aspirin, paracetamol, coumarin, and dopamine-derivatives, all substrates of UGT1A6 [5].

## Diagnostic Principles

Unconjugated hyperbilirubinemia (30–80 μmol/l) in the absence of hemolysis and normal serum liver enzymes should lead to the diagnosis of Gilbert syndrome. Gilbert syndrome, in combination with hemolysis, may lead to considerably elevated serum bilirubin levels. Upon fasting (400 kcal for 48 h) a doubling of serum bilirubin levels is seen in patients with Gilbert syndrome. However, this test lacks specificity. In addition, nicotinic acid administration leads to an increase in serum bilirubin levels but also this test lacks specificity. A liver biopsy to test bilirubin UDP-glucuronosyltransferase activity is not recommended. The UGT1A1*28 gene can be tested by a rapid RT-PCR test. Patients with Gilbert syndrome often complain of fatigue. The cause of fatigue in Gilbert syndrome is unknown.

## Therapeutic Principles

Treatment is not necessary. Fatigue does not correlate to serum bilirubin levels, therefore decreasing serum bilirubin concentrations does not help in improving fatigue.

## Gitelman Syndrome

Siegfried Waldegger[1], Florian Lang[2]
[1]University Children's Hospital, Phillips University, Marburg, Germany
[2]Department of Physiology, University of Tuebingen, Tuebingen, Germany

### Synonyms

Gitelman variant of Bartter syndrome

### Definition and Characteristics

Autosomal recessive renal transport defect leading to hypokalemic alkalosis with hypocalciuria and hypomagnesemia.

### Prevalence

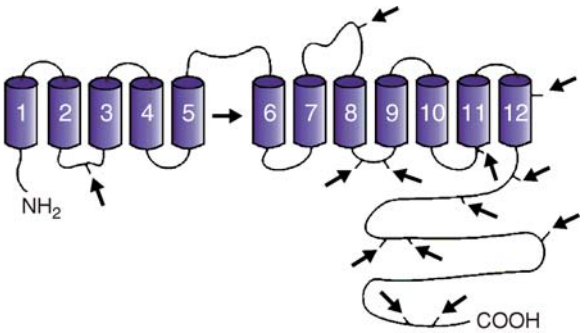
The prevalence of heterozygotes is reported for Swedish and Italian populations to exceed 1%.

### Genes

SLC12A3 coding for the thiazide-sensitive cotransporter TSC, localized on chromosome 16q13 [1].

### Molecular and Systemic Pathophysiology

The TSC is a transporter with 12 transmembrane spanning domains [2]. The described sites of mutations in Gitelman syndrome are shown in Fig. 1. The carrier transports NaCl into the cell and is required for the reabsorption of NaCl in the early distal tubule of the kidney [3]. Failure of NaCl reabsorption in this nephron segment stimulates $Na^+$ reabsorption in other nephron segments. The increased $Na^+$ reabsorption in proximal tubule and Henle's loop enhances the reabsorption of $Ca^{2+}$ leading to hypocalciuria. $Na^+$ reabsorption is further increased in distal tubule segments, i.e. mainly by principle cells of distal tubule and collecting duct. As in those cells $Na^+$ reabsorption drives $K^+$ secretion due to depolarization of the luminal cell membrane, the disorder leads to enhanced renal excretion of $K^+$ with subsequent hypokalemia. Despite enhanced $Na^+$ reabsorption in other nephron segments the disorder leads to renal loss of NaCl, which compromises maintenance



**Gitelman Syndrome. Figure 1** The sites (see *arrows*) of mutation in Gitelman syndrome [4].

of extracellular fluid and blood pressure (hypovolemia, hypotonia). As a result, renin is released, which eventually leads to secondary hyperaldosteronism. Aldosterone stimulates $Na^+$ reabsorption and $K^+$ secretion in principle cells further aggravating hypokalemia. Besides its influence on $K^+$ excretion, aldosterone stimulates distal tubular $H^+$ secretion thus leading to alkalosis and increases renal magnesium excretion thus leading to hypomagnesemia.

### Diagnostic Principles

The coincidence of hypotension, hypokalemia, hypomagnesemia, alkalosis and hypocalciuria points to the disease. Plasma aldosterone levels are high. Family history may reveal genetic origin. Detection of mutations in the TSC gene confirm the diagnosis of this rare disease.

### Therapeutic Principles

Electrolyte (most importantly potassium and magnesium) repletion serves to normalize plasma electrolytes and acid base balance. In severe cases, salt wasting may be blunted by indomethacin, which decreases $PGE_2$ formation and thus disinhibits distal tubular $Na^+$ reabsorption.

## Glanzmann's Thrombasthenia

Hugo ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

### Synonyms

Glanzmann thrombasthenia; GT platelet glycoprotein IIb–IIIa deficiency GP IIb–IIIa complex; Deficiency of platelet fibrinogen receptor; Deficiency of glycoprotein complex IIb–IIIa

### Definition and Characteristics

Rare lifelong hemorrhagic disorder, due to absence of mutation in platelet membrane glycoprotein IIb–IIIa complex, presenting with spontaneous mucocutaneous bleeding, epistaxis, and purpura.

### Prevalence

Very rare disorder (<$1:10^6$ in general population, particularly prevalent in four populations: French gypsies, Iraqi Jews in Israel, Indians, and Jordanian Arabs. In a review of 177 cases 58% was female, probably due to diagnostic suspicion bias (menorrhagia). Majority detected <5 years of age.

### Genes

Autosomal recessive; due to mutation in the integrin, alpha-2b gene (ITGA2B); Gene map locus: 17q21.32; increasing number of mutations has been found, which are registered at http://med.mssm.edu/glanzmanndb.

## Molecular and Systemic Pathophysiology

The glycoprotein IIb–IIIa receptor (integrin alphaIIbbeta3) is one of the most important and prevalent platelet surface receptors (around 80,000/platelet, 15% of total surface proteins). In resting platelets it serves as a low affinity receptor for von Willebrand factor and fibrinogen. Upon activation of platelets outside-inside signal transduction mediates integrin-cytoskeleton interactions.

Patients with severe GP IIb and IIIa deficiency (<5% of normal) are designated type 1. Moderate deficiency (10–20% of normal) is designated type 2, and patients with a primary functional abnormality rather than a deficiency are designated variant type. The type of disease is however not related to the bleeding phenotype.

The hallmark of the disease is due to qualitative or quantitative abnormalities in the platelet membrane glycoprotein complex that serves as receptor for fibrinogen, causing defective platelet plug formation in response to physiological stimuli.

*Clinical Features*: Morbidity comprises major mucocutaneous bleeding, epistaxis, menorrhagia, and purpura. Epistaxis may occur in childhood. Menorrhagia may be excessive and require transfusions. Hemarthroses and deep visceral bleeding are rare. Intracranial bleeding is very rare. In general, severity of bleeding is unpredictable. Pregnancy is usually uncomplicated but delivery poses risks of severe bleeding. The effect on life expectancy is unknown. There is a presumed survival advantage due to protection against arterial thrombotic disorders, but this is unproven. Rarely, venous thrombosis has been reported.

## Diagnostic Principles

Autosomal recessive trait, no bleeding symptoms in heterozygotes; history of bleeding symptoms as indicated, highly variable bleeding disorder, normal platelet count and morphology, long bleeding time, absent or severely impaired platelet aggregation in response to ADP, collagen, thrombin, and epinephrine, absent or diminished clot retraction, normal but possibly reversible platelet agglutination by ristocetin and VWF.

## Therapeutic Principles

In general, the prognosis of Glanzmann's thrombasthenia is excellent, and mortality due to bleeding has been very rare. Supportive care includes blood transfusion when needed. In women, management of menorrhagia may need combined hormonal treatment in addition to supportive care. In case of life-threatening bleeding complications recombinant factor VIIa may be required.

# Glaucoma

Hagen Thieme
Department of Ophthalmology, Johannes Gutenberg University Mainz, Mainz, Germany

## Synonyms

Primary open angle glaucoma; Chronic open angle glaucoma

## Definition and Characteristics

There are many forms of glaucoma affecting practically every age group. The most common type (primary open angle glaucoma) affects the elderly and leads to optic neuropathy with characteristic cupping of the optic nerve head and consecutive loss of visual field. Elevated intraocular pressure is usually one of several important risk factors. Despite the fact that there were mutations shown for some forms of juvenile glaucoma the gene defect or the underlying genetic disposition or cause of primary open angle glaucoma still remains unclear. What is known however is that flow of aqueous humor through the trabecular meshwork is impaired. The trabecular meshwork is a contractile tissue in the chamber angle and forms the main outflow resistance. It is affected by antiglaucoma drugs (pilocarpine and prostaglandines) or is bypassed in case of surgical therapy. Furthermore neurodegenerative elements appear to play a role and glaucoma has even been termed as "Alzheimer's disease of the retina". Consequently the search is ongoing for neuroprotective treatment options [1].

## Prevalence

Prevalence of primary open angle glaucoma depends on age and is 0.5–2% of the population over 40 years of age in Europe and the USA. It increases with age averaging 6% of the over 60 and up to 13% in the over 80 year old group.

## Genes

Only a portion of POAG follows a Mendelian behavior. This variability combined with the fact of the rather late onset of the disease makes the task to identify disease-associated genes difficult. The risk for pedigrees for relatives of POAG patients is reported at 4–16%. So far among the 11 POAG gene loci three genes have been identified: myocilin, optineurin and the WD repeat-containing protein 36 [2]. Myocilin is expressed in the trabecular meshwork as well as in ganglion cells. Optineurin is expressed in ganglion cells.

## Molecular and Systemic Pathophysiology

In glaucoma two separate areas within the eye are affected, one being the anterior part where IOP related changes take place and second the back of the eye where, on the retina level, neurodegenerative tissue damage occurs.

What is evident in glaucoma is the remodeling of the optic nerve head ultrastructure with deep excavation of the disc and loss of collagen in the lamina cribrosa. This tissue forms the gate through which the axons of the ganglion cells leave the eye. On the retinal level ganglion cell loss is most profound. The areas of ganglion cell loss are identical with areas of visual field loss. It has been proposed that besides elevated intraocular pressure impaired blood flow and axonal transport around the optic nerve head is one of the key factors in the pathophysiology of glaucoma. This ultimately leads to apoptosis probably induced by neurotoxic molecules such as glutamate, which has been found to be increased in the vitreous of glaucomatous eyes. Optineurin seems to be involved in Fas-ligand or TNFα-dependent apoptotic pathways.

Excitotoxicity can occur either due to excess of glutamate in the microenvironment caused by discharge of the compound from apoptotic and dying cells or by an overactivation of the N-methyl-D-aspartate (NMDA)-receptor by normal extracellular levels of glutamate. In the absence of glutamate the NMDA receptor is in closed formation, which prevents calcium entry. In the case of glutamate binding it undergoes a conformational change which opens calcium channels. Under physiological conditions, glutamatergic neurons can become depolarized through excitation by neuronal inputs which in turn leads to entry of small amounts of calcium. This calcium entry is magnified in case of glaucomatous neuronal damage probably causing cell death. Therefore glaucomatous neurons appear to be more sensitive to normal levels of glutamate and affect surrounding still healthy neurons. Clinical trials involving NMDA receptor blockers are currently ongoing. These compounds (memantine) have been approved and used for the treatment of Parkinson's and/or Alzheimer's disease since many years.

The outflow system appears to be influenced by a molecule which causes vascular changes: endothelin [3]. The protein causes vasoconstriction and has been implicated in diseases such as pulmonary hypertension. Increased concentrations of endothelin were found in the aqueous humor compared to serum of normal subjects indicating a physiological role of endothelin in the eye. The aqueous endothelin levels are further elevated in glaucoma patients where it could be linked to ongoing and progressive disease. As the outflow system maintains aqueous flow through the trabecular meshwork by contractile mechanisms it could be speculated that endothelin may affect IOP by affecting the contractile status of the meshwork. On the other hand inhibiting trabecular contractions caused by endothelin could be a specific way to lower IOP. Recent studies have shown that compounds such as prostaglandine analogues which are in wide use as IOP lowering drugs work in such a manner [4]. By blocking the contractile response to endothelin (i.e. causing relaxation) in the trabecular meshwork outflow facility is enhanced and IOP lowered. Endothelin acts via endothelin receptor A or B. Both are G-protein coupled receptors leading to calcium mobilization. Currently the exact crosstalk between endothelin receptors and prostaglandine receptors remains to be clarified.

## Diagnostic Principles

Primary open glaucoma has no symptoms in the early stages making detection of glaucoma patients difficult. Estimates of up to 50% undetected and untreated glaucoma patients highlight this fact. Usually elevated intraocular pressures above the norm lead to a first hint towards the diagnosis making screening urgent after the age of 40. Further clinical investigation usually leads to glaucomatous and abnormal visual field exams and optic disc changes. A positive family history for glaucoma may enroll suspects for glaucomatous disease into early treatment. In recent years various scanning laser devices have entered the diagnostic armament enabling ophthalmologists for better follow up exams and detection of progression. This is important in the knowledge that glaucoma is a slow progressing long lasting disease making life-long treatment and follow up exams mandatory [5].

## Therapeutic Principles

Untreated glaucoma leads to blindness in many cases. Therapy of all forms of glaucoma focuses on lowering of intraocular pressure. This is usually achieved by local treatment with eye drops. When a target pressure is not reached penetrating or non penetrating operations are performed which are designed for a better outflow of aqueous humor out of the eye thus lowering intraocular pressure. Currently there is no neuroprotective treatment available, additionally there is currently no causative treatment for this sight threatening disease.

# Glaucoma, Ectopia, Microspherophakia, Stiff Joints, Short Stature Syndrome

►Weill-Marchesani Syndrome

# GLD

►Krabbe Disease

# Glioma Retinae

►Retinoblastoma

# Gliomas

Michael Weller
Department of Neurology, University Hospital Zurich, Zurich, Switzerland

## Definition and Characteristics

Gliomas are intrinsic tumors of the central nervous system (CNS). They include astrocytomas of World Health Organization (WHO) grades I–IV, oligodendrogliomas and oligoastrocytomas of grades II and III, ependymomas of grades I–III and some other rare tumor entities [1,2].

## Prevalence

The annual incidence of glial brain tumors amounts to 5–10/100,000 in Western countries. For specific subtypes of tumors, the incidence varies strikingly among age groups (www.cbtrus.org).

## Genes

Most gliomas are apparently sporadic. Hereditary tumor syndromes are rare; gliomas are part of the spectrum in neurofibromatosis type I (affecting the neurofibromin gene) and type II (merlin), tuberous sclerosis (hamartin, tuberin), Li Fraumeni syndrome (p53) and Turcot syndrome type II (HMLH1, HPSM2).

## Molecular and Systemic Pathophysiology

The origin of sporadic gliomas has remained obscure. Given that the adult brain is essentially composed of post-mitotic cells, it has been proposed that neural progenitor cells are the cellular origin of these lesions. Depending on the grade of malignancy, the tumors grow either in a circumscript pattern or as highly infiltrative lesions and thereby compromise the function of the CNS. Extra-CNS metastases are very rare. Typical molecular alterations include p53 mutation, epidermal growth factor receptor (EGFR) amplification and disruption of the G0/G1 cell cycle checkpoint controlled by the retinoblastoma gene product, cyclin-dependent kinase (CDK) 4 and p16.

## Diagnostic Principles

Clinical symptoms and signs lead to a diagnostic work-up using neuroimaging methods such as magnetic resonance imaging (MRI) or computed tomography (CT), which allow the recognition of neoplastic CNS lesions. While the radiological appearance of these lesions is often highly suggestive of a specific type of tumor, histological evaluation remains the gold standard of diagnosis for glial tumors. Molecular studies such as the analysis of $O^6$-methylguanine DNA methyltransferase (MGMT) gene promoter methylation and the determination of 1p and 19q chromosomal losses are likely to aid in developing a molecular classification of gliomas in the near future.

## Therapeutic Principles

The therapeutic strategies comprise surgical resection, radiotherapy and chemotherapy. The major cytostatic agent for the treatment of gliomas is the alkylating agent temozolomide [3] followed by nitrosourea compounds. MGMT promoter methylation predicts a favorable outcome for glioma patients treated with alkylating agents [4]. The choice of treatment depends mostly on the histological type of glioma (Table 1). Further factors

**Gliomas. Table 1** Treatment options for gliomas

| | Treatment at diagnosis | Treatment at recurrence or progression |
|---|---|---|
| Pilocytic astrocytoma (WHO grade I) | Resection | (Re)-resection or radiotherapy, if resection is not possible |
| Diffuse astrocytoma (WHO grade II) | Resection or biopsy followed by observation or radiotherapy | (Re-)resection and radiotherapy (or chemotherapy) |
| Oligodendroglioma and oligoastrocytoma (WHO grade II) | Resection or biopsy followed by observation or chemotherapy or radiotherapy | (Re-)resection and chemotherapy or radiotherapy |
| Anaplastic astrocytoma (WHO grade III) | Resection followed by radiotherapy (and chemotherapy) | (Re-)resection plus chemotherapy or stereotactic re-radiotherapy |
| Anaplastic oligodendroglioma and oligoastrocytoma (WHO grade III) | Resection followed by radiotherapy or chemotherapy | (Re-)resection and chemotherapy or radiotherapy |
| Glioblastoma (WHO grade IV) | Resection (or biopsy) followed by radiotherapy and chemotherapy | (Re-)resection followed by chemotherapy or stereotactic re-radiotherapy |
| Ependymoma and anaplastic ependymoma (WHO grade II/III) | Surgery, followed by involved-field radiotherapy except for completely resected spinal ependymomas (WHO grade II); craniospinal irradiation for tumors metastastic to the spinal cord and CSF | Surgery and re-radiotherapy where feasible |
| Myxopapillary ependymoma (WHO grade I) | Resection, observation or radiotherapy for incompletely resected tumors | Resection and radiotherapy |
| Subependymoma (WHO grade I) | Resection | Resection, rarely radiotherapy |

that guide treatment decisions include age, general and neurological level of function determined as the Karnofsky performance score and patient preference. Molecular studies such as determination of 1p and 19q chromosomal losses or EGFR or p53 status have not assumed a role in clinical decision making yet.

# Globoid Cell Leukodystrophy

►Krabbe Disease

# Globozoospermia

Bärbel Schütte
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Round-headed spermatozoa; Round-headed spermatozoa syndrome

## Definition and Characteristics

Globozoospermia is a severe feature of teratozoospermia characterized by round nuclei of the spermatozoa

lacking the acrosome, which plays the most important part in fertilization. Furthermore, abnormalities of the mitochondrial sheaths, middle pieces and tails are often associated. Patients with 100% round headed spermatozoa are infertile.

### Prevalence

Globozoospermia is rare and found in <0.1% of infertile males.

### Genes

So far no responsible genes have been detected for human males. The existence of family cases suggest a genetic origin, but the mode of inheritance remains unknown. Multiple genetic components are discussed [1, 2]. Recent knockout studies have identified three candidate genes in spermatozoa of mice with round nuclei lacking an acrosome [3]: HIV-1 Rev-binding Protein (Hrb), expressed in acrosome development, located on chromosome 2, subregion q36.3; Golgi-associated PDZ- and coiled-coil motif-containing protein (GOPC) [4] located on chromosome 6, subregion q21 and casein kinase II alphá catalytic subunit (Csnk2a2) [2].

### Molecular and Systemic Pathophysiology

The acrosome is a unique organelle, which binds to the oocyte zona pellucida, fuses with the oocyte oolemma and is lost in round headed spermatozoa. The acrosome develops from the Golgi-apparatus in the initial phase of spermatogenesis. Although the morphogenic changes of the acrosome in human spermatogenesis has been well documented, its molecular mechanisms are largely unknown. Knockout studies revealed that coiled-coil motif-containing protein (GOPC) is a Golgi associated protein in mice, and is present in the trans-Golgi network as well in the trans-Golgi cisternae. In spermatozoa of mice lacking GOPC the acrosome is completely lost. The primary defect may be the fragmentation of the acrosomal cap in early round spermatids. Male mice with disrupted GOPC have round headed spermatozoa and are infertile [4].

### Diagnostic Principles

Convential semen analysis detects round headed spermatozoa. To identify the various ultrastructural defects transmission electron microscopy is the most commonly used method.

### Therapeutic Principles

Intracytoplasmatic spermatozoa injection (ICSI) is the treatment of choice for patients with globozoospermia. However, ICSI is less successful in those patients compared with other forms of teratozoospermia. Fertilization failures may be due to a deficiency in oocyte-activation capacity.

## Globus Hystericus

►Globus Pharyngeus

## Globus Pharyngeus

Ronnie Fass
Southern Arizona VA Health Care System and Arizona Health Sciences Center, University of Arizona, Tucson, AZ, USA

### Synonyms

Globus pharyngitis; Globus sensation; Globus hystericus

### Definition and Characteristics

A chronic sensation of a lump or foreign body in the throat that is not associated with eating or swallowing difficulties.

### Prevalence

It is prevalent in 2.5–7.3% of the general population. Approximately 4% of the referrals to ear, nose and throat (ENT) clinic.

### Genes
The genetics of globus pharyngeus is unknown.pt

### Molecular and Systemic Pathophysiology
Only the minority of patients (about 15%) with globus pharyngeus demonstrates anatomical abnormalities during examination of the larynx or pharynx. These include vocal fold nodules, vocal fold palsy/paresis, Reinke's edema as well as others. Other findings have been related to globus pharyngeus, including non-palpable thyroid nodules and hyperviscoelasticity of the epipharyngeal mucus. Recent work has implicated laryngopharyngeal reflux (LPR) in patients with ►gastroesophageal reflux disease (GERD) as an important cause of globus pharyngeus. Globus pharyngeus could also be the manifestation of esophageal dysmotility; particularly abnormal upper esophageal sphincter (UES) function (elevated basal pressure) and less commonly achalasia. In patients who lack any of the aforementioned anatomical or physiological abnormalities, globus pharyngeus falls under the category of a functional esophageal disorder.

Psychological abnormalities are common in patients with globus pharyngeus and include depression, anxiety, panic disorder and somatization. Additionally, patients with globus pharyngeus tend to report more life events prior to emergence of symptoms.

### Diagnostic Principles
The report of chronic or intermittent sensation of a lump in the throat in the absence of eating or swallowing difficulties is diagnostic of globus pharyngeus. To determine the underlying cause, a thorough physical examination followed by a fiberoptic laryngeal evaluation are commonly performed. Other tests may include esophageal pH monitoring, proton pump inhibitor therapeutic trial, esophageal manometry, upper endoscopy and psychological evaluation.

### Therapeutic Principles
Gene therapy as well as dietary therapy is not available. Pharmacological therapy depends on the underlying cause. Anti-reflux treatment in the case of GERD, antidepressants in patients with depression or anxiolytics in patients with anxiety. There is anecdotal experience with tricyclics in patients with functional globus pharyngeus. Other treatments available include surgical intervention in some patients with laryngeal anatomical abnormalities. Dilation of the esophagus in those with elevated UES pressure.

## Glomerulonephritis, Crescentic

Hideki Kato, Masaomi Nangaku
Division of Nephrology and Endocrinology, University of Tokyo School of Medicine, Tokyo, Japan

### Synonyms
Necrotizing glomerulonephritis; Rapidly progressive glomerulonephritis; RPGN; (Underlying disorders: Goodpasture's syndrome; IgA nephropathy; Pauci-immune glomerulonephritis)

### Definition and Characteristics
Crescentic glomerulonephritis is a pathological term and signifies a condition that is characterized morphologically by glomerular crescent formation. Kidney biopsy shows this type of histological finding in those patients who present with end-stage renal disease progression to within a period of weeks or months.

Thus, this type is also named rapidly progressive glomerulonephritis (RPGN). However, it should be noted that RPGN is a clinical entity defined by its clinical course.

The term crescentic glomerulonephritis is usually due to one of three disorders, which reflect different mechanisms of glomerular injury. The first is Goodpasture's syndrome (anti-GBM syndrome). This is an autoimmune disease to glomerular basement membrane whereby antibodies are directed against the kidneys and lungs. In addition to kidney failure, approximately 60–70% of the patients have pulmonary hemorrhage. The second is immune complex disorder such as IgA nephropathy, anti-streptococcal glomerulonephritis, lupus nephritis, and mixed cryoglobulinemia. The third is pauci immune glomerulonephritis, which presents necrotizing glomerulonephritis. Pauci immune glomerulonephritis lacks immune deposits in glomeruli, but the majority of patients are positive for MPO-ANCA antibody. This pauci immune glomerulonephritis is considered to be part of the Wegener's granulomatosis/microscopic polyangiitis because the histolopathologic findings in the kidney are indistinguishable from those of Wegener's granulomatosis or microscopic polyangiitis (see Table 1).

## Prevalence

Goodpasture's syndrome is rare, with an estimated incidence in Caucasian populations of between 0.5 and 0.9 cases per million per year. The incidence of pauci-immune glomerulonephritis were four cases per million per year in the United Kingdom. Pauci-immune glomerulonephritis is common in older patients and is the most common disease in this category [1].

## Genes

As is mostly the case in autoimmune diseases, both environmental and genetic factors appear to be important in these diseases; however, definite genes have not been found to be associated with the onset of pauci-immune glomerulonephritis. In Goodpasture's syndrome, genetic factors are reported from the disease occurrence in siblings and twins. Significant associations between Goodpasture's syndrome and HLA class II alleles are reported [2].

## Molecular and Systemic Pathophysiology

Crescent formation appears to represent a nonspecific response to severe injury to the glomerular capillary wall. Rents are induced in the glomerular capillary wall, resulting in the movement of plasma products, including fibrinogen, into Bowman's space with subsequent fibrin formation, the influx of macrophages and T cells, and the release of proinflammatory cytokines, such as interleukin-1 and tumor necrosis factor-alpha.

Goodpasture's syndrome is caused by autoimmunity against a specific component of the GBM that has been identified as the carboxyl terminal, noncollagenous (NC1) domain of type IV collagen chain, alpha3(IV) NC1. Patients of Goodpasture's syndrome have antibodies to alpha3(IV)NC1.

Pauci-immune glomerulonephritis is a necrotizing glomerulonephritis with few or no immune deposits by immunofluorescence or electron microscopy. The majority of patients with renal-limited vasculitis are ANCA-positive, with 75–80% having myeloperoxidase (MPO)-ANCA, and many have the systemic symptoms of a vasculitis. In ANCA-associated vasculitis, priming of neutrophils by cytokines, such as viral infection, causes neutrophil to increase expression of ANCA antigens. Cytokine-primed neutrophils that are exposed to ANCA release toxic oxygen metabolites, and kill endothelial cells. Neutrophils that have been activated by ANCA adhere to endothelial cells and release mediators of inflammation and cell injury, leading to the development of vasculitis [3].

## Diagnostic Principles

An accurate and urgent diagnosis is essential in the patient presenting with clinical findings suggestive of RPGN. Careful physical examination for systemic vasculitis should be done, such as skin, nervous system, musculoskeletal, gastrointestinal, renal, respiratory, and ocular examinations. Patients should undergo renal

**Glomerulonephritis, Crescentic. Table 1** Categories of crescentic glomerulonephritis

| Type | Pathogenesis | Diseases | Immunofluorescence pattern | Strength |
|---|---|---|---|---|
| I | Anti-GBM | Goodpasture's disease<br>Anti-GBM disease | Linear IgG, Weak linear C3 | >2+ |
| II | Immune complex | IgA nephropathy<br>SLE<br>Postinfectious<br>Mixed cryoglobulinemia | Granular Ig and C3 capillary loop/mesangium | >2+ |

biopsy and appropriate serologic assays. These include ANCA, anti-GBM antibodies, antinuclear antibodies, cryoglobulins, and others.

## Therapeutic Principles

Untreated RPGN typically progresses to end-stage renal disease over a period of weeks to a few months. However, patients with fewer crescents may have a more protracted, not so rapidly progressive course. In Goodpasture's syndrome, the treatment of plasmapheresis combined with prednisone and cyclophosphamide is highly recommended. Plasmapheresis removes circulating anti-GBM antibodies and other mediators of inflammation (such as complement), while the immunosuppressive agents minimize new antibody formation. In pauci immune glomerulonephritis, cyclophosphamide combined with corticosteroids is the most commonly used induction therapy. The plasma exchange may be beneficial, especially with severe disease, such as dialysis dependent renal failure or pulmonary hemorrhage. After remission is achieved, which usually occurs within 3–6 months, cyclophosphamide, methotrexate, or azathioprine is usually administered.

# Glomerulonephritis, Focal Proliferative

Hideki Kato, Masaomi Nangaku
Division of Nephrology and Endocrinology,
University of Tokyo School of Medicine,
Tokyo, Japan

## Synonyms

Focal mesangial proliferative glomerulonephritis; (Underlying disease: IgA nephropathy; Lupus nephritis)

## Definition and Characteristics

Focal proliferative glomerulonephritis is one of the pathologic categories and are often observed in IgA nephropathy and lupus nephritis. Focal proliferative glomerulonephritis is classified by renal biopsy specimen as class III IgA nephropathy in Haas classifications (see Table 1) [1]. It is defined as follows: 50% or fewer of the glomeruli are hypercellular. While hypercellularity is segmental, global hypercellularity may be present so long as no more than 50% of glomeruli are hypercellular.

In ISN/RPS WHO classification of lupus nephritis, focal proliferative glomerulonephritis is classified as class III "Focal lupus nephritis" and subclass III(A) "active lesion: focal proliferative lupus nephritis." According to the classification, class III lupus nephritis is defined as active or inactive focal, segmental or global endo- or extracapillary glomerulonephritis involving <50% of all glomeruli (see Table 2) [2].

## Prevalence

Focal proliferative glomerulonephritis is seen in approximately one third of renal biopsy specimen (20–50%) in cases of IgA nephropathy. In lupus nephritis, 20–60% of lupus patients who had renal biopsies show mesangial or focal proliferative lupus nephritis.

## Genes

See also ►IgA Nephropathy and lupus nephritis.

## Molecular and Systemic Pathophysiology

For the pathophysiology of IgA nephropathy, see the chapter of IgA nephropathy.

In lupus nephritis, patients typically have autoantibodies directed against dsDNA, Sm antigen, and C1q. Since infusion of anti-dsDNA antibody eluted from human nephritis kidney is shown to cause proteinuria and renal disease, aggregates of immunoglobulin and complement components are considered to cause kidney injuries at the sites of deposition. Activated glomerular cells, infiltrating macrophages and T cells produce inflammatory cytokines, such as tumor necrosis factor-alpha (TNF-alpha), interleukin-6 (IL-6), transforming growth factor-beta, interferon-gamma, and platelet-derived growth factor. All of these cytokines have the potential to extend renal injury [3].

## Diagnostic Principles

The suspicion of a diagnosis of IgA nephropathy is generally based upon the clinical history and laboratory data. Most patients with IgA nephropathy have a history of gross hematuria, usually following an upper respiratory infection, or microscopic hematuria with or without mild proteinuria incidentally detected on a routine examination. Plasma polymeric IgA1 levels are elevated in 30–50% of cases. The diagnosis and classification can be confirmed only by kidney biopsy with immunofluorescence or immunoperoxidase studies for IgA deposits.

**Glomerulonephritis, Focal Proliferative. Table 1** Histologic classification of IgA nephropathy of Haas [1]

| | |
|---|---|
| **Class I** | **Minimal histologic lesion** |
| | Glomeruli show not more than a minimal increase in mesangial cellularity, without segmental sclerosis, necrosis, or crescents |
| **Class II** | **Focal-segmental glomerulosclerosis-like** |
| | Glomeruli show focal and segmental sclerosis in a pattern resembling primary FSGS, with at most a minimal increase in mesangial cellularity and no crescents or necrosis |
| **Class III** | **Focal proliferative glomerulonephritis** |
| | 50% or fewer of the glomeruli are hypercellular. This hypercellularity may be limited to mesangial areas, or include endocapillary hypercellularity, crescents, or necrosis |
| **Class IV** | **Diffuse proliferative glomerulonephritis** |
| | More than 50% of the glomeruli are hypercellular. This hypercellularity may be limited to mesangial areas, or include endocapillary hypercellularity, crescents, or necrosis |
| **Class V** | **Advanced chronic glomulonephritis** |
| | 40% or more of the glomeruli are globally sclerotic, and/or there is >40% estimated tubular atrophy or loss in the cortex as determined from sections stained with PAS, trichrome, and/or silver stains |

**Glomerulonephritis, Focal Proliferative. Table 2** International Society of Nephrology/Renal Pathology Society (ISN/RPS) 2003 classification of lupus nephritis [2]

| | |
|---|---|
| **Class I** | **Minimal mesangial lupus nephritis** |
| | Normal glomeruli by light microscopy, but mesangial immune deposits by immunofluorescence |
| **Class II** | **Mesangial proliferative lupus nephritis** |
| | Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposits |
| | May be a few isolated subepithelial or subendothelial deposits visible by immunofluorescence or electron microscopy, but not by light microscopy |
| **Class III** | **Focal lupus nephritis** |
| | Active or inactive focal, segmental or global endo- or extracapillary glomerulonephritis involving <50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations |
| Class III (A) | Active lesions: focal proliferative lupus nephritis |
| Class III (A/C) | Active and chronic lesions: focal proliferative and sclerosing lupus nephritis |
| Class III (C) | Chronic inactive lesions with glomerular scars: focal sclerosing lupus nephritis |
| **Class IV** | **Diffuse lupus nephritis** |
| | Active or inactive diffuse, segmental or global endo- or extracapillary glomerulonephritis involving more than 50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is divided into diffuse segmental (IV-S) lupus nephritis when more than 50% of the involved glomeruli have segmental lesions, and diffuse global (IV-G) lupus nephritis when more than 50% of the involved glomeruli have global lesions. Segmental is defined as a glomerular lesion that involves less than half of the glomerular tuft. This class includes cases with diffuse wire loop deposits but with little or no glomerular proliferation |
| Class IV-S (A) | Active lesions: diffuse segmental proliferative lupus nephritis |
| Class IV-G (A) | Active lesions: diffuse global proliferative lupus nephritis |
| Class IV-S (A/C) | Active and chronic lesions: diffuse segmental proliferative and sclerosing lupus nephritis |
| | Active and chronic lesions: diffuse global proliferative and sclerosing lupus nephritis |
| Class IV-S (C) | Chronic inactive lesions with scars: diffuse segmental sclerosing lupus nephritis |
| Class IV-G (C) | Chronic inactive lesions with scars: diffuse global sclerosing lupus nephritis |
| **Class V** | **Membranous lupus nephritis** |
| | Global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations |
| | Class V lupus nephritis may occur in combination with class III or IV in which case both will be diagnosed |
| | Class V lupus nephritis show advanced sclerosis |
| **Class VI** | **Advanced sclerosis lupus nephritis** |
| | More than 90% of glomeruli globally sclerosed without residual activity |

Diagnostic criteria for lupus are usually based on the criteria of the American Rheumatism Association (the American College of Rheumatology or ACR), and if lupus is suspected, further examination must be done, such as more careful systemic physical examination, clinical manifestation, laboratory testing (complete blood count and differential, serum creatinine, serum albumin, erythrocyte sedimentation rate, C reactive protein, urinalysis, creatinine clearance, and proteinuria), antibody testing (antinuclear antibodies, antiphospholipid antibodies, ds-DNA antibodies, anti-Sm antibodies), imaging, and skin or renal biopsies.

## Therapeutic Principles

For the therapy of IgA nephropathy, see the chapter of IgA nephropathy or mesangial proliferative glomerulonephritis.

Therapy of lupus nephritis varies with the type and the severity of disease and an optimal therapy of focal proliferative lupus nephritis is still controversial. If affected glomeruli are few and have no active forms, no immunotherapy or corticosteroids are recommended. If severe focal nephritis up to 50% of glomeruli exists, renal deaths at 5 years are 15–25% [4]. These patients should be treated with immunosuppressive agents, such as cyclophosphamide, mycophenolate, corticosteroids.

# Glomerulonephritis, Membranoproliferative

Anthony Chang, Pradeep V. Kadambi, Jessy J. Alexander
Section of Nephrology, University of Chicago, Chicago, IL, USA

## Synonyms

Mesangiocapillary glomerulonephritis; Lobular glomerulonephritis; MPGN

## Definition and Characteristics

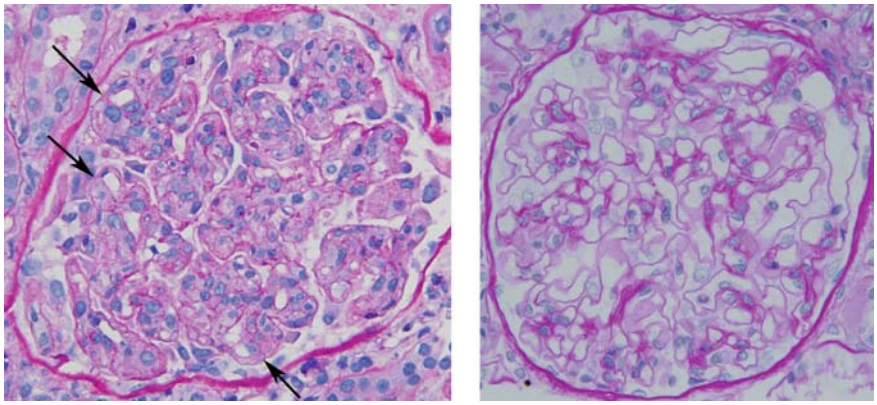
Membranoproliferative glomerulonephritis (MPGN) is a glomerular injury pattern, characterized by accentuation of the lobular architecture with endocapillary proliferation, duplication of the glomerular basement membranes, and immune complex deposition (Fig. 1). MPGN is attributed to primary (idiopathic) and secondary causes. Primary MPGN is divided into types I, II, and III, which can be distinguished on the basis of light, immunofluorescence, and electron microscopy. Type I is characterized by mesangial and subendothelial deposits. Type II (dense deposit disease) is characterized by the presence of serum C3 nephritic factor and prominent elongated intramembranous electron dense deposits that are observed within glomerular or tubular basement membranes or the basal lamina of Bowman's capsules [1]. MPGN type III is similar to type I with the addition of subepithelial or transmembranous deposits. Secondary MPGN is associated with numerous diseases, including hepatitis B and C infection, Sjögren syndrome, cryoglobulinemia, and chronic infection [2].

## Prevalence

The prevalence of MPGN varies with geographical location and is an uncommon cause of chronic glomerulonephritis in the developed world. It remains much more common in regions such as Africa, the Caribbean, India, Pakistan, Malaysia, Papua New Guinea, and South America. Glomerulonephritis represents 10–15% of glomerular diseases in the USA. MPGN affects both sexes equally. MPGN primarily affects young adults under the age of 30.

## Molecular and Systemic Pathophysiology

The pathogenesis of MPGN is not well understood and the antigen has not been identified in primary MPGN. MPGN lacks any unique serological markers and has no pathognomonic clinical features. MPGN remains a histologically defined entity, characterized by mesangial cell proliferation and migration into the glomerular capillary walls, producing an apparent split or double-contoured appearance. The glomerular lesions of MPGN are the result of glomerular deposition and/or *in situ* formation of immune complexes. On gross appearance, the kidneys may be enlarged up to 50%. Histopathologic changes include increased lobulation of the glomerular tufts and infiltration with neutrophils. Immunofluorescence microscopy reveals deposition of immunoglobulin G and complement C3 along the capillary walls and mesangial regions. Hypocomplementemia is a characteristic finding with all types of MPGN with decreased levels of C3 [3]. In patients, mutations in short consensus repeats 9, 16 or 2 of the complement inhibitor factor H have been found to cause MPGN II by preventing the release of factor H from the endoplasmic reticulum. After renal



**Glomerulonephritis, Membranoproliferative. Figure 1** The glomerulus (left) with MPGN demonstrates accentuation of the lobular architecture with marked hypercellularity and duplication of the glomerular basement membranes (arrows) compared with a normal glomerulus (right) (Periodic Acid-Schiff, 400X).

transplantation, type 1 MPGN recurs in about 20–30% of allografts, type II in 50–100%, and little is known about type III [1].

## Diagnostic Principles

The signs and symptoms vary depending on the severity of the underlying condition. Most commonly, patients present with a combination of edema, hypertension, decreased urine output, renal failure, proteinuria, and red cell casts in the urinalysis. Other blood tests to be obtained are serum complement levels, cryoglobulins, and C3 nephritic factor. However, renal biopsy clinches the diagnosis.

## Therapeutic Principles

The treatment of MPGN largely depends on the underlying cause. The most common type is Type I, and Hepatitis C infection is the most common cause of Type I MPGN. Idiopathic Type I MPGN is currently a rare disorder, and should be a diagnosis of exclusion. Most studies evaluating treatment have been performed in patients with Type 1 MPGN. Bad prognostic signs at presentation include nephrotic syndrome, renal failure, hypertension, and the degree of tubulointerstitial fibrosis on renal biopsy.

Nonspecific management: Aggressive control of blood pressure and proteinuria with medications such as angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers, use of diuretics in edematous patients, salt and moderate protein restriction, and use of lipid lowering agents in patients with hyperlipidemia.

Specific measures include the use of corticosteroids that are usually helpful in children, and do not appear to benefit adults, and anti-platelet agents such as aspirin and dipyridamole. The rationale is that platelet consumption is increased in MPGN and may play a role in glomerular injury. Cyclophosphamide has been used with varying degrees of success. More recently, mycophenolate mofetil has been used and found to be superior to corticosteroids alone [4].

# Glomerulonephritis, Membranous

Pierre Ronco[1,2,3], Hanna Debiec[1,2]
[1]INSERM, UMR, Paris, France
[2] University Pierre et Marie Curie, Paris, France
[3]APHP, Hôpital Tenon, Paris, France

## Synonyms

Membranous nephropathy; MGN

## Definition and Characteristics

Membranous glomerulonephritis (MGN) is the most common cause of idiopathic nephrotic syndrome

(leakage of albumin in the urine, resulting in hypoalbuminemia and edema) in white adults, accounting for about 20% of cases. Although spontaneous remission of nephrotic syndrome occurs in about a third of patients, MGN ends for about 30–40% of patients in end-stage renal failure after 10 years [1].

## Prevalence

The prevalence of MGN has not been carefully estimated. Its annual incidence is 30–40 cases per million [2]. Eighty percent of cases are classified as idiopathic, to conceal our ignorance about causes, whereas about 20% present with associated clinical conditions, including infections, autoimmune diseases, and cancers, and these patients are thus classified as having secondary diseases.

## Genes

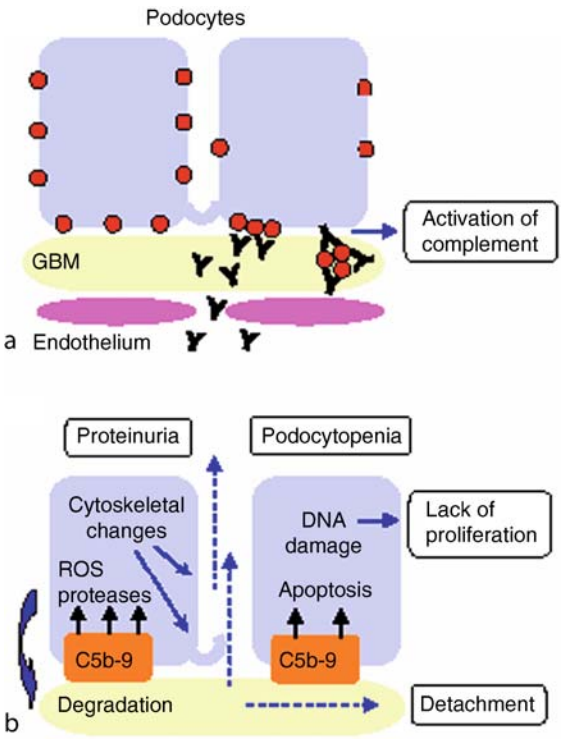
MME, the gene encoding for neutral endopeptidase (NEP), is mutated in the mothers from a subpopulation of patients with antenatal MGN [3]. Two truncating mutations, located in exon 7 and exon 15, respectively, have been reported [3], leading to a functional knockout of the MME gene in the mothers. NEP-deficient individuals reported so far are healthy, and the prevalence of the MME mutations in the general population is not known.

## Molecular and Systemic Pathophysiology

MGN is an antibody-mediated disease, characterized by an accumulation of immune deposits on the outer aspect of the glomerular basement membrane that cause a membrane-like thickening. The immune deposits consist of IgG, often IgG4, thus far unidentified antigens, and the membrane attack complex of complement C5b-9. Functional impairment of the glomerulus causing proteinuria results from the formation of subepithelial immune deposits and complement activation.

NEP, the first antigen involved in human MGN, was identified in neonates born with MGN [4]. This membrane-bound enzyme that can digest biologically active peptides is expressed on the surface of human podocytes and placental cells, as well as on polymorphonuclear leukocytes, lymphoid progenitor cells, and epithelial cells. The infant's mother became immunized during pregnancy against placental cells because she was NEP-deficient. Allo-immune anti-NEP antibodies were transplacentally transferred from the mother to her child, and then reached their target on the podocyte surface where they induced the formation of epimembranous (subepithelial) immune deposits (Fig. 1).

NEP does not seem to be involved in common forms of adult MGN. However, both the antenatal cases of MGN and the experimental model of MGN – Heymann nephritis – [5] give strong evidence that podocytes and their membrane-associated proteins have a pivotal role in MGN by providing antigenic targets for circulating antibodies for in-situ formation of glomerular deposits.



**Glomerulonephritis, Membranous. Figure 1** (a) In-situ formation of immune deposits in neonatal MGN. NEP (*red dots*) serves as pathogenic antigen in the podocyte's cell membrane. It is likely that as for megalin (the antigen of Heymann nephritis), NEP – anti-NEP immune complexes formed on the podocyte membrane are then shed and rapidly immobilized in the glomerular basement membrane. (b) Cellular mechanisms that lead to proteinuria in MGN. C5b-9 formation on the membrane of podocytes leads to various intracellular events, including production of reactive oxygen species and proteases, and cytoskeletal changes. These result in degradation of glomerular basement membrane and redistribution of proteins that compose the slit diaphragm, eventually leading to the development of protein leakage into the Bowman's space (*left*). In addition, C5b-9 attack leads to podocytopenia through apoptosis, lack of proliferation resulting from complement induced DNA damage, and podocyte detachment (*right*). (From Ronco P., Debiec H (2006) Curr Opin Nephrol Hypreteus 15: 258–263).

## Diagnostic Principles

The diagnosis of MGN is based on renal biopsy that shows subepithelial (epimembranous) deposits of IgG (mainly IgG4, and to a lesser extent IgG1) by direct immunofluorescence. Antenatal diagnosis must

be suspected on oligohydramnios and kidney cortex hyperechogenicity.

## Therapeutic Principles

There is no specific treatment available for MGN as yet. Corticosteroids and immunosuppressive drugs are used to decrease non-specifically the production of nephritogenic antibodies, but their efficacy is debated. Renoprotective agents including angiotensin converting enzyme inhibitors and angiotensin receptor antagonists are aimed at reducing urinary protein excretion. Identification of additional podocyte antigens should lead to assays for circulating pathogenic antibodies, which are mandatory for appropriate treatment monitoring, and to targeted therapies aimed specifically at decreasing the production of the pathogenic antibodies.

# Glomerulonephritis, Mesangial Proliferative

Christian Hugo
Department of Nephrology and Hypertension, University of Erlangen-Nuremberg, Erlangen, Germany

## Synonyms

IgA nephropathy; Berger's disease

## Definition and Characteristics

Inflammatory renal disease with an excess of proliferating mesangial cells and matrix expansion due to the deposition of IgA within the mesangium. The disease is characterized by glomerular hematuria, proteinuria and frequently progressive renal insufficiency.

## Prevalence

Glomerulonephritis is most prevalent (up to 1.3% of population) in countries where renal biopsy is widely used (Japan, Europe, North America), but appears to be rare in South America and Africa.

## Genes

Most cases do not appear to be genetic. However, rare families with IgA nephropathy have been identified in which linkage to chromosome 6q22–23 has been shown [1]. Interestingly the ddY mouse model of IgA nephropathy has a susceptibility locus on murine chromosome 10, a region syntenic to human 6q22–23 [2]. Some association of IgA nephropathy has also been shown with various marker genes, including immunoglobulin μ-binding protein 2 [3], Megsin [4], or genes modulating the renin-angiotensin-system [5] in population studies.

## Molecular and Systemic Pathophysiology

To date it is unclear whether IgA nephropathy is one entity with a single pathomechanism or a pathogenic phenotype being caused by several different and/or combined mechanisms [6]. There is some evidence that IgA nephropathy has its roots in an impaired mucosal response to viral or other antigens, leading to access of antigen to the circulation and an enhanced IgA immune response from the bone marrow (and tonsil). Circulating IgA is often elevated, and an increased fraction of polymeric IgA1 is common. Recent studies suggest that the IgA is also abnormal, with a lack of galactose residues in the hinge region resulting in altered O-glycosylation. This alteration in glycosylation may result in impaired clearance via the hepatic asialoglycoprotein receptors with preferential localization to the mesangium (where mesangial cells express Fc receptors for IgA). Binding of immune complexes to the mesangium results in complement activation (alternative pathway) and activation of the mesangial cell with release of inflammatory and vasoactive mediators. This leads to local proliferation and matrix expansion that are driven primarily by the growth factors PDGF and TGF-beta, respectively. The overall outcome results from the consequence of the processes driving the mesangial IgA deposition, the proliferative and inflammatory response, and the normal repair mechanisms.

The underlying mechanism responsible for initiating this process is unknown. A search for viral or other causes has generally been negative. There is some evidence that it may relate to immune deviation of the T cell response, with a preferential Th2 phenotype. Further studies are necessary before any firm conclusions can be made.

## Diagnostic Principles

The clinical manifestation of IgA nephropathy varies substantially. Urine analysis is important, since hallmarks

of this disease are microscopic glomerular hematuria, episodic macroscopic hematuria (frequently infection triggered), proteinuria not in the nephrotic range, and progressive chronic renal failure. The final diagnosis needs to be made via a renal biopsy showing diffuse mesangial deposition of IgA and complement C3 as well as variable IgG (40%) and/or IgM (40%). By light microscopy, glomeruli typically show mesangial hypercellularity as well as mesangial matrix accumulation, with varying degrees of glomerulosclerosis and tubulointerstitial fibrosis, dependent on the disease stage.

### Therapeutic Principles

Therapeutic strategies depend on the extent of renal impairment, proteinuria, and the renal biopsy. The first goal is to lower blood pressure toward the normal range (120/80 mmHg) and to reduce proteinuria below 1 g/24 h, preferably by using ACE-inhibitors or both ACE-inhibitors and angiotensin II receptor blockers. In addition, corticosteroid or fish oil therapy should be considered, if proteinuria is still >1 g/24 h and serum creatinine is either <1.5 mg/dl (steroids) or >1.5 mg/dl (fish oil). Crescentic IgA nephropathy should be treated using intensive immunosuppressive regimens such as cyclophosphamide and corticosteroids with or without plasmapheresis.

## Glomus Tumors

►Paraganglioma

## Glucagon Deficiency Syndromes

Brigitte M. Lobnig
Department of Endocrinology, Diabetology and Rhematology, Duesseldorf University, Duesseldorf, Germany

### Synonyms

Pancreatogenic diabetes mellitus; Glucagon; GCG (for acquired form); none (for hypothesised inherited form)

### Definition and Characteristics

Rare cause of neonatal hypoglycemic states, when other causes of hypoglycemia can be ruled out. Putative recessive inherited disorder. Occurs regularly after pancreatectomy and after pancreatitis.

### Prevalence

A case report published in 1977 hints at a case of inherited glucagon deficiency with normal insulin secretion in a Pakistani consanguineous family. The condition must have an extremely low prevalence, but was questioned in 2002 when a daughter of the same family presented with neonatal hypoglycemia due to hyperinsulinism. Nevertheless, some cases may have escaped detection due to perinatal mortality.

The incidence of symptomatic hypoglycemia in newborns varies from 1.3 to 3 per 1,000 births. Conditions associated with hypoglycemia are prematurity, hypothermia, hypoxia, maternal gestational diabetes and maternal glucose infusion during labor, and some rare states with hyperinsulinism of unknown origin (e.g., hyperplasia of the pancreatic B-cells).

After pancreatitis or surgical pancreas resection, glucagon deficiency of varying degrees is an inevitable condition.

### Genes

The genetic defect has not been characterized in the hypothesized inherited glucagon deficiency. The glucagon gene is characterized as being approximately 9.4 kb, comprising six exons and five introns. Cytogenic map location is chromosome 2: 2q36–q37.

The putative preproglucagon encoded by this gene, 180 amino acids in length and containing glucagon and two glucagon-like peptides, GLP-1 and GLP-2, is very similar to that of other mammalian species (greater than 90% amino acid sequence homology). There is 88% nucleotide sequence homology between the proximal 130 base pairs of the 5 flanking regions of the human and rat glucagon genes. These sequences, highly conserved throughout evolution, are likely involved in the regulation of glucagon gene transcription. Exon 3 is coding for glucagon.

*Glugagon gene structure*: -CAT-TCA-CAG-GGC-ACA-TTC-ACC-AGT-GAC-TAC-AGC-AAG-TAT-CTG-GAC-TOC-AGG-CGT-GCC-CAA-GAT-TTT-GTG-CAG-TGG-TTG-ATG-AAT-ACC-

*Amino acid sequence*: $NH_2$-His-Ser-Gln-Gly-Thr-Phe-Thr-Ser-Asp-Tyr-Ser-Lys-Tyr-Leu-Asp-Ser-Arg-Arg-Ala-Gln-Asp-Phe-Val-Gln-Trp-Leu-Met-Asn-Thr-COOH.

## Molecular and Systemic Pathophysiology

The primary gene product is preproglucagon. Glucagon is synthesized by post-translational processing of a single polypeptide precursor, proglugagon, together with glucagon-like peptide 1 (GLP-1) and 2 (GLP-2) and glicentin (an active enteroglucagon, 69 amino acids, consisting of glugagon with an extension of 32 at the N-terminal and eight amino acids at the carboxy-terminal). Glucagon is a polypeptide hormone of 29 amino acids. The molecular weight is 3,485 Da.

Origin: The hormone is synthesized in A cells or alpha2-cells of the mature pancreas; tissue expression occurs in fetal pancreas at 18–20 weeks of gestation.

The receptor belongs to the G-protein-coupled receptor family B, subfamily B1. Glucagon is also required for early insulin-positive differentiation in developing mouse pancreas. It acts via extracellular receptors. The receptor interacts with stimulatory G proteins ($G_s$). $G_s$ stimulates adenylate cyclase and increases the second messenger cyclic AMP and intracellular calcium levels.

Glucagon stimulates glycogenolysis (liver), gluconeogenesis (liver), and ketogenesis (liver), promotes hydrolysis of lipids (in adipocytes), and controls cell proliferation pathways (intestinal mucosa).

Glucagon counteracts the glucose-lowering effects of insulin, regulates feeding behaviors, and is the most powerful stimulant of hepatic glucose production.

It is elevated during the postprandial absorptive state, during hyperglycemia, exercise, trauma, infection and other stress. In the normal state, glucagon helps to regulate the fuel homeostasis in states of increased demand for fuel. In insulin deficiency states like diabetes mellitus, it accentuates hyperglycemia.

Secretion of glucagon is stimulated by alanine; secretion is inhibited by somatostatin.

In healthy subjects, glucagon seems to be the major counter-regulatory hormone in hypoglycemic or hyperinsulinemic states, and also in the post-prandial state. Along with catecholamines, growth hormone and cortisol, its release is stimulated by hypoglycemia below 3.8 mM (68 mg/dl). Of these hormones, only catecholamines and glucagon are capable of immediate counter-regulation of decreasing glucose levels. Under experimental conditions, isolated glucagon deficiency results in hypoglycemia and reduced glucose utilization in human volunteers.

In pancreatectomy, glucagon deficiency results in hepatic insulin resistance with deregulated persistent endogenous glucose production, with concomitant enhanced peripheral insulin sensitivity. This impedes the management of diabetes mellitus and leads to recurrent hypoglycemia's.

## Diagnostic Principles

The diagnosis is made by exclusion of other causes of hypoglycemia in neonates. Measurement of glucagon levels is made in plasma obtained from heparinized venous blood, put immediately on ice, and centrifuged at 4°C. The protease inhibitor trasylol should be added at 500 IE/ml. The assay used is pancreas glucagon specific antiserum K 964 by Novo Research Institute. The method is described by Heding.

## Therapeutic Principles

Glucagon replacement therapy was effective in some cases of presumed glucagon deficiency. However, the neonatal hypoglycemia due to inherited glucagon deficiency remains questionable. Acquired glucagon deficiency may also be a conditioned in polyglandular failure.

# Glucagon Excess Syndromes

Brigitte M. Lobnig
Department of Endocrinology, Diabetology and Rheumatology, Duesseldorf University, Duesseldorf, Germany

## Synonyms

Glucagon secreting tumor; Glucagonom; (may be associated with multiple endocrine neoplasia (MEN) type-1); Wermer-Syndrome

## Definition and Characteristics

Physiologic glucagon excess occurs in fuel deficient states. Disinhibition of glucagon secretion occurs in insulin-deficient states like type-1 and type-2 diabetes as well as pancreatogenic diabetes mellitus. Secretion by glucagon-secreting malignant tumor of the pancreatic A cells is noticed. Glucagon secretion is seen as a paraneoplastic phenomenon in malignancies. The clinical presentation of glucagons-secreting malignant tumors may be is migrating necrolytic erythema, mild diabetes and stomatitis.

## Prevalence

In healthy subjects, carbohydrate ingestion suppresses glucagon secretion and decreases glucagon levels. In type-2 diabetes mellitus, plasma glucagon levels are increased. Either absolute levels are increased, or levels are inappropriately high. Extremely high levels are found in states of malignancies. The prevalence of MEN1 syndrome is 1 in 100,000, but a number of cases may have escaped detection.

## Genes

MEN-1, the menin gene, coded on chromosome 11q13, comprises ten exons and codes for a 610 amino acid protein. Deletion, nonsense and missense mutations have been identified, most of them in exon 2. Inheritance is autosomal dominant.

## Molecular and Systemic Pathophysiology

Glucagon is synthesized by post-translational processing of a single polypeptide precursor, pre-pro-glucagon, split into glicentin (an active enteroglucagon, 69 amino acids) and pro-glucagon-fragment. Glicentin is reduced to Glucagon, a polypeptide hormone of 29 amino acids. The MEN1 gene encodes for the 610-amino acid protein called menin, which is a nuclear protein of unknown function.

The hormone glucagon is synthesized in alpha2-cells (A-cells) of the mature pancreas. Secretion of glucagon is inhibited by insulin. The peptide precursor pre-pro-glucagon is synthesized in pancreatic A-cells and in intestinal mucosa. In contrast to mucosa cells where the pro-glucagon fragment is split into glucagons-like peptide (GLP1 and GLP2), glicentin is transformed into glucagon in pancreatic A-cells. The glucagon receptor belongs to the G-protein-coupled receptor family B, subfamily B1. Glucagon is also required for early insulin-positive differentiation in the developing mouse pancreas. It acts via extracellular G-protein coupled receptors. The receptor interacts with stimulatory G proteins ($G_s$). $G_s$ stimulates adenylate cyclase and increases the second messenger cyclic AMP and intracellular calcium level. Proteinkinase C is activated. Glycogensynthase is inactivated by glucagon-induced phosphorylation.

Elevated glucagon levels result in enhanced hepatic glucose liberation of glucose, ketones and free fatty acids into the blood.

The cellular basis of systemic effects of elevated glucagon levels in the absence of insulin are: ketogenesis in the liver, ketone body utilization in brains and peripheral tissues, secretion of amino acids from muscle cells and of free fatty acids from adipocytes, blocking of glycolysis in the liver on the level of phosho-fructo-kinase with reduced output of pyruvate and malonyl-CoA, and indirect dis-inhibition of carnitine-palmitoyl-transferase-2 in mitochondrial membranes.

Glucagon is secreted into the microcirculation of the Langerhans islets, and thus gated into the portal system directed to the liver. Thus, a feed-back inhibition of glucagon and the direct stimulation of insulin and somatostatin secretion from the islets are prohibited. Pancreatic glucagon secretion is inhibited by insulin. In an insulin deficient state, like diabetes mellitus, glucagon secretion is deregulated. In a fuel deficient state, systemic insulin levels are down-regulated and glucagon levels are up-regulated. The systemic net effect of glucagon is reduced glucose utilization, blood sugar elevating effect, insulin resistance, enhanced ketone production and utilization.

Glucagon is involved in ketogenesis in type-1 diabetes and insulin resistance in type-2 diabetes.

Gastrointestinal tumors with glucagon secretory activity are derived from the diffuse neuro-endocrine system that occurs in the gastrointestinal tract and in the pancreas (most often corpus and cauda). Glucagonoms are located in the pancreas and only rarely in the duodenum or kidney. Glucagon levels reach 5,000 pg/ml. The hyperglucagonemia is associated with hyperinsulinism and results in a mild diabetic and catabolic state. 80% of glucagonoms are malignant and tend to generate metastases in the liver.

Glucagonoms may be associated with Multiple Endocrine Neoplasia (MEN) type-1.

Glucagon secretion is stimulated by alanine and inhibited by somatostatin, which inhibits exocrine and

endocrine functions of the pancreas islets, including glucagon secretion.

Glucagon excess may occur as a paraneoplastic syndrome associated with several malignancies, for instance lung cancer.

### Diagnostic Principles

It is diagnosed by the exclusion of other causes in diabetes mellitus, measurement of plasma glucagon levels. Diagnostic tools for of Multiple Endocrine Neoplasia (MEN) type-1 if suspected. Increased levels of chromogranine A and neuroenolase may be related to tumor mass. Chemotherapy is based on streptozocin and 5-fluoro-uracil.

### Therapeutic Principles

Surgical removal of glucagon producing tumors is the mainstay of therapy if technically feasible. Glucagon secretion is inhibited by streptozocin, dicarbacine and somatostatin analogs.

### Synonyms

Favism

### Definition and Characteristics

Deficiency of glucose-6-phosphate dehydrogenase (G6PD) is the most common enzymatic disorder of red blood cells resulting in hemolysis, mostly after exposure to drugs with high redox potential, infection or metabolic disturbances [1].

### Prevalence

Worldwide prevalence of 200–400 million people, with highest frequencies in tropical and subtropical zones of the eastern hemisphere, and due to relatively higher incidence in areas where malaria was

endemic, it is believed to offer a survival advantage in these areas [1–2].

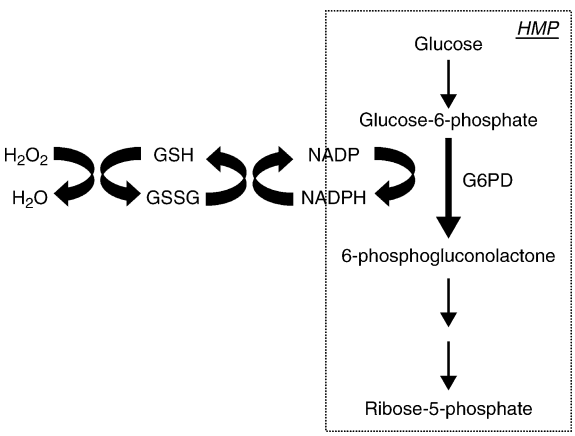
## Genes

G6PD is encoded on the X chromosome (Xq28). G6PD variants are numerous, and variants that result in G6PD deficiency are mostly due to missense point mutations, but deletions have also been described [1–3].

## Molecular and Systemic Pathophysiology

G6PD catalyses the first reaction in the hexose monophosphate shunt which, in tight conjunction with gluthation metabolism, protects intracellular proteins from oxidant injury (see Fig. 1).

As red cells lack mitochondria, their only source of NADPH is the hexose monophosphate shunt. G6PD deficiency was discovered due to the observation of hemolysis in some African-American soldiers on the antimalarial drug primaquine. Normally, G6PD activity falls with increasing red cell age, but even old cells retain enough activity for protection against oxidative stress. Depletion of reduced gluthatione in subjects with G6PD deficiency occurs mainly after exposure to drugs with high redox potential (such as sulfa drugs), infections, metabolic acidosis and in some subjects after consumptions of fava beans ("favism"). This leads to hemoglobin denaturation and distortion of the red cell membrane, leading to both extravascular and intravascular hemolysis with anemia (pallor), increased indirect bilirubin serum levels (jaundice), decreased haptoglobin levels and hemoglobinuria (passage of dark urine). Acute hemolysis may be accompanied by abdominal and back pain. G6PD deficiency is expressed in males carrying a mutant gene, whereas the degree of enzyme deficiency in heterozygous females depends on the degree of expression of the abnormal variant, as well as the degree of inactivation of the normal X gene (Lyon hypothesis; in the female embryo there is random X-chromosome inactivation which remains so throughout subsequent cell divisions). G6PD variants have been classified according to the magnitude of enzyme deficiency and hemolysis [1–3]. Rare related enzymatic disorders of the hexose monophosphate shunt have been described and are reviewed in ref. [1].



**Glucose-6-Phosphate Dehydrogenase Deficiency. Figure 1** G6PD catalyses the first reaction in which nicotinamide adenine dinucleotide phosphate (NADP) is reduced to NADPH. This step is the initiating step of the hexose monophosphate shunt (HMP). Reduced gluthatione (GSH) is an intracellular reducing agent that protects cells against oxidant injury by rapid inactivation of oxidants, and is formed from oxidized gluthation (GSSG) via reduction with NADPH as $H^+$ donor. Intracellular oxidants generate hydrogen peroxide ($H_2O_2$), which is converted to water in association with the formation of GSSG from GSH [1–3].

## Diagnostic Principles

Suspect in any non-immune hemolytic anemia. Spectrophotometric measurement of NADPH generation in hemolysate to which glucose-6-phosphate and NADP is added. Several screening tests are available [1–3].

## Therapeutic Principles

In essence avoidance of exposure to drugs and other offending agents known to precipitate hemolysis.

# Glucosuria, Primary Renal

Jean Francis[1], David S. Geller[2]
[1]Department of Internal Medicine, Hospital of St. Raphael, New Haven, CT, USA
[2]Section of Nephrology, Yale University School of Medicine, New Haven, CT, USA

## Synonyms

Benign renal glucosuria; Familial renal glucosuria; Nondiabetic renal glucosuria

## Definition and Characteristics

Autosomal recessive (severe form) or autosomal dominant (mild form) renal glucose wasting, in the presence of a normal blood glucose concentration and the absence of any signs of general renal tubular dysfunction [1,2].

## Prevalence

Using strict definitions, it is estimated that the incidence of primary renal glucosuria in United States is 1/20,000.

## Genes

Sodium-glucose co-transporter type 2 (SGLT2) localized on chromosome 16p11.2 [1,2].

## Molecular and Systemic Pathophysiology

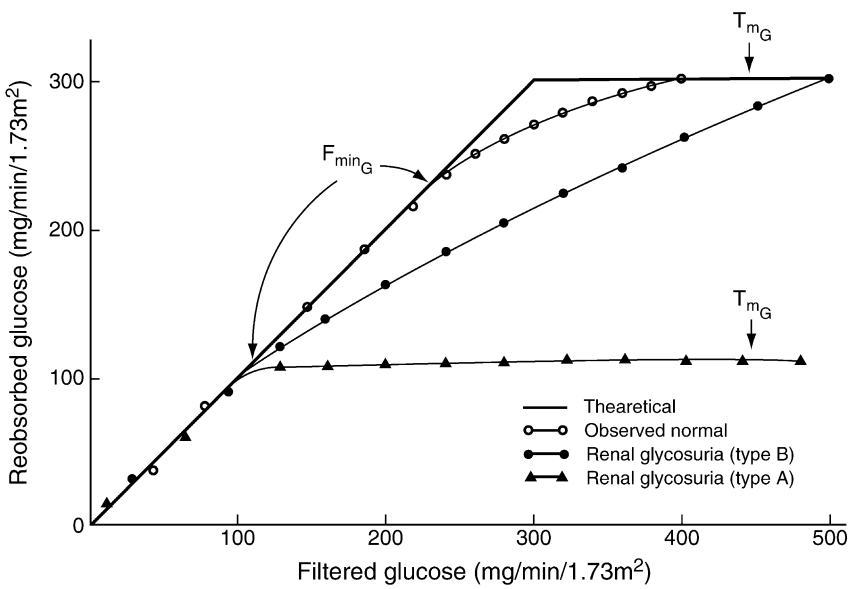
SGLT2 is a sodium-glucose co-transporter with 13 transmembrane spanning domains [1,2]. The kidneys filter approximately 180 g of glucose per day, all of which is normally reabsorbed in the proximal tubule. SGLT2, a 672 amino acid low affinity, high-capacity glucose transporter with 13 transmembrane domains, is the primary vehicle for glucose reabsorption. SGLT2 function is dependent on the sodium electrochemical gradient, favoring filtered glucose reabsorption from the lumen of the proximal tubule [1–3].

Patients genetically deficient for SGLT2 lose much of the filtered glucose in their urine. However, fractional excretion of glucose stays well below 100% in most patients, suggesting the contribution of other glucose reabsorptive pathways [3]. The identity of these other pathways is not known with certainty, but it is suspected that SGLT1, a glucose-galactose transporter primarily expressed in the S3 segment of the proximal tubule and in the small intestine, plays a role [1,3]. The predominant phenotype in patients lacking SGLT1, however, is glucose-galactose malabsorption, with only a mild component of glucosuria [1,3,4].

Primary renal glucosuria is in general asymptomatic. It is usually discovered incidentally on urinanalysis done for other reasons. Severe forms of type O glucosuria (see below) can occasionally cause fasting ketoacidosis and hypoglycemia [5] (Fig. 1).

Three distinct subtypes of primary glucosuria have been described, type A, type B, and type O [5]. Type A glucosuria is characterized by a reduction in both glucose threshold and the maximal glucose reabsorption rate [5]. Type O glucosuria is defined by the complete absence of glucose reabsorption, and thus represents a more severe form of Type A glucosuria [5]. These forms of glucosuria are likely due to mutations that cause a decreased capacity of SGLT2 in all nephrons and thus will lead to a decrease in the maximal transport of glucose (TmG) across the apical membrane of the proximal tubule [5].

Type B glucosuria is characterized by a reduction in the glucose threshold, a normal reabsorptive rate, and increased splay in the glucose reabsorption rate [5]. Type B glucosuria may be due to mutations that decrease



**Glucosuria, Primary Renal. Figure 1** Idealized renal glucose titration curves. $T_{mG}$: Tubular maximum for glucose reabsorption; $F_{minG}$: Minimal threshold for filtered glucose (Reprinted from [5] with permission from the Journal of Clinical Investigation.).

the affinity of glucose transporters in the proximal tubule (e.g. SGLT1). TmG is normal but the splay of the curve is increased [5].

### Diagnostic Principles

Primary renal glucosuria is identified by the presence of renal glucose wasting in the absence of hyperglycemia or other signs of proximal tubular dysfunction, such as aminoaciduria, phosphaturia, organic aciduria, low molecular weight proteinuria or metabolic acidosis [1]. A family history may reveal a genetic origin. Detection of mutations in the SGLT2 gene confirms the diagnosis of this rare disorder [1]. Patients homozygous (or compound heterozygous) for mutations in this gene may have profound glucosuria, losing 160 g/1.73 $m^2$ of glucose in the urine each day, although patients with less severe glucose wasting have been described [1]. Patients heterozygous for such mutations may have mild glucosuria, losing 1–2 g/1.73 $m^2$/day [1].

### Therapeutic Principles

In general, primary renal glucosuria requires no therapy, and in fact, the loss of 50–60 g glucose/day in the urine (or 200–240 calories/day) may be beneficial in overweight patients [1]. Such caloric losses may be poorly tolerated in malnourished populations. While patients with persistent glucosuria might be considered to be at increased risk of urinary tract infections and pyelonephritis, no such association has been described [1].

## Glucosylceramidase Activator Deficiency

►SAP-C Deficiency

## Glut-1 Deficiency Syndrome

Knut Brockmann[1], Dong Wang[2], Darryl C. De Vivo[2]

[1]Department of Pediatrics and Pediatric Neurology, University of Goettingen, Goettingen, Germany

[2]Colleen Giblin Laboratories for Pediatric Neurology Research, Department of Neurology, Columbia University, New York, NY, USA

### Definition and Characteristics

Diffusion of glucose, the principal fuel source for the brain, across the blood-brain barrier is facilitated by glucose transporter protein type 1 (Glut-1). Heterozygous mutations in the SLC2A1 (GLUT1) gene impair glucose transport into the brain [1]. The classic phenotype of this autosomal-dominant condition, designated Glut-1 deficiency syndrome (Glut-1 DS, MIM #606777), is characterized by epilepsy with infant-onset seizures, deceleration of head growth, severe motor and mental developmental delay, and a complex movement disorder with spasticity, dystonia, and ataxia. Since the first description of Glut-1 DS in 1991 [2], a carbohydrate-responsive familial phenotype with clinical features aggravated by fasting and mitigated by carbohydrate intake [3] and single case reports of patients with mild mental retardation and intermittent ataxia or predominant dystonia, but without epilepsy, have been reported.

### Prevalence

The prevalence of Glut1-DS has been estimated to be 1:90,000 in Queensland, Australia. Approximately 200 cases have been diagnosed world-wide.

### Genes

The gene SLC2A1 (GLUT1) is located on chromosome 1 (1p34.2) and consists of ten exons and nine introns. Hemizygosity, heterozygous mutations including missense, nonsense, insertion, deletion, duplication and splice site mutations have been identified [1,4]. Four mutation hotspots (N34, R126, R169, R333) have emerged so far. Most patients carry de novo mutations, but autosomal dominant transmission has been reported in a few families with relatively mild clinical features [3].

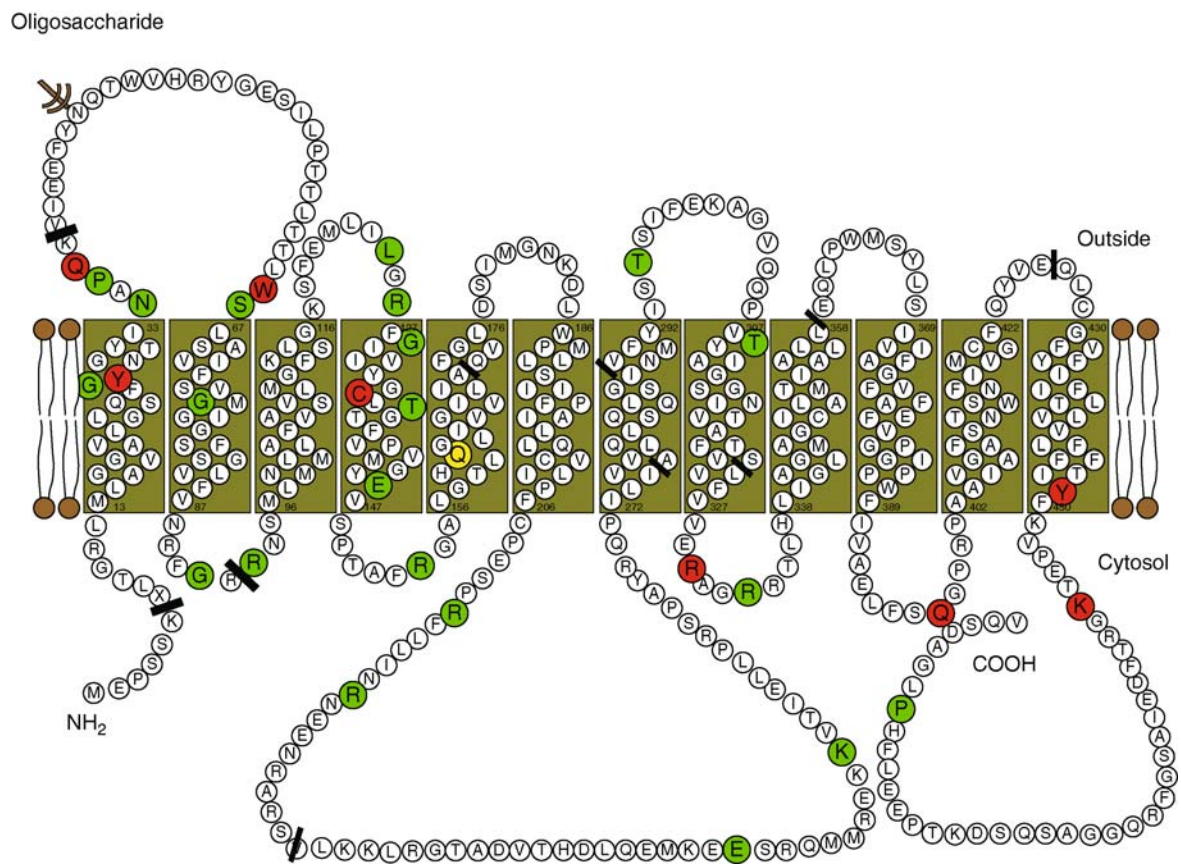
### Molecular and Systemic Pathophysiology

GLUT1 is the first identified member of the solute carrier 2A (SLC2A) family, which now has 13 members with distinct tissue distributions, subcellular localization, and transport kinetics. Glut1, a facilitative glucose

transporter, is constitutively expressed in most tissues and selectively expressed in erythrocytes, brain microvessels, and astroglia. Two distinct molecular forms of Glut1 with molecular weights of 55 and 45 kDa differ only in the extent of glycosylation. The 55 kDa form is found predominantly in the endothelial cells of brain microvessels and erythrocytes, where it is the principal (if not exclusive) glucose transporter. The 45 kDa form is detected in most cells including astrocytes and may be responsible for basal glucose uptake into these tissues. Glut1 is a 492-amino acid integral membrane protein with intracellular amino and carboxyl termini and 12 transmembrane domains, spanning the plasma membrane as alpha-helices (Fig. 1). Presumably two 6-helical domain halves are separated by the large intracellular loop between H6 and H7. The postulated three-dimensional structure is characterized by a channel across the protein that connects the extracellular and intracellular environments [5]. Only one opening is proposed at each end. The central channel is essentially formed by helices 2, 4, 5, 7, 8, and 10. The domains crucial for transport and pathogenicity are clustered in two groups: one around the central channel, and the other in the long intracellular loop. Aberrant Glut1 protein may result from truncation due to frameshift mutations, alteration of substrate binding sites due to missense mutations, or absence of protein due to allele deletion. In all cases, the normal allele contributes approximately 50% of functional Glut1 protein to the plasma membrane. Phenotypic heterogeneity implies other genetic modifiers of the primary pathogenic mutation.

## Diagnostic Principles

Glut1-DS should be considered in any child with otherwise unexplained infantile seizures, slowing of motor and mental development or a movement disorder with ataxia or dystonia. Hypoglycorrhachia and a lowered ratio of cerebrospinal fluid glucose (CSF)/blood glucose to <0.4 [Normal range 0.65 ± 0.01], constitutes the clinical laboratory hallmark. In almost all patients, the CSF glucose concentration is below 40 mg/dL. Lactate concentration in CSF is low-normal or low, usually below 1.3 mmol/L. Uptake studies of



**Glut-1 Deficiency Syndrome. Figure 1** Predicted Glut1 model in the membrane. Grey boxes represent the transmembrane helices. Black bar indicates the intron-exon boundaries. ● missense mutations. ● nonsense mutations. ● both missense and nonsense mutations identified. Other mutations are not represented here (1).

3-*O*-methyl-D-glucose demonstrate reduced glucose transport into erythrocytes. Brain positron emission tomography abnormality is distinctive with hypometabolism diffusely and regionally involving cerebellum, thalamus and mesial temporal lobe. Mutation (gene sequence and FISH assay) analysis of SLC2A1 (GLUT1) confirms the diagnosis [1].

### Therapeutic Principles

Treatment with a high-fat diet produces ketone bodies that diffuse across the blood-brain-barrier facilitated by a monocarboxylic acid transporter, providing an alternative fuel for brain metabolism. This therapy controls the seizures and the movement disorder. The effect on cognition is less impressive. The blood beta-hydroxybutyrate concentration should be maintained in the 4–6 mM range for optimal effect. Thioctic acid and l-carnitine are recommended as oral supplements. Some pharmological agents impair Glut1 function and should be avoided, including caffeine, phenobarbital, diazepam, chloral hydrate, and tricyclic antidepressants [1,2].

## Glutamate Dehydrogenase Hyperinsulinism

►Leucine Sensitivity

## Glutaric Acidemia

►Glutaric Aciduria Type I
►Glutaric Aciduria Type II

## Glutaric Aciduria Type I

Stefan Kölker
Department of General Pediatrics, Division of Inborn Metabolic Diseases, University Children's Hospital, Heidelberg, Germany

### Synonyms

Glutaric acidemia type I; Glutaryl-CoA dehydrogenase deficiency

### Definition and Characteristics

Autosomal recessive cerebral organic aciduria with macrocephaly, frontotemporal cortical atrophy, leukoencephalopathy and acute striatal injury. Acute striatal injury is induced by acute encephalopathic crises precipitated by catabolic state during a vulnerable period in infancy or early childhood. Extracerebral manifestation of the disease is rare [1,2].

### Prevalence

The estimated overall prevalence is 1 in 100,000 newborns (according to neonatal mass screening) but is considerably higher (up to 1 in 300 newborns) in some genetically homogeneous populations such as the Amish community (USA), the Saulteaux/Ojibway (Oji-Cree) Indians (Canada) and the Irish Travelers (Republic of Ireland, UK) [3].

### Genes

The GCDH (glutaryl-CoA dehydrogenase) gene is localized on chromosome 19p13.2; it spans 7 kb and consists of 11 exons.

### Molecular and Systemic Pathophysiology

The GCDH gene codes for a precursor protein of 438 amino acid residues that is imported into the mitochondria and cleaved into a mature protein of 394 amino acids. The active enzyme is a homotetramer that contains one loosely bound molecule of flavin-adenin dinucleotide (FAD) per monomer as coenzyme. More than 150 disease-causing mutations on different exons and introns have been described. R402W (c.1,204C T; exon 10) is the most frequent mutation in the European population (10–20% of alleles) but most mutations are private [3].

GCDH (EC 1.3.99.7) is an FAD-dependent mitochondrial acyl-CoA dehydrogenase catalyzing the oxidative decarboxylation of glutaryl-CoA to crotonyl-CoA in the final catabolic pathways of the amino acids L-lysine, L-tryptophan, and L-hydroxylysine. Inherited deficiency of this enzyme results in an accumulation of substrates

and other metabolites in tissues and body fluids. The most characteristic metabolites are glutaric acid (GA), 3-hydroxyglutaric acid (3-OH-GA), glutaconic acid (less frequently detected) and glutarylcarnitine (C5DC). GA and C5DC are produced from glutaryl-CoA via hydrolysis or carnitine conjugation. Increased formation and urinary excretion of C5DC is a physiological detoxifying mechanism causing secondary carnitine depletion. The generation of 3-OH-GA is less clear but most likely includes oxidation of glutaryl-CoA to glutaconyl-CoA by other mitochondrial acyl-CoA dehydrogenases and subsequent hydration by 3-methylglutaconyl-CoA hydratase.

The pathomechanisms underlying neurologic disease in glutaric aciduria type I are not yet fully understood. An involvement of accumulating metabolites which may act as endogenous toxins is quite likely. Intercerebral accumulation of GA and 3-OH-GA is facilitated by the limited flux of dicarboxylic acids across the blood-brain barrier. Toxic effects of 3-OH-GA and GA were described in neuronal and oligodendroglial cultures induced by activation of neuronal glutamate receptors and ROS production, inhibition of $\alpha$-oxoglutarate dehydrogenase and depletion of intracellular phosphocreatine stores. Synergism of these single mechanisms may result in excitotoxic cell damage and mitochondrial dysfunction during catabolic state. This may be enhanced by secondary carnitine depletion via decreased fasting tolerance due to impaired mitochondrial $\beta$-oxidation of fatty acids. Furthermore, age-dependent and area-specific factors are suggested to modulate the vulnerability to accumulating organic acids [4].

## Diagnostic Principles

Diagnosis should be suspected in macrocephalic neonates with a characteristic organic acid pattern (3-OH-GA, GA) detected by gas chromatography/mass spectrometry and/or increased C5DC concentrations in dried blood spots detected by tandem mass spectrometry (e.g., neonatal screening programs). Confirmation of diagnosis should be made by enzyme analysis of GCDH in fibroblasts or lymphocytes and mutation analysis in the GCDH gene.

## Therapeutic Principles

Dietary restriction of precursor amino acids, in particular l-lysine, is performed to reduce the production of (toxic) organic acids. Prevention of secondary carnitine depletion is achieved by oral supplementation of l-carnitine (start dosage: 100 mg/kg/day). Intensified emergency treatment is performed to prevent or reverse catabolic states (infectious diseases, vaccinations, surgery). This therapeutic strategy has considerably decreased the onset of prognostic relevant striatal injury during acute encephalopathic crises in pre-symptomatically diagnosed children, however, the long-term outcome of this disease is still uncertain. Movement disorders, in particular dystonia, resulting from striatal injury are often difficult to handle. Diazepam, baclofen, and trihexiphenidyl may be beneficial for the pharmacotherapy of movements disorders [1,4,5].

# Glutaric Aciduria Type II

Stefan Kölker
Department of General Pediatrics, Division of Inborn Metabolic Diseases, University Children's Hospital, Heidelberg, Germany

## Synonyms

Glutaric acidemia type II; Multiple acyl-CoA dehydrogenase deficiency

## Definition and Characteristics

Autosomal recessive defects of electron transfer flavoprotein (ETF) or ETF ubiquinone oxidoreductase (ETFQ) resulting in deficiency of mitochondrial flavoprotein dehydrogenases and thus impairment of energy metabolism. The disease course is extremely variable; three different groups have been delineated: Type 1: neonatal onset with multiple congenital anomalies (e.g., facial dysmorphism, polycystic kidneys, anomalies of external genitalia, muscular defects of the anterior abdominal wall); type 2: neonatal onset with hyperketotic hypoglycaemia but without anomalies. Milder

early onset forms may present in late infancy or early childhood with (recurrent) Reye-like episodes, cardiomyopathy, and leukoencephalopathy; type 3: late onset presenting with progressive proximal myopathy (lipid storage myopathy of type I muscle fibres). Patients with neonatal onset usually decease during the first week of life (type 1) or after a few months (type 2) [1].

## Prevalence

There are no accurate figures on the prevalence of this disease. Preliminary data from expanded newborn screening programmes have estimated 1 in 100–200,000 newborns.

## Genes

ETF is a heterodimer ($\alpha$- and $\beta$-subunits) in the inner mitochondrial matrix and is encoded by ETFA (chromosome 15q23-q25) and ETFB genes (chromosome 19q13.3). ETFQ exists as monomer in the inner mitochondrial membrane and is encoded by the ETFDH gene (chromosome 4q32→qter) [2,3].

## Molecular and Systemic Pathophysiology

ETF is an intermediary electron carrier for flavoprotein protein dehydrogenases in the mitochondrial matrix and is reoxidized by ETFQ, which subsequently reduces ubiquinone. Thus, the ETF/ETFQ system acts as a branch of the electron transport system.

Inherited deficiency of ETF or ETFQ results in functional deficiency of several flavoprotein dehydrogenases and an accumulation of upstream substrates and metabolites in body fluids and tissues, such as the organic acids glutaric acid, ethylmalonic acid, D-2-hydroxyglutaric acid, and dicarboxylic acids (e.g., dodecanoic acid, sebacic acid) causing metabolic acidosis, glycine esters (e.g., isovalerylglycine) and carnitine esters (e.g., butyryl-, isovaleryl-, glutaryl-, octanoyl-, myristoleylcarnitine). Glutaric aciduria type II thus combines the biochemical features of some organic acid disorders (glutaric aciduria type I, isovaleric aciduria) and mitochondrial fatty acid oxidation defects (short-, medium- and very long-chain acyl-CoA dehydrogenase deficiencies). Secondary carnitine deficiency is a characteristic sequel of enhanced formation and urinary loss of acylcarnitines. Recently, it has been hypothesized that in some patients glutaric aciduria type II may be induced by defects in the human mitochondrial FAD transporter.

Limited availability of acetyl-CoA from deficient mitochondrial $\beta$-oxidation of fatty acids results in decreased ketogenesis and hyperammonemia (decreased synthesis of N-acetylglutamate) which may trigger encephalopathy and Reye-like syndrome during metabolic decompensation. The limited availability of ketone bodies as alternative energy substrates during fasting as well as reduced allosteric activation of pyruvate carboxylase and decreased gluconeogenesis results in reduced fasting tolerance and hypoketotic hypoglycaemia. Decreased formation of ketone bodies may favour the manifestation of cardiomyopathy. Limited availability of acetyl-CoA also impairs myelination and thus may induce leukoencephalopathy. Secondary carnitine depletion further impairs uptake of long-chain fatty acids into mitochondria of skeletal muscle and hepatocytes leading to fat accumulation (fatty infiltration of liver, lipid storage myopathy of type I muscle fibres) and organ dysfunction (hepatopathy, myopathy). The presence of congential anomalies suggests a specific toxic effect of at least one accumulating metabolite or the necessity of an intact energy metabolism for certain developmental processes. Homozygosity for two null mutations of ETFA, ETFB or ETFDH have been associated with neonatal onset with anomalies (type I disease phenotype), whereas small amounts of residual ETF or ETFQ activity prevent embryonic development of anomalies (type 2). In patients with type 3, residual activity could be rescued up to 59% of controls. These observations highlight a correlation between the biochemical and clinical phenotype [2,3].

## Diagnostic Principles

Glutaric aciduria type II should be suggested in a newborn with hypoketotic hypoglycaemia and metabolic acidosis (with or without congenital anomalies) in the presence of a characteristic organic acid pattern in urine detected by gas chromatography/mass spectrometry and/or a characteristic acylcarnitine profile in dried blood spots detected by tandem mass spectrometry (e.g., expanded newborn screening). The same biochemical pattern is found in Jamaican vomiting sickness which occurs after ingestion of unripe ackees and in severe riboflavin deficiency, however, these conditions are usually easy to exclude. Diagnosis in late-onset patients (type 3) is often more difficult since metabolic acidosis may be absent and the characteristic pattern of organic acids and acylcarnitines may be less pronounced or only intermittently detectable, i.e., during acute metabolic crises. Confirmation of diagnosis should be performed by mutation and/or enzyme analysis. The defect can also be identified by Western blot analysis or immunoprecipitation demonstrating deficient ETF or ETFQ. Prenatal diagnosis of affected fetuses can be performed biochemically or by mutation analysis [4].

## Therapeutic Principles

Since the mitochondrial $\beta$-oxidation of fatty acids is severely affected in this disease, dietary treatment using low-fat, high-carbohydrate diet is usually performed. To reduce energy failure in brain, heart and muscle due to defective ketogenesis, oral administration of D, L-3-hydroxybutyrate (100–1,000 mg/kg per day orally)

may be beneficial [5]. Oral carnitine supplementation (start dosage: 100 mg/kg per day) is used to prevent secondary carnitine depletion. Treatment with oral riboflavin (100–300 mg/day) is particularly effective in patients with riboflavin responsiveness. To avoid deleterious metabolic crises which are precipitated by catabolic state, intensified emergency treatment should be performed during intercurrent infectious diseases. Application of methylene blue as alternative electron acceptor has been tried only in one patient as *ultima ratio* therapy. Most patients who present with neonatal onset, in particular those with anomalies, die within the first weeks of life despite treatment.

# Glutaryl-CoA Dehydrogenase Deficiency

►Glutaric Aciduria Type I

# Glutathione Synthetase Deficiency

Elardus Erasmus, Lodewyk J. Mienie
North-West University, School of Biochemistry, Potchefstroom, South Africa

## Synonyms

5-oxoprolinemia; 5-oxoprolinuria; Pyroglutamicaciduria; Pyroglutamic aciduria; Pyroglutamic academia; GS deficiency

## Definition and Characteristics

Glutathione synthetase (GS) deficiency is a metabolic disorder that affects the normal function of the gamma-glutamyl cycle [1]. The defect is associated with increased plasma and urinary levels of 5-oxoproline and reduced systemic glutathione levels.

## Prevalence

Rare, about 40 patients in 35 families have been described internationally.

## Genes

The gene for GS deficiency is located on chromosome 20q11.2.

## Molecular and Systemic Pathophysiology

Glutathione is metabolized in the gamma-glutamyl cycle sequentially by six different enzymes. The second enzyme in this pathway is glutathione synthetase. A defect in this enzyme results in glutathione synthetase deficiency, an autosomal recessive disorder which is lethal in about 25% of affected cases. Two forms of the defect can be distinguished: an erythrocyte and a multiple tissue variant. The disease is further classified according to clinical phenotype into three groups: mild, moderate and severe [2]. The normal regulatory mechanism of GS is compromised due to the lower levels of the reduced form of glutathione, resulting in overproduction of gamma-glutamyl cysteine. This dipeptide is converted to 5-oxoproline and cysteine of which the former is the cause of the metabolic acidosis and 5-oxoprolinuria [3].

## Diagnostic Principles

Biochemical findings include massive excretion of 5-oxoproline in the urine. The clinical picture includes spasticity, ataxia, tremors, seizures, eye abnormalities, mental retardation and psychosis. Hemolytic anemia is prominent in all the clinical phenotypes. In mild GS deficiency, which is characterized by hemolytic anemia, enzyme deficiency occurs primarily in erythrocytes. Prenatal diagnosis based on 5-oxoproline levels in amniotic fluid is possible [4].

## Therapeutic Principles

High levels of 5-oxoproline results in metabolic acidosis and bicarbonate treatment has been successfully used to correct this problem. Additional treatment is limited to supplements containing *N*-acetyl cysteine [5] to increase the low intracellular glutathione concentrations and antioxidants, such as vitamin E and vitamin C.

# Glycine Encephalopathy

►Nonketotic Hyperglycinemia

# Glycogen Branching Enzyme Deficiency

John Vissing
Neuromuscular Clinic and Research Unit, Department of Neurology, National University Hospital, Copenhagen, Denmark

## Synonyms

Glycogenosis type IV; 1,4-α-D-glucan 6-α-D-[1,4-D-glucano] transferase deficiency; Andersen disease; Amylopectinosis; Adult polyglucosan body disease

## Definition and Characteristics

As the many synonyms of the disease suggest, this condition is associated with multiple phenotypes [1–3]. In its classic form, patients with glycogen branching enzyme deficiency present with progressive hepatic fibrosis leading to hepatomegaly in the first year of life. Due to liver failure, these children infrequently live past age 4. More rarely, cases may present primarily with neuromuscular symptoms. If present at birth, children are usually floppy with severe muscle and neuronal involvement leading to death in the neonatal period. With a later onset in childhood, cardiomyopathy is usually the primary presenting feature. In adult cases (adult polyglucosan body disease), the dominating features are progressive upper and lower motor neuron involvement and sensory loss and a high incidence of dementia.

## Prevalence

Less than 100 cases have been reported in the literature. Exact prevalence estimates are lacking.

## Genes

The disease is autosomal recessive and caused by mutations in the glycogen branching enzyme gene (GBE1) that spans 16 exons and is localized on chromosome 3p14.

## Molecular and Systemic Pathophysiology

Unlike many other enzymes involved in glycogen and glucose metabolism, branching enzyme is thought to be monomeric, and it is therefore difficult to explain the extremely heterogeneous clinical presentation, which is unparalleled by any of the other glycogenoses [3]. The disease is characterized by the accumulation of amylopectin-like polysaccharide (polyglucosan) in most tissues. There is evidence to suggest that the severity of the phenotype is related to the molecular defect and thus the residual GBE activity and level of polyglucosan accumulation [4].

## Diagnostic Principles

Apart from the clinical presentation, the diagnosis can be suggested by findings of PAS-positive diastase-resistant, abnormally stored glycogen that may resemble amylopectin (thus the name amylopectinosis). In branching enzyme deficiency, glycogen has fewer branching points, more α1,4-linked glucose units and longer outer chains. Blood chemistry is suggestive of a severe affection of the liver parenchyma and creatine kinase is elevated. Definite diagnosis rests on biochemical demonstration of reduced branching enzyme activity in liver, cultured fibroblasts or leukocytes and detection of pathogenic mutations in GBE1.

## Therapeutic Principles

No specific treatment exists. In infantile cases with progressive liver failure, liver transplantation has proved beneficial in some [5]. Progressive cardiomyopathy has been treated with heart transplantation in a few patients.

# Glycogen Storage Disease Type II

Arnold Reuser
Department of Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands

## Synonyms

Pompe disease; Acid maltase deficiency; Acid α-glucosidase deficiency; Lysosomal α-glucosidase deficiency; GSD II

## Definition and Characteristics

Autosomal recessive lysosomal glycogen storage disorder caused by acid α-glucosidase deficiency with progressive generalised muscle weakness as prominent clinical feature. Due to genetic heterogeneity, the first clinical manifestations may reveal themselves shortly after birth or with a delay of several decades [1].

## Prevalence

The estimated prevalence of heterozygotes in the Dutch population is 1 in 85, and the different clinical subtypes occur with a combined frequency of 1/40,000. The estimated carrier frequency in Southern China and Taiwan is 0.5–1%, and the disease may occur as frequently as 1/14,000 among the African-American population of New York, USA [1].

## Genes

The gene locus is called "GAA" and is located on chromosome 17q25. More than 200 disease causing mutations are presently known (see: www.pompecenter.nl). They lead to defective α-glucosidase synthesis with partial or complete loss of catalytic function.

## Molecular and Systemic Pathophysiology

All cell types other than the red blood cells have lysosomes; membrane bound intracellular compartments with an acidic interior. These lysosomes contain an estimated 50 different enzymes that work often in concert to degrade a wide variety of macro-molecular substances that are either derived from the intracellular environment – via autophagy – or from the extracellular space – via endocytosis. Inherited deficiency of one of these different enzymes prohibits the degradation of one or several substances and results in a lysosomal storage disorder. The deficiency of acid α-glucosidase in Glycogenosis type II prohibits the lysosomal breakdown of glycogen into glucose and gives rise to intralysosomal accumulation of glycogen. In skeletal muscle, lysosomal deposits of glycogen are seen throughout the muscle fibres. The glycogen-loaded lysosomes disturb the highly ordered configuration of contractile elements and interfere directly with force generation [2]. Secondary changes occur, and irreversible damage to the muscle fiber is eventually seen followed by muscle cell destruction [3,4]. The cardiomyocytes initially respond to the glycogen storage by growing hypertrophic; the septum and the walls of the heart are thickening. Severely affected infants without any residual α-glucosidase activity typically succumb by cardio-respiratory failure in their first year of life. Patients with delayed-onset disease and some residual activity do not develop a cardiomyopathy, but they may become wheelchair bound and ventilator dependent.

## Diagnostic Principles

The combination of generalized muscle weakness, cardiac hypertrophy, feeding problems, respiratory difficulties and delayed motor milestones points to the disease in infants. Children display among other symptoms delayed motor milestones, swallowing

difficulties, and skeletal muscle weakness. Juveniles and adults present with a slowly progressive weakness of the proximal muscles of the lower limbs (waddling gate). PAS-positive glycogen storage is seen in a muscle biopsy when properly fixed with glutaraldehyde and embedded in methacrylate. Measurement of acid α-glucosidase activity in cultured fibroblasts, or in a muscle biopsy commonly reveals over 80%-decreased activity compared to normal. Serum levels of CK, ASAT, and ALAT are frequently elevated. [1]

### Therapeutic Principles

Enzyme replacement therapy is under review. Several patients in clinical studies have experienced beneficial effects of experimental treatment with intravenous infusions of recombinant forms of human acid α-glucosidase [5,6]. A balanced diet and moderate exercise are advised as supportive means [7].

[2]Division of Endocrinology, Children's Hospital Boston and Harvard Medical School, Boston, MA, USA

### Synonyms

Hepatic glycogen synthase deficiency; Glycogen storage disease type 0; GSD0

### Definition and Characteristics

Autosomal recessive deficiency of hepatic glycogen synthase. Inability to store hepatic glycogen results in postprandial hyperglycemia, hyperlactatemia, and hyperlipidemia alternating with fasting ketotic hypoglycemia associated with low alanine and lactate concentrations.

### Prevalence

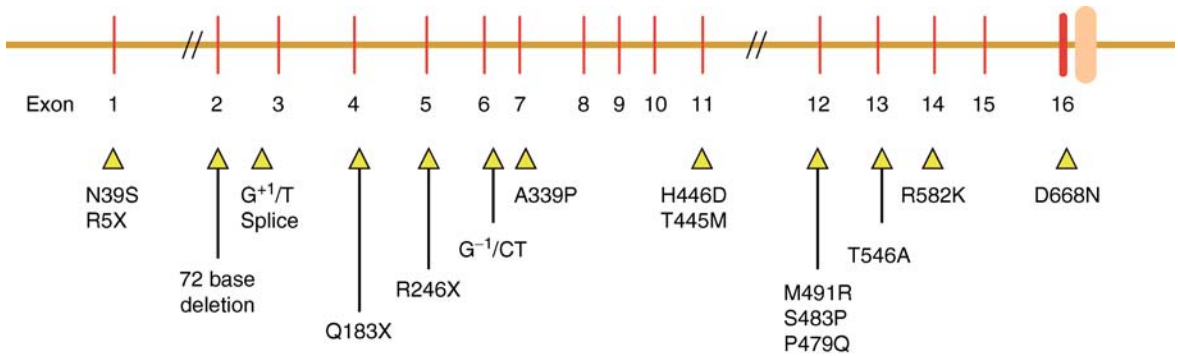
The prevalence of GSD0 is unknown, but it is almost certainly under-diagnosed. To date, 20 cases have been reported from North America, South America, and Europe.

### Genes

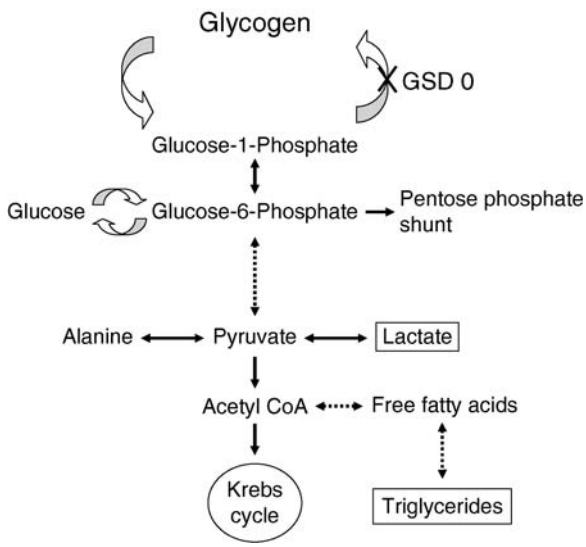
Seventeen mutations, shown in Fig. 1, have been identified in the GYS2 gene located on chromosome 12p12.2. Of the 16 mutations, the only common mutation is in Exon 5 (R246X), which has been found in patients of Italian descent [1,2,3].

### Molecular and Systemic Pathophysiology

Hepatic glycogen synthase catalyzes the formation of α-1,4-linkages that elongate chains of glucose to form glycogen. After a carbohydrate-containing meal, inability to synthesize glycogen leads to postprandial



**Glycogen Synthase Deficiency. Figure 1** Schematic representation of GYS2 gene with mutations that have been found in patients with GSD0. The gene has 16 exons (represented by the lines), and the arrowheads point to the location of the mutation.



**Glycogen Synthase Deficiency. Figure 2** Schematic representation of biochemical pathways affected in glycogen storage disease type 0 [Reprint from Mol Genet Metab, Epub, Weinstein, et al. Hepatic glycogen synthase deficiency: An infrequently recognized cause of ketotic hypoglycemia 2005 with permission from Elsevier.]

hyperglycemia, and glucose is shunted into the glycolytic pathway resulting in hyperlactatemia and hyperlipidemia (Fig. 2).

Presentation of GSD0 is milder than other hepatic glycogenoses due to intact gluconeogenesis and fatty acid oxidation, which slow the decrease in blood glucose levels.

## Diagnostic Principles

Fasting ketotic hypoglycemia and irritability in the morning occurs following discontinuation of overnight feeds. Children with plasma glucose values ranging from 25 to 40 mg/dL (1.5–2.2 mmol/L) may be asymptomatic because increased blood ketone concentrations supply the brain with an alternative fuel. Hypoglycemia typically is documented during a gastrointestinal illness or other periods of poor enteral intake. Fasting hypoglycemia and ketonuria are found in all GSD0 children under the age of five. Patients suspected to have GSD0 can be evaluated by measuring blood glucose and lactate concentrations after a carbohydrate-containing meal or by performing an oral glucose tolerance test [2]. Mutation analysis is becoming the gold standard for diagnosing GSD0 and is now commercially available. Glycogen synthase activity is low or immeasurable in a liver biopsy, whereas the liver glycogen content is only moderately decreased. Liver biopsy is no longer recommended because the procedure is invasive and results may be inconclusive.

## Therapeutic Principles

The goal of treatment is to prevent hypoglycemia and to minimize postprandial lactic acidemia. A high protein, low glycemic index diet is recommended. Despite a high protein diet, young children may continue to experience hypoglycemia. Uncooked cornstarch (1–1.5 g/kg) at bedtime and every 6 h during illness can be used to supplement the diet. Daytime hypoglycemia can be prevented with snacks every 2–4 h, and cornstarch may be beneficial before strenuous physical activity [2].

# Glycogenosis

Yoon S. Shin
Children's Hospital, University of Munich, Munich, Germany

## Synonyms

Defects of the phosphorylase system; Phosphorylase B kinase deficiency

## Definition and Characteristics

Multisystemic disorders of phosphorylase activating enzymes, mostly autosomal recessive traits with an exception of defects in the alpha subunit of phosphorylase b kinase (PBK), of which the mode of inheritance is x-linked [1–4].

## Prevalence

Glycogen storage disease due to defective phosphorylase system represents a heterogeneous group of glycogenoses. They manifest primarily in liver, muscle, or in both, although some forms manifest in the kidney, heart, nervous system or blood cells.

## Genes

Phosphorylases are activated by a complex cascade with the key enzyme PBK, the biggest and most complex protein kinase. The genes of the tissue specific PBK isoenzymes and the respective subunits are accordingly manifold. The gene mutations of other protein kinases such as cAMP-dependent protein kinase have been reported to cause glycogen storage disease. In Table 1, the genes and the enzymes responsible for this group of disorders and the approximate incidence of each subtypes are given. Altogether, this group accounts for more than 25% of all cases of glycogenoses [1–4].

## Molecular and Systemic Pathophysiology

PBK is a regulatory protein kinase that stimulates glycogen breakdown, receiving input from hormonal and neuronal signals transmitted through the second messengers $Ca^{2+}$ and cAMP, and responding by phosphorylating and thus activating glycogen phosphorylase. PBK consists of four subunits in a hexadecameric complex, $(\alpha\beta\gamma\delta)_4$, and each of these has isoforms or splice variants differentially expressed in various tissues. Aberration in one or more isoforms of PBK caused by mutations in the respective genes results in deficiency of an active phosphorylase, phosphorylase a. This in turn yields accumulation of glycogen in target tissues. Consequently, PBK deficiency occurs in numerous subtypes which differ in tissue involvement, manifestation and prognosis. The liver type can be caused mostly by mutations in one of three different genes. The most common form, X-linked liver PBK is caused by mutations of PHKA2 and the autosomal recessive forms by mutations of PHKB or PHKG2. Two PHKG2 mutations (H144Y and L225R) has been reported in a German family associated with infantile progressive liver cirrhosis [5]. The skeletal muscle type, not affecting the liver, can be divided into three

**Glycogenosis. Table 1**

* altogether 1:100,000

subtypes: a lethal infantile form with generalized hypotonia and respiratory insufficiency, a juvenile form with muscle pain, fatigue and myoglobinuria and an adult form with exercise intolerance and muscle weakness. Up to now only one PHKA1 missense mutation and two PHKB mutations (Q657K, Y770C) were detected among a few adult patients with a low PBK and phosphorylase a activity in muscle. No sequence abnormalities in the seven above mentioned genes were found in other patients.

## Diagnostic Principles

As with all glycogenoses, principally there are three steps to confirm a diagnosis. Firstly, one should check glycogen accumulation biochemically and/or histologically in blood cells as well as in respective affected tissues. Secondly, the activity of three enzymes, phosphorylase a, phosphorylase b and phosphorylase kinase must be measured. For the first two enzymes, endogenous phosphorylases can be determined by tracing the incorporation of the substrate glucose 1-p into glycogen, and for the third by following the activation rate of commercially available phosphorylase b from rabbit muscle at different pH values [2–4]. Typical liver or muscle forms can easily be detected by these methods using blood cells or biopsies. However, the detection of variant forms is rather difficult, since the identity of enzymes involved in the specific forms has yet to be established. The last diagnostic step, the gene analysis, can offer a secure diagnosis, but also be problematic. Except for the x-linked forms, we do not really know which genes to investigate.

## Therapeutic Principles

No plausible, causal and effective therapy is known. We apply only supportive measures by recommending frequent meals containing carbohydrates for the liver forms and protein and vitamin rich diets for isolated muscle forms.

## Synonyms

Glycogen storage disease type II; Acid maltase deficiency; Pompe disease

## Definition and Characteristics

Glycogenosis type II is hallmarked by accumulation of glycogen in the lysosomes, associated with a progressive weakness of skeletal muscle and a cardiomyopathy as most prominent clinical features. Age of onset of these clinical symptoms depends on the residual activity of the lysosomal enzyme acid 1–4 α-glucosidase (AGLU). Discrimination is made between early onset, infantile and late onset (>5 years of age) glycogenosis type II but there is no defined difference in the molecular defect. Complete lack of enzyme activity will lead to death due to cardio-respiratory insufficiency before the age of two years. Residual activity of the enzyme in muscle varies between 0 and100% and seems to be related to the age of onset of clinical complaints, but local variation in and between muscles may contribute to this range.

In early onset, children fail to reach hallmarks in their motor development such as rolling over, sitting or walking. In late onset, the primary symptoms are weakness of the extremities. This muscle weakness is progressive and patients become wheelchair bound. Since the respiratory muscles are affected as well, patients will become dependent on breathing aids.

Glycogenosis type II is frequently misdiagnosed as muscle dystrophy. Glycogenosis type II patients

however show an increased cardiac size on echography and often also thickening of the tongue.

## Prevalence

Based on the mutation pattern, the prevalence of insufficient activity of AGLU is estimated to be 1:40,000 births in the Caucasian population. Since not all the mutations lead to a decrease in enzyme activity of more then 75%, and due to misdiagnosis of patients, the number of registered patients worldwide is significantly lower. The disease is inherited in an autosomal recessive way.

## Genes

Mutations of the AGLU gene leading to glycogenosis type II are extensively described. Over 40 mutations of the gene have been described in patients. An excellent overview is provided by Ausems and co-workers [1]. The frequency of a mutation partly depends on the ethnic origin of the patients. Frequent mutations include the R854X mutation in Afro-Americans, the 2741AG→-CAGG insertion in Turkish patients and the G925A mutation in European patients. The C1935A transversion is frequently found in Chinese patients with infantile GSD II, while in The Netherlands, infantile glycogenosis type II patients often show homozygosity or compound heterozygosity for the 525delT and the del exon 18 mutations. Most late onset GSD II patients carry the IVS1(–13T→G) mutation combined with either the 525delT or the del exon 18 mutation [1].

## Molecular and Systemic Pathophysiology

GSD II is caused by mutation in the gene encoding for the lysosomal enzyme acid 1–4 α-glucosidase (AGLU). This enzyme hydrolyzes glycogen engulfed by the lysosome into glucose, which is subsequently released to the cytoplasm across the lysosomal membrane. Changed enzymatic structure and hence activity, as a result of a mutation in the gene will lead to reduced or absent hydrolysis and subsequent accumulation of glycogen in the lysosomes. Accumulation occurs in all organs but is most progressive in organs that have a high cytoplasmic concentration of glycogen, such as heart and skeletal muscle and liver.

So far, no conclusive explanation has been offered for the underlying mechanism of contractile dysfunction in myocytes containing swollen lysosomes filled with glycogen. It has been hypothesized that glycogen accumulation and associated water cause an increase in lysosomal volume to such an extent that the hydrogen pumps in the lysosomal membrane are no longer able to maintain the characteristic low pH required for the proper functioning of the other, genetically unaffected lysosomal enzymes. This would cause an overall decreased lysosomal activity and eventually cytotoxicity in the myocyte [2,3]. Furthermore, the swollen lysosomes disturb the highly organized architecture of the muscle cell which most probably hampers its contractile behavior and causes structural damage that will ultimately lead to destruction of (parts of) the myofibers [4]. Eventually, repair of the damaged muscles by activation of satellite cells will drain the satellite cell pool and will no longer be able to keep pace with the damage, resulting in deteriorated muscle function.

## Diagnostic Principles

Glycogenosis type II is clinically characterized by muscle weakness. Hallmarks in motor development are delayed or not achieved in glycogenosis type II patients. Although an increased cardiac size and thickening of the tongue are reported in later stages of the disease, definite diagnosis and distinction from other muscle dystrophies can only be made with a muscle needle biopsy. Staining with periodic acid Schiff's reagents will reveal lysosomal accumulation of glycogen as large intensely red spots. Activity of AGLU must be assessed biochemically in the biopsy material to confirm diagnosis.

## Therapeutic Principles

Until recently, no effective therapy for glycogenosis type II existed. In the last few years, clinical trials have started in which recombinant AGLU is administered to patients with different disease severities. Though still in the experimental stage, the results of these trials look very promising. It is to be expected that this medication will be more widely available in the next few years. Success seems highest when therapy is started in the early stages of disease, where damage to the muscles is still relatively mild [5]. Early diagnosis is therefore, of paramount importance.

# Glycogenosis Type III

Stefan Kiechl
Department of Neurology, University Clinic Innsbruck, Innsbruck, Austria

## Synonyms

Glycogen storage disease type III; GSD-III; Cori-Forbes disease; Limit dextrinosis

## Definition and Characteristics

GSD-III is transmitted as an autosomal recessive trait and originates from deficiency of glycogen debrancher enzyme – a large monomeric protein with a molecular mass of 165–175 kD (1,532 amino acids) and two catalytic domains, the oligo-1,4-1,4-glucantransferase (T) and amylo-1,6-glucosidase (G) [1]. Clinical presentation and disease onset are highly heterogeneous. Based on the pattern of organ involvement and residual enzyme activities four disease subtypes can be differentiated: GSD-IIIa (75–80%, deficiency of T + G in liver and muscle), GSD-IIIb (15–20%, T + G in liver), GSD-IIIc (<5%, G ± T in muscle) and GSD-IIId (<5%, T in liver and muscle). Hepatic disease manifestations usually present in childhood with the characteristic clinical triad of hepatomegaly, hypoglycemia and growth retardation, and resolve during adolescence. Exceptionally, liver damage progresses and ends up in cirrhosis and carcinoma (<5%). Neuromuscular symptoms may begin in childhood but more commonly manifest in adult life up to an age of 65. The typical phenotypes are a minimal variant myopathy with minor complaints (40%), generalized moderate-to-severe myopathy (50%), distal myopathy or neuromyopathy (10%) and myopathy of respiratory muscles (<1%) [2]. The course of disease may be complicated by cardiomyopathy (<5%) or exercise intolerance and myalgia (50%).

## Prevalence

The prevalence of GSD-III is usually around 1 per 100,000 subjects but approaches rates as high as 1 per 3,000–5,000 in special ethnicities like the Faroese population or non-Ashkenazi Jews of North Africa [1,3,4].

## Genes

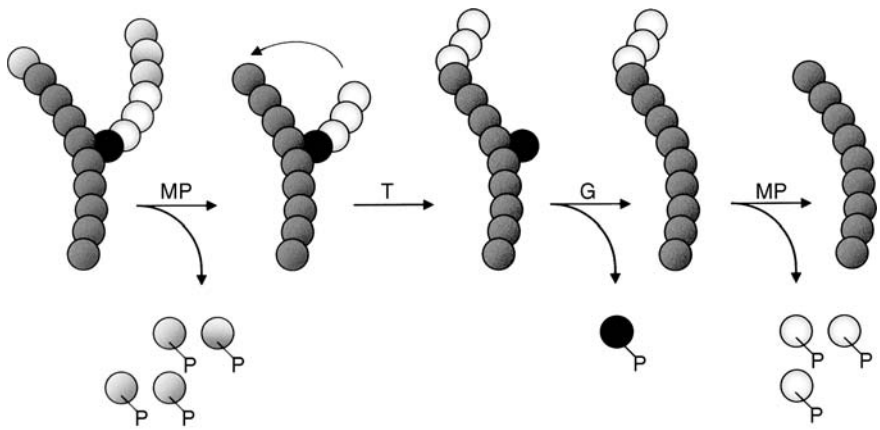
The AGL gene encoding for the glycogen debrancher enzyme is localized on chromosome 1p21, spans 85 kb and contains 35 exons [1,3].

## Molecular and Systemic Pathophysiology

In physiological glycogen breakdown the debrancher enzyme catalyzes the transfer of three glucose units from a short glycogen branch to the top of another and then hydrolyzes the 1,6 branch point of the remaining glucose residue (Fig. 1).

Deficiency of the enzyme has two consequences – an inadequate glucose supply from hepatic and/or muscle glycogen and the storage of abnormally structured glycogen in various tissues.

About 50 GSD-III mutations including small deletions, insertions and splice site mutations have been identified so far and the list is steadily growing [3,4]. The genetic abnormalities are scattered around the AGL gene without true hot spots and usually result in a premature stop codon. Most mutations occur in individual patients and, vice versa, most patients are compound heterozygotes with different combinations of mutations. Exceptions are the ethnicity-specific mutations in North African Jews (4455delT) and in subjects from the Faroe Island (1222C > T), which each account for a majority of disease cases [3,4]. In both populations founder effects have been proposed. A further exception



**Glycogenosis Type III. Figure 1** Muscle phosphorylase (MP) degrades glycogen chains until four glucosyl units remain before a 1,6 branch point. The debrancher enzyme catalyzes the transfer of three glucose units from the short glycogen branch to the top of another (oligo-1,4-1,4-glucantransferase (T)) and then hydrolyzes the 1,6 branch point of the remaining glucose residue (amylo-1,6-glucosidase (G)).

is GSD-IIIb in which an excellent genotype–phenotype correlation was found to exist. Most if not all of these patients carry one of two mutations located in exon 3 (17delAG or 16C→T) which have not been identified in other GSD-III subtypes [3].

The heterogeneous mutational background and differential control of debrancher enzyme expression in liver and muscle (six different splice variants) may partly explain the prominent phenotypic variability of GSD-III.

### Diagnostic Principles

In the case of clinical symptoms suggestive of GSD-III, strong supportive evidence may be offered by an ischemic forearm exercise test (absence of a normal lactate peak), glucagon test (no response), electromyography (emergence of denervation activity along with a myopathic muscle action potential spectrum), blood analyses (elevated creatine kinase) and liver or muscle biopsy (non-membrane-bound PAS-positive vacuoles) [1,2]. Establishment of a definite diagnosis requires the documentation of debrancher enzyme deficiency in liver, muscle or other tissues or the identification of underlying AGL mutations practicable in special ethnicities and GSD-IIIb (see above).

### Therapeutic Principles

In children with GSD-III, nocturnal intra-gastric feeding and oral cornstarch therapy have been used to prevent hypoglycemia and enhance growth [1]. In a few cases with severe progressive myopathy, a high-protein diet has successfully been employed to improve muscle strength [2]. Putatively, the amino acid load serves as a substrate for up-regulated gluconeogenesis and thus reverses muscle catabolism. No pharmacological or gene therapy is currently available.

### Synonyms

CDG; Carbohydrate deficient glycoprotein syndrome

## Definition and Characteristics

Congenital disorders of glycosylation are a rapidly growing young group of inherited disorders affecting the glycosylation of proteins including N-glycosylation via an amino group of asparagine, O-glycosylation via a hydroxyl group of serine or threonine or rarely other amino acids and glycosylphosphatidylinositol (GPI) anchor synthesis [1]. Currently 22 disorders belong to the group of CDG but some disorders affecting glycosylation are currently not included in the nomenclature [2].

While disorders affecting the N-glycan precursor synthesis in the endoplasmic reticulum and the transfer of the precursor onto the nascent protein are termed CDG type I, those affecting the modification and synthesis of glycans in the Golgi are termed CDG type II. CDG are further categorized by alphabetic ordering according to their time of discovery. Disorders with impaired glycosylation where the molecular cause could not yet be detected are termed CDGx. About 1% of the human genes are involved in glycosylation processes.

Most of the known disorders of glycosylation are multisystem disorders with severe psychomotor retardation. However, single disorders show a very distinct and small pattern of symptoms.

By far most of the cases of CDG are CDG Ia patients accounting for about 90% of all known patients.

## Prevalence

CDG Ia: ~1:20.000–50.000
All CDG slightly higher

## Genes

See Table 1.

## Molecular and Systemic Pathophysiology

Glycosylation is of general importance for the viability of humans and most complex organisms. Severely impaired or absent glycosylation is not compatible with life. Consequently, the most frequent mutation in CDG Ia resulting in a loss of function of the coded protein was never seen in homozygous form suggesting that the mutation is already lethal in an early developmental stage [1].

In CDG type I the transfer of an N-glycans precursor on the protein is absent mainly resulting in a hypoglycosylation, while in CDG II the synthesis of a glycan on the protein is disturbed generally resulting in a truncated or modified glycan.

While some CDG only impair restricted organ systems (CDG Ib, CDG IIc, CDG IIf) most disorders are multisystem disorders with profound neurological and developmental impairment. Due to the role of

glycoproteins for blood clotting, in several CDG clotting parameters are disturbed and the activity of single clotting factors is decreased.

### Diagnostic Principles

All CDG type I and some CDG type II can be diagnosed by investigation of serum transferrin. Isoelectric focusing was first used for the analysis detecting negatively charged sialic acids at the end of the N-glycans. Currently quantification of different glycoforms of transferrin is predominantly done using HPLC. Since the clinical picture of the CDG subtypes does not always allow a single CDG to be distinguished, further analysis must be done using enzyme assays (CDG Ia, CDG Ib) or analysis of dolichol-linked oligosaccharides using metabolic labeling of patient fibroblasts [1]. Genetic analysis is available for every characterized CDG. Some CDG of type II (CDG IIb, IIc, IIf) cannot be diagnosed by transferrin screening. However, these CDG are likely to be diagnosed by the specific clinical picture and subsequently by analysis of specific glycans.

### Therapeutic Principles

Only two members of the CDG family can be treated. CDG Ib is treated with oral intake of mannose; most of the patients show a rapid and complete cure of the main symptoms, protein losing enteropathy, clotting problems and hepathopathy within some weeks while normalization of transferrin glycosylation takes months [3].

CDG IIc patients show leucocytosis, recurrent infections and mild psychomotor retardation. Oral treatment with fucose normalizes the leucocytosis and infection rate but does not influence the mental retardation [4].

While some more CDG can be cured on the cellular level in vitro, no effective treatment is available for patients other than for CDG Ib and IIc.

## GM2 Activator Protein Deficiency

Ute Schepers, Thomas Kolter, Konrad Sandhoff
LIMES Institute Program Unit Membrane Biology and Lipid Biochemistry, Kekulé- Institute, University Bonn, Bonn, Germany

### Synonyms

AB-variant of GM2-gangliosidoses

### Definition and Characteristics

Autosomal recessive defect in the GM2 activator protein leads to massive lysosomal accumulation of ganglioside GM2 especially in neuronal cells. Together with Tay-Sachs and Sandhoff's disease, GM2 activator protein deficiency belongs to the class of GM2 gangliosidoses [1].

### Prevalence

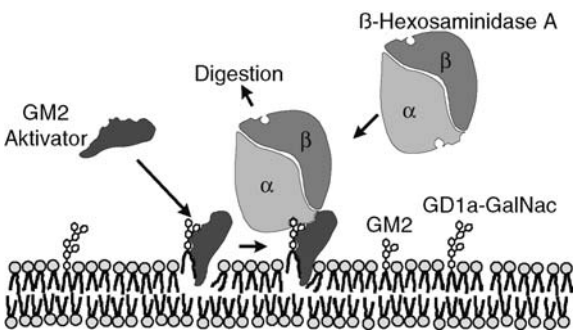
Worldwide, only six cases have been reported and no data of heterozygote frequency among general population are known.

### Genes

GM2A, localized on chromosome 5q32–33 and a non-functional pseudogene was identified on chromosome 3. Only five mutations have been reported (Fig. 1) [2].

### Molecular and Systemic Pathophysiology

Clinical phenotypes vary with an onset of 5 up to 65 month suggesting a slightly delayed onset and course in comparison with classical Tay Sachs disease. Severe cortical nerve-cell losses are seen, with most of the remaining cortical neurons (and those outside the central nervous system) being swollen. Likewise, widespread



**GM2 Activator Protein Deficiency. Figure 1** Model of the GM2 activator stimulated degradation of ganglioside GM2 by human β-hexosaminidase A [3].

cortical gliosis and secondary demyelination are observed. Macular cherry-red spots and the beginning of optic atrophy appear in the eye background. Dementia, convulsive phases, dysphagia, decerebrate spastic ("frog") posturing, respiratory tract infections, and distress mark the progression of the disease.

The clinical and pathologic findings are similar to those in Tay-Sachs disease. Presence of swollen neurons with accumulation of storage material within the lysosomal compartment. Non-digested membranes form intra-lysosomal vesicular structures, the so called membranous cytoplasmic bodies.

## Diagnostic Principles

Since GM2 activator is a nonenzymatic protein, diagnosis can only be achieved by lipid analysis, direct sequencing of GM2A cDNA and ELISA.

## Therapeutic Principles

Only supportive treatment is available to date.

# GM2 Gangliosidosis Type I

Dianna C. Martin, Barbara L. Triggs-Raine
Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, MB, Canada

## Synonyms

$G_{M2}$ gangliosidosis B, B1 or pseudo AB variant; Hexosaminidase A deficiency; HEXA deficiency; TSD; Tay-Sachs-Disease

## Definition and Characteristics

Tay-Sachs disease (TSD) [MIM 272800] is an autosomal recessive lysosomal storage disorder caused by mutations in the HEXA gene that result in a deficiency of β-hexosaminidase A (HEXA; EC 3.2.1.52). The level of residual activity is inversely correlated with the severity of symptoms. The most common form of the disease, the acute infantile form, results from a complete deficiency of HEXA [1]. Symptoms develop within the first 6 months of life and include an exaggerated startle response, progressive muscle weakness and loss of motor skills. Progressive neurodegeneration continues, characterized by seizures, blindness, spasticity and eventually a vegetative state that culminates in death, typically before age 4. A classic clinical feature is the "cherry red spot" observed during funduscopic examination. Additional rare forms of the disease include a sub-acute juvenile form that presents between 2 and 10 years of age and a chronic form that presents later in development (10 years to adulthood). Patients suffer from symptoms of cerebellar and anterior horn cell disease, such as ataxia, dysarthria, dysmetria, dystonia, proximal muscle weakness and muscle atrophy and the chronic disease may include psychosis [2].

## Prevalence

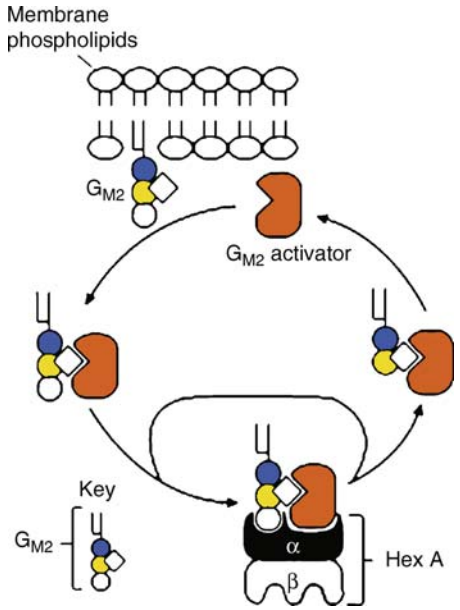
The highest risk for TSD is in the Ashkenazi Jewish population where the carrier frequency is ~1:27. However, successful carrier screening programs in North America have reduced TSD births among Ashkenazi Jews to levels below the incidence in the general population (~1:360,000). Elevated carrier frequencies have also been reported among French Canadians, Moroccan Jews, Pennsylvania Dutch and Louisiana Cajuns.

## Genes

More than 100 mutations have been identified within the HEXA gene. Three mutations (c.1278insTATC, c.1421 + 1G > C, c.805G > A) account for ~98% of alleles causing TSD in the Ashkenazi Jewish population [1]. There are other population-specific mutations, but only c.1073 + 1G > A has a significant frequency in the general population. Two benign mutations (c.739C > T and c.745C > T), that cause apparent HEXA deficiency but pose no risk for significant disease, account for ~35% of enzyme-defined non-Jewish TSD carriers [1]. Compound heterozygotes with a disease-causing and a benign mutation are healthy, but have a HEXA level in the disease range, i.e. HEXA pseudodeficiency.

## Molecular and Systemic Pathophysiology

There are two major β-hexosaminidase isoenzymes, HEXA and HEXB. HEXB is composed of two



**GM2 Gangliosidosis Type I. Figure 1** Model for $G_{M2}$ ganglioside hydrolysis by HEXA. (Used with permission, see reference [4], as modified in "Genes and Disease," Bethesda (MD), National Library of Medicine).

β-subunits encoded by HEXB, while HEXA is composed of one α-subunit encoded by HEXA and one β-subunit. Although the α- and β-subunits have a similar tertiary structure, only the αβ-heterodimer has the capacity to degrade the acidic $G_{M2}$ ganglioside [3]. $G_{M2}$ ganglioside in the membrane is bound by the $G_{M2}$ activator protein to form a soluble complex that is hydrolyzed by HEXA (Fig. 1).

A HEXA deficiency leads to intralysosomal accumulation of $G_{M2}$ ganglioside, primarily in the tissues of the nervous system where it is most abundant. Neurons "ballooned" by the accumulation can easily be visualized by electron microscopy, but how the accumulation disrupts neuronal function is still being debated. Similar pathology is seen in related diseases, $G_{M2}$ gangliosidosis AB variant [MIM 272750] and ►Sandhoff disease [MIM 268800], which are caused by mutations in the $G_{M2}$ activator-encoding gene (GM2A) or HEXB respectively. These mutations also lead to $G_{M2}$ ganglioside accumulation due to either an inability to form active HEXA (Sandhoff disease) or to inability to solubilize the substrate for cleavage by HEXA (AB variant).

The mutations that cause infantile TSD completely disrupt the production of active HEXA. A rare B1 variant of TSD (pseudo AB variant $G_{M2}$ gangliosidosis) is caused by mutations that partially or completely inactivate the α-subunit, but do not interfere with folding or assembly into HEXA. The resulting enzyme cannot degrade $G_{M2}$ ganglioside, but the active β-subunit can hydrolyze the neutral substrates typically employed in enzymatic assays. This variant can only be distinguished by using charged substrates specific for the α-subunit of HEXA. Mutations causing later-onset forms of TSD often reduce normal folding and assembly of HEXA, but allow some active enzyme to be made.

## Diagnostic Principles

Identification of carriers and diagnosis of TSD is accomplished using enzymatic assays for HEXA activity with synthetic fluorogenic substrates and DNA-based molecular analyses. Prenatal testing is typically offered for couples that have had a previous child with TSD or where both parents have been identified as enzyme-defined TSD carriers. In the latter case, molecular analysis for benign mutations is essential to avoid unnecessary prenatal testing.

## Therapeutic Principles

To date, there is no treatment for TSD, limiting management to supportive care for affected individuals and their families. Current research into potential therapies is focused on enzyme-replacement and substrate deprivation.

# Goiter

Seda Sancak[1], Ralf Paschke[2]
[1]Marmara University Medical School, Istanbul, Turkey
[2]III. Medical Department, University of Leipzig, Leipzig, Germany

## Definition and Characteristics

Euthyroid goiter is defined as a diffuse or nodular thyroid enlargement that is not due to inflammatory processes. It ranges from the slightly and diffusely enlarged thyroid

of children to the excessive enlargement of the mostly nodular thyroid gland in adults [1].

## Prevalence

In areas with iodine-deficiency, endemic goiter usually has a prevalence of >10% in schoolchildren between the ages of 6 and 12 years, whereas in nonendemic areas the prevalence is by definition less than 5% [1,2].

## Genes

Euthyroid goiter is a complex genetic disease. Candidate genes which likely contribute to goiter are the thyroglobulin (TG) gene, the thyroid-stimulating hormone receptor (TSHR) gene, the $Na^+/I^-$ symporter (NIS) gene, the thyroid peroxidase gene (TPO), Pendrin gene (SLC26A4), the thyroid oxidase 2 gene (THOX2), multinodular goiter candidate gene region 1 (MNG1) on 14q31, MNG2 on Xp22, and possible candidate gene region on chromosomes 2q, 7q and 8p, each identified in one family and a region on 3p (MNG4) which was identified in four families [1–3].

## Molecular and Systemic Pathophysiology

In contrast to solitary nodular thyroid disease, which has a more uniform clinical, pathological, and molecular picture, euthyroid MNG and toxic MNG comprise a mixture of nodular entities, i.e., one usually finds a combination of hyperfunctional, hypofunctional, or normally functioning thyroid lesions within the same thyroid gland. The sum of the functional properties of these thyroid nodules within an MNG ultimately determines the functional status in the individual patient, who may be euthyroid (normal TSH and free thyroid hormone levels), subclinically hyperthyroid (low or suppressed TSH and normal free thyroid hormone levels), or overt hyperthyroid (suppressed TSH and elevated free thyroid hormone levels) [1,2].

In areas without endemic goiter, multinodular goiter (MNG) is often referred to as sporadic nontoxic goiter [2].

The main epidemiological determinant for the development of MNG and TMNG is iodine deficiency. However, thyroid nodules (and goiter) also occur in individuals without exposure to iodine deficiency and not all individuals in an iodine-deficient region develop a goiter [2]. Additional etiological factors are several goitrogens, cigarette smoking, female gender, and age [1].

Therefore, most likely interactions between environmental factors and individual genetic predispositions ultimately determine the onset of the goiter. Manifestation of euthyroid goiter at an early age or the clustering of goiters in families suggest a genetic susceptibility, whereas environmental determinants are most likely to have additive or triggering effects [1].

Patients with TMNG usually have a history of long-standing MNG [2].

As described in Fig. 1 genetic factors most likely determine whether an individual reacts to iodine deficiency with adaptive regulations or with maladaptation which will lead to thyroid enlargement. The increased proliferation in thyroid hyperplasia results in increased chances for spontaneous mutations. Moreover, DNA damage is most likely also induced by the compensatory increase in $H_2O_2$ action. Depending on which genes are hit by these somatic mutations they will either confer constitutive activation of the cAMP cascade (e.g., TSH-R and Gs α mutations) thus stimulating growth and function or primarily stimulate growth (cold nodules) of thyroid epithelial cells. Furthermore, in a proliferating thyroid gland there is altered growth factor expression (IGF-1, TGF-β1, or epidermal growth factor). The small foci of thyroid cells with somatic mutations will progressively develop into thyroid nodules [2].

## Diagnostic Principles

Clinical features in a patient with MNG can be attributed to thyroid enlargement and thyrotoxicosis in the case of TMNG [2].

Serum TSH is the most frequently used test in the initial evaluation [4,5]. If TSH levels are suppressed, the measurement of serum free thyroid hormones and thyroid peroxidase antibody (TPO Ab, if TSH is increased) levels should be obtained [5].

On functional grounds, nodules are classified as either cold, normal or hot, depending on whether they show decreased, normal or increased uptake on scintiscan [2].

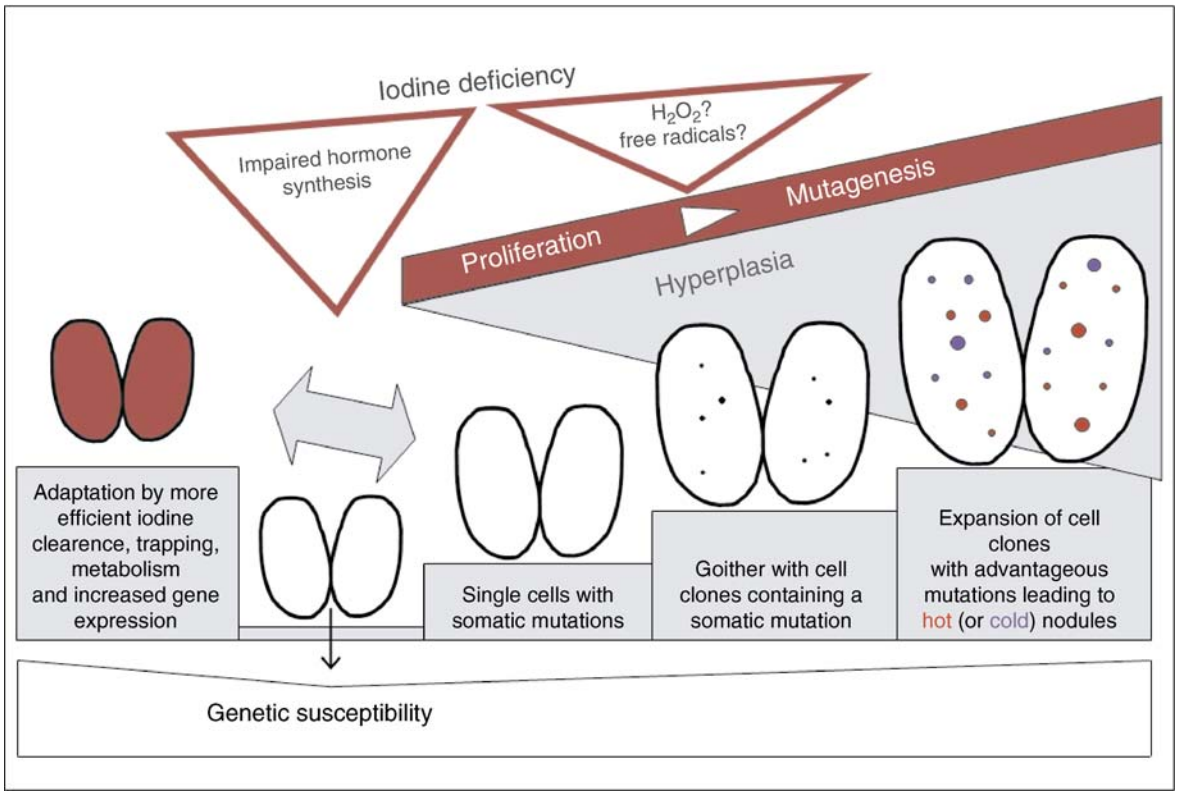
High-resolution US is the most sensitive test available to detect thyroid lesions to measure their dimensions accurately, to identify their structure and evaluate diffuse changes in the thyroid gland [4,5].

The risk for malignancy in MNG is about 5%. The most specific and sensitive method to differentiate malignant from benign nodules is the fine needle aspiration biopsy (FNAB). In MNG, the FNAB sampling should be focused on lesions characterized by suspicious US features rather than on larger or clinically dominant nodules [5]. Moreover, hot nodules are almost always benign [5].

## Therapeutic Principles

The majority of patients with goiter have few or no clinical symptoms. Therefore, in case of euthyroidism and exclusion of malignancy, many need no treatment [4].

Routine LT4 treatment in patients with nodular thyroid disease is not recommended [5]. Furthermore, TSH suppression may lead to symptoms of hyperthyroidism, reduced bone density and atrial fibrillation,



**Goiter. Figure 1** Hypothesis for thyroid nodular transformation. The starting point for the development of MNG is hyperplasia due to genetically determined maladaptation to goitrogenic stimuli (e.g., iodine deficiency). Iodine deficiency increases mutagenesis directly (compensatory production of $H_2O_2$/free radicals) or indirectly (proliferation and increased number of cell divisions). Subsequently, hyperplasia forms cell clones. Some of them contain somatic mutations of the TSH-R, leading to AFTNs (*red dots*), or contain mutations that lead primarily to proliferation and to dedifferentiation and therefore CTNs or cold adenoma (*blue dots*).

especially in elderly patients and postmenopausal women. Nodule regrowth is usually observed after cessation of LT4 therapy [5]. Because thyroid nodules are more often detected in iodine-deficient areas than in iodine-sufficient areas, iodine supplementation is the first choice in thyroid nodule prevention [2,4].

Indications for surgery or radioiodine include local symptoms related to the growth of the nodule or goiter or hyperthyroidism whereas the suspicious or malignant FNAB results should be treated by surgery [4,5].

## Goldberg Syndrome

►Galactosialidosis

# Gonadotropin Deficiency

►Hypogonadotropic Hypogonadism

# Goodpasture Syndrome

Dorin-Bogdan Borza
Division of Nephrology, Vanderbilt University School of Medicine, Nashville, TN, USA

## Synonyms

Goodpasture's disease; Anti-glomerular basement membrane (anti-GBM) antibody disease with pulmonary hemorrhage; Pulmonary-renal syndrome

## Definition and Characteristics

Goodpasture's disease is characterized by the clinical triad of rapidly progressive crescentic glomerulonephritis with pulmonary hemorrhage and circulating and kidney-bound anti-glomerular basement (anti-GBM) autoantibodies. In the absence of lung symptoms, the disease is designated as anti-glomerular basement membrane (anti-GBM) antibody disease. Regardless of the pattern of renal and pulmonary involvement, the autoantibodies bind specifically to the α3(IV) collagen chain, also known as the Goodpasture autoantigen [1].

## Prevalence

Goodpasture's disease is a rare autoimmune disease with an incidence of 0.5–1 per 1,000,000 people per year in the Western countries.

## Genes

The target of autoantibodies is the α3 chain of type IV collagen, encoded by the COL4A3 gene on chromosome 2. There are no known associations between COL4A3 alleles and susceptibility to Goodpasture disease. Mutations in α3(IV) collagen have been implicated in the pathogenesis of autosomal recessive and dominant forms of Alport syndrome and thin GBM disease. A small proportion of Alport patients that receive a renal allograft develop post-transplant anti-GBM antibody nephritis, clinically similar to Goodpasture's disease.

## Molecular and Systemic Pathophysiology

Rapidly progressive glomerulonephritis and pulmonary hemorrhage are mediated by the binding of IgG autoantibodies to α3(IV) collagen in the glomerular and alveolar basement membranes, respectively. In vivo, the GP autoantigen is a component of the α3α4α5(IV) collagen network and has a tissue restricted distribution. The autoantibodies target two conformational epitopes within the α3(IV) noncollagenous (NC1) domain, which are sequestered within the quaternary structure of an NC1 hexamer complex [2]. GP disease is believed to be triggered by a primary insult to lungs or kidneys that causes unmasking of cryptic GP epitopes. Clinically, GP disease has been associated with exposure to organic solvents and hydrocarbons, smoking, or viral infections, but causal links has not been demonstrated [3].

## Diagnostic Principles

Light microscopic examination of renal biopsy reveals rapidly progressive crescentic and necrotizing glomerulonephritis. The hallmark feature of the disease is linear deposition of IgG autoantibodies along the GBM, often accompanied by complement deposition, which are revealed by direct immunofluorescence staining. Circulating antibodies to the α3(IV) NC1 domain are detected by antigen-specific ELISA. Up to one third of anti-GBM positive patients also have anti-neutrophil cytoplasmic antibodies (ANCA), most often against myeloperoxidase.

## Therapeutic Principles

The standard treatment is a combination of plasma exchange, immunosuppression with cyclophosphamide and corticosteroids (methylprednisolone). Early therapeutic intervention has a good prognosis and the renal function is usually preserved in patients with low serum creatinine and less than 50% crescents. Patients that progress to end-stage renal disease require renal replacement therapy (dialysis or transplantation). The disease rarely recurs in the native kidney or the renal allograft.

## Gorlin Syndrome

Sonja Ständer, Heiko Traupe
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Nevoid basal cell carcinoma syndrome; NBCCS; Basal cell nevus syndrome (OMIM 109400); Gorlin-Goltz syndrome

### Definition and Characteristics

Autosomal dominant tumor suppressor gene defect leading to multiple cutaneous basal cell carcinomas (BCC) (up to 80% of the patients), and variable expression of a variety of other symptoms such as odontogenic keratocysts of the jaw (75%), palmoplantar pits (65–87%), bifid ribs (45%), polydactylia, cleft or lip palate, spina bifida, cortical defects of bones, macrocephaly, hypertelorism, calcified flax cerebri. Various benign and malignant neoplasms can be associated such as ovarian and cardiac fibromas, medulloblastomas, rhabdomyosarcoma and fetal rhabdomyoma [1].

### Prevalence

The prevalence has been estimated to be 1:56,000 and there is no gender preponderance [2].

### Genes

PTCH gene, localized on chromosome 9q22.3, loss of heterozygosity.

### Molecular and Systemic Pathophysiology

The tumor suppressor gene Patched (PTCH) is the human homologue of a Drosophila segment polarity gene, and encodes a transmembrane protein that acts as a negative regulator of hedgehog (HH) signaling. The PTCH protein has 12 hydrophobic membrane-spanning domains, intracellular amino- and carboxyl-terminal regions and two large hydrophilic extracellular loops where HH ligands bind. Up to now, a large series of mutations in exons including splicing mutations of the PTCH gene have been reported (review in [3,4]; Mutation Database http://www.cybergene.se/PTCH) resulting in truncated mostly non-functional PTCH protein. Mutations of PTCH gene have also been found in patients with sporadic basal cell carcinoma, trichoepitheliomas, primitive neuroectodermal tumor, breast cancer, colon cancer and meningeoma.

The HH signaling pathway is a key regulator of embryonic development controlling proliferation and cell fate determination (Toftgard). In the absence of a HH ligand, PTCH interacts and thereby represses signaling by the co-receptor Smoothened (SMOH) resulting in inhibition of the transcription of downstream genes such as GLI-1, FUSED, and COSTAL2, which control many cell functions including growth. After binding of a HH member such as sonic hedgehog (SHH), PTCH activity is blocked and target gene transcription is activated. In basal cell nevus syndrome, the PTCH gene is inactivated due to various mutations causing de-repression of SMOH and thus leading to constitutive activation of the HH pathway. Elevated activity of GLI-1 leads to cellular proliferation at the expense of maturation of the target cells into a postmitotic state. Since the HH pathway is necessary for the regular development of segments or the orientation of the body axis, truncated expression of PTCH leads to developmental anomalies. According to the two-hit-hypothesis, only the presence of a second mutation in somatic cells contributes to neoplastic transformation into e.g. BCC. The second mutation can be induced for example by X-ray-irradiation.

### Diagnostic Principles

The diagnosis of NBCCS can be made when two major or one major and two minor criteria are fulfilled. Major criteria for the diagnosis of basal cell carcinoma are: more than two BCC or one BCC before the age of 30 (Fig. 1), jaw cysts, three palmar pits (Fig. 2) or plantar pits, calcification of the falx cerebri, relative of first degree with basal cell carcinoma syndrome. Minor criteria are skeletal anomalies, makrocephalia, cardial or ovarial fibromas, polydaktylia, and development of solid neoplasia. Diagnostic X-ray procedures should be minimized and treatment with ionizing radiation has to be avoided because of a highly increased risk of multiple BCC.

**Gorlin Syndrome. Figure 1** Basaliomas in basal cell carcinoma syndrome.

**Gorlin Syndrome. Figure 2** Palmar pits in basal cell carcinoma syndrome.

## Therapeutic Principles

In general, all neoplasms including BCC should be excised completely. Moreover, large jaw cyst should be removed completely because of a local destructive behavior. Alternative topical therapies, e.g. application of topical immunomodulators such as 5% imiquimod cream are often recommended for inoperable BCC in old patients [5]. No gene, dietary or pharmacological therapy is available as of yet.

# Gorlin-Goltz Syndrome

►Gorlin Syndrome

# Gout

Michael A. Becker
Department of Medicine, University of Chicago Pritzker School of Medicine, Chicago, IL, USA

## Synonyms

Monosodium urate crystal deposition disease; Urate gout; Podagra

## Definition and Characteristics

Gout is a heterogeneous group of diseases resulting from tissue deposition of monosodium urate or uric acid crystals from extracellular fluids supersaturated with respect to uric acid, the end product of human purine metabolism [1]. ►Hyperuricemia, defined as a serum urate concentration exceeding the limit of urate solubility (approximately 6.8 mg/dL or 405 μM), reflects extracellular fluid urate supersaturation and is the pathogenetic common denominator through which diverse influences predispose to crystal deposition and clinical events [2]. The clinical manifestations of urate crystal deposition are limited to: recurrent attacks of acute inflammatory arthritis, sometimes leading to chronic degenerative arthropathy, accumulation of potentially destructive crystalline aggregates (tophi), especially in connective tissue structures, uric acid urolithiasis and renal impairment (gouty nephropathy) [2]. Renal impairment in gout is, however, most often associated with co-morbid states (hypertension,

hypertriglyceridemia, obesity, atherosclerosis, metabolic syndrome X) that are common among persons with gout [3]. Moreover, although hyperuricemia is a necessary accompaniment of gout, it is, in the majority of instances, insufficient for clinical expression of crystal deposition disease.

### Prevalence

The prevalence of gout varies with the prevalence of hyperuricemia in the population studied. In Europe and North America, where hyperuricemia is found in 5% or more of adult men, prevalence estimates range from 0.3 to 0.8%, depending on the means of ascertainment. Much higher rates are encountered among some Asian-Pacific groups, but in all populations prevalence in men substantially exceeds that in women [2].

### Genes

Multiple X-linked and autosomal loci are implicated in gout, including HPRT (Xq26–q27.2) and PRPS1 (Xq22–q24) in HPRT deficiency and PRPP synthetase overactivity respectively, G6PC (17q21) and G6PT1 (11q23) in type I glycogen storage disease and the uromodulin (UMOD) gene in the interval 16p11.2p–p12 in hereditary juvenile gouty nephropathy [4]. No specific locus has been implicated in "primary metabolic gout", but a co-dominant major gene acting on a polygenic background has been proposed [5].

### Molecular and Systemic Pathophysiology

Excessive urate body pools result from either increased uric acid production or decreased renal uric acid clearance or both [1]. The resulting hyperuricemia creates the risk of urate crystal deposition that may ultimately provoke an acute inflammatory response (gouty arthritis), chronic low-grade inflammation (tophus formation) or degenerative changes, most often in bones and joints. In acute gouty inflammation, phagocytosis of urate crystals by neutrophils plays a central role, but this clinically observable interaction is preceded by activation of resident cells in the synovium with release of proinflammatory cytokines (TNFα, IL-1, IL-6, IL-8) and chemokines [1].

### Diagnostic Principles

An absolute diagnosis of gout requires demonstration, most often by polarized light microscopy, of urate crystal deposition. This is usually achieved in samples obtained by needle aspiration of synovial fluid from an actively or previously affected joint or by aspiration from a tophus.

### Therapeutic Principles

Pharmacological therapy [3] has three distinctive aims: (i) reduction of acute gouty inflammation by anti-inflammatory agents (NSAIDs, colchicine, corticosteroids), (ii) prophylaxis of acute attacks (colchicine, NSAIDs) and (iii) reversal of hyperuricemia (xanthine oxidase inhibitors, uricosuric agents). Dietary management of hyperuricemia with a low purine diet is usually of marginal benefit, but weight reduction, reduction of meat and seafood intake and restriction of alcohol use (particularly beer) demonstrably lessen the risk of gout. Surgery to remove functionally limiting or infected tophi is occasionally needed.

# Graft-Versus-Host Disease

Hanneke M. Van der Straaten,
Leo F. Verdonck
Department of Hematology, University Medical Center Utrecht, Utrecht, The Netherlands

## Synonyms

Graft versus host reaction; GVHD

## Definition and Characteristics

A complex pathophysiological process in which T-cells from the donor initiate an immunological attack on cells and tissues of the recipient.

*Types*: GVHD can be divided into acute GVHD, defined to occur up to 100 days after transplantation and chronic GVHD that continues from day 100 on. The skin, liver and gut are principally involved in acute GVHD, whereas chronic GVHD can affect almost any organ, although GVHD of the skin is the most frequent manifestation in both acute and chronic GVHD.

## Prevalence

GVHD occurs in 30–80% of recipients of allogeneic hematopoietic stem cell transplantations.

## Molecular and Systemic Pathophysiology

Graft-versus-host disease (GVHD) is a major complication of allogeneic hematopoietic stem cell transplantation (SCT). It occurs when transplanted donor derived T-lymphocytes recognize major or minor histocompatibility complex (MHC) proteins and their associated peptides expressed by recipient antigen presenting cells (APCs). The pathophysiology of GVHD, although its exact mechanism still needs to be clarified, involves three sequential phases. During the first phase the conditioning regimen, which is given before SCT, causes injury to the host environment. This results in activation of the immune system (afferent phase). The second phase consists of donor T-cell activation, proliferation and differentiation (afferent phase). Finally, in the third phase the donor T-cells (and NK-cells) cause a cellular and inflammatory, partly cytokine mediated attack, on host target tissues (efferent phase).

## Diagnostic Principles

Grading of GVHD is diagnosed clinically and confirmed pathologically by skin or mucosal biopsy and classified according to standard criteria.

## Therapeutic Principles

Standard treatment of both acute and chronic GVHD includes high dose steroids. If this treatment fails, a variety of treatments targeting T-cells or T-cell cytokines are administered to patients with either acute or chronic GVHD. However, when patients fail to respond to high dose steroids, the prognosis is generally very poor.

*Prevention*: GVHD can largely be prevented by a T-cell depleted graft. However T-cell depletion gives an increased risk of graft failure and is associated with an increased risk of relapse of the underlying malignant disease (graft vs. leukemia effect). A second way of preventing GVHD is the prophylactic administration of immunosuppressive drugs. Furthermore, both approaches can be combined. At present, prophylactic immunosuppressive treatment generally uses the combination of methotrexate and cyclosporine or mycofenolate mofetil and cyclosporine.

## δ-Granule Defects

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

### Synonyms

δ-storage pool deficiency; δ-storage pool disease; δ-SPD

### Definition and Characteristics

Bleeding diathesis due to abnormal platelet secretion induced by several agonists, impaired aggregation and decreased contents of dense granules in platelets. Defects are due to deficiency in the non-metabolic pool of adenine nucleotides contained in platelet δ-granules.

### Prevalence

Rare disease, but fairly common among patients with congenital abnormalities of platelet function (10–18%).

### Genes

Autosomal recessive in some families and autosomal dominant in others. In a family with the autosomal dominant form an association with acute myelogenous leukemia suggested that a gene involved in SPD would be located adjacent to a gene influencing the susceptibility to leukemia.
*Gene map locus*: unknown

### Molecular and Systemic Pathophysiology

δ-SPD platelets have decreased levels of δ-granule ATP, ADP, serotonin, calcium and pyrophosphate, representing the storage pool. Platelets normally store >90% of the bodies' serotonin, but the saturation levels are reduced in δ-SPD platelets. Platelet aggregation studies with different agonists may vary substantially among patients, with about 25% of patients with a normal response to ADP and only 33% with a typical secretion defect. Specific defects in aggregation and stabilization of aggregates have been observed. The interaction of δ-SPD platelets with subendothelium was impaired in an ex vivo flow model [1]. Defects in prothrombinase activity have not been consistently reported.

*Clinical Features*: Patients have a mild to moderate bleeding diathesis indicated by mucocutaneous bleeding, easy bruising, post-surgical bleeding in severe cases. Only one case of intracranial bleeding has been reported.

### Diagnostic Principles

Characterized by bleeding diathesis of variable degree and a mild to moderate increase in bleeding time. Platelet studies show abnormal secretion to different agonists, decreased platelet content of total ADP and ASTP, increase in the ratio ATP/ADP >2.5–3.0 and normal serum levels of thromboxane B2. In addition, decreased content of dense granules by fluorescent probes of electron microscopy can be assessed.

### Therapeutic Principles

Supportive care.

## Granulocytosis

►Neutrophilia

## Granuloma Annulare

Martin Mempel, Dietrich Abeck
Department of Dematology and Allergology, Technische Universitæt Munich, Munich, Germany

### Definition and Characteristics

Benign granulomatous inflammation of the skin of unknown origin. Typically, ring shaped non-itching infiltrated erythemas are seen. Clinically, two forms

have to be discriminated: Localized granuloma annulare is typically seen in young children and predominately affects the distal extremities. It is usually self-limiting and not associated with systemic conditions. Disseminated granuloma annulare is more often seen in adult patients. In this particular condition involvement of the proximal extremities and the trunk with exanthematous presentation of small red papules is more common. The disseminated form seems to be associated with systemic conditions such as IDDM and HIV infection [1,2]. As a rare subtype perforating granuloma annulare has been described.

*Histopathology*: The granulomatous infiltrate in granuloma annulare is usually found in the dermis. Palisading mononuclear cells are seen around degraded collagen fibers and mucin infiltrates representing foci of necrobiosis. These infiltrates are surrounded by and mixed with T-lymphocytes, predominately of the CD4-type [3].

## Prevalence

Granuloma annulare is a common eruption seen by the dermatologist. However, exact data on its prevalence are missing.

## Genes

A genetic association has not been identified so far.

## Molecular and Systemic Pathophysiology

Little is known of the exact etiopathogenic events leading to granuloma annulare. Most probably, skin specific T-cells which are activated and positive for pro-inflammatory cytokines are the crucial population of leucocytes leading to the formation of the typical GA lesion. These CD4-positive T-lymphocytes are positive for the type I cytokins IL2, IFNγ, and TNFα and thereby recruit further immunocytes such as non-specific T-cells, granulocytes and antigen-presenting cells into the skin [4]. A particular antigen within the necrobiotic infiltrate is discussed.

## Diagnostic Principles

In the majority of cases, the typical clinical presentation leads to the appropriate diagnosis. In cases of doubt, histopathological evaluation will usually give clear results. Differential diagnosis mainly includes granulomas of different origin such as cutaneous sarcoidosis, leprosy, foreign body granuloma but also profound mycosis.

## Therapeutic Principles

There is no gold standard for the treatment of granuloma annulare. The localized form is usually self limiting and requires only occasionally active therapeutic interventions. Local injections of corticosteroids, cryotherpay and occlusive tapes are used. The disseminated form often presents as rather refractory disease which requires various therapeutic strategies. Phototherapy including PUVA and UVA1 have been described [5]. Alternatively, fumaric acid, isotretinoin, dapsone, and hydroxychloroquine have been reported.

# Granuloma, Eosinophilic

Ismat Ghanem, Samer El Hage
Department of Orthopedic Surgery, Hotel-Dieu de France Hospital, Saint Joseph University, Beirut, Lebanon

## Synonyms

Langerhans' cell histiocytosis; Histiocytosis X; Hand-Schüller-Christian disease; LCH; Letterer-Siwe disease

## Definition and Characteristics

Langerhans' cell histiocytosis (LCH) is a non-neoplastic proliferative disease of unknown origin that may affect almost any organ [1]. It is a rare group of disorders with a wide spectrum of clinical presentations, from the mildest, a solitary eosinophilic granuloma (EG), to the most severe multisystem involvement. The hallmark of LCH in most patients is an osseous lesion. When the bone is the only organ involved, the disease is referred to as

eosinophilic granuloma. When more organs are affected by this granulomatous disorder, causing cranial lesions, diabetes insipidus and exophtalmos, it is referred to as Hand-Schüller-Christian disease. The disseminated and acute form of LCH is called Letterer-Siwe disease; it is more often seen in infants and children who are less than three years old and has the worse prognosis (Fig. 1). In skeletal LCH, almost any bone may be the site of origin. Epiphyseal involvement is exceptional. Two major prognostic factors have been identified in the medical literature of the last twenty years, age at the time of diagnosis and organ involvement [2,3].

## Prevalence

5/1,000,000 children aged between 1 and 15. It affects both genders with a slight male predominance (1.5:1) and predominates in children and young adults, although presentation in the older adult is not exceptional [2,3].

## Molecular and Systemic Pathophysiology

The Langerhans' cell (LC) is part of the reticuloendothelial system. Bone marrow gives birth to the Langerhans' cell precursor under the influence of the granulocyte macrophage colony stimulating factor (GM-CSF) and tumor necrosis factor α (TNFα). This circulating LC precursor expresses CD1a, a mature LC specific marker, but doesn't contain Birbeck granules; it will become located in epithelia where it will acquire the characteristics of the LC, both Birbeck granules and the CD1a antigen. In the normal subject, the LC is located in the supra-basal region of the stratified squamous epithelium of the skin and mucous membranes, but also in transitional epithelium, such as in the bronchi, esophagus and colon. The LC plays a standby function in the immune system. Along with the CD1a antigen, LCs express on their surface molecules of class II of the major histocompatibility complex (MHC). They capture non-self antigens to which they are exposed, process them through internalization and fragmentation to finally associate them with MHC class II molecules before migrating via the lymphatic route to the paracortical T zone of lymph nodes. In EG, an inflammatory pattern is seen, with the presence of eosinophils (hence the denomination "eosinophilic granuloma"), lymphocytes and macrophage cells, which are sometimes multinucleated. The granuloma progresses in three phases [3,4]:

- A *proliferative phase*, during which there is a proliferation of mononucleated LC expressing the CD1a antigen
- A *granulomatous phase* with appearance of zones of necrosis and accumulation of leukocytes
- A *xanthomatous phase* characterized by gradual replacement of the granuloma by fibrous tissue, with lipid accumulation in the mononuclear cells, which express less and less CD1a antigen. This is why pathologists talk about a "mature" form of EG in the advanced cases of LCH.

**Granuloma, Eosinophilic. Figure 1** Eosinophilic granuloma of the ilium in a 2-year-old child.

## Diagnostic Principles

Patients with EG may present with a variety of symptoms including pain, lump, serous ear discharge, limping, pathological fracture or neurological signs. The typical radiographic appearance is a well defined, punched out, destructive radiolucent oval area with varying sizes in the spongiosa, with or without mild peripheral sclerosis, and with periosteal new bone formation and varies depending on the site of involvement, the stage of evolution and skeletal or multiorgan involvement. MRI is excellent for analyzing the three dimensional expansion of the tumor in the marrow and the neighboring soft tissues, as well as for staging. CT scan is used to evaluate the extent of bone involvement in some particular areas such as the skull, spine, pelvic and shoulder girdles. Bone scan has a high false negative rate in this disease and is therefore of little value in the imaging of bony lesions of LCH. Biopsy is essential to confirm diagnosis. The "Writing group of the Histiocyte Society" has established histological criteria essential for the diagnosis [5]:

- *Presumptive diagnosis*: very explicit aspect on pathology.
- *Clear diagnosis*: very explicit aspect on pathology with at least two of the following criteria:
  - ATPase positive
  - Protein S-100 positive

- D-mannosidase positive
- Fixation of peanut lectin

- *Obvious diagnosis*: Birbeck granules in electronic microscopy or positive staining of CD1.

### Therapeutic Principles

Compared to the usually benign and spontaneously regressive evolution of isolated bony lesions (EG), the prognosis of disseminated forms, whether acute, sub-acute or chronic (especially LS disease) is much less favorable. Many treatment modalities have been described in the literature, involving both orthopedic surgeons and hemato-oncologists, with sometimes a tendency toward over-treatment and a subsequent significant rate of complications. The natural history of solitary EG is ordinarily favorable, whether spontaneously or following a simple biopsy/curettage [4]. The most devastating complications are bone fragilization and neighboring soft tissue invasion. The use of heavy therapeutic modalities is unreasonable given the relatively benign evolution. The course of Hand-Schüller-Christian disease is less favorable than that of EG and often mandates the utilization of heavy chemotherapeutic regimens, with variable efficiency and definite local and systemic iatrogenic complications [4]. Treatment of Letterer-Siwe disease is systemic (steroids and chemotherapy) but the natural history remains disappointing, and the complication rate high [4].

## Granulomatous Arteritis

►Vasculitis, Large Vessel

## Granulomatous Colitis

Johannes G. Bode
Department of Gastroenterology, Hepatology and Infectiology, University-Hospital, Heinrich-Heine University Duesseldorf, Duesseldorf, Germany

### Definition and Characteristics

The term granulomatous colitis describes a typical histological pattern of granulomatous inflammation. Characteristic feature of granulomatous inflammation is the development of a more or less demarked nodule formed by macrophages or their descendants such as epitheloid or giant cells (=granuloma).

### Prevalence

The incidence depends on the respective origin of the granulomatous colitis. The incidence e.g. of Crohn's disease shows geographic and ethnic variations with a frequency of 6–7 per 100,000 in central Europe. The incidence of tuberculosis, which might occasionally also cause a granulomatous colitis/enteritis, is approximately 12 per 100,000 whereas the incidence of other causes of granulomatous colitis such as chronic granulomatous disease is less than 0.5 per 100,000.

### Genes

Underlying gene defects have been described particularly in the context of Crohn's disease, chronic granulomatous disease and other hereditary disorders associated with the development of granulomatous colitis.

Chronic granulomatous disease is due to loss of function mutations in the genes encoding the different subunits of the NADPH oxidase (gp91(PHOX) (76%), p47(PHOX) (18%), p67(PHOX) (4%), and p22 (PHOX) (3%). Detailed molecular descriptions of mutations in X-linked and autosomal recessive chronic granulomatous disease have been published.

Mutations within the NOD2 gene (also referred to as CARD 15) have been associated with an increased risk of Crohn's disease. Furthermore, mutations in the genes OCTN1 (a transporter of small cationic molecules) and DLG5 (a so-called scaffolding protein) correlate with an increased risk for the development of inflammatory bowel disease.

Mutations within the glucose 6 phosphate translocase gene is responsible for glycogen storage disease type 1.

### Molecular and Systemic Pathophysiology

The pathophysiology of granulomatous colitis depends on the type of the underlying disorder (see Table 1).

**Granulomatous Colitis. Table 1** Etiological categories of the different disorders which might cause granulomatous colitis

Common feature is the formation of granuloma as a special manifestation of chronic inflammation [1,2].

The pathogenesis of Crohn's disease is unclear. Basically two major themes have been evolved: (i) dysregulation of an otherwise normal immune system directed against luminal bacteria or their products found in the intestinal lumen. (ii) intrinsic alterations in mucosal barrier function leads to the induction of an immune responses to organisms in the intestine which normally do not elicit a response. This could be due to e.g. impaired expression of host antimicrobial peptides as e.g. α- or β-defensines allowing an enhanced invasion of intestinal microbes into the mucosa.

In the case of tuberculosis granuloma formation occurs as an expression of the immune response against mycobacteria, particularly mycobacterium tuberculosis, africanum or bovis. Other infectious causes of granulomatous colitis are pathogenic Yersinia species, salmonella and campylobacter species. In rare instances parasitic infections may also lead to granulomatous inflammation of the colon (e.g. schistosomiasis and anisakiosis).

Chronic granulomatous disease is a hereditary disorder which can be associated with the development of a granulomatous colitis [3]. It encompasses a heterogeneous group of disorders characterized by genetic defects mainly localized within the genes encoding the different subunits of the NADPH-oxidase, impairing the ability of phagocytes to generate reactive oxygen intermediates from molecular oxygen. These defects manifest primarily as an immunodeficiency resulting in frequent, severe bacterial infections. Moreover, these patients are prone to the formation of excessive granulomata, which may, if located in the gastrointestinal tract give rise to symptoms suggestive of inflammatory bowel disease.

Another rare hereditary disorder which has been reported to be associated with the development of granulomatous colitis is the Hermansky-Pudlak syndrome [4], a collection of related autosomal recessive disorders characterized by oculocutaneous albinism and platelet storage disease. Moreover granulomatous colitis is occasionally associated with glycogen storage disease type 1b [5].

## Diagnostic Principles

Ileo-colonoscopy including biopsy is the cornerstone of the diagnosis of granulomatous colitis. Biochemical parameters and a blood picture should be assessed, particularly leukocyte/neutrophile count, ESR and CRP and with respect to glycogenosis lactic acid, serum levels of glucoses and triglycerides should be determined. Microbiological examination of the stool or of biopsies should be performed to rule out an infectious cause such as tuberculosis. Chronic granulomatous disease is proven by detection of impaired NADPH oxidase function and subsequently altered production of reactive oxygen species. The diagnosis of a glycogenosis is confirmed by DNA testing for common mutations within the glucose 6-phosphate translocase gene and enzyme analysis.

## Therapeutic Principles

Infectious causes of granulomatous colitis have to be treated with an appropriate antibiotic treatment, if

feasible adapted to a respective resistogram. Patients with Crohn's disease but also those with granulomatous colitis due to hereditary disorders should be primarily subjected to an immunosuppressive or immunomodulatory therapeutic strategy adapted to the extent and the severity of the disease. In the case of chronic granulomatous disease bone marrow transplantation after an ablative radiochemotherapy has been proven to be effective.

## Synonyms

CGD

## Definition and Characteristics

Chronic granulomatous disease (CGD) is associated with defective phagocyte intracellular killing that is manifested clinically by recurrent, severe bacterial and fungal infections often beginning during infancy [1]. These infections typically consist of cutaneous and hepatic abscesses, lymphadenitis, pneumonia and osteomyelitis. The most common infectious organisms seen in CGD include Staphylococcus aureus, Serratia marscesens, Burkholderia cepacia complex, Aspergillus species, and Nocardia species. Patients also develop diffuse granulomatous lesions in hollow viscera that may result in obstruction of the genitourinary and/or gastrointestinal tracts.

## Prevalence

Estimated to be ~1 in 200,000 live births, but may be higher.

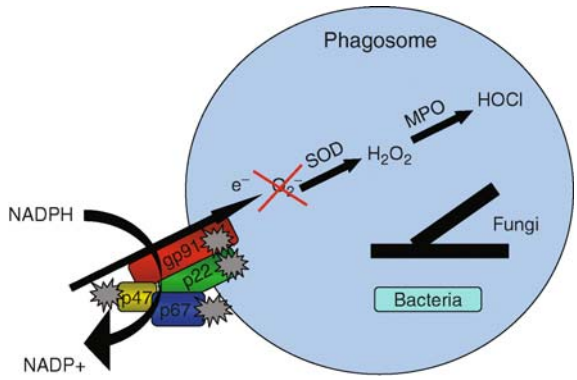
## Genes

CYBB encodes the 91 kD membrane bound protein $gp91^{phox}$ (phagocyte oxidase), CYBA encodes the 22kD membrane bound protein $p22^{phox}$, NCF1 encodes the 47 kD cytosolic protein $p47^{phox}$, NCF2 encodes the 67kD cytosolic protein $p67^{phox}$.

## Molecular and Systemic Pathophysiology

CGD is an inherited set of disorders caused by a defect in one of four structural protein components of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase system [1]. Two of these components form a membrane bound heterodimeric cytochrome $b_{558}$ embedded in the secondary granule consisting of a glycosylated heavy chain, $gp91^{phox}$ and a light chain, $p22^{phox}$ (Fig. 1).

The other two affected components are found in the cytosol, and consist of $p47^{phox}$ and $p67^{phox}$ (Fig. 1). Two additional non-structural cytosolic components consist of a 40 kd protein ($p40^{phox}$) and the GTP binding protein, Rac. Following neutrophil activation the secondary granule fuses with the phagolysosome assembling the complete NADPH oxidase complex on the



**Granulomatous Disease, Chronic. Figure 1**
Neutrophil oxidative burst. Schematic drawing of the structural proteins comprising NADPH oxidase and the generation of the oxidative burst following neutrophil activation in the process of intracellular killing of phagocytosed bacterial or fungal organisms. A defect in any of these four proteins prevents the generation of reactive oxygen species and interferes with the effective killing of microorganisms.

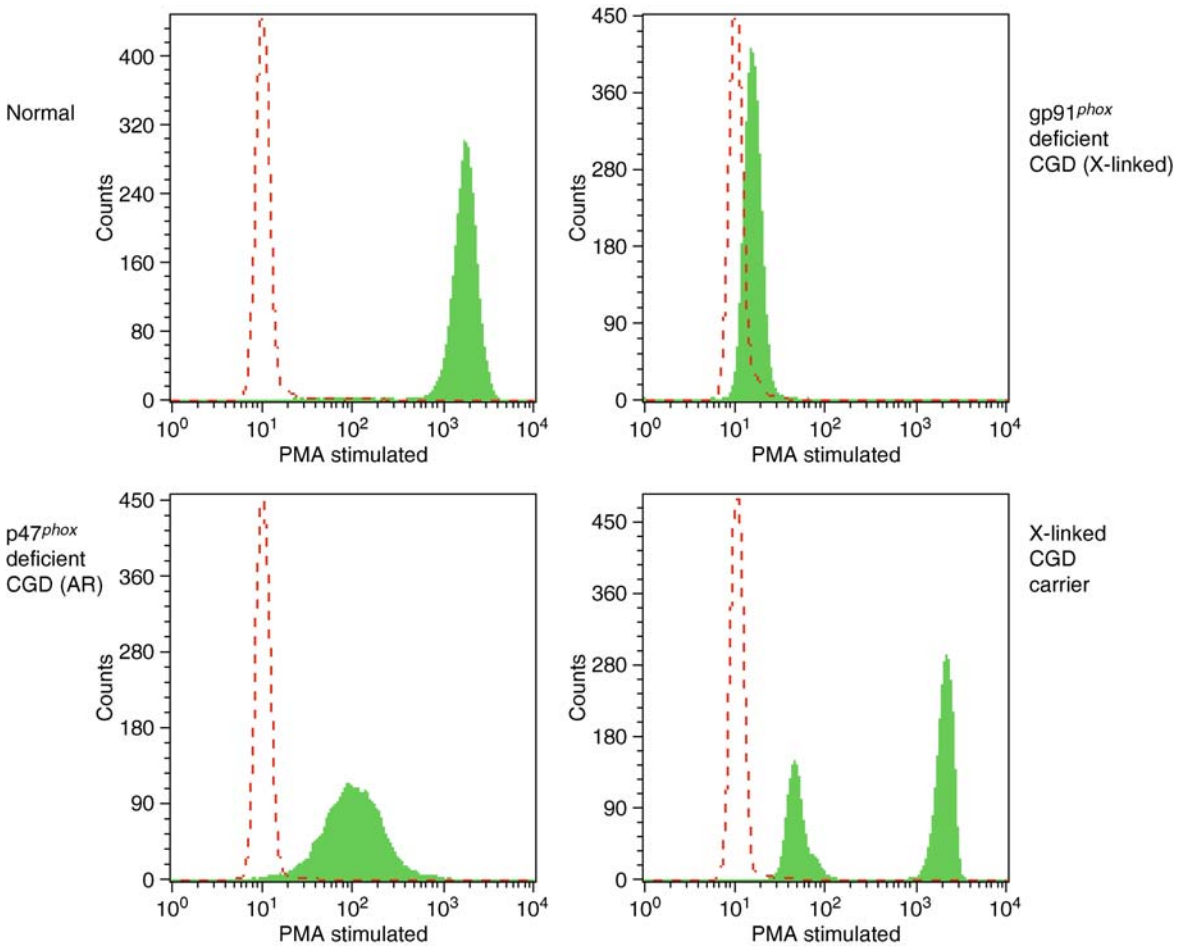
phagolysosome membrane and transferring electrons to molecular oxygen and generating superoxide and other reactive oxygen species. Recently it has been demonstrated that the generation of superoxide activates primary granule proteins that mediate the killing of microorganisms within the phagolysosome [2]. When one of the structural proteins is defective, the NADPH oxidase system does not function normally leading to a failure in the production of superoxide (Fig. 1). This results in ineffective bacterial and fungal killing and sets the stage for the recurrent and chronic infections seen in CGD.

DNA sequencing has documented that mutations in the gene encoding gp91$^{phox}$ lead to the X-linked recessive (XL) form of CGD, the most common CGD genotype (60–80%). The other forms of CGD are the result of autosomal recessive (AR) mutations in one the other three structural protein components, with p47$^{phox}$ deficiency being the most common (20–30%) of the AR cases. Deficiencies in p67$^{phox}$ and p22$^{phox}$ are infrequent and constitute <5% of CGD cases respectively. Patients with the p47$^{phox}$ deficiency form of CGD have a better prognosis than those with the X-linked recessive form of CGD [3].

## Diagnostic Principles

The diagnosis of CGD can be established with a variety of screening tests for NADPH oxidase activity including the dihyrorhodamine-123 (DHR) (Fig. 2) flow cytometry assay, the nitroblue tetrazolium reduction test (NBT), a chemiluminescence test (with luminol) and the ferricytochrome c reduction assay [1].

In addition, specific testing for the four protein components of NADPH oxidase can be done by immunoblotting to further characterize the defect.



**Granulomatous Disease, Chronic. Figure 2** Histograms of DHR flow cytometric assays. Unstimulated neutrophils (*dotted red lines*) and PMA stimulated neutrophils (*solid green tracings*) from a control subject (*upper left panel*), an X-linked CGD patients (*upper right panel*), an AR p47phox deficient CGD patient (*lower left panel*) and maternal carrier of X-linked CGD (*lower right panel*). Patient tracings demonstrate the defective oxidative burst in CGD while the maternal carrier tracing demonstrates two cell populations representing neutrophils with a normal *CYBB* gene and neutrophils with a mutant *CYBB* gene.

Finally, the definitive diagnosis can be established by mutation analysis based on the specific gene sequencing focused on the four structural protein components of NADPH oxidase

### Therapeutic Principles

The current management approach in CGD patients focuses on optimizing the prevention of infections as much as possible based on using prophylactic antibiotics and antifungals (daily trimethoprim-sulfamethoxazole and itraconazole) [1]. In addition, a double blind study established that three times weekly interferon gamma given subcutaneously improved the clinical outcome in CGD, decreasing the number and severity of infections by 70% [1]. Providing good skin care and avoiding situations that expose the CGD patient to problematic pathogens such as Aspergillus species (working with mulch, raking leaves) is also an important part of the clinical management in CGD. The other main axiom of management is to treat all infections early and aggressively including surgical drainage of deep-seated abscesses. The combination of prophylactic therapies along with aggressive management of infections has dramatically improved the prognosis of CGD patients. The therapy of granulomas relies primarily on corticosteroid therapy moving to low dose and alternate day therapy as quickly as possible. Currently, the only curative therapy for CGD is a stem cell (bone marrow) transplantation [4]. However, there is the potential for serious toxicity from this approach and it remains unclear as to which patients should be considered for stem cell transplantation. A very small trial of gene therapy in CGD demonstrated evidence of correction but it is too early to conclude if this is a durable or viable form of curative therapy in CGD at this juncture [5].

## Granulomatous Myopathy

►Granulomatous Myositis

## Granulomatous Myositis

Bennett Myers[1], David Herrmann[2]
[1]Dent Neurological Institute, Orchard Park, NY, USA
[2]Departments of Neurology and Pathology, University of Rochester, Rochester, NY, USA

### Synonyms

Granulomatous myopathy

### Definition and Characteristics

Granulomatous myositis is a term that encompasses inflammatory myopathies of diverse etiologies, which share as a common feature granulomas on muscle biopsy. The two most common forms are those associated with sarcoidosis and cryptogenic granulomatous myositis, but other rare etiologies and associations include vasculitides (Wegener's granulomatosis), connective tissue disorders (rheumatoid arthritis), inflammatory bowel disease (IBD), infections (tuberculosis, syphilis) and paraneoplastic overlap syndromes related to thymomas (e.g. thymoma with a variable combination of myasthenia gravis, granulomatous myositis, myocarditis and thyroiditis or thymoma with granulomatous myositis, primary biliary cirrhosis and pancytopenia) [1,2]. The specific clinical features of sarcoid-associated granulomatous myositis are covered in a separate chapter (see sarcoid myopathy). The cryptogenic form may differ from the sarcoid-associated form by having more distal muscle involvement, although it more commonly is predominantly proximal. The cryptogenic form may also be less responsive to corticosteroid therapy than the sarcoid form [3].

### Prevalence

Sarcoidosis is the most common cause of granulomatous myositis. Sarcoidosis has a prevalence of 40 per 100,000 [4]. Among sarcoid patients, 50–80% will have granulomas on random muscle biopsy, while only 1.42.3% of all sarcoid patients will have a symptomatic sarcoid myopathy. The prevalence of cryptogenic granulomatous myopathy has not been established, while the other reported forms are very rare and limited to case reports and small series in the literature.

### Genes

Sarcoidosis is associated with class I HLA-B8 and class II HLA-DR3 in Eastern Europeans and with HLA-Dw52 in Japanese [4]. No HLA or other genetic associations have been reported with the cryptogenic variety.

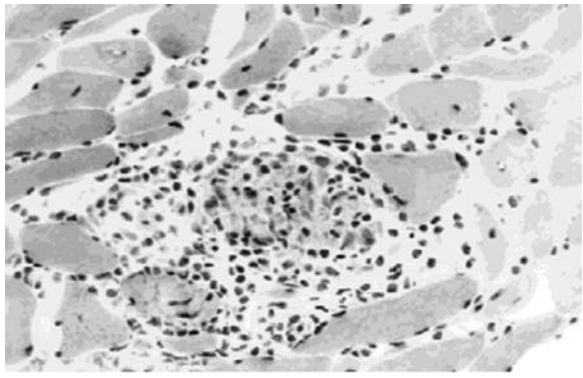
## Molecular and Systemic Pathophysiology

The pathophysiology of granulomatous myositis is determined by its underlying cause. In the case of infectious etiologies, the granuloma formation is a direct response by the immune system to invasion of the muscle by the pathogen. The underlying immune system dysfunction in connective tissue disease- and vasculitides-associated granulomatous myopathies results in granuloma formation, and in some instances, in direct attack on the muscle fibers themselves [5]. In most instances of granulomatous myositis, muscle fiber injury is thought not to be due to a direct attack by the immune system, but instead to be a secondary "bystander" effect of interferon-gamma, interleukin-2 and other Th1 cytokines and pro-inflammatory factors, which both cause the formation of, and are released by, the granulomas or to be due to direct mechanical effects of the granulomas. The common finding of endomysial chronic inflammation primarily composed of lymphocytes and plasma cells and/or foci of chronic perivascular inflammation separate from any granulomas suggests that direct mechanical effects can only be partially responsible for observed muscle damage.

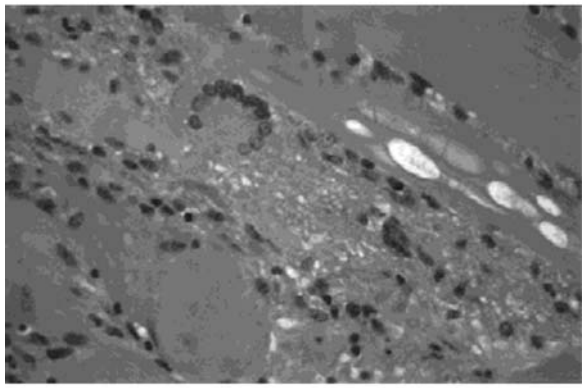
The granulomas in sarcoid-associated and cryptogenic granulomatous myositis are pathologically indistinguishable. They are composed of infiltrating mononuclear cells, which are predominantly T lymphocytes and activated macrophages, as well as multinucleated giant cells [5]. The T cells are arranged so that the CD4 helper cells are at the center of the granuloma and the less numerous CD8 cells are at the periphery. Multinucleated giant cells, the hallmark of granulomas, are identified by their histological appearance and positive immunostaining for lysozyme and α 1-antichymotrypsin, with negative desmin and myoglobin immunocytochemistry [5] (Fig. 1).

## Diagnostic Principles

Features suggestive of a granulomatous myositis include weakness that may be painful without sensory abnormalities, elevated CPK or aldolase levels and needle EMG that demonstrates increased insertional activity, abnormal spontaneous activity, short duration, polyphasic and low amplitude motor unit action potentials and early recruitment. Identification of granulomas on muscle is required for diagnosis of granulomatous myositis. Pathologically, sarcoid associated and cryptogenic granulomatous myositis are identical, making the presence or absence of other organ involvement by sarcoidosis the key to clinically differentiating the two conditions. The other, less common forms of granulomatous myositis are identified by other clinical features indicative of the underlying condition (as in the vasculitides, IBD and thymoma associated overlap syndromes) or on pathological features of the muscle biopsy (demonstrating the presence of an infectious agent).



a



b

(b) Muscle fiber degeneration, an endomysial mononuclear cell infiltrate and Langhans-type giant cell formation. H&E, magnification × 230.

## Therapeutic Principles

The treatment of granulomatous myositis is influenced by the underlying etiology, when a systemic disorder is present. Oral corticosteroids are the mainstay of therapy in cryptogenic granulomatous myositis, with other forms of immunosuppression, such as cyclosporine, azathioprine, methotrexate, cyclophosphamide and chlorambucil, being reserved for resistant cases or as steroid-sparing agents [4]. Thymectomy is performed in conjunction with immunotherapy when a granulomatous myositis occurs in the setting of thymoma. The prognosis of thymoma-associated granulomatous myositis has historically been poor [1]. The treatment of sarcoid myopathy is reviewed in a separate chapter (see ►Sarcoid Myopathy).

# Graves' Disease

Zaki Kraiem[1], Yaron Tomer[2], Terry F. Davies[3]
[1]Faculty of Medicine, Technion, Haifa, Israel
[2]Division of Endocrinology, University of Cincinnati, Cincinnati, OH, USA
[3]Division of Endocrinology, Mount Sinai School of Medicine, New York, NY, USA

## Synonyms

Basedow's disease

## Definition and Characteristics

Graves' disease is an autoimmune thyroid disease characterized by biochemical and physiological manifestations of increased levels of thyroid hormones (hyperthyroidism) [1–3]. The clinical definition requires the additional demonstration of diffuse thyroid gland activity by radioiodine scanning or ultrasound. Circulating autoantibodies specific to hyperthyroid Graves' disease behave as thyroid stimulating antibodies, binding to epitopes in the extracellular domain of the thyrotropin (TSH) receptor of thyroid cells and mainly activating adenylate cyclase and the cAMP-protein kinase A and C cascades. These antibodies not only induce thyroid hormone hypersecretion, but also hypertrophy and hyperplasia of the thyroid follicles, resulting in a characteristic diffuse goiter. Graves' disease also affects the eyes (Graves' ophthalmopathy) and, occasionally, the skin (localized dermopathy, or pre-tibial myxedema). The thyroid in Graves' disease is characterized by a non-homogeneous lymphocytic infiltration with an absence of follicular destruction. Although the intrathyroidal lymphocyte population is mixed, the majority are T lymphocytes. However, it is the intrathyroidal plasma cells which are a major source of autoantibodies, with important contributions from the cervical lymph nodes and bone marrow.

## Prevalence

One of the most common of thyroid diseases, and the most common cause of hyperthyroidism in areas of iodine abundance. Surveys in England and the United States indicated a prevalence of about 2% in women and a prevalence about one tenth as frequent in men.

Graves' disease is most common in the third and fourth decades of life, occurs in the elderly and is rare before the age of 10 years. Thyroid enlargement is the most common manifestation of the disease but on occasion may be absent, particularly in men. The signs and symptoms usually begin gradually and the most common are nervousness, palpitations, fatigue, heat intolerance, weight loss and ophthalmopathy. Exacerbation of these manifestations of thyrotoxicosis is known as accelerated hyperthyroidism or thyroid storm.

## Genes

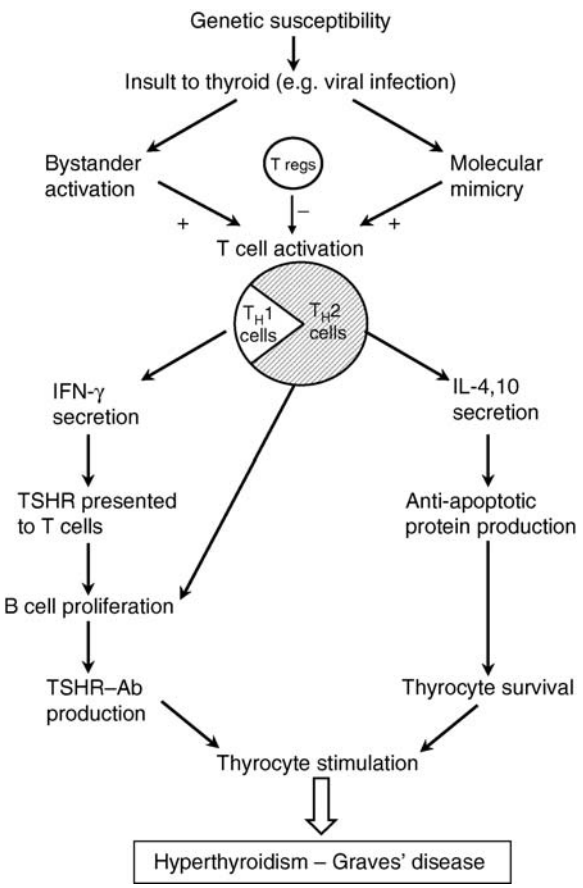
Predisposition to Graves' disease is determined by a combination of genetic susceptibility, environmental factors and an endogenous distinctive immune repertoire [4]. Some Graves' disease susceptibility genes are most likely immune modifying genes which increase the susceptibility to autoimmunity in general (e.g. HLA, CTLA-4, CD40), while others may be specific to Graves' disease (e.g. thyroglobulin, TSH receptor). Chief amongst the risk factors is the female sex and this may be due to epigenetic phenomena such as X chromosome inactivation (XCI), and/or the modulation of the autoimmune response by sex steroids. Additionally, pregnancy itself (via maternal microchimerism and/or postpartum Graves' hyperthyroidism) contributes to the this marked sex difference in disease presentation. Other putative risk factors include: infection, emotional stress, iodine and iodine-containing drugs, cigarette smoking and radiation.

## Molecular and Systemic Pathophysiology

In genetically susceptible persons, mostly women (in a 5:1 ratio or greater), thyroid-specific T cells become activated and secrete cytokines which stimulate B cells to produce TSH receptor-stimulating antibodies which then cause hyperthyroidism. The two major mechanisms prevailing regarding the mechanisms of activation of thyroid-specific T cells are molecular mimicry (specificity crossover) and bystander activation [1–3]. Structural similarity (specificity crossover) between a bacterial or viral infectious agent and an intrathyroidal antigen could cause activation of thyroid antigen-specific T cells. In the bystander hypothesis, an intrathyroidal insult, such as a viral infection, could stimulate production of interferon-γ and other cytokines (e.g. interleukin-1, tumor necrosis factor-α) by non-thyroid specific infiltrating (bystander) T cells. This, in turn, would induce thyroid follicular cells to express HLA class II molecules, allowing these cells to present thyroid autoantigens, such as the TSH receptor, to T cells. Activated by such a mechanism, as well as by costimulatory molecules (e.g. CD28), these thyroid

antigen-specific T cells would induce B cell proliferation and production of TSH receptor-stimulating antibodies, resulting in the hyperthyroidism observed in Graves' disease (Fig. 1).

An attractive, recent hypothesis has suggested that the fate of thyrocytes in autoimmune disease is dictated by the composition of infiltrating T cells [5]. The type of T cells which predominate, in turn, regulate which cytokines are produced and the cytokines, in turn, determine, via a balance between pro-apoptotic and anti-apoptotic proteins expressed, thyroid cell survival or suicide. Infiltrating T helper 1 ($T_H1$) cells produce cytokines which tip the balance in favor of pro-apoptotic proteins, leading to a cell suicide pathway and thyroid tissue destruction and consequent hypothyroidism characteristic of Hashimoto's thyroiditis. In contrast, in Graves' disease infiltrating T helper 2 ($T_H2$) cells induce a cytokine profile favoring thyrocyte survival and stimulation, and thus hyperthyroidism. Additionally, regulatory T cells (CD4+, CD25+) have a profound influence on T cell activation and have been found to be less effective in a wide variety of autoimmune diseases including those of the thyroid gland.



**Graves' Disease. Figure 1** Immunopathogenesis of Graves' disease.

It is believed that Graves' ophthalmopathy and dermopathy result from an autoimmune response to a common autoantigen(s) located in the thyroid and orbit (and skin). The currently favored candidate antigen is the TSH receptor expressed in fibroblasts and adipocytes. Regardless of the nature of the self-antigen causing the local accumulation of lymphocytes, the subsequent events in the pathogenesis of Graves' ophthalmopathy and dermopathy appear to be cytokine-mediated activation of fibroblasts, resulting in secretion of glycosaminoglycans by these cells and osmotic attraction of water, ultimately leading to enlargement and disruption of orbital muscle and increased adipose tissue. This leads to the characteristic clinical signs of proptosis and pretibial myxedema.

## Diagnostic Principles

This is based on the clinical and biochemical manifestations of hyperthyroidism. The serum TSH level, when measured using a sensitive immunoassay, is almost totally suppressed and serum free thyroid hormone [thyroxine ($T_4$) and triiodothyronine ($T_3$)] levels are increased. The assay of serum TSH receptor antibodies may be useful in confirming the diagnosis, severity and prognosis of Graves' disease.

## Therapeutic Principles

The ideal treatment for Graves' disease, correcting the underlying autoimmune process and restoring normal function of the thyroid and orbits, is not available. Existing therapies for both the hyperthyroid and ophthalmic manifestations are only palliative in that they may relieve but do not cure the disease. Current modalities of treatment consist of antithyroid drugs (inhibiting thyroid hormone synthesis), radioactive iodine (destroying thyroid tissue) and surgery (removing thyroid tissue) [1–3]. Radioactive iodine is the most favored definitive treatment but antithyroid drugs (Propylthiouracil, Methimazole) are often used as the initial choice. Treatment for the ophthalmopathy and dermopathy has traditionally been corticosteroid suppression of the immune response but (new immunomodulatory approaches e.g., Rituximab) are being evaluated.

# Gray Platelet Syndrome

James G. White
Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN, USA

## Synonyms

GPS

## Definition and Characteristics

The gray platelet syndrome (GPS) [1] is a rare, giant platelet disorder associated with thrombocytopenia (decreased number of platelets in circulating blood), and in some cases mild bleeding symptoms.

## Prevalence

GPS is an autosomal recessive disorder [1]. On rare occasions it may involve more than one member of the same family. As a result, cases of GPS appear sporadically, and when bleeding problems are mild or absent, the condition may not be diagnosed.

## Genes

The precise genetic defect responsible for the GPS has not been determined.

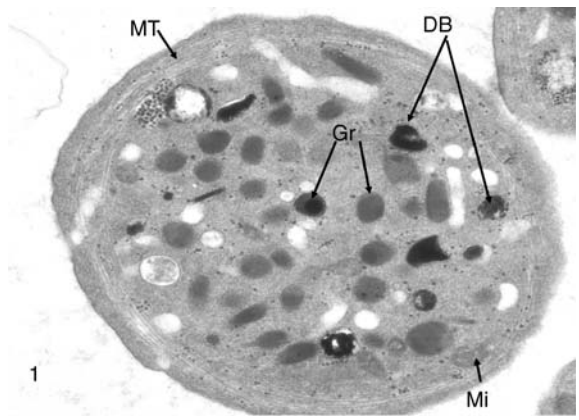
## Molecular and Systemic Pathophysiology

The basic defect in the GPS is found in bone marrow megakaryocytes, the parent cells of circulating platelets [2]. Molecules destined to be concentrated in alpha storage granules (α Gr) include platelet-specific secretory proteins synthesized only in megakaryocytes, platelet selective molecules that are synthesized by megakaryocytes and relatively few other cells and molecules not synthesized by megakaryocytes, but are taken up by the parent cell through channels of the demarcation membrane system, by channels of the open canalicular system of platelets and by vesicular trafficking. The alpha granules containing these substances develop from vesicles budding from the megakaryocytic trans-Golgi face. The vesicles ultimately fuse together to form the alpha granules in megakaryocyte cytoplasm. Alpha granule membranes formed from the vesicles and containing the platelet specific and platelet selective proteins form in large numbers and are 200–500 nm in diameter. As proteins are concentrated within them the alpha granules develop "structure linked latency", a characteristic feature of storage granules and lysosomes that prevents loss of their contents into the cytoplasm of the megakaryocyte and unstimulated platelet (Fig. 1).

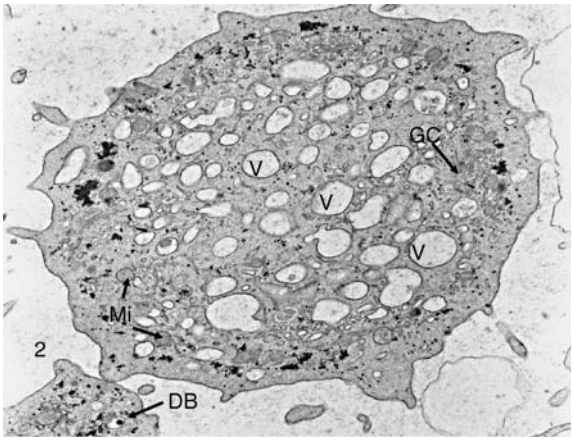
Alpha granules form in GPS megakaryocytes, but fail to develop structure linked latency. As a result their contents are almost completely lost before leaving the megakaryocyte and circulating platelets are nearly devoid of alpha granules [2]. Only swollen vacuoles remain in platelets as a sign that GPS megakaryocytes could form the organelles. It is uncertain how the defect in granule formation is related to development of giant platelets in the GPS. Despite the virtual absence of alpha granules and their large size, GPS platelets function reasonably well in vitro and in vivo. As a result patients with GPS seldom have significant bleeding problems, unless the thrombocytopenia associated with the giant platelet disorder is severe or the patient has an unrelated bleeding disorder (Fig. 2).

## Diagnostic Principles

The first patient found to have the GPS was referred because of a low platelet count (thrombocytopenia). Examination of Wright stained blood smears revealed large platelets that lacked granules in their cytoplasm [1]. They were relatively gray and that appearance led to the name of the disorder, the Gray Platelet Syndrome. There are other hypogranular platelet conditions that must be differentiated from the GPS, including the white platelet syndrome [3] and the medich giant



**Gray Platelet Syndrome. Figure 1** Thin section of normal human platelet viewed in the transmissions electron microscope. A circumferential coil of the microtubule (MT) lying just under the plasma membrane supports the cytoplasm contains many alpha granules (Gr), a few dense bodies (DB) and occasional mitochondria (Mi).



**Gray Platelet Syndrome. Figure 2** Thin section of Gray Platelet Syndrome platelet. Dense bodies (DB) and mitochondria (Mi) are present in their usual numbers, but alpha granules are absent. Only empty vacuoles (V) remain to indicate that alpha granules were formed in the parent cell (megakaryocyte), but their contents have leaked out into the bone marrow and circulation. A Golgi complex (GC) is also present in this large platelet.

platelet disorder [4]. Examination of thin sections of patient platelets in the electron microscope is essential for accurate diagnosis.

Recently, confusion has arisen regarding whether the GPS is a unique autosomal recessive disorder or may be a component of other genetic syndromes. Mori et al described the GPS in three generations of a family, concluding it was an autosomal dominant variant. However, close study of the electron micrographs presented in their publications revealed that family members had the White platelet syndrome [3], not GPS. Tubman and colleagues [5] have reported an X-linked gray platelet syndrome due to the GATA-1, Arg 216 Gln mutation. Males had a mild bleeding disorder, thrombocytopenia and large agranular platelets characteristic of the GPS. Obligate female carriers were asymptomatic, but had dimorphic platelets on peripheral blood smears. Their findings suggested that the X-linked thrombocytopenia with thalessemia is within a spectrum of disorders constituting GPS. Another recent investigation of platelets ultrastructural pathology in the X-linked recession GATA-1, G208S mutation revealed some hypogranular platelets in affected males similar to those in patients with GPS, but the majority were uniquely abnormal. Parallel membrane sheets were present in platelet cytoplasm as well as platelets in platelets and platelets attached to platelets making up a large percentage of the macrothrombocytes. The aberrations were clearly different from those found in the GPS. Study of obligate female carriers of the GATA-1 mutation revealed a significant number of giant platelets in all of them resembling those in affected males but different from individuals with the GPS. Thus, the GPS described by Raccuglia [1] appears to be a unique autosomal recessive giant hypogranular platelet disorder, different from all other giant hypogranular platelet syndromes.

### Therapeutic Principles

Bleeding problems are mild in patients with GPS. Therefore, radical treatments, such as bone marrow transplantation, are not necessary. Aspirin and non-steroidal anti-inflammatory agents are to be avoided. The patient should be blood typed and cross-matched for surgical procedures, and platelet transfusion available.

### Synonyms

Creatine deficiency syndrome; GAMT

### Definition and Characteristics

Autosomal recessive deficiency of creatine synthesis [1]. Main clinical manifestations include mental retardation and epilepsy. Extrapyramidal movement disorder and pathologic signal intensities in the basal ganglia (globus pallidus) are observed in some but not all patients. The degree of mental retardation is severe in most

patients with IQ's below 40 and severely delayed speech development. Autistic features and autoaggressive behavior are commonly observed. Epilepsy may be resistant to conventional drugs. Affected patients appear normal at birth and develop first symptoms within the first months of life [2].

## Prevalence

The true prevalence is unknown. Since the first description of GAMT deficiency in 1996, about 20 patients have been diagnosed worldwide [2].

## Genes

The human GAMT gene (OMIM # 601240) has been mapped to chromosome 19p13.3. The GAMT gene spans about 5 kb (genomic DNA: GenBank accession no. AF188893) and consists of six exons (cDNA: GenBank accession no. Z49878). GAMT [EC 2.1.1.2] is a cytosolic protein which is expressed ubiquitously with highest activities in liver and pancreas and lower in kidney. Apreciable amounts are also present in neuronal, ovary, Sertoli, and epididymal cells.

## Molecular and Systemic Pathophysiology

Creatine is synthesized mainly in liver, kidney and pancreas by two enzymatic reactions catalyzed by arginine:glycine amidinotransferase (AGAT) and by guanidinoacetate methyltransferase (GAMT). Creatine is transported via the blood stream to tissues including skeletal muscle and brain and taken up against a large concentration gradient via an active sodium dependent creatine transport system (CRTR). GAMT catalyzes the second of the two reactions in creatine biosynthesis, effecting synthesis of creatine and *S*-adenosylhomocysteine from guanidinoacetate and *S*-adenosylmethionine.

Deficiency of GAMT activity results in deficiency of creatine and accumulation of guanidinoacetate mainly in brain and body fluids. Deficiency of creatine in the brain results in loss of capacity of the creatine/creatine-phosphate system to store and transmit phosphate bound energy. Guanidinoacetate is an epileptogenic neurotoxic substance, and its accumulation is a significant factor in the pathogenesis of GAMT deficiency. In the affected patients, point mutations, deletions and insertions resulting in missense or framshift of the GAMT gene have been described. However, no correlation between the severity of the clinical phenotype and the type of mutation could be established [2]. Studies in a GAMT deficient knock out mouse have contributed to the elucidation of the pathogenetic role of guanidinoacetate in human GAMT deficiency [3,4].

## Diagnostic Principles

Accumulation of guanidinoacetate is pathognomonic of GAMT deficiency. Therefore determination of this compound in urine, plasma and/or CSF is diagnostic. Methods for determination of guanidinoacetate are mainly based on gas chromatography – mass spectrometry and tandem masspectrometry. Additional diagnostic hints are deficiency of creatine/creatine phosphate in the brain as determined by in vivo proton magnetic resonance spectroscopy, and abnormally low urinary creatinine excretion which is directly proportional to the intracellular body creatine pool. Diagnosis is confirmed by mutation analysis. Determination of GAMT activity is possible in fibroblasts and virus transformed lymphoblasts [5]. So far, no experience is available with prenatal diagnosis.

## Therapeutic Principles

Oral substitution of creatine corrects brain creatine deficiency and leads to considerable clinical improvement. A significant reduction of guanidinoacetate accumulation is effected by additional dietary restriction of arginine, which is the main substrate for guanidinoacetate formation, and by supplementation of ornithine. It is not known so far, if early recognition (e.g., by newborn screening) and presymptomatic treatment might lead to a better outcome.

# Guillain-Barré Syndrome and Variants

Guido Stoll, Klaus V. Toyka
Department of Neurology, University of Wuerzburg, Wuerzburg, Germany

## Synonyms

GBS

## Definition and Characteristics

The Guillain-Barré (-Strohl) syndrome (GBS) is an acute areflexic paralytic peripheral neuropathy. GBS follows identifiable respiratory tract or gastrointestinal infections in about 65% of cases and is probably caused by an autoimmune attack to myelin or axolemma components triggered by molecular mimicry during host defense against infections [1]. GBS encompasses at least four sub-entities, acute inflammatory demyelinating polyradiculoneuropathy (AIDP), acute motor axonal neuropathy (AMAN), acute motor and sensory axonal neuropathy (AMSAN) and Miller Fisher's syndrome (MFS) [2]. AIDP, AMAN and AMSAN share the common features of an acutely developing paresis of more than one limb due to nerve affliction, hypo- or areflexia with minor or no sensory involvement, deterioration over less than 4 (-6) weeks and subsequent spontaneous cessation of the underlying immune process leading to complete or partial recovery. MFS is characterized by the triad of acute ophthalmoplegia, ataxia and areflexia. A purely sensory or autonomic counterpart of GBS exists.

## Prevalence

Incidence in the general population is 1.2–1.9 cases/100,000. In Europe and North America AIDP grossly prevails over AMAN, while the opposite is the case in China. MFS accounts for less than 5% of all GBS cases.

## Genes

No definite relation between HLA and T-cell receptor gene polymorphisms and susceptibility to GBS has been shown.

## Molecular and Systemic Pathophysiology

Histopathological examinations of biopsy and autopsy material from GBS patients revealed massive T-cell and macrophage infiltration in spinal nerves, roots and distal nerve parts and thereby established the concept of an immune-mediated process underlying nerve injury [1,2]. In AIDP, demyelination prevails over axonal injury, which nevertheless can occur secondary to demyelination due to nerve constriction by edema formation. Macrophages adhere to the outer surface of the myelin sheaths of peripheral nerves and roots in AIDP and strip off myelin from the axons leading to slowing of nerve conduction due to loss of insulating myelin (segmental demyelination) or to conduction block. Antibodies (abs) against myelin antigens play a decisive role in AIDP since deposits of the terminal complement complex (TCC) guiding the macrophage attack could be demonstrated on myelin sheaths. In contrast to AIDP, the macrophage attack in AMAN is directed against the perinodal axolemma, which show TCC deposits at this particular location, but not on myelin sheaths. Morphological findings explain the predominant axonal pathology. Evoked muscle action potentials are severely diminished in these patients, but nerve conduction velocities (NCV) are grossly preserved until nerves eventually become unexcitable due to axonal degeneration. Abs against different nerve targets are associated with GBS variants [3]. Patients with AMAN often have increased ab titers to gangliosides expressed at the axolemma such as GM1, GM1b and GD1a. Patients with MFS typically show GQ1b and GT1a abs in their serum. In support of a functional role of these abs, macro-patch clamp studies revealed that serum and IgG fractions from patients with MFS and GBS can block neuromuscular transmission [4]. Based on additional observations in experimental autoimmune neuritis, the animal model for human GBS, it is likely that many other factors such as cytokines, arachidonic acid derivates and reactive oxygen species are also instrumental in the multifactorial pathophysiology of GBS [5]. As one of the most peculiar features, GBS is a self-limiting, monophasic disease and thus does not require long-term immunosuppression. The intrinsic mechanisms of spontaneous disease control are not yet fully elucidated, but programmed cell death (apoptosis) of autoreactive T-cells may play a role [5]. In contrast to classical GBS, some patients presenting initially as GBS further develop a chronic-progressive or chronic relapsing course, which requires reclassification as acute-onset chronic inflammatory demyelinating polyneuropathy (CIDP). These patients deserve long-term immunomodulatory treatments.

## Diagnostic Principles

The clinical diagnosis of GBS is based on the typical history of an acute flaccid paresis of more than one limb reaching peak disability within 4 (-6) weeks. Any preceding pulmonary or gastrointestinal infection may have been mild or even passed unnoted. Sensory symptoms are often present, but of minor degree, muscle reflexes must be suppressed or absent. In up to 25% of patients, muscle weakness is so severe as to require artificial ventilation and autonomic dysfunction with cardiac arrhythmias may become life threatening.

Cerebrospinal fluid shows raised protein concentrations but a normal cell count, except in patients with concomitant viral infections such as HIV. The differential diagnosis of an acute paralytic disorder such as GBS includes myasthenia gravis, poliomyelitis, electrolyte disturbance, botulism, rare intoxications and acute myopathy as well as acute brainstem and spinal cord disorders. Electrophysiological studies are mandatory to establish the diagnosis. In AIDP, F-wave and distal motor latencies may be delayed early on. Within days, nerve conduction block and slowing of NCV become evident at major nerve trunks. In AMAN, due to the predominant axonal pathology, evoked muscle action potentials are decreased or lost with long preservation of NCV. Sensory nerve conduction remains normal in AMAN, but profound changes are seen in AMSAN. The clinical features of ophthalmoplegia resembling ocular myasthenia, ataxia and areflexia are typical for the MFS variant of GBS.

### Therapeutic Principles

Since GBS is a self-limiting disease, therapeutic efforts aim at shortening the duration of the acute inflammatory disease phase to avoid the axonal injury that mostly accounts for long-term disability. Patients with AIDP can recover quickly due to rapid regression of conduction blocks and remyelination of demyelinated nerve segments by Schwann cells. Despite appropriate treatment however, 15% of GBS patients are left severely disabled and up to 50% show moderate to mild residual disability at 1 year due to axonal injury; mortality is now around 3% in Western countries in clinical centers with modern neurocritical care facilities. Several large randomized controlled trials have established that GBS (mainly AIDP and AMSAN) patients benefit from plasmapheresis (PE) during the first 4 weeks. PE eliminates circulating antibodies, complement components and other potentially noxious humoral factors but it is also a strong immunomodulator. PE treatment leads to faster recovery and almost halves the proportion of patients requiring ventilation at 4 weeks into the disease (reduction from 27 to 14% in one large trial). Patients with milder disease may also profit. Treatment of GBS patients with intravenous immunoglobulin (ivIG) is as effective as PE as shown in comparative trials. The standard regimen has been 0.4g/kg/day on 5 consecutive days. Immunomodulatory mechanisms of ivIG in GBS patients involve blockade of Fc receptors, provision of anti-idiotypic or competitive, non-pathogenic antibodies, interference with T-cell function and cytokine release and blockade of complement activation. Side effects are modest with only IgA deficiency being a contraindication because of anaphylactic reactions. GBS patients may still deteriorate under any of the effective treatments, requiring reinstitution of the same or another treatment series. Surprisingly, glucocorticosteroids proved ineffective in a large trial. In patients with further deterioration exceeding 6–8 weeks after onset, the diagnosis of a subacute or chronic progressive/relapsing polyneuritis (CIDP) should be considered. This distinction is of relevance since CIDP presents a different disease entity featuring a positive steroid response, and a better outcome on long-term immunomodulation.

# Gynecomastia

Valéria Lamounier-Zepter
Medical Clinic III, University of Dresden, Dresden, Germany

## Definition and Characteristics

Benign enlargement of the male breast secondary to a proliferation of the glandular tissue.

## Prevalence

36% of healthy men aged 17–58 years.

## Genes

X chromosome abnormalities (XXY karyotype in Klinefelter syndrome; SRY gene in XX males); AR gene, located on the Xq11-Xq12 region of the long arm of the X chromosome (syndromes of androgen insensitivity); 17HSD-3 gene, located on chromosome band 9q22; 3β-HSD gene, located on chromosome band 1p13.

## Molecular and Systemic Pathophysiology

Estrogens are the major hormones responsible for the proliferation of breast tissue, whereas androgens antagonize this effect. Thus, an excess of estrogens or a deficient androgen production leads to increases in the circulating estrogen/androgen ratio with a relatively increased estrogen effect on the breast. In males, estrogens are mainly produced in extragonadal tissues (adipose tissue, liver, muscle) through the aromatization of androgens. Direct secretion of estrogens by the testes accounts for approximately 20% of total estrogens. On the contrary, 95% of testosterone is derived from the testes with little peripheral conversion from adrenal precursors[1].

Excess of estrogens may result from tumors of steroid-producing organs (adrenal and testis) and tumors (lung and gastrointestinal) with paraneoplastic human chorionic gonadotropin (hCG-β) production. hCG-β stimulates testicular production of estrogens disproportionate to testosterone production leading to imbalance in the estrogen/androgen ratio.

Increased peripheral aromatization of androgens to estrogens is found in obesity, liver disease, and hyperthyroidism. A rare cause of gynecomastia is a congenital increase in peripheral tissue aromatase activity. This disorder is inherited in an autosomal dominant manner and seems to involve a mutation in the $P450_{arom}$ gene. Gynecomastia is also observed in individuals with true hermaphroditism through estrogen production by the ovarian tissue[1].

Common causes of gynecomastia are acquired disorders of testicular function such as trauma and radiation of the testis and infectious disease. Low testosterone concentrations and elevated serum gonadotropin are also observed in renal failure, and these effects seem to be reversed by transplantation [2].

Congenital disorders associated with low testosterone levels are cryptorchidism, Klinefelter syndrome, 46, XX sex-reversed males, anorchia (vanishing testis syndrome), and defects in testosterone biosynthesis such as 17β-hydroxysteroid dehydrogenase (17HSD-3) deficiency and 3β-hydroxysteroid dehydrogenase (3β-HSD) deficiency.

Some congenital disorders such as X-linked Kennedy syndrome and Reifenstein syndrome show quantitative or qualitative abnormalities in the androgen receptor (AR), with a resultant unopposed effect of estrogen on the breast. Circulating androgens levels are normal or raised, and estrogens are also normal or elevated due to the lack of androgen inhibition at the pituitary gland with increased gonadotropin secretion and consequently increased testicular estrogen production[3].

Medications are common causes of gynecomastia through diverse mechanisms such as an estrogen-like or an anti-androgenic effect, displacement of estrogens from sex hormone-binding globulin (SHBG), and enhancement of the peripheral aromatase activity. Physiologic gynecomastia may occur transiently in newborns and adolescents, and is also common in senescence[2].

## Diagnostic Principles

Screening of disorders associated with gynecomastia – serum levels of LH, FSH, testosterone, estradiol, hCG-β, SHBG; tests of liver, kidney, and thyroid function; drugs intake; cytogenetic studies[4].

## Therapeutic Principles

Primary causes of gynecomastia should be identified and corrected. Tenderness, severe psychologic problems, or suspected malignancy may warrant surgery. Pharmacological treatments include antiestrogens or aromatase inhibitors.

# Gyrate Atrophy

►Gyrate Atrophy of the Choroid and Retina

# Gyrate Atrophy of the Choroid and Retina

Klaus Ruether
Department of Ophtalmology CVK, Charité, Berlin, Germany

## Synonyms

Gyrate atrophy; Atrophia gyrata; Hyperornithinemia

## Definition and Characteristics

Gyrate atrophy of the choroid and retina (GA) is a recessively inherited chorioretinal degeneration due to a metabolic defect. The defect affects the ornithine metabolism leading to hyperornithinemia which is caused by a generalized deficiency of the mitochondrial matrix enzyme ornithine-δ-aminotransferase (OAT) [1]. The gene for OAT is located on chromosome 10. The severity of the disease is associated with different kind of OAT-mutations. Symptoms of the disease are night blindness beginning during childhood and a progressive loss of peripheral vision. This loss of visual field leads to tunnel vision and later, between the 5th and 6th decade, to a severe visual handicap up to blindness.

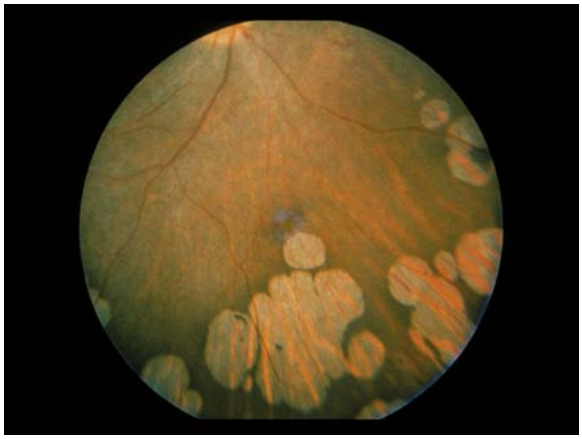
Morphologically, the disease is characterized by peripheral garland-shaped zones of chorioretinal atrophy (Fig. 1) sparing the macula at the beginning. Later on during life the macula becomes also involved causing deterioration of visual acuity. Secondary changes of the fundus include optic atrophy, narrowing of retinal vessels and opacities of the vitreous.

## Prevalence

Not known; very rare (<1:100,000); prevalence in Finland probably higher than in other countries.

## Genes

There is no report about inheritance patterns other than autosomal recessive. The gene for the ornithine-δ-aminotransferase (OAT) maps to chromosome 10 (10q26) in humans and to chromosome 7 in mice. The OAT-gene is 21 kb long and contains 11 exons. OAT gene sequences are also found on the X-chromosome (Xp11.2).



**Gyrate Atrophy of the Choroid and Retina.**
**Figure 1** Typical garland-shaped zones of the peripheral retina in a patient suffering from gyrate atrophy.

## Molecular and Systemic Pathophysiology

Ornithine-δ-aminotransferase is the most relevant enzyme for the ornithine metabolism. The ornithine levels of affected patients is 10–20 times higher than in healthy individuals. This applies to serum, urine, spinal fluid and aqueous humor. However, the chorioretinal diseases is the most relevant feature of the disease. The occurrence of subcapsular cataracts by the end of the second decade is probably secondary to the chorioretinal disease. Although tubular aggregates are found in type II fibers of skeletal muscle Sipila et al. described only a discrete muscle dysfunction in affected patients which slowly progresses [2]. In addition there seems to exist a mild brain disease.

The pathophysiology has not been fully understood until today. It has been hypothesized that ocular and muscular disease are mediated by hyperornithinemia-induced deficiency of creatine phosphate. In addition, there seems to be a direct toxicity of ornithine to the retinal pigment epithelial cells [3].

## Diagnostic Principles

Patients or parents search the contact to a medical doctor because of visual problems. Either night vision problems or visual field constrictions are the leading symptoms whereas the reduction of the visual acuity is a later symptom. Beside the routine ophthalmologic examination the crucial tests are visual field testing and the electroretinogram (ERG). The first often shows a concentric visual field constriction, the latter the pattern of a rod-cone-degeneration, i.e. the potentials of the rods are earlier diminished than those of the cones. At that point, the features are very similar to those of retinitis pigmentosa, a group of diseases characterized by a rod-cone-degeneration without

hyperornithinemia. Funduscopy is the crucial examination revealing the garland-shaped atrophy (Fig. 1). At that moment it is mandatory to examine the serum levels of ornithine.

## Therapeutic Principles

As ornithine is generated mainly from arginine which is part of the dietary protein the main therapeutic principle is an arginine restricted diet [4]. Although systematic studies about the effect of such a diet are not possible due to the low number of patients the long term observation of the treated patients by Kaiser-Kupfer implicate an effect if treatment is initiated early in life. It must be mentioned that an arginine restricted diet is not easy and therefore the compliance sometimes low. In some patients a treatment by Vitamin B6 (pyridoxine) is effective to lower ornithine-serum levels. This should be tried beside the diet.

As GA is an autosomal recessively inherited disorder gene therapy is a future option. For this purpose it was essential to create animal models which have been realized as mouse models by gene targeting [5]. Interestingly, the neonatal mice showed a life-threatening hypoornithinemia. In this model the arginine restricted diet has also been applied and the retinal degeneration could be prevented.

## HAE

►Angioedema, Hereditary

## Hailey-Hailey Disease

Dieter Metze
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Familial benign chronic pemphigus [1]

### Definition and Characteristics

Hailey-Hailey disease is an autosomal dominant skin disorder characterized by erosive plaques. The disease usually starts between the second and fourth decade. The course of the disease is characterized by spontaneous exacerbations and remissions with marked predilection for the intertriginous areas [2].

Hailey-Hailey disease presents with vesicles, papules, crusted erosions, and oozing plaques. Pain and unpleasant smell lead to a social handicap. Lesions can be triggered on almost all body sites by minor trauma, friction, tape stripping, and inflammation caused by UV radiation, allergens, toxic components or infectious agents. Finger nails may show asymptomatic longitudinal white bands. Mucosal involvement is unusual [1].

### Prevalence

The disease is rare.

### Genes

Hu et al. identified mutations in the ATP2C1 gene on chromosome 3q21–q24, which encodes the human homologue of an ATP-powered pump that sequesters calcium into the Golgi in yeast [3]. Mutations included nonsense, frameshift insertion and deletions, splice-site mutations, and missense mutations in functional domains [3,4].

### Molecular and Systemic Pathophysiology

Regulation of cytoplasmic calcium is impaired in cultured keratinocytes from Hailey-Hailey disease patients, and the normal epidermal calcium gradient is attenuated in vivo. The ultrastructural hallmark of the disease is a peculiar type of acantholysis, where, despite the dissolution of desmosomes, keratinocytes remain linked together by well-preserved adherens junctions (incomplete acantholysis, Hailey-Hailey-like pattern of acantholysis). The adherens junction-actin system is not only essential for calcium induced formation of desmosomes and organization of the keratin filaments but also possesses cohesive properties [5].

### Diagnostic Principles

Clinically, the diagnosis can be difficult and must be confirmed by a skin biopsy. Histology of the epidermis shows hyperplasia, incomplete acantholysis with clefts and scale-crusts. The dermis contains a variable inflammatory infiltrate.

### Therapeutic Principles

Pharmacological therapy consists of topical corticosteroids with or without antiseptics or antibiotics. Other treatments include dermabrasion and carbon dioxide laser vaporization.

# Haim-Munk Syndrome

Vanessa F. Cury, Ricardo S. Gomez, Luiz De Marco
Departments of Pharmacology and Oral Pathology, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

## Synonyms

HMS; Cochin Jewish disorder; Keratosis palmoplantaris with periodontopathia and onychogryphosis; Keratosis palmo-plantaris congenital, with periodontosis, arachnodactily and a peculiar deformity of the terminal phalanges (MIM #245010)

## Definition and Characteristics

Haim-Munk syndrome (HMS) is a rare autosomal recessive type IV palmoplantar ectodermal dysplasia that involves abnormal hyperkeratosis of the palm of the hands and sole of the feet as well as destruction of the periodontium leading to a premature tooth loss [1]. In addition, other clinical findings shared by these patients include acro-osteolysis, arachnodactyly, atrophic changes of the nails and deformity of the fingers, and recurrent pyogenic skin infections. The presence of these clinical features, particularly arachnodactyly and nail deformities (onycogryphosis) distinguish HMS from Papillon-Lefèvre syndrome (PLS, MIM #245000). Furthermore, skin manifestations in HMS are more extensive and severe, and the periodontium is less severely affected, in contrast to PLS.

## Prevalence

Haim and Munk (1965) estimated the disease allele frequency to be 0.1 in the Cochin population.

## Genes

HMS locus was mapped to chromosome 11q14–q21 [2], a region where the lysosomal protease cathepsin C gene (CTSC) maps [3]. The CTSC gene consists of seven exons that encode a 463-amino acid polypeptide. To date, only two mutations in the CTSC gene have been reported in families affected by HMS: a mutation in codon 286 of exon 6 (2127A→G, Q286R) in one inbred Jewish non-Ashkenazi family from Cochin, India and a mutation in codon 196 of exon 4 (587T→C, L196P) in one Brazilian kindred [4,5].

## Molecular and Systemic Pathophysiology

The pathophysiologic role of cathepsin C (or dipeptidyl aminopeptidase I; E.C.3.4.14.1), is still unclear. CSTC is expressed in many organs as the epithelial areas affected by HMS (palmoplantar), the keratinized gingiva and immune cells such as alveolar macrophages, neutrophils, cytotoxic lymphocytes and mast cells. Lack of functional cathepsin C in HMS may be due to reduced host response against specific microbial agents. The enzyme acts as both an endopeptidase and an exopeptidase; it is important in intracellular and extracellular protein degradation as well as activation of serine proteases such as granzymes A and B, cathepsin G and leukocyte elastase. These proteinases have been implicated in a variety of inflammatory and immune processes, including phagocytic destruction of bacteria. Leukocyte functions (neutrophil phagocytosis, lytic activity and chemotactic response) are also depressed due to lack of CSTC activity.

## Diagnostic Principles

Clinical examination is important to substantiate or exclude Haim-Munk syndrome. Affected individuals are diagnosed with Haim-Munk syndrome when all of the following features are present:

- Severe early onset periodontitis
- Thick, rough, and scaly patches of skin on the forearms and legs
- Palmoplantar keratoderma (Fig. 1a)
- Arachnodactyly (Fig. 1b)
- Abnormal changes of the nails (Fig. 1a)
- Recurrent pyogenic skin infections (Fig. 1c)

Radiology is used to view the thin and tapering bone deformities in the fingers (Fig. 1b) and dental problems (Fig. 1d) associated with Haim-Munk syndrome.

One must consider Papillon-Lefèvre syndrome (only palmoplantar keratoderma and severe periodontitis) in the differential diagnosis of HMS.

## Therapeutic Principles

A multidisciplinary approach is important for the care of patients with HMS. The palmoplantar keratoderma is usually treated with emollients. Urea and salicylic acid may be added to enhance their effects. Oral retinoid is the mainstay in the treatment of both keratoderma and periodontitis associated with HMS. Treatment may be more beneficial if it is started during the eruption and maintained during the development of the permanent

teeth. Effective treatment for the periodontitis includes extraction of the primary teeth combined with oral antibiotics and professional teeth cleaning. In some cases, extraction of the permanent teeth and use of dental prosthesis or dentures can be helpful.

## Hallux Valgus

Dror Robinson, Eitan Melamed
Rabin Medical Center, Petach Tikwa, Israel

### Synonyms

Bunion

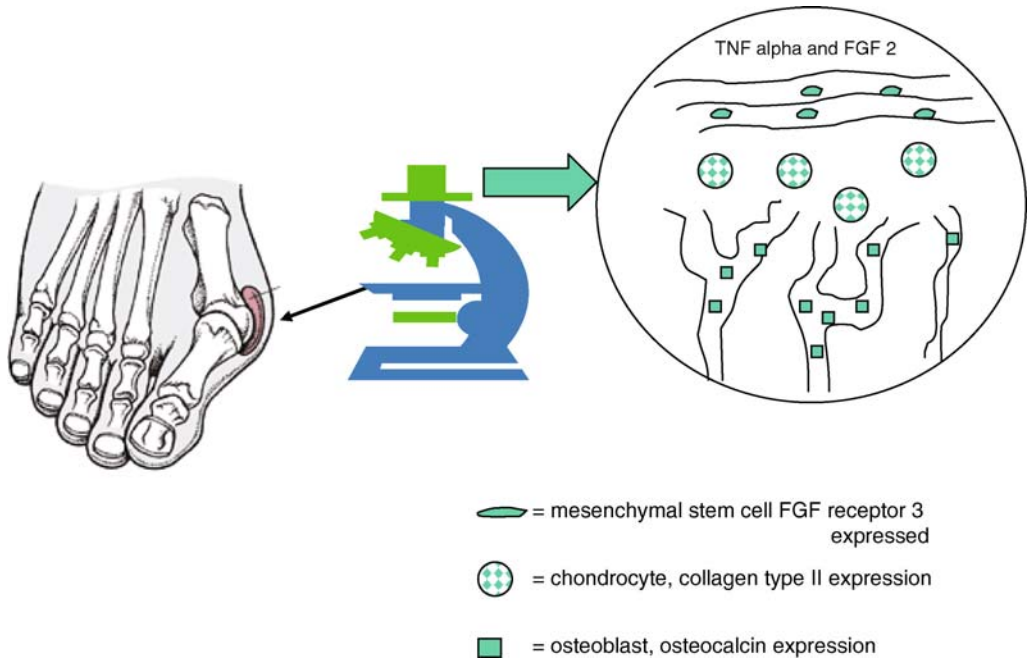
### Definition and Characteristics

Displacement of the first proximal phalanx laterally is followed by a pronation deformation of the phalanx, sesamoid dislocation and later bunion formation at the medial aspect of the great toe metatarsus.

Environmentally influenced (shoewear related, gender related) with clear genetic inheritance often sex-linked.

### Prevalence

Prevalence of hallux valgus increases with age reaching 37% in the geriatric population [1].



**Hallux Valgus. Figure 1** Diagram of bunion formation.

## Genes

Some genetic variants related to noggin or BMP-4 mutation (fibrodysplasia ossificans progressiva) [2], and generalized connective tissue laxity as in Marfan's syndrome or hypermobility syndrome [3]. The more common type appear to be due to mechanical deformation leading to FGF expression and recruitment of mesenchymal stem cells that differentiate into bone [4]. These cells are responsible for bunion formation.

## Molecular and Systemic Pathophysiology

Some deformities of the midfoot tend to facilitate formation of the hallux valgus deformity. These include: metatarsus primus adductus in which the first metatarsal tends to deviate medially, pes planovalgus in which the foot tends to pronate and the longitudinal arch collapses. Shoewear dramatically increases the frequency of hallux valgus deformity. As in most patients with hallux valgus a mild sensory abnormality is noted [5] it has been theorized that imbalance of the muscles due to a sub-clinical neurological lesion is induced by constrictive shoewear.

Rare syndromes in which BMP-4 to noggin imbalance occur are accompanied by severe juvenile-onset hallux valgus deformity [2] (Fig. 1).

Bunion formation in hallux valgus is an interesting phenomenon, in which post-skeletal-maturity bone-growth occurs. In prior studies, it has been shown that FGF-2 released by local inflammation [4], is responsible for recruitment of mesenchymal stem cells and their differentiation into osteoblasts. Thus, the bunion consists of several histological layers. The most superficial cells express collagen type IIa and FGF-receptor-3 and appear to be mesenchymal progenitors. The deeper zone consists of cells expressing collagen type II and aggrecan while the deeper layers consist of cells expressing osteocalcin, alkaline phosphatase and collagen type I.

## Diagnostic Principles

The diagnosis is made clinically.

## Therapeutic Principles

Choice of appropriate shoeware, local antiinflammatory treatment and in severe cases surgical correction.

# Hand-Foot-and-Mouth Disease

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Hand-foot-and-mouth disease is characterized by vesicular stomatitis and cutaneous lesions on the palms and soles (Fig. 1) [1]. The disease has an incubation period of 3–6 days [1]. There is usually a mild prodrome consisting of low-grade fever, anorexia, sore mouth, and malaise. Children younger than 10 years are most commonly affected [1]. Oral lesions occur chiefly on the anterior buccal mucosa and tongue, where the vesicular surfaces are eroded rapidly, leaving ulcers with erythematous borders. The lips and often the gingivae are spared. The lesions on the palms and soles are papules or vesicles on a surrounding zone of erythema. Less commonly, the dorsal or lateral surfaces of the hands and feet may also be affected. Lesions on the buttocks are common, but typically they do not progress to vesiculations. The lesions are non pruritic and usually resolve without crusting. Nail matrix arrest has been reported following hand-foot-and-mouth disease. Hand-foot-and-mouth disease caused by enterovirus 71 generally is more severe than that attributable to coxsackievirus A 16 or other viruses and may be complicated by interstitial pneumonia, pulmonary edema, pulmonary hemorrhage, aseptic meningitis, encephalitis, acute flaccid paralysis, myocarditis, or even death [1,2].

## Prevalence

The exact prevalence is not known. The disease is highly contagious and occurs most often in the summer months. It may occur in mini epidemics. Enterovirus 71 has caused large outbreaks in Southeast Asia.

**Hand-Foot-and-Mouth Disease. Figure 1** A 3-year-old girl with hand-foot-and-mouth disease. Note the vesicles on the palms and soles.

## Molecular and Systemic Pathophysiology

The disease is usually caused by coxsackievirus A16. Less commonly, it is caused by coxsackieviruses A4, A5, A6, A7, A9, A10, A24, B2 to B5, enterovirus 71, and echoviruses. All are RNA viruses and they spread by fecal-oral and respiratory routes. Spread to other family members commonly occurs. In the enterovirus 71 strains, the substitution of alanine with valine at position 170 of the VP1 region of the genogroup C2 is believed to be a virulent factor [3]. Enterovirus 71 is neurotropic and possesses a unique ability to invade the ventral brain stem, cerebellum and spinal cord [4]. Acute pulmonary edema caused by enterovirus 71 is neurogenic in origin secondary to invasion of the medullary vasomotor and respiratory centers [4]. Risk factors for fatalities are vomiting, atypical physical findings, and leukocytosis [2]. The peripheral lesions of hand-foot-and-mouth disease consist of a subepidermal mixed lymphocytic and polymorphonuclear infiltrate with acantholysis of the overlying epidermis [5] .

## Diagnostic Principles

Hand-foot-and-mouth disease has to be differentiated from herpetic gingivostomatitis, and herpangina. Patients with herpetic gingivostomatitis are more toxic looking and have a higher fever and cervical lymphadenopathy. Also, the lesions are limited to the oral cavity and do not involve the palms and soles. In herpangina, the lesions occur mainly in the posterior oropharynx with no involvement of the palms and soles. Other differential diagnosis include aphthous ulcers, erythema multiforme, contact dermatitis, and Behcet's disease. The diagnosis is mainly clinical and no laboratory test is usually necessary.

## Therapeutic Principles

The disease is usually benign and resolves in 5–10 days. Treatment is mainly symptomatic.

## Hantavirus Pulmonary Syndrome

Jae-Hwan Nam
Laboratory of Viral Immunology, Department of Biotechnology, The Catholic University of Korea, Bucheon, Gyeonggi, Korea

### Synonyms

HPS; Hantavirus cardiopulmonary syndrome; HCPS

### Definition and Characteristics

Hantavirus pulmonary syndrome (HPS) was initially reported in 1993 in the Four Corners region in the southwest of the United States. The primary reservoir of HPS-causing hantaviruses in the United States is the deer mouse (Peromyscus maniculatus). The viruses are spread from infected rodents in urine, feces and saliva, and are transmitted to humans by aerosols [1].

### Prevalence

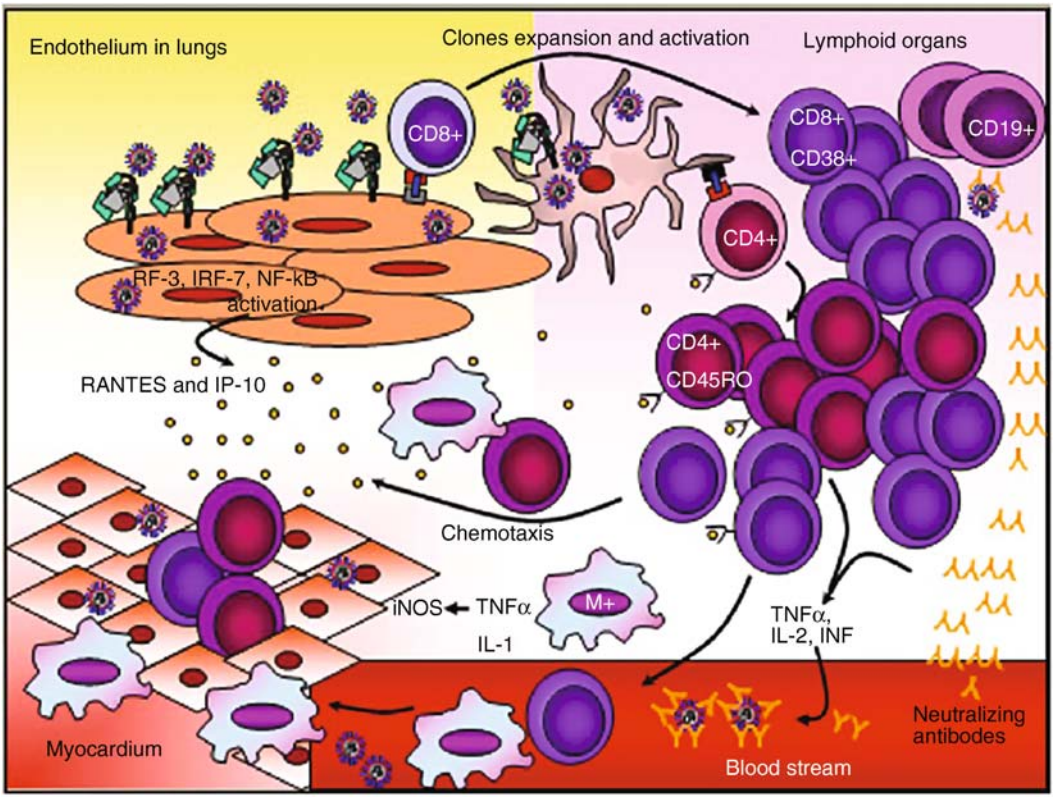
The Center for Disease Control and Prevention (CDC) has confirmed 438 cases of HPS for the period 1993–2006 (up to May 10) in the United States. Of these cases, 35% (154) were fatal [2].

### Genes

Various viruses of the genus Hantavirus (family Bunyaviridae) are the cause of HPS. These hantaviruses include Sin Nombre (SNV), Black Creek Canal, Bayou, and New York (NY–1V) viruses in North America; Laguna Negra, Andes (ANDV), Juquitiba, Castelo dos Sonbos, Araraquara (ARAV), and Anajatuba viruses in South America; and Choclo virus in Central America. Hantaviruses are enveloped viruses with negative-sense RNA genomes organized in three segments: S (small) encoding the nucleocapsid (N) protein; M (medium) encoding two envelope glycoproteins (G1 and G2); and L (large) encoding an RNA-dependent RNA polymerase (L) protein. The cytoplasmic tail of the G1 protein of HPS-inducing hantaviruses have an immunoreceptor tyrosine-based activation motif (ITAM), whereas nonpathogenic hantavirus strains and hantaviruses causing hemorrhagic fever with renal syndrome (HFRS) have no ITAM in the G1 protein, suggesting that ITAM might play a crucial role in HPS pathogenesis. Certain human leukocyte antigens (HLA), including HLA–B*35 and HLA–Cw*04, may be associated with highly efficient SNV antigen presentation, suggesting that HLA–B*3501 is associated with severe HPS and implying involvement of CD8 + T-cells [1].

### Molecular and Systemic Pathophysiology

Hantaviruses causing HPS use $\alpha_v\beta_3$ and $\alpha_{II}\beta_3$ integrins as receptors, in contrast to nonpathogenic hantaviruses, which use $\alpha_v\beta_1$ integrins. The important pathophysiology of HPS is interstitial pneumonitis, which results in capillary leakage in the lung. Infected human lung microvascular endothelial cells secrete RANTES and IP–10 chemokines, which are chemotactic for mononuclear leukocytes. Migration of activated T cell subsets (CD4 + , CD8 + , CD29+) can be stimulated by IP–10, and RANTES can activate T-cells that release inflammatory cytokines, including interleukins and interferons such as IL-2, IL-5, and IFN-γ. The lungs, spleen, and heart of HPS patients have many CD4 + and CD8 + T cells and a high number of cytokine-producing cells. TNF–α induces iNOS (inducible nitric oxide synthase) to produce nitric oxide (NO), which triggers cell injury and heart contractile dysfunction. The above data are in accord with the report of induction of NO in HPS. In addition, TNF–α also induces protein kinase C, which is required to regulate endothelial permeability, and IL–2, which increases vascular permeability and causes capillary leakage. Early-phase HPS patients activate SNV-specific CD8 + and CD4 + T-cells by MHC loaded with SNV epitopes, suggesting that SNV-specific CD8 + T-cells contribute to HPS pathology. These T cells secrete excess TNF–α and IFN–γ, which are critical for HPS pathogenesis. Therefore, it is possible that respiratory failure in HPS, triggered by alveolar capillary



**Hantavirus Pulmonary Syndrome. Figure 1** Scheme of the immune response in relation to pathogenesis in HPS. Firstly, HPS-inducing hantaviruses probably replicate in dendritic cells (DCs) during early infection. Secondly, hantavirus-mature DCs could efficiently stimulate T-cells in the secondary lymphoid organs, which reach the infected organs (such as kidney, heart, spleen, pancreas, lymph nodes, skeletal muscle, intestine, adrenal, adipose tissue, urinary bladder, and brain) via the bloodstream. Thirdly, the proinflammatory cytokines produced by infected DCs and migrating T cells may enhance hantavirus-induced endothelial cell leakage and the severe edema associated with HPS (from reference [1] with permission).

leakage, will result from an intense CD8 + T cell immune response in the lung (Fig. 1) [1].

## Diagnostic Principles

The indirect immunofluorescent antibody (IFA) test, IgM capture ELISA and Western blot analysis were developed to detect hantavirus-specific antibodies. In addition, RT–PCR assay was developed to detect viral genomes. It is clinically difficult to diagnose HFRS and HPS cases in the early phase of infection, but the following symptoms are strongly suggestive of HPS: fever, myalgia, and a history of potential rural rodent exposure, together with shortness of breath, thrombocytopenia, leukocytosis with left shift (a higher ratio of immature to mature neutrophils), and atypical lymphocytes [3].

## Therapeutic Principles

No antiviral drug or immunotherapeutic agent for hantavirus disease is clinically available. Ribavirin has been shown to have in vitro and in vivo activity for hantavirus [4]. Interestingly, Zidovudine and Amantadine also effectively inhibits hantavirus replication in A549 cells [5]. Type I interferons (IFN–α and IFN–β) hinder hantavirus replication effectively. In addition, Nam et al. found that 2′, 5′–oligoadenylate synthetase (OAS) and Mx1 genes, key regulators of IFN induction, are up-regulated in hantavirus-infected A549 cells [6]. Moreover, ANDV stimulates MxA protein expression in endothelial cells and MxA protein is colocalized with ANDV N–protein, suggesting that the MxA–N interaction prevents production of new viral particles [1].

## Synonyms

Hartnup disorder

## Definition and Characteristics

Autosomal recessive transport defect of neutral amino acids in the kidneys and small intestine leading to pellagra-like skin rash, cerebellar ataxia and psychotic behavior.

## Prevalence

Approximately one in 30,000 newborns [1]. No ethnic predilection has been reported.

## Genes

Neutral amino acid transporter gene mapped on human chromosome 5p15 [2,3]. Genetic heterogeneity has been suggested.

## Molecular and Systemic Pathophysiology

The transport of neutral amino acids (e.g., alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophane, histidine, glutamine and asparagine) by the intestinal mucosa and renal tubules is impaired. Unabsorbed tryptophane in the intestine is converted to indole by bacteria, absorbed, converted to 3-hydroxyindole in the liver and excreted in urine in large amounts, leading to indicanuria. Many children with Hartnup disease remain asymptomatic. In symptomatic patients, the major clinical manifestation is cutaneous photosensitivity caused by niacin deficiency due to reduced availability of tryptophane [4]. Intermittent ataxia is also observed in some patients.

## Diagnostic Principles

Urinary amino acid analysis shows a unique pattern of increased excretion of neutral amino acids.

## Therapeutic Principles

Nicotinamide supplementation (50–300 mg/day) ameliorates skin rash and ataxia. Sunlight protection is further helpful.

## Hashimoto's Thyroiditis

Seda Sancak[1,2], Ralf Paschke[2]
[1]Marmara University Medical School, Istanbul, Turkey
[2]III. Medical Department, University of Leipzig, Leipzig, Germany

### Synonyms

Hashimoto's disease; Goitrous autoimmune thyroiditis [1]

### Definition and Characteristics

Positive thyroid peroxidase antibodies (TPO Ab), elevated serum thyrotropin, lymphocytic infiltration of the thyroid gland and presence of a goiter on clinical examination [1].

### Prevalence

The most common cause of acquired hypothyroidism [1,2], sevenfold more common in women [1] with increasing incidence after the age of 45 [3].

### Genes

There is a genetic predisposition for Hashimoto's thyroiditis, as patients with human leukocyte antigen (HLA) class I and class II (HLA-DR3, HLA-DR4, HLA-DR5), polymorphisms in the region of the cytotoxic T lymphocyte antigen 4 (CTLA-4) gene on chromosome 2q33 or on chromosomes 6p, 13q32, 12q22 are more susceptible to the development of Hashimoto's thyroiditis [4].

### Molecular and Systemic Pathophysiology

Hashimoto's thyroiditis is characterized by diffuse lymphocytic infiltration, gradual destruction of the gland and fibrosis. The size of the thyroid follicles is reduced and they contain sparse colloid. Although the follicles are small, the individual thyroid cells often appear enlarged and contain cytoplasm that is granular and pink (oxyphil change). Such cells are known as Hürthle or Askanazy cells [1].

The etiology of Hashimoto's thyroiditis remains unclear but genetic, environmental factors and immunotherapeutic agents are believed to contribute to their development [4].

It is believed that the autoimmune process begins with the activation of CD4 (helper) T lymphocytes that are specific for thyroid antigens. For this two mechanisms have been suggested. One hypothesis is referred to as molecular mimicry which postulates that an infection with a virus or bacterium containing a protein which is similar to a thyroid protein activates the thyroid-specific T-cells [1].

The other hypothesis proposes the induction of expression of major histocompatibility-complex (MHC) class II proteins by the affected thyrocytes as a major requirement for antigen presentation to CD4 T-cells [1,2,4].

When activated, reactive CD4 T-cells can stimulate cytotoxic (CD8) T-cells and recruit autoreactive B cells into the thyroid. Autoreactive B cells produce and secrete the TPO antibodies [1,2,4]. It is believed that the main mechanism responsible for hypothyroidism is the direct killing of thyroid cells by CD8 cells [1].

Nongenetic factors may be endogenous or exogenous. Endogenous factors such pregnancy are an important risk factor for autoimmune hypothyroidism [4]. Autoimmune throiditis is more common in geographic regions with the high intake of iodine which very likely increases the immunogenicity of thyroglobulin and thereby the prevalence of lymphocytic infiltration of the thyroid [1,4]. Drugs such as amiodarone, lithium and interferon-alfa have various effects on the immune system and thereby exacerbate autoimmune thyroiditis [1,4].

### Diagnostic Principles

A test for TPO antibodies and measurement of the serum thyrotropin is generally sufficient to confirm the diagnosis [1]. The hallmark of chronic autoimmune thyroiditis is the presence of TPO autoantibodies [1].

Individuals with normal thyroid function, but TPO autoantibodies, may be at increased risk of progression to overt thyroid disease. In the Whickham follow-up study, women with thyroid autoantibodies had an eightfold higher likelihood of developing overt hypothyroidism over 20 years than did antibody-negative women [3].

The initial finding is a firm, symmetric, painless goiter [2]. The thyroid gland can be nonpalpabel or diffusely enlarged. Rarely, the gland can be painful and tender [1]. About 10% of patients have atrophic thyroid glands [2]. Patients may be hypothyroid or euthyroid. Or in some cases hyperthyroidism may alternate with hypothyroidism most likely due to the destruction of thyroid follicles with a transient release of thyroid hormones and the subsequent fibrosis of the organ. Moreover, transitions to Graves' disease are possible [1,2].

Ultrasonography typically shows a hypoechogenic pattern [1,2]. The thyroid scintigraphy does not show uptake and is unnecessary [1,2]. Thyroid-associated ophthalmopathy can occur but is not common [1].

### Therapeutic Principles

If overt hypothyroidism or subclinical hypothyroidism with high TPO antibody concentrations is present which usually progresses to overt hypothyroidism and which may be associated with hyperlipidemia and atherosclerotic heart disease, levothyroxine sodium is the treatment of choice [2].

The goal of the replacement therapy is the normalization of serum thyrotropin values.

The TPO antibody concentration does not decrease with levothyroxine sodium therapy, except for some patients with hypothyroidism [2]. Irrespective of the initial serum thyrotropin concentration in patients with Hashimoto's thyroiditis and a large goiter, thyrotropin-suppressing doses of levothyroxine sodium can be given for a short term to decrease the size of the goiter. The goiter size will decrease by 30% after 6 months of therapy with levothyroxine sodium [2]. If the size of the goiter does not decrease replacement doses aiming at a normal TSH should be resumed [2].

Fine-needle aspiration biopsy is indicated if there is a dominant nodule or enlarged lymph nodes to rule out lymphoma and thyroid carcinoma [2].

Selenium (Se) supplementation may decrease TPO antibodies and improve the inflammatory activity [5].

Susan Kupka
Department of General, Visceral and Transplant Surgery, University Hospital of Tuebingen, Tuebingen, Germany

### Synonyms

Pendred syndrome; Waardenburg syndrome; Usher syndrome; Treacher Collins syndrome; BOR syndrome; Alport syndrome; LQT syndrome; Norrie syndrome; Stickler syndrome

### Definition and Characteristics

Syndromic hearing impairment (HI) is associated with other clinical symptoms, e.g., blindness, cardiac arrhythmia, or pigment abnormalities [1]. More than 500 syndromes including HI were described up to date. These syndromes are based on mutations in genes that have an important function in other tissues as well as the cochlea. The clinically most important and common ones are listed in the Table 1.

### Prevalence

The prevalence is dependent on the particular syndrome.

### Genes

A large number of genes involved in syndromic hearing impairment have been identified yet, including, e.g., genes encoding structural proteins, ion channels, ion transporters, transcription factors, and motor proteins. The most important are listed in Table 1.

### Molecular and Systemic Pathophysiology

The pathophysiology is dependent on the particular syndrome.

### Diagnostic Principles

Clinical classification is based on the additional symptoms occurring besides hearing impairment.

### Therapeutic Principles

Hearing impaired patients are equipped with hearing aids. Further therapeutic options are based on the syndrome.

**Hearing Impairment, Syndromal. Table 1** Summary of several syndromes including hearing impairment according to their importance

| Syndrome | Additional symptoms | Mode of inheritance | Genes | OMIM * |

# Hearing Loss, Noise-induced and Acoustic Trauma

Stefan K. Plontke, Hans-Peter Zenner
Department of Otorhinolaryngology – Head and Neck Surgery, University of Tuebingen, Tuebingen, Germany

## Synonyms

NIHL; Acoustic overexposure

## Definition and Characteristics

Excessive acute or chronic noise exposure (continuous noise, impulse noise or blast injuries) can lead to inner-ear damage with temporary or permanent sensorineural hearing loss which may be accompanied by tinnitus. In severe cases of blast injuries the middle ear may be damaged resulting in conductive hearing loss. Impulse noise can lead to more severe damage to the inner ear than continuous noise can. Important criteria for the development of noise-related injury are the sound pressure levels (SPL), the rapidity with which sound levels increase, the exposure time and individual sensitivity (susceptibility). Depending on these factors, a noise exposure may lead first to a temporary threshold shift (TTS) and/or tinnitus. If a complete restitution after a temporary threshold shift/tinnitus does not occur in the recovery phase, a permanent inner ear injury results ("permanent threshold shift" = PTS).

NIHL and acoustic trauma are accompanied by multiple morphological changes in the peripheral and central auditory system [1].

## Prevalence

According to estimates of the WHO approximately 300 million people worldwide have moderate to profound hearing loss in both ears. NIHL is the second most common form of sensorineural hearing loss after age-related hearing loss. NIHL is one of the most common occupationally induced disabilities.

## Genes

The individual susceptibility or vulnerability to noise varies which is due to an interaction of environmental factors and genes. Certain knockout mice (SOD1−/−, GPX−/−, PMCA2−/−, CDH23+/−) are more sensitive to noise overexposure than their wildtypes [1,2].

## Molecular and Systemic Pathophysiology

There are two fundamental mechanisms of hearing damage as a consequence of noise overexposure. Mechanical trauma may lead directly to damage of the architecture of the inner ear structures. The increase in pathological activity caused by excessive sound stimulation may result in a metabolic stress response. Metabolic causes of noise damage can involve ischemia of the stria vascularis, disruption of the potassium recycling pathways and breakdown of the endocochlear potential, excitotoxicity following excessive release of glutamate and the production of reactive oxygen (ROS) and nitrogen species (RNS). Irrespective of the underlying mechanism, this may result in cell death due to necrosis or apoptosis. The affected tissue structures in the cochlea are the organ of Corti with hair cells and supporting cells, the spiral limbus, the spiral ligament and the stria vascularis. In addition, the synapses of the afferent neuron of the auditory nerve and the spiral ganglion cells can be damaged. Also central auditory nervous changes are found after noise overexposure [1,3].

The induction of oxidative stress reactions by noise is emphasized by the following results of animal-experimental studies: (i) Excessive acoustic stimulation leads to an increase in harmful, reactive oxygen species (ROS) in the cochlea, as has been shown from measurements of hydroxyl radicals and superoxide anions. (ii) After excessive acoustic exposure the activity of endogenous anti-oxidative mechanisms increases in the inner ear, e.g. glutathione. (iii) The activation of anti-oxidative systems attenuates acoustic trauma-induced hair cell loss and threshold shifts. (iv) The weakening of endogenous anti-oxidative systems by pharmacological inhibition of the glutathione system or genetic manipulation (deletion of the superoxide dismutase gene or mutation of the glutathione peroxidase gene) promotes morphological and functional damage from noise exposure [3].

There appears to be an enhancement of the damaging effect of noise if an additional exposure with ototoxic substances is present, leading to a reduced thresholds of damage to the inner ear for either of the substances (see also ►Ototoxicity) [3].

## Diagnostic Principles

Audiologically, in NIHL a threshold shift in the pure tone audiogram (characteristically in the high frequencies and especially around 3–6 kHz), recruitment, amplitude reduction or loss of otoacoustic emissions, and a loss in speech intelligibility are found [3].

## Therapeutic Principles

Current clinical pharmacological therapeutic strategies aim at preventing initial ROS production or the late formation of ROS and RNS species that appear 7–10 days after noise exposure, maintaining cochlear blood flow, restoring calcium balance in cells and neurons, preventing calcineurin activation and/or caspase formation. Protective and therapeutic interventions that have been shown at least partially effective in prevention of morphological and physiological auditory damage in animals include antioxidant agents, $Mg^{2+}$, neurotrophins, glucocorticoids, calcineurin inhibitors, caspase inhibitors, c-jun-kinase inhibitors, and Src protein tyrosine kinase inhibitors [1–3].

In humans, only Magnesium-aspartate has shown some efficacy in reducing PTS due to gun-shot noise when taken regularly and before the noise exposure. The mechanism is most likely related to $Mg^{2+}$-blockage of the NMDA-receptor of the Typ I afferent auditory nerve fiber thus preventing excessive calcium influx during acoustic overexposure [3]. So far, however, clinical studies with a high degree of evidence demonstrating a therapeutic efficacy for any pharmacological substance are missing. Therefore, the reduction of noise emission from occupational and social noise sources and – in situations where this is not possible – the use of hearing protectors is of highest priority. In most industrialized countries occupational noise exposure is therefore regulated by laws [1,3].

H

# Hearing Loss, Non-syndromal

Susan Kupka
Department of General, Visceral and Transplant Surgery, University Hospital of Tuebingen, Tuebingen, Germany

## Synonyms

NSHL

## Definition and Characteristics

Non-syndromic severe to profound neurosensory hearing impairment (NSHL) is a heterogeneous class of disorders showing different pattern of inheritance and involving a multitude of different genes [1]. Non-syndromic HI is classified according to the mode of inheritance in X-chromosomal (DFN; 1–3%), autosomal dominant (DFNA; 10–15%), autosomal recessive (DFNB; 70%), and mitochondrial forms (<1%) inherited NSHL. The first locus was detected by Wallis and coworkers in 1988 resulting in a rapid rise of genetic NSHL research [2]. Up to now, the number of known loci totals over 60 and is increasing every year [1].

## Prevalence

NSHL is one of the most common human sensory disorders affecting 1 in 1,000 children, with at least 60% of cases being inherited.

## Genes

Although our knowledge of genes being involved in the development of HI accumulated during the past 5 years, little is known about the molecular basis of normal auditory function. Since the physiology of the inner ear is very complex, 100–150 genes and gene products are estimated to play a role in the inner ear and in the procedure of hearing in general.

To date, 28 genes for non-syndromic HI have been identified. These genes play important roles for the normal inner ear: in the development, structure, ion exchange, and further physiological function. Among these genes, GJB2 is the most frequently involved in the development of NSHL. Mutations within the GJB2 gene have been established as a major cause of inherited and sporadic non-syndromic HI in different populations with mutation frequencies varying between 10 and 75% in analyzed patients [3–5].

## Molecular and Systemic Pathophysiology

The pathophysiology depends on the particular syndrome. Several of those genes encode transport proteins involved in the recycling of $K^+$. The GJB2 gene encodes the gap junction protein connexin 26 (beta-2, GJB2) that is expressed in several tissues and in the cochlea. Gap junctions constitute a major system of intercellular communication that is important for the exchange of electrolytes, second messengers, and metabolites. Gap junctions may play a role in $K^+$ circulation between different cochlea components [6].

## Diagnostic Principles

Since GJB2 has only one coding exon, molecular diagnosis of mutations can be made simple and cost effective. In daily medical practice, DNA is extracted from blood, followed by PCR and sequencing. Based on these techniques, variations of the GJB2 nucleotide sequence can be detected. In addition, the mitochondrial gene 12SrRNA (mutation A1555G) can be screened.

## Therapeutic Principles

To date, no therapy for NSHL is available. In general, affected persons are equipped with hearing aids.

►Coronary Artery Disease

# Heart Block

►Atrioventricular Conduction Disturbances

# Heart Failure

Gohar Azhar, Jeanne Y. Wei
University of Arkansas for Medical Sciences, GRECC and CAVHS, Little Rock, AR, USA

## Synonyms

Cardiac insufficiency; Congestive cardiac failure; CCF; Systolic heart failure; SHF; Diastolic heart failure; DHF; Systolic ventricular dysfunction; Diastolic ventricular dysfunction

## Definition and Characteristics

Heart failure is a clinical syndrome characterized by the inability of the heart to pump blood commensurate with the requirements of the body [1,2]. Two functional subsets of heart failure that are commonly encountered are diastolic heart failure (DHF) and systolic heart Failure (SHF). SHF is associated with reduced cardiac contractile function and an ejection fraction of 40% or less. DHF can occur in the presence or absence of systolic dysfunction, and is characterized by impaired cardiac relaxation [3–5]. Moderately severe left heart failure can result in secondary right heart failure or biventricular failure. Right heart failure can occur generally in conditions of severe tricuspid regurgitation, severe pulmonary disease or pulmonary hypertension, and in extreme cases, can also result in secondary left heart failure or biventricular failure. Morphologically, heart failure can be the end result of hypertrophic or dilated cardiomyopathy and/or valvular heart disease [1–5]. Familial gene mutations comprise about 20–50% of idiopathic dilated cardiomypathies.

## Prevalence

Over 5 million patients in the United States have CHF, and there are 1 million hospitalizations for CHF each year. The incidence is 500,000 new cases each year. The prevalence of heart failure rises dramatically from <1% in individuals under 60 years to over 10% in those older than 80 years.

## Genes

Familial dilated cardiomyopathy has been linked to mutations in the following genes: lamin A/C; troponin T; α-actinin; titin; desmin; troponin C; cardiac sodium channel α subunit, SCN5A; δ-sarcoglycan; phospholamban; metavinculin; cypher/ZASP; myosin-binding protein-C; LIM protein gene, thympoietin; β myosin heavy chain; cardiac actin; α tropomyosin; telethonin; troponin I; dystrophin; tafazzin. Other causes of cardiomyopathies, including the familial hypertrophic variety, are associated with β myosin heavy chain, myosin light chain, α tropomyosin, troponin T and I, cardiac actin, nkx2.5 and presenilin, PSEN1 and PSEN2 gene mutations [1,2].

## Molecular and Systemic Pathophysiology

Common causes of CHF include ischemic, hypertensive heart disease and valvular heart diseases, resulting in cardiomyopathy. Other less common causes include alcoholic cardiomyopathy, viral myocarditis, infiltrative diseases (sarcoidosis, amyloidosis), metabolic disorders (thyroid), cardiotoxins, and drug toxicity. Progressive CHF usually results in reduced cardiac output and a clinical syndrome of left heart failure with pulmonary edema, which might be followed by right heart failure with peripheral edema and hepatic congestion and abdominal ascites. In certain systemic diseases CHF can occur with supra-normal cardiac function, when the metabolic body demand significantly exceeds the supply such as in thyrotoxicosis, severe anemia, arteriovenous shunting, Paget's disease, and thiamine deficiency. Most patients with end-stage heart failure experience fatigue and weight loss and develop progressive loss of skeletal muscle resulting in cardiac cachexia [5]. In the initial stages of compensated CHF, there is elevation of atrial naturetic peptide, (ANP) brain naturetic peptide (BNP), which helps vasodilate and cause naturesis, thus reducing fluid over-load. Elevation of other cytokines such as angiotensin, TNFα, interleukins 1 and 6 can depress cardiac function and have a negative feed-back effect. The molecular etiology of familial dilated cardiomyopathy can be divided mechanistically into mutations in genes that interfere with transmission of force (e.g. actin, dystrophin) generation of force (e.g., β myosin heavy chain, troponin C), with alteration of nuclear structure (e.g., lamin A/C), with alteration of stretch function (e.g., LIM protein), and genes causing abnormalities in calcium regulation that impact contractile function (e.g., phospholamban). Interestingly, Glu54Lys and Glu40Lys in α tropomyosin gene cause dilated cardiomyopathy whereas Glu62Gln, Ala63-Val, Lys70Thr and Val95Ala mutations in the same gene result in hypertrophic cardiomyopathy [1].

One of the genes that have recently been associated with both cardiomyopathy and CHF in rodents and humans is serum response factor (SRF). SRF has also been demonstrated to be increased with normal aging and might predispose the heart to the development of CHF by reducing cardiac reserve capacity [3,5].

## Diagnostic Principles

Diagnosis of CHF is clinical, based on severity of symptoms and signs of heart failure on examination [1,2]. Further substantiating evidence can be obtained

with chest X rays, EKGs, echocardiogram and/or radionuclide scintigraphy for ejection fraction and regional wall motion analysis. Scintigraphy is useful when echocardiography is technically suboptimal, such as in patients with severe pulmonary disease.

### Therapeutic Principles

Correction of reversible causes such as uncontrolled hypertension, myocardial ischemia and treatment of underlying disease states as hypo or hyperthyroidism. Diuretic treatment to reduce fluid overload, ACE inhibitors and β-blockers are cornerstones of treatment [1–5]. Carvedilol a nonselective $\beta_1$- and $\beta_2$-receptor blocker has been shown to reduce mortality by 30–35%. Vasodilators such as nitrates are useful in pre-load reduction in reducing symptoms of pulmonary congestion. Certain conditions might require antiarrhythmic therapy, and in certain medically refractory cases, cardiac transplantation or cardiomyoplasty may be beneficial.

## Heart Hypertrophy

Y. James Kang
Departments of Medicine, Pharmacology and Toxicology, University of Louisville School of Medicine, Louisville, KY, USA

### Synonyms

Cardiac hypertrophy; Hypertrophic cardiomyopathy

### Definition and Characteristics

The most commonly described heart hypertrophy is an enlarged or oversized but non-dilated left ventricle. The increase in the mass of the left ventricle results from the sum of the individual cardiomyocyte hypertrophy. At the cellular level, an increase in cell size, enhanced protein synthesis, and heightened organization of the sarcomere collectively contribute to cardiomyocyte hypertrophy. Atomically, there are two different types of hypertrophy: concentric and eccentric. Concentric hypertrophy is characterized by parallel addiction of sarcomeres and lateral growth of individual cardiomyocytes. Eccentric hypertrophy results from an addition of sarcomeres in series and longitudinal cell growth. Functionally, heart hypertrophy can be described as adaptive or maladaptive. The adaptive or physiological hypertrophy is characterized by an increase in the size of the left ventricle, but preserved contractile function of the heart, so that the output of the heart remains normal. In contrast, maladaptive or pathological hypertrophy is characterized by an abnormal contractility of the heart along with a reduced cardiac output while the left ventricle size increases. Therefore, heart hypertrophy itself may not be a disease condition. It can accompany an increased physiological demand such as the growth after birth or under the training of exercise. However, it is a disease condition when it accompanies many forms of cardiovascular disease, such as ischemic heart disease, cardiac valvular disease, heart failure, and hypertension. A unique disease condition is hypertrophic cardiomyopathy, which represents a hypertrophied and non-dilated left ventricle in the absence of other heart or systemic disease. It is now recognized that pathological hypertrophy is a risk factor for malignant arrhythmia, sudden cardiac death and heart failure [1].

### Prevalence

It is difficult to estimate the prevalence of heart hypertrophy in the general population. However, it is estimated that the occurrence of hypertrophic cardiomyopathy is about 1:1,000 to 2:1,000, but this is only a portion of the overall heart hypertrophy population.

### Genes

Mutations in the gene that encodes for β-cardiac myosin heavy chain (located to chromosome 14) have been identified to be associated with hypertrophic cardiomyopathy. However, many other forms of heart hypertrophy that accompany cardiac or systemic disease are secondary to primary disease conditions.

### Molecular and Systemic Pathophysiology

Heart hypertrophy initially is an adaptive response to pressure or volume overload of the heart. Many disease conditions can cause heart hypertrophy, including ischemic heart disease, hypertension, valvular disease, and aortic stenosis. However, mutations of sarcomeric proteins lead to heart hypertrophy in the absence of cardiac and systemic disease, which is often referred to as hypertrophic cardiomyopathy. Further development of heart hypertrophy becomes maladaptive or detrimental and is a risk factor for malignant arrhythmia, sudden cardiac death, and heart failure. The hypertrophic transformation of the heart can be divided into three

stages: (i) developing hypertrophy, in which the left ventricle load exceeds output, (ii) compensatory hypertrophy, in which the systolic wall stress is normalized by increased wall mass so that the cardiac output remains normal under resting conditions, (iii) decompensatory hypertrophy, in which ventricular dilation and progressive declines in cardiac output take place [2]. A number of pathophysiological components of heart hypertrophy have been identified under different stages of the development. In particular, the detrimental changes include left ventricular outflow obstruction, diastolic dysfunction, myocardial ischemia, cardiac arrhythmia, sudden cardiac death, and heart failure. These cardiac and systemic changes most accompany the third stage of the hypertrophic development. At the molecular level, there is a myriad of alterations in the expression of multiple genes. However, the predominant change is the reactivation of fetal gene programs. In particular, up-regulation of β-cardiac myosin heavy chain, α-skeletal actin, and atrial natriuretic peptide is the molecular hallmark of heart hypertrophy. The overall increases of protein synthesis in cardiomyocytes constitute the mass increase of the heart.

## Diagnostic Principles

Serum markers such as increases in atrial natriuretic peptide are indicative of heart hypertrophy. Echocardiography is a reliable and non-invasive diagnostic procedure for heart hypertrophy. The progression of heart hypertrophy and its transition to heart failure can be diagnosed by a combination of multiple parameters such as echocardiographs, electrocardiographs, stress testing, and molecular markers.

## Therapeutic Principles

In the past, the treatment of heart hypertrophy has not been a mainstay of clinical practice. Patients with hypertrophied hearts have been treated for other cardiac or systemic complications such as heart failure. Recent studies have demonstrated that therapies focusing on heart hypertrophy are beneficial and can prevent the transition to heart failure. In particular, heart hypertrophy can be reversed by drug treatment [3], micro-nutritional manipulation [4], and left ventricle assist device [5].

# Heart Muscle Diseases, Toxic

Katsuhiko Yoshizawa[1,2], Abraham Nyska[3]
[1]Drug Safety Research Laboratories, Astellas Pharma Inc., Osaka, Japan
[2]Pathology II, Kansai Medical University, Moriguch, Japan
[3]Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel

## Synonyms

Cardiotoxicity; Cardiotoxicosis; Toxic myocarditis

H

## Definition and Characteristics

Toxic heart muscle disease is characterized by a clear cause and effect relationship, whether the cause is an overdose, a side effect, or a hypersensitivity reaction in the heart. Chemicals and metabolites may induce altered cardiac functional changes, including electrocardiogram abnormalities (arrhythmias, tachycardia, fibrillation, QT prolongation), hypotension resulting from abnormalities in ion movements (cardiac channelopathies), and dysfunctions of the cell membrane (oxidative stress leading to membrane peroxidation), contractility, and energy-production systems. Hypersensitive reaction (hypersensitivity myocarditis) arises after previous use of the drug without incident, and does not relate to the magnitude of the dose of the drug, clinical signs are consistent with classic allergy, or persistence of symptoms until the drug is discontinued. This type of response may be an immunologically mediated reaction, in which the drug or its metabolites act as a hapten and combine with an endogenous macromolecule.

## Prevalence

The effects of new drugs on ventricular repolarization, especially QT prolongation, are now the most common cause of drug withdrawal from the market and delay in regulatory approval for marketing [1]. However, clinicians may unknowingly give potential cardiotoxic drugs, as in the case of administration of beta–adrenergic receptor agonists that induce pharmacologically predictable dose-related and potency-related adverse effects, including tachycardia and myocardial necrosis. Recently, some selective COX-2 inhibitors have been reported to increase the risk of myocardial infarction and atherothrombotic events and have led to the withdrawal of rofecoxib from global markets [2]. Moreover, FDA advisory committee recommended a "black box" warning describing the cardiovascular risks (increased heart rate, increased blood pressure, myocardial infarction, or stroke) of amphetamines and methylphenidate used to treat attention deficit-hyperactivity disorder. Myocardial infarction is not predicted by

preclinical animal toxicity studies of COX-2 inhibitors, amphetamines, and methylphenidate.

## Genes

Cardiac muscular death associated with apoptosis occurs on the heart following ischemic or drug-induced injury. In the early periods the death occurs predominantly through apoptotic pathways, whereas necrosis occurs at later time points following the insult. Bax, p53, β 1 receptor, p38 α MAPK, SMAD6, JAK-2, and ceramide. were reported as cardiac pro-apoptosis signaling mediators, while BCL-2, Bcl-$X_L$, TGFβ1, ET-1, β 2 receptor AKT/PKB, PI3 kinase, ERK1/2, NFκB, calcineurin, and STAT-3 were reported as cardiac anti-apoptosis signaling mediators [3]. Chronic cardiotoxicity induced by anthracycline reveals the increased gene levels of STARS (striated muscle activator of Rho signaling), SNF1-kinase, AXUD1 (AXIN1-upregulated protein 1), and BTG2 (B-cell translocation gene 2). Anthracycline induces down-regulation of GATA-4 and serves to trigger the induction of cardiomyocytic apoptosis. GATA-4 has been regarded as a cardiac survival factor and an anti-apoptotic factor regulating BCL-2 gene and required for the adaptive stress response of the adult heart.

## Molecular and Systemic Pathophysiology

Myocardial lesions in drug-induced cardiotoxicity vary from merely functional alterations to morphological (histological or subcellular only) changes [4]. The morphologic reactions to toxic injury encompass a wide variety of cardiac lesions, including subcellular alterations (i.e. reduced number or altered mitochondria, as in the case of azidothymidine), myofiber hypertrophy, dilated cardiomyopathy, myocardial degeneration (hydropic, myofibrillar, fatty), myocardial necrosis (coagulative, with contract band), inflammation, fibrosis, and vascular changes. A cellular inflammatory reaction may be poorly developed in toxic heart muscle disease due to anti-neoplastic or immunosuppressive drugs. Vasoactive drugs can impair blood flow within coronary vessels, thus producing localized ischemia, and focal necrosis may occur in the myocardium supplied by an affected vessel. Hypersensitive reactions are characterized by eosinophilic infiltration mingled with mononuclear cells, lymphocytes, and plasma cells. The absence of extensive myocardial necrosis or fibrosis distinguishes this type of reaction from others.

## Diagnostic Principles

The histopathological pattern of lesion development may help determine whether the myocardial damage is due to effects of coronary vasculature (in which case lesions tend to be multifocal) or due to direct myocardial cell toxicity (in which case lesions tend to affect much or all of the myocardium diffusely). Myocardial cells have a limited number of ways in which they react to toxic agents, and the basic pattern of lesion development, degeneration, necrosis with inflammation, interstitial cell proliferation, and final repair by fibrosis, is the same regardless of the mechanism of toxicity. Adverse effects may occur even at normal doses (idiosyncratic reaction) and are usually difficult to predict. Idiosyncratic reaction is most commonly caused by unexpected differences in drug absorption, distribution, metabolism, excretion, or metabolic drug-drug interaction in genetically predisposed individuals. An increase in serum cardiac troponin levels is a sensitive and specific marker for myocardial necrosis [5]. Cardiac troponins (cTnT, cTnI) are released within 4–12 h following the cardiac injury. Natriuretic peptides (ANP, BNP) are also cardiac hormones released in response to atrial or ventricular load-induced stress, and their plasma levels are inversely correlated with measures of cardiac function.

## Therapeutic Principles

The main strategy for preventing cardiotoxicity remains careful monitoring with radionuclide angiography, echocardiography, or serum cardiac markers. Withdrawal of drug treatment should be recommended as soon as the side effect of cardiac function occurs. Patient maintenance is according to conventional management of congestive heart failure. In the case of anthracyclines therapy, dexrazoxane, an iron chelator, and the radioprotective agent amifostine are used to protect against cardiac injury. Other strategies that have been evaluated are dietary glutamine supplementation and the use of the antioxidant probucol. Clinicians should notice that other drug-induced toxicity is frequent in patients with heart failure, as there is the possibility that drugs are cleared at a lower rate due to a decreased activity of cytochrome P450 isoforms. While many cardiotoxic drugs are tolerated by most patients with the adequate usage and they offer reliable protection from diseases, health professionals should be aware of the fact that there is always a risk.

## Heat Stroke

►Hyperthermia

## Heberden's Nodes

Graeme Jones
Musculoskeletal Unit, Menzies Research Institute, Hobart, TAS, Australia

### Synonyms

Nodal osteoarthritis

### Definition and Characteristics

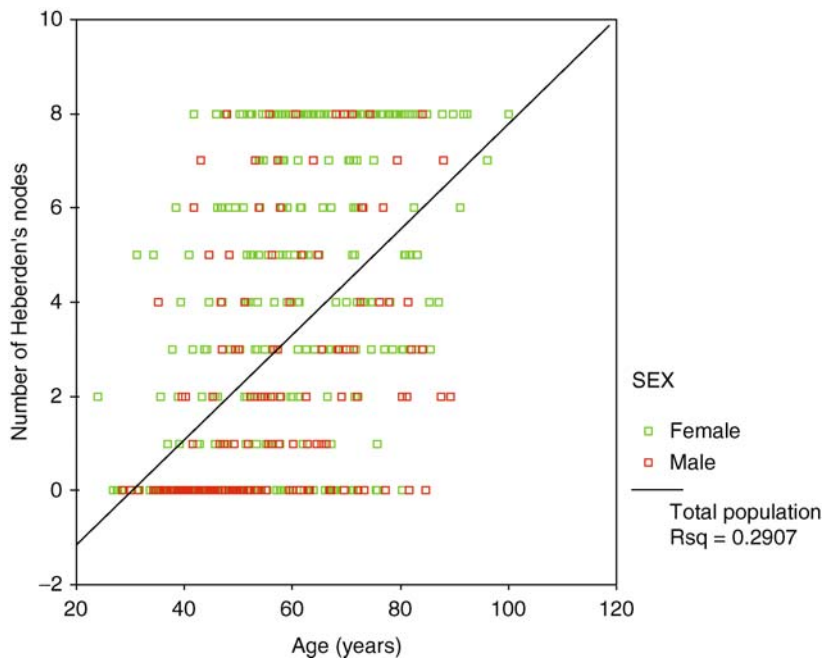
Heberden's original description of "digitorum nodi" remains largely valid "What are those little hard knobs, about the size of a small pea, which are frequently seen upon the fingers, particularly a little below the top, near the joint? They have no connexion with the gout, being found in persons who never had it: they continue for life; and being hardly ever attended with pain, or disposed to become psoriasis, are rather unsightly and inconvenient, though they must be some little hindrance to the free use of fingers" [1]. These are generally the first sign a person is going to develop osteoarthritis and are commonly associated with primary generalized osteoarthritis.

### Prevalence

Rare before age 40 years apart from post-traumatic disease. Prevalence increases sharply with age in both sexes but especially in females (Fig. 1). Virtually all have nodes by age 80.

### Genes

There is a well defined genetic predisposition to this disease. Concordance is higher in monozygotic compared to dizygotic twins [2]. Prevalence and severity is increased in those with affected family members with an estimated heritability of 28% [3]. The inheritance is complex and likely polygenic. No specific genes have been conclusively identified to date.



**Heberden's Nodes. Figure 1** Association between age and number of Heberden's nodes in a Tasmanian population.

**Heberden's Nodes. Figure 2** Typical Heberden's nodes overlying the distal interphalangeal joints.

## Molecular and Systemic Pathophysiology

The pathophysiology has been largely unknown until recently. In a carefully controlled autopsy series [4], the development of Heberden's nodes contrasts with the generally known sequences of the osteoarthritic process. They do not reveal superficial fibrillation or irregularities of the coloring of the ground substance, but an increased ossification within the marginal area of the subchondral bone. These changes cause a progression and also an increase in thickness of the tidemark. Lastly, this leads to irregularities and horizontal ruptures at the interface between the calcified and noncalcified layer although the cartilage surface is completely intact. These ruptures start to increase and they lead to a disruption of the hyaline cartilage. These changes are unique to Heberden's nodes and can be differentiated from controls by a histological scoring system involving macroscopic grading, pannus, cell structure and cartilage (both hyaline and fibrous) particularly in the marginal areas. A recent MRI based study [5] showed that Heberden's node formation occurred at regions where soft tissue bulged through the capsule between the dorsal tendons and collateral ligaments. In addition, prominent collateral ligament thickening or disruption was evident even in joints where cartilage was partially preserved. From epidemiologic studies, the main risk factors are genetic factors, increasing age, female sex and possibly handedness. Both hormone therapy and hormonal factors have an uncertain role with the majority of studies suggesting no effect. The role of occupation and physical activity (in the absence of injury) is uncertain but Heberden's nodes are very common after digital fracture. Smoking may protect against Heberden's nodes suggesting a role for neovascularization in their development.

## Diagnostic Principles

Diagnosis is generally clinically based on hand examination (Fig. 2).

Heberden's nodes are commonly (but not always) associated with underlying radiographic osteoarthritis in the distal interphalangeal joints with a correlation of 0.73 [3]. Semi quantitative scoring systems have been developed based on hand photography. These are valid and reproducible but do not take severity into account.

## Therapeutic Principles

Patients with Heberden's nodes often have transient inflammation in the early stages which later settles. They are often asymptomatic. Treatment revolves around associated pain and disability, which is modest but significantly associated with nodes. The disability is primarily mediated through pain, thus, this is the main therapeutic target. There are few clinical trials but consensus has been developed on what should be measured in trails specifically of hand osteoarthritis. Relief of symptoms can occur with analgesics such as paracetamol, nonsteroidal anti-inflammatory agents (oral or topical), topical capsaicin and corticosteroid injections. Functional aids can assist with tasks such as opening jars. Surgery is rarely required.

### Definition and Characteristics

Helicobacter (H.) pylori is a Gram-negative microaerophilic spiral shaped bacterium. The flagellated bacterium successfully colonizes the hostile environment of the stomach of a wide variety of mammals. In humans, H. pylori causes chronic gastritis, peptic ulcer disease, gastric cancer (identified as a group 1 carcinogen by the WHO), and mucosa associated lymphatic tissue (MALT) lymphoma.

### Prevalence

Infection with H. pylori occurs worldwide and is the most common chronic bacterial infection in man. Notably, the prevalence varies greatly among countries and among population groups within the same country. H. pylori colonizes the stomachs of 50% of the population in developed countries and approx. 80% in the developing world. The infection is acquired by oral ingestion of the bacterium and is mainly transmitted within families. The main source of transmission is the mother within families. The overall prevalence of H. pylori is strongly correlated with socioeconomic conditions. Factors such as density of housing, birth order, number of siblings, overcrowding, sharing a bed and lack of running water have all been linked to a higher rate of H. pylori infection [1].

### Genes

The course of H. pylori induced gastroduodenal disease is highly variable and determined by both, host and microbial factors.

The H. pylori genome ($1.65 \times 10^6$ bp) codes for approximately 1,500 proteins. Not only is H. pylori ubiquitous but it also possesses strong phylogeographic structure, suggesting that bacterial polymorphisms reflect human phylogeography and historical migrations. Recently, a study showed that H. pylori and humans share an intimate association, suggesting that the microbe and humans were evolving predating the "out of Africa" event [4]. Accordingly, H. pylori has probably accompanied anatomically modern humans since their origins.

The genome of H. pylori encodes for several virulence factors that render the colonization of his niche possible.

It has been reported that proinflammatory cytokine gene polymorphisms in the interleukin-1B (encoding IL-1β), IL-1RN (encoding the naturally occurring receptor antagonist for IL-1β), IL-10, and tumor necrosis factor alpha (TNFα), all contribute to increased risk of gastric carcinoma and its precursors (gastric atrophy and hypochlorhydria). These genetic risk markers belong to inflammation-related cytokines that exert their effect as part of the innate and adaptive immune response against the infection. Equally important in the appropriate handling of H. pylori infection are the receptors of the innate immune response. Important receptors of innate immunity are Toll-like receptors (TLRs). A functional TLR 4 Asp299Gly

polymorphism is associated with the development of the premalignant gastric abnormalities of hypochlorhydria and atrophy, and also with increased risk of noncardia gastric carcinoma.

## Molecular and Systemic Pathophysiology

Gastric motility and acidity normally prevents human stomach from bacterial colonization. Natural selection has provided H. pylori with several mechanisms to evade these mechanisms primary defenses and establish persistent infection, such as the ability to withstand acidic gastric pH and motility (Table 1). The bacterial factors that enable H. pylori to persist in the gastric lumen are still being studied, but considerable insight has been gained through the analysis of the H. pylori genome, the creation of H. pylori isogenic mutants, and the use of animal models. H. pylori exclusively colonizes gastric type epithelium, which suggests specific recognition of cell type by the bacterium (Fig. 1).

Data suggest that bacterial attachment is partially mediated by Lewis blood group antigens, thus individuals of certain Lewis phenotype or those of positive secretory status may express specific receptors on the cell surface in greater density, may be more susceptible to infection. However, the final role of Lewis antigen expression in bacterial attachment is not clear. The homologous structures of H. pylori lipopolysaccharide (LPS) and host Lewis antigens may lead to an autoimmune response with subsequent cell injury. LPS from H. pylori signals via TLR 2 and is capable, in contrast to most other LPS, to inhibit TLR 4 triggered signaling.

Functional differences between strains of H. pylori may relate to virulence and tissue damage. One such difference is the expression of an 87 kD vacuolating cytotoxin (VacA) which causes cell injury in vitro and gastric tissue damage in vivo. All H. pylori contain the gene encoding for VacA, but only strains with the cytotoxin-associated gene A (cagA), coding for a 128–140 kD protein (CagA) coexpress VacA. VacA is a passive urea transporter capable of increasing the permeability of epithelium to urea, thereby creating a favorable environment for H. pylori infectivity. CagA is not cytotoxic but is antigenic and can be detected serologically. Its function is unknown but it might play a role in transcription, excretion or function of VacA. Notably, H. pylori can secrete its CagA protein via a type IV secretory apparatus into gastric epithelial cells. Infection leads to a vigorous local and systemic humoral response. H. pylori causes continuous gastric inflammation in virtually all infected persons [2,3].

## Diagnostic Principles

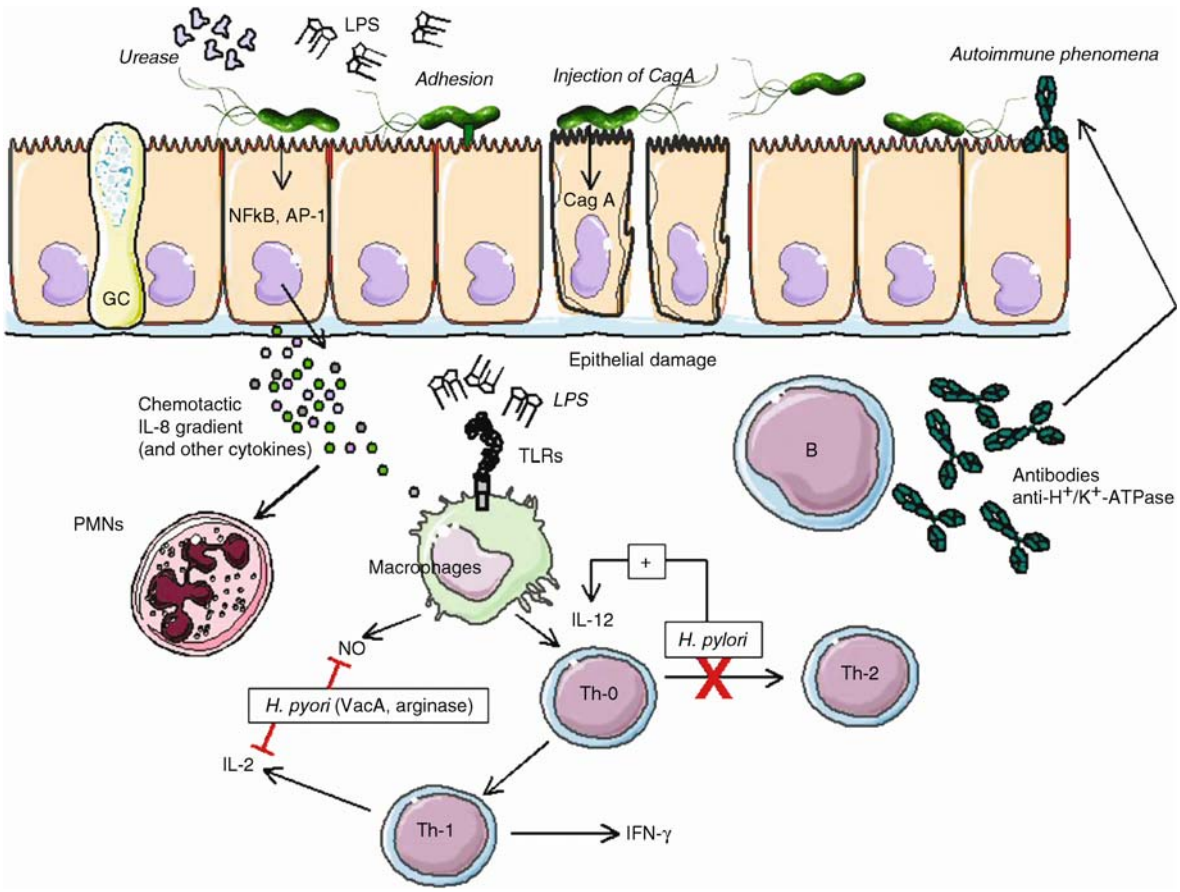
Diagnosis of H. pylori infection focuses on the direct detection of microbes in gastrointestinal tissue e.g. from biopsy samples and subsequent culture or on detection of surrogate markers indicating the presence of H. pylori in the stomach. Several invasive and non-invasive tests are currently available. The gold standard is upper gastrointestinal tract endoscopy with biopsy and subsequent histology (sensitivity > 95%, specificity 100%). Detection of urease activity (sensitivity 93–97%, specificity >95%), and culture (sensitivity 70–80%, specificity 100%) are additional invasive methods. Non-invasive methods are serology for immunoglobulin G (IgG) with widely varying sensitivity and specificity, urea breath test (sensitivity 95–100%, specificity 91–98%), and H. pylori stool antigen test (sensitivity 91–98%, specificity 94–99%).

## Therapeutic Principles

Therapy of H. pylori is aimed on complete eradication of the organism. Once the organism is cleared from the stomach, re-infection rates are low, thus treatment is durable. The cornerstone of treatment are antibiotic agents, however as an eradication regimen must have cure rates of at least 80% (according to intention-to-treat analysis) without major side effects and with minimal induction of bacterial resistance, this cannot be reached by antibiotics alone. Luminal acidity influences effectiveness of antimicrobial agents, thus it is necessary to combine proton-pump inhibitors or ranitidine bismuth citrate. So-called triple therapies,

**Helicobacter Pylori-induced Gastroduodenal Disease. Table 1** H. pylori proteins that may contribute to gastric colonization

| Product | Gene(s) | Function | Targeted host defense |
|---|---|---|---|
| Urease | ure operon | Gastric acid neutralization | Gastric acid |
| Flagellae | flaA, flab, flg and flbA | Motility | Gastric peristalsis |
| Lewis antigens | galT, futA, futB and futC | Adherence to gastric epithelium, molecular mimicry | Gastric peristalsis, humoral immune response |
| Adhesins | babA, others | Adherence to gastric epithelium | Gastric peristalsis |



**Helicobacter Pylori-induced Gastroduodenal Disease. Figure 1** H. pylori infection and inflammatory response H. pylori resides in the mucus layer. Colonization of this hostile niche is possible due to various adaptive mechanisms e.g. urease secretion. Firm binding to epithelial cells via BabA and injection of CagA into the host cell will lead to IL-8 production via NFκB and AP-1 (contact between H. pylori and gastric epithelial cells results in a rapid activation of NFκB, which is followed by increased IL-8 expression) and subsequently disruption of the epithelial barrier caused e.g. by TNF-α driven apoptosis. The IL-8 secretion acts as a chemoattractant for polymorphonuclear cells (PMNs) and macrophages. Antigenic substances such as heat shock proteins (HSP), LPS and urease are found in the gastric lumen. The LPS of H. pylori has a particularly low inflammatory potential and mimics Lewis blood group antigens. Macrophages sense LPS and are activated mainly via TLR-2, whereas TLR-4 activation can be blocked by H. pylori LPS. Macrophages add to IL-8 production and are involved in activation of further immune cells (particularly T-helper cells; Th-0, Th-1 and Th-2). T helper cells respond with a biased Th-1 response to H. pylori. A more pronounced Th-2 response towards H. pylori is at least in part inhibited by the microorganism e.g. by stimulating IL-12 secretion. B cells secrete antibodies targeted against H. pylori – occasionally these antibodies target also gastric $H^+/K^+$-ATPase, thus the organism's molecular mimicry triggers autoimmunity leading to autoimmune chronic gastritis. Changes in gastric cytokine milieu will lead to changes in acid secretion and gastric homeostasis thus contributing to pathology. GC goblet cell LPS Lipopolysaccharide PMNs polymorphonuclear cells TLRs toll-like receptors NO nitric oxide.

combining two antimicrobial substances and an anti-secretory drug have been extensively studied and have been approved by the Food and Drug Administration (FDA). Basically amoxicillin, clarithromycin, metronidazole, tetracycline and bismuth are used as antibiotics.

# Hemangioblastoma

►Angiosarcoma

# Hemangioma, Capillary

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Infantile hemangioma; Strawberry hemangioma

## Definition and Characteristics

Typically, infantile hemangiomas are not clinically apparent at birth [1]. They usually appear in the first few weeks of life as areas of pallor, followed by telangiectatic patches [1]. They then grow rapidly in the first 3–6 months of life. Superficial lesions are bright red, protuberant, and sharply demarcated and are often referred to as "strawberry hemangiomas" or "capillary hemangiomas" (Fig. 1).

Deep lesions are bluish and dome-shaped. Hemangiomas consist of collections of dilated vessels surrounded by masses of proliferating endothelial cells. Infantile hemangiomas continue to grow until 9–12 months of age, at which time the growth rate slows down to parallel the growth of the child. Involution begins in most cases by the time the child is 3–4 years old. A central graying of the lesion and shrinkage in size are the visible stages of this process. Half of these lesions will show complete involution by the time a child reaches age 5; 70% will have disappeared by age 7; and 95% will have regressed by ages 10–12 [1]. When involution is complete, the skin looks completely normal; partial involution may leave an atrophic scar with a few telangiectatic vessels. Other complications include hemorrhage, ulceration, disfigurement, and vital structure compromise. An infantile hemangioma usually occurs sporadically and in isolation. Occasionally, it is associated with PHACES syndrome (posterior fossa malformations, hemangiomas, arterial anomalies, cardiac defects or coarctation of the aorta, eye abnormalities, and sternal defects) and PELVIS syndrome (perineal hemangioma, external genitalia malformations, lipomyelomeningocele, vesicorenal abnormalities, imperforate anus, and skin tags) [2]. Lesions over the lumbosacral area may be associated with spinal dysraphism, urogenital abnormalities, and rectal abnormalities [2].

**Hemangioma, Capillary. Figure 1** A 2-year-old girl with an infantile hemangioma on her left thigh.

## Prevalence

Infantile hemangioma occurs in 4–10% of infants [3,4]. The female to male ratio is approximately 3:1 [3]. Other risk factors include prematurity, low birth weights, white ethnicity, multiple gestations, older maternal age, placenta previa, and pre-eclampsia.

## Genes

The genes encoding indoleamine 2,3-dioxygenase, insulin-like growth factor 2 (IGF2) angiopoietin-1, angiopoietin-2, basic fibroblast growth factor (bFGF), and vascular endothelial growth factor (VEGF), and Tie2 play a significant role in the pathogenesis of infantile hemangiomas [3].

## Molecular and Systemic Pathophysiology

An infantile hemangioma might result from a somatic mutation which slows the maturation of endothelial progenitor cells to endothelial cells [3]. Infantile hemangioma stains with a panel of immunohistochemical markers such as glucose-transporter-1 protein, Lewis Y antigen, and Merosin which distinguishes it from other vascular malformations [2]. As these markers are expressed in placental microvasculature, infantile

hemangioma might originate from embolized placental tissue or a somatic mutation which causes angioblasts to differentiate toward a placental microvascular phenotype [2]. The involution of the hemangioma is characterized by ICAM-1 (CD54) expression and a spare infiltrate of $CD8^+$ suppressor T-cells [3].

### Diagnostic Principles

The diagnosis is mainly clinical. Infantile hemangiomas have to be differentiated from rapidly-involuting congenital hemangiomas and non-involuting congenital hemangiomas which are fully formed at birth [3].

### Therapeutic Principles

The majority of infantile hemangiomas require no treatment. Indications for active intervention include severe or recurrent hemorrhage unresponsive to treatment, threatening ulceration in areas where serious complications might ensue, interference with vital structures, and significant disfigurement [5]. Treatment options include systemic or intralesional corticosteroids, interferon-α, pulsed-dye laser, and surgical resection [5].

## Hematemesis

Johannes G. Bode
Department of Gastroenterology, Hepatology and Infectiology, University-Hospital, Heinrich-Heine University Duesseldorf, Duesseldorf, Germany

### Definition and Characteristics

Hematemesis (vomiting of blood or coffee-ground like material) is the leading symptom of major upper gastrointestinal bleeding and is frequently associated with melena (black, tarry stools).

### Prevalence

Acute upper gastrointestinal bleeding is a common medical emergency which carries hospital mortality in excess of 10% and an annual incidence of about 100/100,000 [1] and results in high patient morbidity and medical care costs. Major causes of upper gastrointestinal bleeding are:

- Peptic ulcer disease 40–79%
- Gastritis/duodenitis 5–30%
- Esophageal varices 6–21%
- Mallory-Weiss tear 3–15%
- Esophagitis 2–8%
- Tumors 2–3%

Other disorders, such as Dieulafoy's lesion, gastric arteriovenous malformations and portal hypertensive gastropathy, are rare and in total account for less then 15% of all events of upper gastrointestinal bleeding. Very rare causes of upper gastrointestinal bleeding are hemobilia or hemosuccus pancreaticus.

### Genes

Most of the causes of hematemesis are not due to an inherited disorder or can be primarily attributed to hereditary factors. The Osler-Weber-Rendu syndrom is inherited as an autosomal dominant trait with varying penetrance and expression. Mutations are found in at least four genes, with the two major disease genes the endoglin gene on chromosome 9 and the activin receptor-like kinase 1 encoding gene on chromosome 12. Cavernous malformations such as the Blue ruber red naevus syndrome can be sporadic or familial. Three genetic loci localized to Chromosome 7q (CCM1), 7p15-p13 (CCM2) and 3q25.2-q27 responsible for familial cavernous malformations have been reported.

### Molecular and Systemic Pathophysiology

Upper gastrointestinal bleeding is due to a broad spectrum of different disorders and hence is not reducible to a single underlying pathomechanism. As summarized in Table 1

**Hematemesis. Table 1** Etiological categories of the different disorders which might cause upper gastric bleeding

| Non-tumor ulcerative or erosive disorders | Complications of portal hypertension | Vascular malformations | Traumatic or post-interventional causes | Tumors |
|---|---|---|---|---|

the different disorders can be roughly classified into five broad etiological categories: (i) non-tumor ulcerative or erosive disorders such as peptic ulcer disease, hemorrhage gastritis or esophagitis (ii) bleeding caused by complications of portal hypertension, e.g. esophageal, gastric or duodenal varices or hypertensive gastropathy (iii) vascular malformations such as idiopathic angiomas, Osler-Weber-Rendu syndrome or the so called watermelon stomach (iv) traumatic or post-surgical causes and (v) the different benign or malignant tumors of the duodenum, the stomach and the esophagus.

Most of these disorders such as peptic ulcer disease, esophagitis or portal hypertension again are the result of a multitude of underlying pathological conditions or risk factors. Thus, for example the major risk factors for peptic ulcer disease are helicobacter pylori infection, stress, gastric acid and the use of nonsteroidal antiinflammatory drugs (NSAIDs) [2] whereas esophagitis is the result of such different pathological conditions as reflux, chemotherapy, viral (herpes simplex virus, cytomegalovirus) or fungal (candida) infections. Likewise, portal hypertension is due to a multitude of different underlying hepatic disorders leading to liver-cirrhosis, obliteration of the hepatic veins or systemic/organ disorders causing thrombosis of the portal vein.

### Diagnostic Principles

The cornerstone for clarification and treatment of upper gastrointestinal bleeding is the early endoscopy of the upper gastrointestinal tract [3]. Moreover endoscopic, clinical, and laboratory features should be assessed for risk stratification of patients who present with upper gastrointestinal bleeding.

### Therapeutic Principles

In the acute situation endoscopic treatment of the bleeding cause as well as measures for hemodynamic stabilization are prior [4]. However, under some conditions angiographic intervention might be the only possibility to sustainable treat the bleeding cause [4]. Furthermore, depending on the respective underlying disorder more specific therapeutic approaches (e.g. suppression of gastric acid, eradication of helicobacter pylori upon peptic ulcer disease, medical reduction of portal pressure, surgery) might be required to consolidate the success of the endoscopic/angiographic measures and to prevent from relapse [2,3].

## Hematochezia

Johannes G. Bode
Department of Gastroenterology, Hepatology and Infectiology, University-Hospital, Heinrich-Heine University Duesseldorf, Duesseldorf, Germany

H

### Definition and Characteristics

The term hematochezia describes the passage of maroon or bright red blood or blood clots per rectum [1]. Hematochezia is the leading symptom of lower gastrointestinal bleeding (distal of the ligament of Treitz) but also occurs in up to 11% of a massive upper gastrointestinal bleeding if intestinal blood passage is faster than 8–10 h. If blood passage takes more than 8–10 h oxidation of hematin in the gut will lead to black and tarry stools also termed as melena.

### Prevalence

The incidence of lower gastrointestinal bleeding is estimated to be between 20 and 30 per 100,000 adult population at risk. The incidence increases with age, with a greater than 200-fold increase from patients with an age of 20 years to the age of 80 years. Major sources of lower gastrointestinal bleeding are [2,3]:

Colon (~85%)

- Diverticulosis of the colon 4–48%
- Cancer/polyps 7–33%
- Colitis/ulcers 9–18%
- Anorectal (hemorrhoids, fissures and rectal ulcers) 4–10%
- Ischemia 3–9%
- Radiation colitis 4–7%
- Angiodysplasia 2–8%

Small bowel (~5%)

- Angiodysplasia 70–80%
- Meckels diverticel 30% (males younger than 30 years)
- Tumors 5–10%
- Rare causes of bleeding from the small bowel are enteritis, inflammatory bowel disease, vasculitis and aortenteric fistula

In most series, diverticulosis is the leading cause of lower gastrointestinal bleeding whereas angiodysplasia accounts only for 2–6% of all causes of lower gastrointestinal bleeding. However, angiodysplasia may be the most frequent cause in patients over the age of 65. Moreover, in subjects under the age of 50 hemorrhoids are the most common cause of rectal bleeding which is usually minor and thereby distinguished from other sources of lower gastrointestinal bleeding. Likewise, bloody diarrhea due to infectious causes can sometimes be distinguished from other causes of lower gastrointestinal bleeding because of the clinical setting.

## Genes

Only in a minority of the cases of hematochezia hereditary disorders are the responsible cause. However, particularly vascular malformations can be due to an underlying hereditary disorder such as the marfan syndrome. The majority of patients with the typical Marfan phenotype harbor different mutations involving the fibrillin 1 gene located at chromosome 15q-21.1 which is an important component of both elastic and nonelastic connective tissues. In approximately 10% of patients with Marfan Syndrom an inactivating mutation of the transforming growth factor-beta receptor may be responsible. Other congenital diseases which are associated with vascular anomalies and hence might cause lower gastrointestinal bleeding are the blue rubber bleb nevus syndrome, Klippel-Trenaunay syndrome, Ehlers-Danlos syndrome and the hereditary hemorrhagic telangiectasia. The latter, also termed as the Osler-Weber-Rendu syndrome, is associated with mutations in at least four genes from which the two major disease genes are the endoglin gene on chromosome 9 and the activin receptor-like kinase 1 encoding gene on chromosome 12. Mutations within three genetic loci localized to Chromosome 7q (CCM1), 7p15-p13 (CCM2) and 3q25.2-q27 have been reported to be responsible for cavernous malformations such as the blue rubber bleb nevus syndrome. The Ehlers-Danlos syndrome is a group of inherited disorders due to defects in type III collagen that cause hyperelasticity and fragility of the skin and hypermobility of the joints and as a rare but serious complication spontaneous rupture of large and medium sized arteries, usually without dissection.

## Molecular and Systemic Pathophysiology

Lower gastrointestinal bleeding and therefore hematochezia as its major clinical symptom is due to a broad spectrum of different disorders and hence is not reducible to a single underlying pathomechanism [2,4]. Based on their etiology the different underlying disorders can be roughly classified into several categories (summarized in Table 1): (i) anatomic alterations such as diverticulosis (ii) vascular disorders, e.g. angiodysplasia, chronic or acute intestinal ischemia (iii) inflammatory causes like viral, fungal, parasitic or bacterial infections or idiopathic/autoimmune

**Hematochezia. Table 1** Etiological categories of the different disorders which might cause lower gastric bleeding

| Anatomical, traumatic and post interventional causes | Vascular | Inflammatory | Tumors |
|---|---|---|---|
| **Diverticulosis**<br>**Surgical anastomosis**<br>**Post-biopsy or polypectomy** | **Angiodysplasia:**<br>• Hemangioma<br>• Colonic varices<br>• Congenital arteriovenous malformations<br>• Osler-Weber-Rendu disease<br>• Ehlers-Danlos syndrome<br>• Marfans syndrome<br>**Radiation induced telangiectasia**<br>**Vasculitis** | **Infectious colitis/enteritis:**<br>• Cytomegalovirus<br>• Herpes simplex virus<br>• Candida albicans<br>• Entamoeba histolytica<br>• Yersinia<br>• Salmonella<br>• Shigella<br>• Campylobacter<br>• Enterohemorrhagic escherichia coli<br>**Ischemic colitis**<br>**Chronic inflammatory bowel disease:**<br>• Colitis ulcerosa<br>• Crohn's disease<br>**Radiation-induced colitis**<br>**Drug induced ulcer:**<br>• NSAR | **Benign:**<br>• Polyp<br>– Adenomatous<br>– Harmatomatous<br>– Hyperplastic<br>• Lipoma<br>• Leiomyoma<br>**Malignant:**<br>• Adenocaricnoma<br>• Leiomysarcoma<br>• Lymphoma<br>• Karposi sarcoma<br>• Carcinoid<br>• Metastatic tumor<br>• Melanoma |

conditions such as chronic inflammatory bowel disease (iv) tumors.

## Diagnostic Principles

Endoscopic examination of the colon and the upper gastrointestinal tract should be performed [3]. Particularly if bleeding is expected to come from the small bowel enteroscopy by push-endoscopy or double balloon endoscopy might be required. In some cases an angiographic examination might be helpful to both diagnose and treat the bleeding cause.

## Therapeutic Principles

In the acute situation endoscopic treatment of the bleeding cause and hemodynamic stabilization is prior [3,4]. However, under some conditions angiographic intervention is the only possibility to effectively treat the bleeding cause [3]. Furthermore, depending on the respective underlying disorder more specific therapeutic approaches (e.g. surgery) might be required to consolidate the success of the endoscopic/angiographic measures and to prevent from relapse.

# Hematuria

Clifford E. Kashtan
Department of Pediatrics, University of Minnesota Medical School, Minneapolis, MN, USA

## Synonyms

Familial hematuria; Hereditary nephritis; Alport syndrome; Alport syndrome–diffuse leiomyomatosis complex; Alport syndrome–mental retardation complex; Thin basement membrane nephropathy; Epstein syndrome; Fechtner syndrome

## Definition and Characteristics

Hematuria (blood in the urine) is a common symptom of diseases of the urinary tract, including the kidneys. For the purposes of this essay, familial hematuria is defined as a group of genetic disorders of glomerular capillaries that are characterized clinically by the onset of persistent hematuria during childhood. Hematuria may be the presenting feature of other heritable diseases, including polycystic kidney disease, hypercalciuria and other forms of hereditary urolithiasis, which will not be discussed here.

*Alport Syndrome:* Alport syndrome is a generalized disorder of basement membranes resulting from defective incorporation of a type IV collagen network composed of α3, α4 and α5 type IV collagen chains. Although basement membranes containing the α3α4α5 (IV) network are present in many tissues, clinical abnormalities of the kidney, inner ear and eye dominate the phenotype. All affected males, and about 95% of affected females, exhibit microscopic hematuria from early in childhood. Episodic macroscopic hematuria may also occur. With maturation, affected males develop proteinuria, hypertension and decreased renal function. Virtually all affected males with the X-linked form of Alport syndrome eventually require dialysis or kidney transplantation, with about 50% of affected males reaching end-stage kidney disease by age 25, 90% by age 40 and nearly 100% by age 60. About 75% of affected females with the X-linked form of Alport syndrome eventually develop proteinuria, with end-stage kidney disease occurring in about 15% by age 40 and about 30% by age 60. The renal phenotype of males and females with the autosomal recessive form of Alport syndrome is similar to that of males with X-linked Alport syndrome. The renal disease associated with the autosomal dominant form of Alport syndrome typically progresses much more slowly, with end-stage kidney disease frequently delayed until 50 years of age or later. Individuals with Alport syndrome frequently exhibit sensorineural deafness that is first detectable in males with X-linked Alport syndrome, and males and females with autosomal recessive Alport syndrome, in late childhood. The hearing deficit initially affects high frequency sounds but gradually extends into the conversational range, requiring hearing aids. Specific ocular defects, including anterior lenticonus, perimacular retinal flecks, posterior corneal vesicles and recurrent corneal erosions, occur in 20–30% of males with X-linked Alport syndrome and a similar percentage of those with autosomal recessive Alport syndrome.

*Thin Basement Membrane Nephropathy*: Thin basement membrane nephropathy is an autosomal dominant

disorder characterized by the onset of microscopic hematuria in childhood. Affected individuals may have episodic macroscopic hematuria. In the great majority of patients, hematuria is the only symptom; development of proteinuria, hypertension or reduced kidney function is unusual. There is no extrarenal phenotype in thin basement membrane nephropathy.

*Epstein and Fechtner Syndromes*: Epstein and Fechtner syndromes are rare autosomal dominant disorders consisting of hematuria, progressive nephropathy, sensorineural deafness and macrothrombocytopenia. Patients with Fechtner syndrome also exhibit characteristic leukocyte inclusions.

## Prevalence

*Alport Syndrome*: It has been estimated that Alport syndrome occurs in 1:50,000 live births.

Thin basement membrane nephropathy: Estimates of the prevalence of thin basement membrane nephropathy range from 1 to 9% of the population.

## Genes

*Alport Syndrome* (Table 1): There are three genetic types of Alport syndrome (AS): X-linked (XLAS), autosomal recessive (ARAS) and autosomal dominant (ADAS). XLAS accounts for about 80% of patients and results from mutations in COL4A5, which encodes the α5 chain of type IV collagen [α5(IV)]. ARAS (about 15% of patients) arises from mutations affecting both alleles of COL4A3, which encodes α3(IV), or COL4A4, which encodes α4(IV). About 5% have ADAS due to heterozygous mutations in COL4A3 or COL4A4. Hundreds of mutations in COL4A3, COL4A4 and COL4A5 have been described, including deletions and major rearrangements, missense mutations, nonsense mutations and splicing defects. Nearly all are unique.

*Alport Syndrome–Diffuse Leiomyomatosis Complex (AS-DL):* In a small number of families, XLAS is associated with leiomyomas (smooth muscle tumors) of the esophagus, tracheobronchial tree and, in females, external genitalia. AS-DL is a contiguous gene syndrome, resulting from deletions that span the 5′ ends of the adjacent, 5′-to-5′-oriented, COL4A5 and COL4A6 genes. An interesting feature of these deletions is that, while any length of COL4A5 may be involved, the breakpoint on the COL4A6 side must lie within the second intron of the gene. If the deletion extends beyond the second intron, the patient will have XLAS without leiomyomatosis.

*Alport Syndrome–Mental Retardation Complex (AS-MR):* An association of XLAS with mental retardation and midface hypoplasia has been described in two families transmitting deletions of COL4A5 that extend beyond the 3′ (telomeric) end of the gene. In one of the families, where the deletion extends 2 Mb beyond the 3′ end of COL4A5, elliptocytosis is an additional component of the phenotype. Several genes located in the deleted region downstream from COL4A5 are candidate loci for X-linked mental retardation.

*Thin Basement Membrane Nephropathy* (Table 1): Thin basement membrane nephropathy (TBMN) is an autosomal dominant disorder. About 40% of TBMN families exhibit heterozygous mutations in COL4A3 or COL4A4. Although most individuals with heterozygous mutations in COL4A3 or COL4A4 have TBMN, some have ADAS, for unknown reasons.

*Epstein and Fechtner Syndromes* (Table 1): These disorders result from mutations in MYH9, which encodes nonmuscle myosin heavy chain IIA. Epstein and Fechtner syndromes belong to a family of giant platelet disorders due to MYH9 mutations that also includes Sebastian syndrome and May-Hegglin anomaly.

## Molecular and Systemic Pathophysiology

Type IV collagen, the major collagenous constituent of basement membranes, comprises a family of six protein

**Hematuria. Table 1**

| | Locus | Protein |
|---|---|---|
| **Alport syndrome** | | |
| X-linked | COL4A5 | α5(IV) |

chains designated α1(IV)–α6(IV). Type IV collagen α chains synthesized in epithelial and endothelial cells associate into trimeric molecules that in turn form networks through intermolecular interactions. Three type IV collagen networks have been recognized in mammalian basement membranes, according to trimer composition: α1α1α2, α3α4α5 and α5α5α6. The α1α1α2 network is found in all basement membranes, while the α3α4α5 and α5α5α6 networks exhibit restricted distributions. Mutation in any one of the three component chains of α3α4α5 trimers can prevent formation of the α3α4α5 network. Mutations in COL4A5 also interfere with α5α5α6 network formation.

The clinical phenotype of Alport syndrome reflects abnormalities in the incorporation of the α3α4α5 network in selected basement membranes of the kidney (glomerular basement membrane, or GBM), cochlea (basement membrane of the Organ of Corti) and eye (corneal basement membrane, Descemet's membrane, anterior lens capsule and Bruch's membrane). In the majority of males with XLAS, and patients of either gender with ARAS, the α3α4α5 network is absent from all basement membranes. Females with XLAS typically exhibit mosaic patterns of expression of the α3α4α5 network in basement membranes.

Although many aspects of the molecular pathophysiology of Alport syndrome are poorly understood, there is a growing body of information regarding the consequences of absent or abnormal α3α4α5 networks in tissues. The case of anterior lenticonus is perhaps the most straightforward. Absence of the α3α4α5 network is associated with marked attenuation of the anterior lens capsule. Over time the lens becomes deformed, presumably as a result of the mechanical weakness of the lens capsule, with protrusion of the central portion of the lens into the anterior chamber.

The absence of α3α4α5 networks has somewhat different consequences in the kidney. Since fetal GBM is normally composed of α1α1α2 networks, glomerular development occurs normally in Alport patients. However, the transition in GBM from α1α1α2 networks to α3α4α5 networks that normally takes place during glomerular maturation does not occur, with the result that the mature Alport GBM contains α1α1α2 networks rather than α3α4α5 networks. Early in Alport syndrome, the GBM exhibits marked attenuation, analogous to the anterior lens capsule. Hematuria is thought to result from focal ruptures of weakened glomerular capillary walls, with leakage of red blood cells into Bowman's space. At this stage of the disease, glomerular filtration rate and barrier function (the capacity to minimize protein traffic across the glomerular capillary wall) are normal. However, this is not a static situation: α1α1α2 networks accumulate progressively in the GBM; types V and VI collagens, which are normally minor components of the GBM, are deposited in substantial amounts; other extracellular matrix proteins that are normally absent from GBM, such as the laminin α2 chain appear in the GBM. The alterations in gene regulation that mediate these changes have not been identified. Simultaneously, the GBM exhibits progressive thickening and disorganization, and glomerular barrier function deteriorates, resulting in proteinuria. These glomerular events are eventually joined by pro-fibrotic processes in the renal interstitium, leading to deterioration in glomerular filtration.

A third variation appears to take place in the cochlea of human Alport subjects. In control cochleae, α3α4α5 networks are present in the spiral limbus, the spiral ligament and the basement membrane situated between the organ of Corti and the basilar membrane. However, these chains are not expressed in the cochleae of males with XLAS. Examination of well-preserved cochleae from men with XLAS have revealed a unique zone of separation between the organ of Corti and the underlying basilar membrane, as well as cellular infiltration of the tunnel of Corti and the spaces of Nuel within the organ of Corti. In theory, these anatomical changes could alter the tuning of basilar membrane motion and hair cell stimulation, resulting in diminished hearing sensitivity. Sounds of different frequencies excite different regions of the cochlea, with a gradient from high frequency sounds at the base of the cochlea to low frequency at the apex of the cochlea. Progressive separation of the organ of Corti from the basilar membrane, beginning at the base of the cochlea and proceeding toward its apex, could account for the gradual progression of the hearing defect from high frequency sounds to conversational speech.

The course of XLAS in affected females is probably influenced by X-inactivation patterns, although conclusive evidence supporting this hypothesis is lacking. As discussed above, the typical male with XLAS exhibits complete absence of α3α4α5 networks in GBM. Since normal males have only one COL4A5 allele, it is clear that a single normal COL4A5 allele provides sufficient α5 (IV) substrate for α3α4α5 network formation. In contrast, a single mutant COL4A5 allele prevents formation of the α3α4α5 network, despite the presence of normal COL4A3 and COL4A4 alleles. In females with XLAS, GBM-producing cells, presumably podocytes, will have either an active normal COL4A5 allele and produce normal α3α4α5 trimers, or an active mutant COL4A5 allele, preventing formation of normal α3α4α5 trimers. The glomeruli of a female with XLAS would be expected to exhibit a mixture of normal, α3α4α5-positive GBM and abnormal, α3α4α5-negative GBM. The severity of renal, cochlear and ocular involvement in a woman with XLAS would then depend on the balance of wild-type and mutant alleles resulting from random X-chromosome inactivation, and the consequent impact on α3α4α5 networks in the relevant basement membranes.

In those individuals with TBMN due to heterozygous mutations in COL4A3 or COL4A4, α3α4α5 networks are expressed in basement membranes, but probably at reduced levels. The GBM of TBMN is diffusely attenuated, and hematuria probably arises from focal ruptures of the glomerular capillary wall, as in patients with Alport syndrome. However, the preservation of some level of α3α4α5 network in GBM appears to prevent the over-expression of α1α1α2 networks, types V and VI collagens and other extracellular matrix proteins observed in Alport syndrome. The GBM of TBMN patients remains attenuated throughout life, and never exhibits the thickening and disorganization that characterize Alport GBM. This persistence of GBM attenuation probably accounts for the fact that TBMN patients maintain normal glomerular filtration and barrier function. The preservation of α3α4α5 networks in cochlear and ocular basement membranes may explain why TBMN patients do not have extrarenal symptoms.

Nonmuscle myosin heavy chain IIA (NMMHC-IIA), the protein product of MYH9, is expressed in platelets, neutrophils, glomerular visceral epithelial cells (podocytes) and several cell types of the cochlea, including sensory and supporting hair cells in the organ of Corti. Megakaryocytes and platelets from patients with MYH9 mutations exhibit a 50% reduction in NMMHC-IIA. Maturation of megakaryocytes in these patients appears to be unaffected, although the final step of platelet formation is abnormal, perhaps due to defective segmentation. Neutrophil inclusions contain aggregates of mutant and wild-type NMMHC-IIA chains. The most consistent abnormality in the kidney appears to be focal fusion of visceral epithelial cell foot processes. The GBM does not exhibit the characteristic alterations seen in Alport syndrome. There is substantial variability in the renal phenotype among related individuals with MYH9 mutations, leading to speculation about the possible influence of modifier genes.

## Diagnostic Principles

*Alport Syndrome:* The presence of two of the following diagnostic criteria establishes the diagnosis of Alport syndrome:

1. Family history of hematuria progressing in males to end-stage renal disease
   - About 10–15% of males with XLAS have de novo mutations, so family history may be negative for renal disease. Family history may also be negative in patients with ARAS, although one or both parents may have hematuria.
2. Characteristic thickening of the glomerular basement membrane and splitting of the lamina densa, detected by electron microscopy of kidney biopsy specimens
   - Children with Alport syndrome may exhibit only diffuse GBM attenuation, making differentiation from TBMN a challenge.
3. Progressive, high-frequency sensorineural deafness
   - The hearing deficit is frequently detectable by audiometry in later childhood (5–10 years of age) in boys with XLAS and both boys and girls with ARAS.
4. Anterior lenticonus or perimacular retinal flecks
   - These changes are pathognomonic of Alport syndrome. Anterior lenticonus is usually not detectable until later adolescence.
5. Characteristic abnormalities of renal basement membrane expression of type IV collagen α3, α4 and α5 chains (i.e., the α3α4α5 network) by immunostaining of renal biopsy specimens
   - It is important to note that normal renal basement membrane expression of type IV collagen α3, α4 and α5 chains cannot by itself exclude a diagnosis of Alport syndrome.
   - XLAS: About 80% of XLAS males exhibit complete absence of α3, α4 and α5 chains in renal basement membranes. 60–70% of XLAS females exhibit mosaic staining patterns for these proteins.
   - ARAS: The characteristic pattern is complete absence of α3, α4 and α5 chains in GBM, absence of α3 and α4 chains in Bowman's capsules and distal tubule basement membranes, but persistence of α5 chains in Bowman's capsules and distal tubule basement membranes (as a component of α5α5α6 networks).
   - ADAS: Results of immunostaining for α3, α4 and α5 chains are normal.
6. Characteristic abnormalities of epidermal basement membrane expression of the α5 chain of type IV collagen by immunostaining of skin biopsy specimens
   - The normal epidermal basement membrane expresses α5α5α6 networks. The α3α4α5 network is not expressed in epidermal basement membranes of normal subjects.
   - It is important to note that normal epidermal basement membrane expression of the α5 chains cannot by itself exclude a diagnosis of Alport syndrome.
   - XLAS: About 80% of XLAS males exhibit complete absence of α5 chains in epidermal basement membrane. 60–70% of XLAS females exhibit mosaic staining patterns for this protein. ARAS and ADAS: Results of immunostaining for the α5 chain in epidermal basement membrane are normal.

7. Mutations in COL4A3, COL4A4 or COL4A5 genes
   – XLAS: The rate of detection of mutations in COL4A5 in males with XLAS is 80–90% by direct sequencing.
   – ARAS: Direct sequencing identifies ~90% of mutations in COL4A3 or COL4A4 in ARAS patients with consanguineous parents.

*Thin Basement Membrane Nephropathy*: A diagnosis of TBMN can be made on the basis of clinical and pedigree data; renal biopsy may be unnecessary. Criteria for a clinical diagnosis of TBMN include *all* of the following criteria:

– Isolated hematuria. Kidney function, urine protein excretion and blood pressure are normal.
– Positive family history of hematuria, consistent with autosomal dominant transmission.
– Negative family history of kidney failure.

Renal biopsy may be used to confirm a suspected diagnosis of TBMN. Histological diagnosis is based upon the finding of diffuse attenuation of GBM, as determined by electron microscopy, and the absence of other abnormalities by light microscopy (glomerular cellular proliferation or glomerulosclerosis, immunofluorescence microscopy (glomerular deposition of immunoglobulin or complement) or electron microscopy (lamina densa splitting or fusion of glomerular visceral epithelial cell foot processes). Diffuse GBM attenuation is present when mean GBM width is greater than 2 SD below age- and gender-specific mean values.

Immunostaining of renal biopsy specimens for type IV collagen chains can provide useful adjunctive data. In a patient with diffuse GBM attenuation and who satisfies clinical criteria for TBMN, normal immunostaining for type IV collagen α3, α4 and α5 chains (i.e., the α3α4α5 network) supports a diagnosis of TBMN.

The role of molecular studies in the diagnosis of TBMN has yet to be settled. Since 50–60% of TBMN patients have mutations at loci other than COL4A3 and COL4A4, molecular studies may not be cost-effective until technological advances (e.g. chip-based assays) lead to reduced prices.

*Epstein and Fechtner Syndromes*: Diagnosis of *MYH9* disorders depends on the presence of macrothrombo-cytopenia. Patients with Epstein and Fechtner syndromes may exhibit, or have a family history of, hematuria, proteinuria, hypertension, kidney failure, or sensorineural deafness. Patients with Fechtner syndrome also exhibit neutrophil inclusion bodies.

## Therapeutic Principles

*Alport Syndrome*: There have been no randomized treatment trials in patients with Alport syndrome, and there are no therapies that have been proven beneficial. Most pediatric nephrologists, and likely the majority of nephrologists treating adult patients, initiate treatment with an angiotensin converting enzyme inhibitor (ACEI) in Alport patients with overt proteinuria, a maneuver intended to retard progression to end-stage kidney failure. If proteinuria does not respond to ACEI treatment, an angiotensin receptor blocker or aldosterone antagonist may be added.

The outcomes of kidney transplantation in patients with Alport syndrome are typically excellent, with graft survival rates comparable to those of patients with structural renal disease (e.g., renal dysplasia or obstructive uropathy) as an underlying diagnosis. About 3% of males with XLAS develop anti-glomerular basement membrane antibody-mediated glomerulonephritis in their renal allografts (allograft anti-GBM nephritis). In these patients the antibody target is typically the α5(IV) chain in the GBM of the allograft. Anti-GBM nephritis may also occur in males and females with ARAS; in these cases the target of the immune response is typically the α3(IV) chain. About 75% of allografts affected by anti-GBM nephritis are lost despite treatment (plasmapharesis and cytotoxic therapy), and the risk of recurrence in subsequent allografts is very high. Allograft anti-GBM nephritis appears to result from failure to develop immune tolerance to certain α3α4α5 epitopes.

*Thin Basement Membrane Nephropathy*: Since TBMN is not a progressive disorder, no therapy is required. However, individuals carrying a diagnosis of TBMN should have regular medical follow-up. Some patients who are given a diagnosis of TBMN develop additional evidence of renal disease, such as proteinuria, hypertension and reduced kidney function. These patients may actually have Alport syndrome. There has also been speculation that patients with TBMN may be more susceptible to development of glomerulosclerosis.

*Epstein and Fechtner Syndromes*: Treatment of the renal aspects of these disorders is based upon regular follow-up and management of symptoms such as hypertension as they arise. Successful renal transplantation, with transfusion of platelets as needed, has been described.

# Hemochromatosis, Hereditary

Klaus Schümann[1], Günter Weiss[2]
[1]Technical University Munich, Munich, Germany
[2]Department of Internal Medicine I, Medical University, Innsbruck, Austria

## Synonyms

Primary, genetic hemochromatosis

## Definition and Characteristics

The term "hereditary hemochromatosis" (HH) encompasses a number of autosomal recessive inborn errors of iron metabolism with excessive iron absorption and pathological tissue iron deposition [1,2].

## Prevalence

0.3–0.5% and 8–12% of Caucasian White populations are homozygous and heterozygous for HFE-HH, respectively. HFE mutations are found in 64–90% of clinically apparent HH cases across Europe and the USA. The penetrance of the disruption seems to be 25–50%.

## Genes

So far, five genes have been identified to cause HH (HFE/6p21.3, TfR2/7q22, SLC40A1/2q32, HEMP/19q13.1, HJV/1q21) [2,3].

## Molecular and Systemic Pathophysiology

Over decades, increased iron absorption in homozygous HH leads to progressive iron deposition in tissues, due to impaired hepcidin function [2,3], and to subsequent organ damage due to iron-catalyzed formation of toxic radicals. When untreated, HH leads to hepatic failure and cirrhosis, hepatocellular carcinoma, diabetes, skin pigmentation, cardiac failure, impotence, and arthritis. Heterozygous HH has little clinical implications [1].

HFE mutations in classic HH (type 1) may occur in combination with mutations in the other genes. The major HFE transcript is ~4.2 kb with alternative splicing variants. The 343-amino acid HFE protein consists of six domains: a signaling peptide, three extracellular domains, a transmembrane region, and an intracellular region. The most common mutation of HFE, which is ubiquitously expressed, is a single base substitution of tyrosine for cystein in exon 4 at amino acid 282 (C282Y). Substitution of histidin for aspartate (H63D) is another rarer HFE mutation. These mutations reduce hepcidin expression and, thus, increase intestinal iron absorption. Moreover HFE, a nonclassical major histocompatibility complex (MHC) class I protein, interferes with TfR-mediated iron uptake, though the implications of this interaction are incompletely understood. Mutations in the TfR2-gene (type 3) are rare and lead to a phenotype analogous to type 1. The rare juvenile HH is caused by mutations in the gene encoding hemojuvelin (HJV – type 2A), going along with severely impaired hepcidin function. Another type of juvenile HH is caused by direct mutation of the hepcidin gene (HAMP – type 2B). Mutation of HAMP and HJV leads to a very severe disease form showing symptoms of iron overload before the age of 30. Hepcidin is a principal downregulator of iron transfer across the small intestine, but also across the placenta and for iron release from macrophages. Hepcidin is expressed in the liver as an 84 amino acid precursor, the circulating form consisting of the C-terminal 25-aminoacid fraction. Normally, its synthesis seems to be upregulated at high transferrin saturation or high iron-load in liver, but also during inflammation. It functions by binding to the iron-exporter ferroportin, leading to ferroportin degradation, which downregulates intestinal iron absorption and iron export from the RES. The impairing function of hepcidin is compromised in all forms of HH [2]. Mutation of the iron-exporter ferroportin itself (gene SLC40A1) leads to the autosomal dominant ferroportin disease in which dysregulation in iron metabolism is distinct from HH. In this disease, phlebotomy is effective, though less well tolerated than in HH [2].

## Diagnostic Principles

Transferrin saturation >45% and/or serum ferritin concentration >300 µg/l are suspicious for hemochromatosis. Hepatic iron content exceeds 490–550 µM/g dry wt. The hepatic iron index exceeds 2 (i.e., hepatic iron concentration [µM Fe/g dry wt.]/patient age [years]). Liver biopsy to check for fibrosis and siderosis should be done at serum ferritin concentrations >1,000 µg/l. Genetic analysis for abnormal HFE must be performed, and siblings need to be screened for HH. More detailed gene analysis for the less common forms of HH may be performed [1].

## Therapeutic Principles

Venesection and the iron chelator desferrioxamine are used to remove iron from the body, the progress of which needs to be controlled by regular serum ferritin determination. Live expectation is normal, if the disease is recognized in time, e.g., by genetic screening of siblings, and if body iron status is controlled from early years onward [1].

## Synonyms

HUS; Atypical HUS; D− HUS; Familial HUS; Sporadic HUS; Typical HUS; D+ HUS

## Definition and Characteristics

Hemolytic uremic syndrome (HUS) is a severe kidney disease that is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. The epidemic form of HUS is the most common form and usually manifests by infection with toxin producing Escherichia coli of the serotype 0157:H7 or Shigella dysenteriae serotype 1. This form is common in children and is often associated with diarrhea (typical HUS, D+ HUS). The second form (atypical form) can be sporadic or familial, and usually is not associated with diarrhea. This atypical form is a genetic disease components affecting the alternative complement system. In these patients, the disease is often triggered by stress situations like infections, drugs, or pregnancy [1].

## Prevalence

The overall incidence of typical HUS is estimated to be 2 cases per 100,000 persons/year in Europe. The incidence for atypical HUS (aHUS) is 0.2–0.5 cases per 100 000 persons/year.

## Genes

The familial form of HUS can be caused by an ADAMTS13 mutation resulting in a defect of the von Willebrand Factor-cleaving protease (vWFCP) or by a defective regulation of the alternative complement pathway. Multiple scenarios including mutations in genes coding for complement components and regulators, gene deletions, and gene conversion have been reported. In addition, autoantibodies directed against the complement regulator Factor H (CFH) predispose to the disease. At present, more than 80 HUS associated mutations were described in the gene coding for the CFH [2]. The vast majority represent heterozygous missense mutations that result in single amino acid exchanges, deletions, or insertions. These mutations cluster in the two most C terminal domains (short consensus repeats) of the CFH protein. Also gene conversion that leads to a fusion gene composed of exons derived from CFH and of the complement Factor H-related 1 (CFHR1) gene has been reported in HUS. In addition, homozygous as well as heterozygous deletion of a large 84 kDa genomic fragment by non allelic homologues recombination events in chromosome 1 results in loss of CFHR1 and CFHR3 genes has been reported in aHUS [3]. Several mutations in the genes coding for membrane-bound complement regulator MCP (CD46), the serine protease Factor I, as well as complement component Factor B have been determined in aHUS. Also compound heterozygous mutations in CFH and MCP were identified in single HUS patients. For further information on the genetic defects, see www.fh-hus.org.

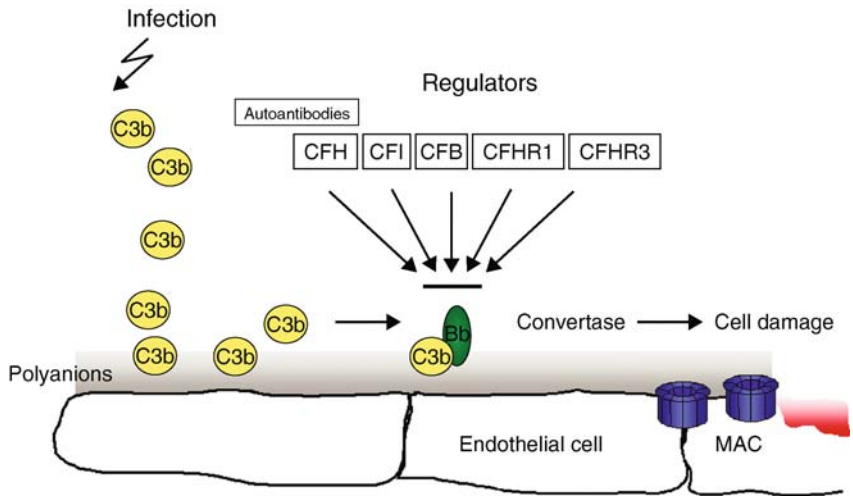
## Molecular and Systemic Pathophysiology

Under conditions of stress such as during infections, when complement activation occurs at very high levels, high amounts of active complement components like C3b are locally generated. Under these conditions, vascular endothelial cells require maximum protection to avoid complement-induced cell damage. The coordinated action of all regulators, soluble regulators acquired to the cell surface, together with the membrane-bound regulators, are necessary to inactivate complement attack. Thus a combined activity of all available regulators is required for surface protection of bystander cells. In case of reduced activity of one of these regulators or due to the presence of inactivating autoantibodies, the cell surfaces are not properly protected and result in complement-mediated damage and platelet activation (Fig. 1).

The central amplification convertase C3bBb is formed on the surface of, e.g., endothelial cells and the reported defects that explain about 50–60% of aHUS cases include mutations in components that either form the amplification convertase C3 and Factor B or include regulators of the enzyme Factor H (CFH), Factor I (CFI) as well as deletion of the genes coding for Factor H-related proteins CFHR1 and CFHR3. Similarly autoantibodies to Factor H are associated with aHUS.

## Diagnostic Principles

Diagnostic work up of a patient with suspected aHUS includes (i) assessment of vWFCP activity level and – if



**Hemolytic Uremic Syndrome. Figure 1** The atypical form of HUS is a disease caused by defective regulation of the alternative complement pathway.

reduced – sequence analysis of the ADAMTS13 gene and measurement of vWFCP autoantibodies; (ii) detailed analysis of the complement system including C3, C4, APH50, and CH50; and (iii) analysis of complement regulatory proteins prioritized according to their frequency (i.e., Factor H; CFHR1/CFHR3 > Factor I > MCP > Factor B) on protein and genetic level, as well as screening for Factor H autoantibodies. In rare cases, protein function analysis might be required.

Renal biopsy is not considered standard in the diagnostic work up of HUS, since the disease presents with distinct clinical findings, and a renal biopsy is associated with a high bleeding risk. Typical features would include the presence of microvascular platelet-rich thrombi with a variable degree of glomerular and tubulointerstitial damage (typical HUS – acute changes; aHUS – potential for chronic glomerular and/or tubulointerstitial changes).

## Therapeutic Principles

For patients with typical HUS, a specific therapeutic concept does not exist. Treatment consists of careful fluid management, supply of high calorie amounts, supportive medication, e.g., for hypertension, and dialysis for patients with acute renal failure. For patients with aHUS and ADAMTS13 mutation treatment consists of replacement of vWFCP via periodical plasma infusion – typically 10–20 ml per kg body weight every 14 days. For patients with aHUS, the therapeutic principle consists of the reconstitution of the control of the activity of the alternative pathway C3 convertase C3bBb. Soluble complement regulators can be replaced via periodical plasma infusion. Gain of function mutations (Factor B) and mutations of membrane-bound regulators can be counterbalanced by Factor H also supplied via plasma infusion. Autoantibody-mediated aHUS usually responds well to both plasma exchange and plasma infusion.

All treatment measures mentioned are periodically administered according to the half-life of the key complement regulatory protein Factor H. Factor H half-life of about 6 days constitutes treatment cycles of 12–14 days.

# Hemophilia A

Hugo ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

Classic hemophilia; Factor VIII deficiency

## Definition and Characteristics

Lifelong hemorrhagic disorder, due to absence and/or functional defect in factor VIII molecule.

## Prevalence

Rare disorder with an estimated incidence of 1 in 5,000–10,000 male births, in all ethnic groups in every part of the world.

## Genes

Sex-linked recessive disorder; due to defective and/or deficient factor VIII molecules; all sons of affected hemophilic males are normal; all daughters are obligatory carriers of the factor VIII defect. Sons of carriers have a 50% chance of being affected, while daughters of carriers have a 50% chance of being carriers [1,2].

*Gene map locus*: Xq28.

## Molecular and Systemic Pathophysiology

Cloning of the factor VIII gene eventually led to the possibility of finding mutations in patients with hemophilia A and specific mutations are now being used for antenatal diagnosis and carrier screening. Mutation analysis may also help to predict the chance of inhibitor formation (see below). Those patients with the largest gene mutations have the highest percentage of inhibitors [3].

The reduced factor VIII concentration and/or function in plasma diminishes the factor IX cofactor function, impairing the potential of the tenase complex. The latter is critically important in driving prothrombin activation, and the result is diminished thrombin and fibrin formation, which causes the characteristic hemorrhagic tendency. The presence of minute amounts of factor VIIIa may restore the tenase complex function.

Classic hemophilia is characterized by excessive hemorrhage particularly in soft tissues (hematomas) and joints (hemarthroses). The clinical phenotype is indicated as mild, moderate or severe, with a certain degree of overlap. Grossly, hemorrhagic tendency associates with the level of factor VIII as follows. Severe (≤1% of normal): spontaneous hemorrhage from early childhood, recurrent spontaneous hemarthroses and other hemorrhages for which replacement therapy is indicated. Moderate (1–5% of normal): hemorrhages secondary to trauma or surgery and occasional spontaneous bleeding. Mild (6–30% of normal): hemorrhages secondary to trauma or surgery and rarely spontaneous bleeding.

Joint bleeding is the most prevalent complication of hemophilia (about 75% of total bleeding complications), occurring mostly in large joints, particularly knees, elbows and ankles. Joint deformation is a feared complication in the long term. Pseudotumors are rare complications of potential harm, hematuria, neurologic complications due to bleeding, mucous membrane hemorrhage are also feared complications. Other major complications relate to therapy. Over 90% of the older hemophilia patients have contracted antibodies to HIV due to transfusion related transmission in the past. In addition, hepatitis B and C are major threats. A second type of major complication is the development of anti-factor VIII antibodies develop in 20–50% of patients [1–3].

## Diagnostic Principles

Patients with severe hemophilia A have a prolonged activated partial thromboplastin time (APTT), a prolonged whole blood clotting time, while prothrombin time (PT), thrombin-clotting time and bleeding time are normal. In mild hemophilia the APTT may only be slightly prolonged, also depending on the type of reagents used. Mixture of hemophilic and normal plasma normalizes a prolonged APTT; in the presence of an inhibitor (antibody) of factor VIII. The mixture will be prolonged upon longer incubation. Factor VIII antigen and activity can be quantitated. In the presence of a normal antigen level, and reduced clotting activity, a dysfunctional factor VIII molecule is present. The level of factor VIII is expressed in units (1 unit equals the amount in 1 ml of normal plasma).

## Therapeutic Principles

In general, care should be taken to avoid unnecessary disturbance of the hemostatic system, i.e. by eliminating NSAID's, aspirin and other agents that interfere with platelet function, by avoiding intramuscular injections, by carefully scheduling surgical procedures, taking care to have available sufficient factor VIII concentrate.

The major therapeutic issue to deal with is the choice of the optimal replacement therapy. Although the chances of viral transmission have been markedly reduced with current inactivation procedures, the transmission of other thermosresistant viruses including parvovirus B19, or prions, makes plasma based therapy a suboptimal form of treatment. Recombinant factor VIII preparations are now available, are effective and quite safe (immunogenicity not increased as compared to plasma concentrate). The choice of treatment now mainly depends on issue of safety, availability, and not in the least cost. In patients with inhibitors against factor VIII treatment is further complicated. Porcine factor VIII (in the absence of anti-porcine factor VIII antibodies!), activated prothrombin complex concentrates and recombinant factor VIIa, the latter two products used to bypass the factor VIII–IX intrinsic route, are now available but issues of costs and safety mainly limit the application. Finally, clinical gene

therapy trials are being performed and the results are encouraging in terms of efficacy and safety [4,5].

# Hemophilia B

Hugo ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

Christmas disease (named after the boy bearing this form); Factor IX deficiency

## Definition and Characteristics

Lifelong hemorrhagic disorder due to absence or functional defect of factor IX molecule. Clinically indistinguishable from hemophilia A. Severity depends on the plasma level of factor IX: "severe" (<1% activity in plasma; <0.01 IU/ml), "moderate" (1–5% activity, 0.01–0.05 IU/ml), or "mild" (5–25% factor IX activity, 0.05–0.25 IU/ml). The gene product is a 415-aminoacid serine protease synthesized in the liver and the largest vitamin K dependent protein. Vitamin K is needed for terminal gamma carboxylation of glutamic acid residues to form Gla domains, crucial for normal function [1,2].

## Prevalence

Rare disorder with an estimated prevalence of 130 in $10^6$ males. Incidence of 1:30,000 live male births, in all ethnic groups in every part of the world.

## Genes

X-linked recessive bleeding disorder due to defective and/or deficient factor IX molecules; all sons of affected hemophilic males are normal, all daughters are obligatory carriers of the factor IX defect. Carrier females are usually asymptomatic except for a few cases of bleeding during pregnancy [3].
*Gene map locus*: Xq27.1–q27.2

## Molecular and Systemic Pathophysiology

Factor IX gene was mapped in 1984 on Xq27.1. The gene spans 34 kb and contains eight exons. More than 2,100 mutations in the gene are recorded (www.kcl.ac.uk/ip/petergreen/haemBdatabase.html), in all regions of the gene, majority point mutations, two thirds missense.

Factor IX is involved in secondary hemostasis where it acts as a protein in the intrinsic coagulation system to catalyze the formation of factor Xa. Factor IX is activated either by the factor VIIa-tissue factor complex, or by factor XIa, to form the tenase complex with factor VIII on phospholipids and in the presence of calcium ions. The deficiency or functional defect of factor IX causes delayed activity of the intrinsic system and impaired fibrin formation, causing the characteristic hemorrhagic tendency. Bleeding can be prevented or arrested by replenishment of factor IX [1–3].

In general the hemophilias are characterized by excessive hemorrhages particularly in soft tissues (hematomas) and joints (hemarthroses). The "severe" phenotype is characterized by spontaneous joint and muscle bleeding; bleeding after injuries, accidents and surgery. The "moderate" phenotype has bleeding into joints and muscles after minor injuries and excessive bleeding after surgery and dental extractions. The "mild" phenotype does not show spontaneous bleeding, but only after surgery, dental extractions and accidents.

Other complications are related to treatment: a major problem is the development of antibodies against infused protein concentrate, the "inhibitors"; the risk is about 50% in those with gene deletions or rearrangements, in other mutations the risk is <20% and for missense mutations the risk is 0%. Other complications relate to the transmission of infectious organisms such as hepatitis C.

## Diagnostic Principles

Patients with severe hemophilia B have a prolonged activated partial thromboplastin time (APTT), while prothrombin time, thrombin clotting time and bleeding time are normal. Factor IX antigen and activity can be quantified. In the presence of a normal antigen level, and reduced clotting activity, a dysfunctional factor VIII molecule is present. The level of factor IX is expressed in units (1 unit equals the amount in 1 ml of normal plasma).

## Therapeutic Principles

In general, care should be taken to avoid unnecessary disturbance of the hemostatic system, i.e. by eliminating NSAID's, aspirin and other agents that interfere with platelet function, by avoiding intramuscular injections,

by carefully scheduling surgical procedures, taking care to have available sufficient factor IX concentrate.

The major therapeutic issue to deal with is the choice of the optimal replacement therapy. Although the chances of viral transmission have been markedly reduced with current inactivation procedures, the transmission of other thermoresistant viruses including parvovirus B19, or prions, makes plasma based therapy a suboptimal form of treatment. Recombinant factor IX preparations are now available, are effective and quite safe (immunogenicity not increased as compared to plasma concentrate). The choice of treatment now mainly depends on issue of safety, availability, and not in the least cost.

*Gene Therapy*: Advantages are single gene disease, relative small gene, no precise regulation of amount of protein necessary to control bleeding, not confined to specific organ. Pitfalls: efficiency and safety of vectors. Present state: low levels of factor IX in first human studies. Potential of prenatal gene therapy [4,5].

# Hemophilia C

Hugo ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

Plasma thromboplastin antecedent deficiency; Factor XI deficiency; Rosenthal syndrome

## Definition and Characteristics

Trauma or surgery related bleeding symptoms, particularly in homozygotes, while heterozygous (mild form) may be completely asymptomatic; 20–50% may bleed excessively upon tissue trauma [1]. Spontaneous bleeding does not occur and also patients with severe factor XI deficiency may remain asymptomatic until for instance surgery is performed at a late age.

## Prevalence

Highly prevalent in Ashkenazy Jews, in whom the heterozygote frequency runs up to 10%. Incident cases occur in non-Jewish populations.

## Genes

Autosomal disorder, after first description by Rosenthal considered a dominant disease with variable expression. Currently, major (homozygous) and minor (heterozygous) variants are distinguished. Inheritance is best considered as incompletely recessive or "intermediate" form of inheritance [2]. Most prevalent in Ashkenazy Jews where two mutations (Glu117stop and Phe283Leu) are responsible for most abnormal alleles. In non-Ashkenazy Jews 38 mutations have been recorded, the majority being nucleotide substitutions (missense/nonsense) [2–4].
*Gene map locus*: 4q35.

## Molecular and Systemic Pathophysiology

The factor XI gene consists of 15 exons and 14 introns and is 23 kb long. A database of frequent mutations is being maintained [3,4]. Molecular diagnosis has become important for instance in individuals with a bleeding diathesis but a low normal plasma factor XI level. Factor XI is unique in that it exists as a homodimer, with two identical 80 kD monomers. After activation it remains in dimeric form, essential for its function.

Theoretically, factor XI is a protein from the classic contact route of coagulation, linking factor XII-kallikrein activity to the intrinsic system. Several groups of investigators have, however, established that the preferred route of activation of factor XI may be by thrombin and the thrombin-factor XI activation loop is now considered an important amplification pathway for hemostasis and thrombin generation. This mechanism is also involved in amplifying the activation of the fibrinolysis inhibitor TAFI (thrombin activatable fibrinolysis inhibitor) in vivo [5]. These mechanisms are probably relevant for the site of bleeding, which is usually from organs that also have a high intrinsic fibrinolytic activity such as the bladder. In case of factor XI deficiency, not only clotting but also fibrinolysis may be not sufficiently inhibited and bleeding may occur. Rare cases of inhibitors against factor XI have also been observed; in one series of 118 Israeli patients seven had an inhibitor, but sofar inhibitors have only been observed in homozygous patients that had received transfusions [4].

Homozygous or compound heterozygous deficiency of factor XI results in a variable bleeding phenotype, particularly evident after tissue trauma (accidental or by surgery) in visceral membrane-covered tissues such as bladder. In women, factor XI deficiency may be a contributing cause of menorrhagia. In heterozygous individuals not more than 50% may bleed excessively, and the observed frequencies vary considerable due to differences in study methodology. In addition, there may be biological variations in the antigen and activity levels of factor XI within the same individual, as observed in one study with three heterozygous patients [1].

### Diagnostic Principles

Patients with severe hemophilia C have a prolonged activated partial thromboplastin time (APTT), while prothrombin time (PT), thrombin-clotting time and bleeding time are normal. In mild hemophilia C the APTT may only be slightly prolonged, also depending on the type of reagents used. Mixture of hemophilic and normal plasma normalizes a prolonged APTT; in the presence of an inhibitor (antibody) of factor XI, the mixture will be prolonged upon longer incubation. Factor XI antigen and activity can be quantitated.

### Therapeutic Principles

Management options consist of tranexamic acid and factor XI concentrate. Tranexamic acid is quite effective during surgical procedures in high risk areas such as bladder. Plasma derived factor XI concentrate is available in case of bleeding complications. In general, treatment is confined to those situations in which patients are actively bleeding, or undergo procedures expected to cause significant blood loss. Prophylactic treatment is not indicated. Recombinant factor VIIa is a promising treatment option and also applicable in patients with inhibitors [1].

## Hemorrhoids

Mark Oette
Clinic for Gastroenterology, Hepatology, and Infectious Diseases, University Clinic Duesseldorf, Duesseldorf, Germany

### Definition and Characteristics

The disorder of hemorrhoids is defined by pathological enlargement of the corpus cavernosum recti. This anatomical site consists of subepithelial arteriovenous communications between the A. rectalis superior and the superior, middle, and inferior rectal veins. Under physiological conditions, the tension of these cushions contributes to the resting pressure of the anal continence organ to an extent of 10–15% [1]. Thus, they play a substantial role for the closure of the anal canal. The development of hemorrhoids is characterized by a disintegration of muscular and elastic elements, leading to growth and congestion of vascular structures. Internal hemorrhoids are located above the linea dentata, external hemorrhoids can be found below this line. Hemorrhoids are subdivided into four categories (see Table 1).

Clinical symptoms of small hemorrhoids consist of itching, swelling, and bleeding. Large hemorrhoids tend to bleed more often, pain may be common, hygiene and

**Hemorrhoids. Table 1** Categories of hemorrhoids

| Stage | Symptoms |
|---|---|
| I | Small cushions, visible only in proctoscopy |
| II | Intermittent protrusion of nodules with spontaneous retraction |
| III | Prolapse of larger nodules, manual reposition necessary |
| IV | Incarceration of prolapse, reposition not possible<br>Thrombosis of protruded hemorrhoids |

incontinence problems are possible. Complications of internal hemorrhoids are rare, whereas a thrombosis of external hemorrhoids is often the single symptom.

## Prevalence

Hemorrhoids are very common, although precise data on the epidemiology of this disorder are rare. It is assumed that hemorrhoids can be found in less than 5% of the general population with a peak prevalence between 45 and 65 years [2]. Hospital-based proctoscopy studies determined a prevalence of up to 80% [2].

## Molecular and Systemic Pathophysiology

A familial disposition of hemorrhoids has been postulated. However, associated genes and the underlying mechanisms are yet to be characterized.

The pathophysiology of hemorrhoids is not fully understood. A lack of fiber intake, chronic constipation, and pregnancy have been associated with hemorrhoids. However, the scientific basis for these assumptions is weak [2]. An increased anal resting pressure may play a role in the pathophysiology of hemorrhoids. The development of hemorrhoids is induced by a histological modification due to aging of unstriated muscular tissue (M. canalis ani) embedding the submucosal plexus of the anorectal transition [1]. Together with a decay of elastic elements, this leads to a loss of structural integrity of the arteriovenous plexus. The result is abnormal swelling of the corpus cavernosum recti driven by blood pressure. The most important complications are bleeding and incarceration of prolapsed nodules. Portal hypertension is a predisposing factor for the development of varices of the anorectum, but the incidence of hemorrhoids is not higher in these patients [2].

## Diagnostic Principles

Upon inspection, only external hemorrhoids and nodules representing hemorrhoids of stage 3 or 4 can be identified. Due to the arteriovenous pressure within the cushions, digital examination is of minor use in detecting hemorrhoidal lesions. Gold-standard of the diagnosis is endoscopic examination of the anorectum. Hemorrhoidal bleeding produces bright-red blood, dark blood points to a more proximal bleeding site. Fecal occult blood testing is not helpful for the diagnosis of hemorrhoids, and, if positive, should lead to complete evaluation of the colon.

## Therapeutic Principles

General measures to reduce the clinical manifestation of hemorrhoids are to increase fiber intake and to avoid straining at stool. Topical treatment consists of creams and suppositories, mostly to control itching, pain, or discomfort due to hygiene problems. Data on the success of these strategies are rare [2]. Classical operation procedures are Milligan-Morgan's or Miles-Gabriel's segmental hemorrhoidectomy, Longo's stapling procedure, and Parks' plastic operation [3]. Major complications of surgery are early (1%) and late (0.2–2.5%) bleeding and urinary retention (exceeding 50%) [3]. Stapled hemorrhoidopexy was found to be associated with a higher long-term risk of recurrence and episodes of anal prolapse compared to standard surgical treatment in a meta-analysis [4]. Furthermore, it was more likely to be associated with long-term symptom recurrence and the need of additional surgery [4]. Non-operative methods of eradication are sclerotherapy, haemorrhoid artery ligation led by Doppler sonography (Morinaga), cryotherapy, Barron ligation, bipolar diathermy, infrared photocoagulation, and Lord's dilatation. In different meta-analyses, rubber band ligation was more effective than the other techniques, but was associated with more pain [3]. Smaller hemorrhoids are the domain of non-operative treatment; surgical treatment is more adequate for large hemorrhoids and complicated lesions [2].

# Hepatic Encephalopathy

Dieter Häussinger
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

Portosystemic encephalopathy; Hepatic coma

## Definition and Characteristics

Neuropsychiatric syndrome, which can develop during the course of acute (e.g. fulminant hepatic failure) or chronic liver disease (e.g. cirrhosis). Hepatic encephalopathy (HE) is of metabolic origin and thus potentially reversible. Symptoms include cognitive and fine-motoric deficits whose severity can vary from mild personality changes and motoric impairment (tremor) to deep coma. Episodes of hepatic encephalopathy (HE) in cirrhotic patients are precipitated by a variety of conditions such as bleeding, infections, trauma, sedatives and diuretics. Subclinical (latent, minimal) HE describes a syndrome in which neuropsychological deficits are not clinically overt, but are detectable by psychometric testing.

## Prevalence

About 97% of patients with HE suffer from liver cirrhosis, whereas 3% develop HE due to acute liver failure. Depending on the population under study, the prevalence of subclinical and manifest HE in cirrhotics was reported to be 20–70%.

## Genes

Because HE is caused by liver insufficiency, there are no specific underlying gene defects. However, one report suggests some predisposition by polymorphisms in the intestinal glutaminase gene. Further, hyperammonemia can be caused by a variety of inborn errors of amino acid metabolism and urea cycle defects. These also give rise to CNS symptoms, which are not summarized under the term hepatic encephalopathy.

## Molecular and Systemic Pathophysiology

An impairment of metabolic liver function (especially a diminished capacity for ammonia detoxication via hepatic urea and glutamine synthesis) and portosystemic blood shunting allow neurotoxins to reach the brain. Among these neurotoxins ammonia plays a major role. Ammonia detoxication in brain occurs predominantly by astroglial glutamine synthesis. Glutamine accumulation in astrocytes results in glial swelling and HE is currently seen as the clinical manifestation of a low grade chronic cerebral edema [1,2]. A first indication for the presence of a low grade cerebral edema in patients with cirrhosis was derived from $^{1}$H-MRS studies on the human brain in vivo, which identified the myo-inositol signal to reflect an osmosensitive myo-inositol pool, whose depletion in the brain from HE patients together with an increased glutamine/glutamate signal is suggestive for a disturbance of astrocyte volume homeostasis in brain in the sense of a cellular, cytotoxic edema [1,2]. The existence of a low grade cerebral edema in cirrhotic patients with HE in vivo was also demonstrated in studies on magnetization transfer ratios and by quantitative cerebral water mapping based on a new MR technique for fast quantitative mapping of $T_1$ and water content. An increase in brain water is already found in minimal HE and increases with HE severity. Based on this and data from animal and in vitro studies, it was hypothesized that HE in cirrhosis reflects the clinical manifestation of a low grade cerebral edema, which exacerbates under the influence of precipitating factors and thereby triggers cell hydration-dependent alterations of astrocyte function [1,2]. Such precipitating factors are heterogenenous and include excessive oral protein intake, trauma and infections, gastrointestinal bleeding, sedatives, diuretics and electrolyte disturbances [3]. All these conditions involve components, such as increased ammonia, inflammatory cytokines (e.g. TNF-α, interferons), benzodiazepines and electrolyte disturbances, which were shown to induce astrocyte swelling in vitro. Thus, the action of precipitating factors may integrate at the level of astrocyte swelling.

One major consequence of astrocyte swelling in HE is the generation of oxidative/nitrosative stress. In cultured astrocytes and in rat brain in vivo, ammonia, inflammatory cytokines, benzodiazepines and hyponatremia induce the formation of reactive oxygen species and nitric oxide (NO) through NMDA-receptor

and $Ca^{2+}$-dependent mechanisms, involving NADPH oxidases, the mitochondria and neuronal nitric oxide synthase. There is a close relationship between astrocyte swelling and oxidative stress. On the one hand, astrocyte swelling induces oxidative stress through a NMDA receptor- and $Ca^{2+}$-dependent mechanism and on the other, NMDA receptor activation and oxidative stress trigger astrocyte swelling. This points to an auto-amplificatory signaling loop between astrocyte swelling and oxidative stress. Consequences of oxidative/nitrosative stress in response to astrocyte swelling and HE-relevant neurotoxins are a covalent modification of tyrosine residues in astrocytic proteins through nitration and the formation of oxidized RNA species. Astrocytes located near the blood brain barrier exhibit especially high levels of protein tyrosine nitration (PTN), with unknown consequences for blood brain barrier permeability. PTN involves distinct proteins, such as glutamine synthetase and the extracellular signal regulated kinase Erk-1. Upregulation of the PBR results in an increased synthesis of neurosteroids with positive $GABA_A$-receptor modulatory activity, such as allopregnanolone and allotetrahydrodeoxy-corticosterone and may contribute to the high GABAergic tone found in patients with HE. The recent finding that ammonia induces RNA oxidation in neurons and astrocytes may result – via disturbances of translation efficacy and local synaptic protein synthesis – in multiple alterations of neurotransmitter receptor systems, as found in the brain of patients with HE.

Studies employing magnetoencephalography in patients with cirrhosis and HE revealed a stronger cortico-muscular coherence with a shift to lower frequencies, when compared to controls, indicating a pathologically slowed and synchronized motor cortical drive [4]. The extent of these changes correlated with the severity of hepatic encephalopathy and are apparently triggered by altered thalamocortical oscillatory coupling. Thus, neurotoxin- and hydration-sensitive thalamic structures may act as pacemakers for an abnormally low-frequent and rigid thalamo-cortical and cortico-muscular coupling and may explain some motor and cognitive defects in HE patients. A current model on the pathogenesis of HE is given in Fig. 1.

## Diagnostic Principles

Manifest HE is usually diagnosed from the clinical picture. Laboratory tests and imaging devices may be useful for differential diagnosis and the detection of precipitating factors. Subclinical HE is diagnosed by batteries of computerized psychometric tests and more easily by determination of critical flicker frequency.

## Therapeutic Principles

The most important therapeutic measure is the detection and vigorous treatment of precipitating factors [5]. Other therapeutic measures intend to diminish ammonia production and to improve ammonia detoxication. Lactulose enemas, bowel cleaning, ornithine aspartate were shown to be effective in controlled randomized trials. Current therapy largely aims at lowering ammonia, but the emerging better understanding of the complex pathogenesis of HE will offer new therapeutic options.

## Synonyms

Hepatic triglyceride lipase deficiency; HTGL deficiency

## Definition and Characteristics

Complete hepatic lipase (HL) deficiency is a rare genetic disorder, inherited as an autosomal recessive or codominant trait. The absence of HL leads to pathologic levels of circulating lipoproteins and an increased risk of premature cardiovascular disease (CVD).

## Prevalence

HL deficiency is one of the rarest disorders in lipoprotein metabolism, with only seven families documented to date worldwide (17 patients) [1–4].

## Genes

In humans, the gene coding for HL (LIPC) is localized on chromosome 15 (q21-q-23) and spans more than 60 kb with nine exons totalizing 1.6 kb [5].

## Molecular and Systemic Pathophysiology

HL is a 476 amino acid glycoprotein lipolytic enzyme that is primarily synthesized and secreted from hepatocytes, and anchored to the liver sinusoidal surface by heparin sulfate proteoglycans. HL plays a major role in the regulation of intravascular lipid metabolism. It catalyzes the hydrolysis of triglycerides (TG) and phospholipids of intermediate-density lipoprotein (IDL) remnants, large buoyant low-density lipoproteins (LDL), and high-density lipoproteins (HDL), thereby leading to the formation of smaller, more dense lipoprotein particles. To date, 12 mutations in the HL gene have been identified but only five of those mutations (A174T, R186H, S267F, L334F et T383M) have been associated with a loss of HL protein function and the typical dyslipidemic phenotype of HL deficiency. Most of the patients with HL deficiency described to date were heterozygotes for two of these mutations. In general, the absence of HL activity perturbs intravascular lipoprotein metabolism, and leads to a typical dyslipidemic phenotype that includes elevated plasma TG and phospholipid levels, an accumulation of IDL, TG-enriched LDL and HDL, as well as the presence of β-migrating very-low density lipoproteins (VLDL). This profile is believed to accelerate atherosclerosis and to increase the risk of premature CVD [1–4].

## Diagnostic Principles

The coexistence of lipoprotein abnormalities such as elevated phospholipid and TG levels, TG-rich LDL and HDL and β-VLDL in the absence of dysbetalipoproteinemia and secondary factors such as obesity points to the disease. Personal and familial history of premature CVD may also be co-existent. Clinical assessment of post-heparin HL activity confirms the diagnosis of HL deficiency.

## Therapeutic Principles

Lipid lowering therapy with statins and/or fibrates improves the disturbed lipid profile associated with complete HL deficiency.

# Hepatic Steatosis

Sören V. Siegmund, Stephan L. Haas, Manfred V. Singer
Department of Medicine II (Gastroenterology, Hepatology and Infectious Diseases), University Hospital of Heidelberg at Mannheim, Mannheim, Germany

## Synonyms

Fatty liver; Fatty liver disease; FLD; Nonalcoholic fatty liver; NAFL; Nonalcoholic fatty liver disease; NAFLD; Alcoholic fatty liver; AFL; Alcoholic fatty liver disease; AFLD; Metabolic fatty liver disease

## Definition and Characteristics

Fatty liver is defined as an accumulation of lipid in the liver exceeding 5% of liver weight, or light-microscopical visualization of more than 5% of hepatocytes containing fatty droplets [1]. Total lipid accumulation may contribute up to 50% of liver weight, of which more than half is usually triglycerides, and in some cases phospholipids. Lipid accumulation can be macrovesicular (more common, large lipid droplets displacing the nucleus laterally) or microvesicular (small perinuclear lipid vesicles), depending on the disease process. The etiology is multifactorial, the most common causes being insulin resistance/type II-diabetes, obesity, and nutritional or toxic factors (such as ethanol). The majority of patients with fatty liver are clinically asymptomatic, while some show mild symptoms such as fatigue or right upper abdominal discomfort. Severe fatty liver may present with symptoms of jaundice, abdominal pain, nausea, vomiting, and tender hepatomegaly [1]. Although hepatic steatosis is commonly considered a benign condition of the organ, there is evidence that it may render the liver more susceptible to toxic substances or injury [2].

## Prevalence

The prevalence of fatty liver ranges between 15 and 39%, with higher values among women, obese individuals and type II diabetics. The highest prevalence is recognized in the fifth or sixth life decade, although prevalence among children is increasing [3].

## Genes

Heterozygosity for C282Y HFE mutation in the hereditary hemochromatosis gene and mutations in the apolipoprotein B gene or in the microsomal triglyceride transfer protein (MTTP) gene seem to be directly associated with higher risks for development of fatty liver [2].

## Molecular and Systemic Pathophysiology

Fatty liver results from a net increase of fat in hepatocytes. The major reason is increased insulin resistance due to elevated levels of (i) tumor necrosis factor (TNF)-α, which down-regulates insulin-induced phosphorylation of insulin-receptor substrate-1 and reduces the expression of the insulin-dependent glucose-transport molecule Glut4, (ii) leptin, which induces dephosphorylation of insulin-receptor substrate-1, (iii) fatty acids, which inhibit insulin-stimulated peripheral glucose uptake, and (iv) other factors [4]. These mechanisms lead to an increased hepatic production of free fatty acids (FFAs) from glucose due to hyperinsulinism, and to increased circulating levels of FFAs due to an enhanced peripheral lipolysis. The increased uptake of FFAs by the liver exceeds its capacity to metabolize them by mitochondrial β-oxidation and to remove them by secretion into the blood as very low-density lipoproteins (VLDL). Toxic substances such as ethanol exhibit a different mechanism in causing fatty liver. Ethanol metabolism alters the intramitochondrial redox potential via generation of NADH by alcohol dehydrogenase. This impairs β-oxidation and tricarboxylic acid cycle activity, resulting in elevated intrahepatocellular free fatty acids, and augmented formation of triacylglycerol [1]. Ethanol increases the metabolization of fatty acids by upregulation of lipogenic enzymes, such as hepatic L-α-glycerophosphate acyltransferase or fatty acid synthase. Furthermore, ethanol inhibits the endogenous fatty acid receptor and transcription factor peroxisome proliferator-activated receptor (PPAR)-α, which plays a central role in fatty acid degradation [5]. Other causes of fatty liver can be amiodarone, corticosteroids, calcium channel blockers, chloroquine, estrogens, tamoxifen, tetracycline, valproic acid or conditions such as jejuno-ileal bypass, extensive small bowel resection or inflammatory bowel disease [1].

## Diagnostic Principles

Laboratory test result abnormalities are mostly minimal and comprise mild elevations of the serum aminotransferases, alkaline phosphatase, or γ-glutamyl transpeptidase. In severe cases, serum markers of liver disease may be highly elevated, including direct bilirubin. Liver function markers, such as albumin or choline esterase may be decreased. The presence of alternative or coexisting clinical conditions (e.g., hepatitis C) should be assessed using the relevant laboratory test. Regarding imaging diagnostics, fatty liver can be detected by ultrasound sonography, CT scan or magnetic resonance imaging. Liver biopsy, the most sensitive diagnostic tool,

should be performed only (i) in symptomatic patients with elevated liver enzymes for more than 6 months, (ii) if symptoms and diagnostic criteria worsen or (iii) there is doubt in the diagnosis or the cause of fatty liver [1].

### Therapeutic Principles

Mild forms of fatty liver do not require therapy, but need follow-up examinations [1]. Therapeutic principles are (i) management of associated conditions, such as insulin resistance type II diabetes and obesity, (ii) discontinuation of potentially hepatotoxic drugs such as ethanol and (iii) pharmacological therapy, e.g., with antioxidants or ursodeoxycholic acid, in patients at "high risk" for developing advanced liver disease, i.e., patients older than 45 years with diabetes and steatohepatitis.

►Hepatic Lipase Deficiency

## Hepatitis

►Hepatitis, Chronic

## Hepatitis, Acute

Tobias Heintges
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University Duesseldorf, Duesseldorf, Germany

### Definition and Characteristics

Inflammation of the liver in response to various agents or conditions such as toxins, pathogens, autoimmune diseases, or metabolic disorders causes acute hepatitis. Inflammation lasting for less than 6 months is termed acute hepatitis, conditions lasting longer than 6 months are defined as chronic hepatitis.

### Prevalence

Prevalence is dependent on the medical condition causing acute hepatitis. The most frequent form is viral hepatitis. However, different viruses are found more or less frequently in different regions of the world (see individual viruses).

### Molecular and Systemic Pathophysiology

Common pathogens include viruses, e.g., hepatitis viruses A to E, cytomegaly virus, Ebstein-Barr virus [1]. Bacterial infections inducing acute hepatitis are not as common and include infections with Mycobacterium tuberculosis (granulomatous hepatitis), Treponema pallidum (syphilis of the liver), or leptospirosis (Weil's disease). Autoimmune hepatitis can be caused by abnormal immune reaction [2]. Drug-induced hepatitis is dependent on the intake of a wide variety of compounds in conjunction with individual genetic susceptibility. Various toxins have been found to induce hepatitic reactions as well [3]. Moreover, intake of ethanol in doses higher than 20 g/day in women and 60 g/day in men may induce acute hepatitic reactions as well. However, these changes are usually found after long-lasting exposition to ethanol and are mainly chronic; namely, combinations of pathogens, e.g., chronic hepatitis C infection and heavy alcohol intake may induce severe hepatitic episodes.

### Diagnostic Principles

Different grades of jaundice in conjunction with weakness may lead the clinician to suspect acute hepatitis in a patient. Laboratory values ALT and AST (transaminases) are almost always elevated. Elevated bilirubine resembles the amount of jaundice found. Serum markers of cholestasis are γ-GT and AP. Liver biopsy and subsequent histological assessment can prove the diagnosis of hepatitis by showing hepatic cell

necrosis throughout the entire liver with subsequent leukocyte infiltration. Histology may help in distinguishing the etiology of acute hepatitis, e.g., differentiate viral hepatitis from drug-induced hepatitis [3]. Hepatitis viruses A to E can be diagnosed by detection of viral antigens, viral DNA/RNA, or specific antibody responses [4]. Autoimmune hepatitis can be diagnosed by a scoring system of various parameters [5]. Metabolic disorders such as hemochromatosis or Wilson's disease can be diagnosed by various metabolic markers or liver histology [5].

### Therapeutic Principles

General therapy includes unspecific measurements, e.g., bed rest. However, the benefit of these measurements including a special diet is unproven. Specific therapy is strongly dependent on the underlying condition causing hepatitis (see individual disease).

## Hepatitis, Autoimmune

Ralf Kubitz, Dieter Häussinger
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University Duesseldorf, Duesseldorf, Germany

### Synonyms

AIH; Lupoid hepatitis; Autoimmune liver disease; Autoimmune chronic active hepatitis; Chronic aggressive hepatitis; Plasma cell hepatitis

### Definition and Characteristics

Autoimmune hepatitis is an inflammatory disease of the liver of unknown etiology. AIH regularly progresses towards cirrhosis without spontaneous resolution. The disease is characterized by the presence of autoantibodies, by hypergammaglobulinemia and by interface hepatitis and plasma cell infiltrates on histology [1,2]. AIH is frequently associated with other autoimmune diseases, such as autoimmune hemolytic anemia, pernicious anemia, idiopathic thrombocytopenic purpura, inflammatory bowel disease, celiac disease, proliferative glomerulonephritis, fibrosing alveolitis, pericarditis and myocarditis, Graves disease/M. Basedow, autoimmune thyroiditis, diabetes mellitus, rheumatoid arthritis, Sjögren syndrome, systemic sclerosis, mixed connective-tissue disease, erythema nodosum, leukocytoclastic vasculitis, febrile panniculitis, lichen planus or uveitis.

### Prevalence

Autoimmune hepatitis can occur at any ages with females being affected in 80–90%. The incidence of AIH type 1 was reported to be up to 19 persons per million, the prevalence is 116 to 169 patients per million persons. AIH type 2 mainly occurs in children. When AIH occurs in elderly patients it is sometimes preceded and triggered by an HCV infection.

Among patients with chronic liver diseases the frequency of AIH averages 10–20%. Among patients selected for liver transplantation 3–6% suffer from AIH. If AIH is untreated the 5-years survival is as low as 50%.

### Genes

The HLA haplotypes B8, B14, DR3, DR4, and Dw3 are associated with AIH. Gene deletions in the complement C4 (C4AQO) or HLA-DR3 positivity are related to an earlier disease manifestation. HLA-B8 and HLA-DR3 positive patients have a poorer response to therapy. In HLA-DR4 positive patients extrahepatic symptoms are more frequent.

Other potential genes associated to AIH include the immunoglobulin-, the T-cell receptor-, FAS- and TNFα-genes or promoters.

### Molecular and Systemic Pathophysiology

In AIH hepatocytes present autoantigens together with human leukocyte antigen class II (HLA II). This may be triggered by viral infections (e.g., HAV, HBV, EBV or measles) or by chemicals (e.g., alpha methyldopa, interferon, melatonin, minocycline, nitrofurantoin, oxyphenisatin, and tienilic acid) due to an individual genetic predisposition. Putative autoantigens are the membrane bound asialoglycoprotein receptor, the cytosolic UGA-suppressor tRNA associated protein (recognized by anti-SMA and anti-LP antibodies), argininosuccinate lyase and formiminotransferase cyclodeaminase (recognized by anti-LC1 antibodies) and Cyp2D6/P450-IID6 (recognized by LKM-1 antibodies in AIH type 2).

The presentation of an autoantigen results in the attraction of antigen processing cells which stimulate the clonal expansion of cytotoxic T-cells reactive to the autoantigen. Liver acini are infiltrated by these

cytotoxic T lymphocytes which release cytokines and trigger the local necro-inflammatory response.

## Diagnostic Principles

Clinically, AIH may present as an acute (in one third of patients) or chronic disease. Typical symptoms are fatigue, jaundice, mild pruritus, epigastric pain, anorexia, diarrhea, myalgia and arthralgia, skin rashes (e.g., acne), edema, amenorrhea, hirsutism and chest pain due to pleuritis. Findings on clinical examination include hepatomegaly, jaundice, spider naevi, splenomegaly, ascites and signs of encephalopathy.

Several liver diseases must be excluded by appropriate test before the diagnosis of AIH can be made. These include: chronic viral hepatitis, alcoholic hepatitis, chemical- or drug-induced liver injury, Wilson's disease, hereditary hemochromatosis, α1-antitrypsin deficiency, primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC).

*Autoantibodies* can be found regularly in AIH. These antibodies may be the anti-nuclear antibodies (ANA), the anti–smooth muscle antibodies (ASMA) which overlaps with the anti-actin antibodies (AAA), the anti-liver and kidney microsomal antibodies (anti-LKM-1; antigen: Cyp2D6), the soluble liver antigen antibodies (anti-SLA; antigens: cytokeratins 8 and 18), the antineutrophil cytoplasmic antibodies (ANCA), the liver-specific asialoglycoprotein receptor antibodies, the hepatic lectin antibodies and others. ANA and/or ASMA are found in type 1 AIH. Furthermore, SLA antibodies, which were formerly believed to be characteristic for a third type of AIH, may be present in AIH type 1. LKM-1 antibodies are found in type 2 AIH [2,3].

When ANCA are positive, the diagnosis of an overlap of AIH with primary sclerosing cholangitis (PSC) should be considered. Approx. 6% of AIH patients may concurrently suffer from PSC. Antimitochondrial antibody (AMA) may be found in the overlap syndrome when AIH and primary biliary cirrhosis (PBC) occur together (in 7% of AIH patients).

*Hypergammaglobulinemia* is a regular finding in AIH, typically of the IgG type. Normal values of γ-globulins are below 2 g/dl but reach 3–4 g/dl or even up to 6g/dl in AIH. Lack of hypergammaglobulinemia makes the diagnosis of AIH unlikely. Gammaglobulin levels may be used to monitor disease development under therapy.

On *liver biopsy*, interface hepatitis is a prerequisite of the diagnosis of AIH. Plasma cell infiltration supports the diagnosis but is neither specific nor necessary for the diagnosis of AIH. Centrilobular necrosis is another finding of AIH, especially of early stages. It may progress towards panacinar (lobular) hepatitis and eventually to the classical pattern of interface hepatitis. By definition (International Autoimmune Hepatitis Group, 1999) AIH is non-viral and non cholestatic and does not include signs of bile duct injury or ductopenia.

## Therapeutic Principles

Immunosuppressant drugs (steroids and azathioprine) are the basis of therapy. According to the AASLD guidelines [1,2] absolute indications to initiate therapy are (1) 10-times increased levels of aspartate aminotransferase (AST/GOT) or (2) 5-times increased AST-levels plus ≥ 2-times elevated gammaglobulin levels or (3) bridging or multiacinar necrosis (requiring liver biopsy). Relative indications are (1) symptoms (eg, fatigue, arthralgia, jaundice) (2) AST and/or gammaglobulin less than absolute criteria or (3) interface hepatitis. No indications for therapy are: (1) inactive cirrhosis, preexistent comorbid conditions, or drug intolerances. (2) decompensated liver disease. The indications are discussed controversial in the literature because some patients with decompensated liver cirrhosis and AIH may respond well to therapy and, notable, reversal of fibrosis and cirrhosis in AIH has been reported upon treatment. If immunosuppression is impossible in advanced AIH or due to drug side effects, liver transplantation should be considered.

As in other autoimmune diseases, AIH is treated by an initial therapy (typically with an improvement of serum aminotransferases within two weeks) followed by a maintenance therapy. Initial therapy may either consist of a mono-therapy with steroids (criteria for mono-therapy arise from potential side effects of azathioprine. Criteria may be: cytopenia, TPMT-deficiency, malignancy, pregnancy) or a combination of steroids and azathioprine (criteria for a steroid-sparing regimen may be: diabetes, postmenopause, osteoporosis, obesity, acne, emotional lability, and hypertension). According to the AASLD guidelines, mono-therapy comprises 60 mg/d prednisone during the first week, followed by 40 mg during the second week, 30 mg during the third and fourth week and 20 mg until an end point is reached (see below). The combination therapy consists of half the dose of prednisone together with 50 mg azathioprine. Treatment failure to standard therapy is observed in almost 10% of patients. In those cases, high dose prednisone (60 mg/d), prednisone (30 mg/d) plus azathioprine (150 mg/d), a calcineurin inhibitor (cyclosporine or tacrolimus) or mycophenolate mofetil may be used.

When liver enzymes improve after initial therapy, maintenance therapy may consist of mono-therapy with azathioprine, which should be given at least one year after liver enzymes have normalized. Other parameters of drug treatment response are cessation of symptoms, normalization of bilirubin and hypergammaglobulinemia or disappearance of inflammation on histology. Because normalization of aminotransferases correlates with

histologic remission in only 50% of patients, a liver rebiopsy is justified before drug withdrawal, since drug withdrawal is associated with a relapse rate of 50% within 6 months and of 80% within 3 years. Relapse may be treated by the same medication; however, a second relapse usually reoccurs, necessitating an infinite immunosuppressant therapy, which should be titrated until AST levels are less than 5-fold of upper limit of normal.

# Hepatitis, Chronic

Andreas Erhardt
Department of Gastroenterology, Hepatology and Infectious Diseases, Heinrich-Heine-University of Duesseldorf, Duesseldorf, Germany

## Synonyms

Chronic hepatitis

## Definition and Characteristics

Chronic hepatitis represents a series of liver disorders characterized by varying degrees of hepatic necrosis and inflammation lasting longer than 6 months [1]. Chronic hepatitis in a strict sense encloses chronic viral hepatitis, autoimmune hepatitis and drug-induced chronic hepatitis and cryptogenic hepatitis.

The present classification of chronic hepatitis is based upon clinical and histopathologic variables including its cause, histologic activity (grade) and degree of fibrosis (stage). Several scoring systems for grading and staging have been established (e.g., HAI score, Ishak score, Knodell score, Metavir score, Desmet/Scheuer score). A former histopathological classification of chronic hepatitis distinguished *chronic persistent hepatitis* from courses with more severe disease activity termed *chronic aggressive or active hepatitis*. The aetiology of chronic hepatitis comprises infections with hepatotropic viruses (hepatitis B virus, hepatitis C virus, hepatitis D virus), chronic toxic liver injury (e.g., drugs), autoimmune diseases (e.g., autoimmune hepatitis, overlap syndromes) and unknown causes (cryptogenic hepatitis). Clinical and histological features of chronic hepatitis can also be seen in metabolic disorders (Wilson disease, nonalcoholic steatohepatitis [NASH], alcoholic steatohepatitis [ASH], hereditary haemochromatosis, alpha1-antitrypsin deficiency), primary biliary cirrhosis (PBC) or primary sclerosing cholangitis (PSC). Important histological features may include periportal necrosis, piecemeal necrosis/interface hepatitis (disruption of the limiting plate of periportal hepatocytes by inflammatory cells), confluent necrosis (necrosis between portal tracts or portal tracts and central veins called bridging necrosis), hepatocyte degeneration (e.g. ballooning, acidophilic change) and portal inflammation [2]. The inflammatory cells are predominantly lymphocytic. Fibrous tissue can be deposited in and around portal tracts, may extend from the portal tracts into the hepatic lobules for varying distances or even surround parenchymal nodules as in cirrhosis.

Liver cirrhosis can develop after decades and carries the risk for development of hepatocellular carcinoma (annual rate of 1–6%). Incidence of cholangiocarcinoma is increased in virus induced hepatitis and cholestatic liver diseases (primary biliary cirrhosis, primary sclerosing cholangitis).

## Prevalence

The worldwide prevalence varies significantly between the different aetiologies ranging from 2 to 4 million (e.g., autoimmune hepatitis) to 350 million (e.g., chronic hepatitis B).

## Genes

Each of different chronic hepatitis leads to deregulation of a variety of genes described in detail in the specific chapters.

## Molecular and Systemic Pathophysiology

An imbalance towards a TH2 cytokine profile with down-regulation of the TH1 response is a common feature in most chronic infections whereas an uncontrolled cytototoxic T-cell response, the induction of auto-antibodies and association with histocompatibility haplotypes is typical of auto-aggressive disorders. Immunological features can also observed in primarily metabolic (e.g., NASH, Wilson disease) and cholestatic diseases. Direct toxicity resulting in increased apoptosis or necrosis is a further common pathophysiological mechanism observed throughout different aetiologies.

## Diagnostic Principles

A predominant elevation of alanine aminotransferase (ALT) over aspartate aminotransferase (AST) is typically found in chronic hepatitis caused by infectious agents and autoimmune disorders. A predominant elevation of AST indicates toxic liver injury also reflected in the deRitis quotient (relation AST/ALT) >1. Increased serum levels of alkaline phosphatase, GGT and bilirubin are suggestive of cholestatic hepatitis. Liver biopsy is important for determination of aetiology

(e.g., autoimmune hepatitis, NASH) and exact grading and staging. More detailed parameters are mentioned in the specific chapters. Liver dysfunction is indicated by a decrease of albumin and/or prothrombin time and increase of bilirubin.

### Therapeutic Principles

Treatment recommendations are given in the specific chapters.

## Hepatitis, Chronic Viral

Andreas Erhardt
Department of Gastroenterology, Hepatology and Infectious Diseases, Heinrich-Heine-University of Duesseldorf, Duesseldorf, Germany

### Definition and Characteristics

Virus-induced hepatitis lasting longer than 6 months since onset of symptoms. Major hepatotropic viral agents are hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (HDV).

Characteristics of hepatitis B, C, D viruses and infection course are shown in Table 1 [1,2]. Chronicity rates of 5–10% for HBV have been reported in adults, but chronicity rates rise to 90% after perinatal HBV infection. Three major clinical courses are distinguished in chronic HBV infection: (i) chronic hepatitis B with elevated transaminases and/or histological activity being either HBeAg-positive or HBeAg-negative (ii) immune-tolerant, highly viremic HBsAg carrier status with normal or only mildly elevated transaminases mostly after perinatal inoculation (iii) inactive, low viremic HBsAg carrier status with normal or only mildly elevated transaminases. HDV is an incomplete virion, that needs the HBV surface protein (HBsAg) for its propagation. In HDV superinfection to underlying HBV infection chronic outcomes are found in over 90% of cases, whereas chronicity rates are only 5–10% in simultaneous HDV/HBV infection. Chronic courses are reported for 60–80% of HCV infections. Natural course of chronic viral hepatitis is highly variable with no to rapid progression to liver cirrhosis depending on viral factors (e.g. virus genotypes, mutations, co-infections), host factors (e.g. genetic polymorphisms, immunological response, race, gender) and comorbidities (e.g. alcohol intake, aflatoxin exposure, adipositas). Clinical course can be asymptomatic in up to 30% of patients with constantly or intermittently normal transaminases usually associated with a slow progression to cirrhosis except in perinatal HBV infection. On the other hand 20–30% of infections progress to cirrhosis within 10–20 years. Progression to cirrhosis occurs earlier and more frequent in chronic hepatitis D co-infection than in chronic HBV or HCV mono-infection. Presence of cirrhosis predisposes to the development of hepatocellular carcinoma occurring at an annual rate of 1–6%.

### Prevalence

It is estimated that 350 million people are infected by HBV. High endemic areas comprise East Asia and certain African countries. HDV infection affects about 15 million persons world-wide. Despite its necessity of

**Hepatitis, Chronic Viral. Table 1** Characteristics of hepatitis viruses B, C and D

| | HBV | HCV | HDV |
|---|---|---|---|
| Virus family | Hepadnaviridae | Flaviviridae | Satellites |
| Genome type | Partially ds/ss DNA, circular | Plusstrand RNA | Minus strand RNA, circular |
| Genome size | 3.2 kb | 9.3 kb | 1.7 kb |
| Virion size (nm) | 42 | 45 | 36 |
| Envelope | Enveloped (HBsAg) | Enveloped (E1, E2) | "Enveloped"(HBsAg) |
| Genotypes | A–H | 1–6 | I–III |

| Incubation (days) | 30–180 | 15–180 | 30–180 |
| Chronification | 5–10% | 60–80% | Superinfection: >90% |
| | | | Simultaneous HBV/HDV infection: 5–10% |

HBV co-infection regional prevalence of HDV does not parallel that of HBV. Classic HDV endemic areas are the Mediterranean Basin, the Middle East and the Amazonas region. Around 170 million people are infected by HCV worldwide with a highly variable geographical distribution.

## Genes

Host genes involved in virus clearance or chronification are PKR (Protein kinase R), SOCS (suppressor of cytokine signaling), endogenous interferons and genes regulating innate immune response (TLRs [toll like receptors], MDA5 [melanoma differentiation associated gene 5] RIG-I [retinoic acid inducible gene I], TRIF [TIR domain-containing adapter inducing IFNβ], CARDIF [CARD adapter inducing IFNβ also termed IPS-1, VISA, MAVS], IKK complex, IRF-3 [interferon regulatory factor-3], ATF-2/c-Jun, NF-kappa B and MAPK) [3]. A wide range of host gene polymorphisms have described to be involved in fibrosis progression (e.g. Interleukin-10, TGF-β, TNF, HFE [hemochromatosis genes], ApoE and HLA haplotypes) [4]. Virus genetic factor like mutations in the HBV precore region (G1896A nucleotide exchange), the HBV basal core promoter (nucleotide exchange G1764A) or mutations in the NS5A region of HCV have been shown to influence the natural course and the response to interferon therapy. The HBV X gene plays an important role in viral replication, apoptosis and cancerogenesis through its action as transcriptional activator on a variety of regulatory genes (e.g. NF-kappa B, AP1/2, ATF/CREB, NF-AT), modulator of signal transduction pathways (MAP kinases and WNT/β-catenin), cell cycle deregulator and direct interaction partner with regulatory proteins (e.g. DDB1 and 2, ZIP proteins, ATF3) [5]. An emerging number of mutations in the HCV NS5B gene and the HBV polymerase gene confer resistance to nucleos(t)idanalogues used for antiviral treatment. The NS3/4A serine protease/helicase of the HCV has been shown to modulate innate immune response as it can cleave TRIF and CARDIF. Virus genotypes are associated with differences in interferon response (response rate for HBV genotypes: A>B/C>D; response rates for HCV genotypes II>III>IV>I).

## Molecular and Systemic Pathophysiology

HBV-related liver disease is mainly due to lysis of infected hepatocytes by cytotoxic T-lymphocytes. Multiple functions including viral replication, apoptosis and cancerogenesis have been attributed to the HBV X gene. In chronic HDV infection viral cytotoxicity has been implicated as important pathogenic mechanism. In hepatitis C a strong TH2 cytokine profile is associated with chronic infection. Neutralizing antibodies are produced during HCV infection against B-cell epitopes within the core-, envelope-, NS3- and NS4-proteins but are mostly ineffective due to emergence of viral mutations. The HCV NS3/4A protease/helicase can hamper innate immune response through cleavage of TRIF and CARDIF and in addition interfere with apoptosis, cell growth and cancerogenesis which has also been described for the HCV core protein.

## Diagnostic Principles

An elevation of liver transaminases, predominantly alanine aminotransferase (ALT), is typically found in chronic viral hepatitis. Liver dysfunction is reflected by a decrease of albumin and/or prothrombin time and increase of bilirubin.

Detectable HBsAg (Hepatitis B surface antigen) indicates HBV infection. Active replication is verified by the presence of HBV DNA in serum (by PCR, branched DNA assay or transcription mediated assay). A HBV DNA level above 2000 IU/ml is a threshold for antiviral treatment and an important and independent risk predictor for the progression of the disease, the development of liver cirrhosis and hepatocellular carcinoma. Screening for HDV infection occurs through HDV antibody detection and should be performed in every HBsAg-positive patient. Active HDV replication is determined by detection of HDV RNA with RT-PCR. Enzyme immunosorbent assays (EIA) for identification of specific antibodies are highly sensitive for the diagnosis of chronic hepatitis C. Testing for HCV RNA (e.g. by PCR, branched DNA assay, transcription mediated assay) is the diagnostic gold standard for confirmation of replicative HCV infection. Pretherapeutic testing requires quantitative determination of viral load as viral kinetics under therapy have been established as treatment predictor. Determination of viral genotypes is recommended in chronic hepatitis C and B because of its therapeutic implications.

## Therapeutic Principles

Treatment indications are given in Table 2.

Chronic hepatitis B can be treated with oral nucleos(t)idanalogues (lamivudine 100 mg/d, adefovir 10 mg/d, entecavir 0.5–1 mg/d, telbivudine 600 mg/d, tenofovir 245 mg/d) or pegylated alpha-interferons s.c. Low viral load, high ALT levels, HBV genotype A and short disease duration are favorable response parameters for the treatment with pegylated interferons (PEG-IFN alpha2a 180 µg/week s.c. or PEG-IFN alpha2b 1,0–1.5 µg/week s.c. for 6–12 months) allowing to achieve durable virus suppression in 30–50% of patients. Interferons have various side effects and are contraindicated in patients with decompensated cirrhosis. Nucleos(t)idanalogues are well tolerated but relapse rates are high after treatment discontinuation. Therefore, antiviral therapy with nucleos

**Hepatitis, Chronic Viral. Table 2** Treatment indications for chronic viral hepatitis

| Type | Treatment indications |
|---|---|
| Hepatitis B | *Patients who should be treated:* |
| | HBeAg-positive or HBeAg-negative, HBV-DNA >2000 IU/ml, ALT≥ 2 ULN or histology > minimal inflammatory activity/minimal fibrosis |
| | Viremic patients with (decompensated) cirrhosis |
| | *Patients who usually do not need treatment:* |
| | HBsAg carriers: repeatedly HBV-DNA negative or HBV-DNA concentrations below <2000 IU/ml, repeatedly normal transaminases and at most minimal inflammatory activity/minimal fibrosis in the liver biopsy |
| Hepatitis C | Patients with fibrosis and/or high inflammatory activity |
| Hepatitis D | Patients who have inflammatory activity and/or fibrosis |

(t)idanalogues should be performed long-term. HBeAg positive patients should be treated for at least 6 or even better for 12 months beyond HBeAg seroconversion. The treatment duration for HBeAg negative patients is not exactly defined, in general, continuous therapy is necessary. When choosing an oral drug for the therapy of hepatitis B the antiviral efficacy, the response durability, the resistance barrier, and the stage of liver disease should be taken into account. Permanent HDV suppression can be achieved by treatment with pegylated interferon-alpha. The duration of therapy should be at least 12 months.

Treatment of chronic HCV infection includes the combination of pegylated interferon-alpha (PEG-IFN alpha2a 180 µg/week s.c. or PEG-IFN alpha2b 1.0–1.5 µg/week s.c.) with ribavirin (800–1200 mg daily). A >2$\log_{10}$ decrease or negativation of HCV RNA from baseline at week 12 is an important predictor for successful treatment. In case of insufficient decrease of viral load therapy should be discontinued. In HCV genotype I and IV treatment duration is 48 weeks resulting in sustained response rates of 40–50%. Sustained response rates of 70–80% are achieved in HCV genotype II and III patients with a treatment duration of 24 weeks. Liver transplantation may be required in endstage liver disease.

# Hepatitis, Granulomatous

Frank Lammert[1], Johann Lorenzen[2]
[1]Department of Internal Medicine I, University Hospital Bonn, Bonn, Germany
[2]Institute of Pathology, Clinic of Dortmund gGmbH, Dortmund, Germany

## Synonyms

Hepatic (epitheloid cell) granulomas

## Definitions and Characteristics

Granulomatous hepatitis is a chronic exudative and proliferative inflammatory reaction of liver tissue that occurs in association with infections, systemic diseases or drugs and is characterized by nodular inflammatory infiltrates (granulomas) composed of macrophages, epitheloid cells, lymphocytes, and fibroblasts. A granuloma is a focal accumulation of epitheloid cells, which are transformed macrophages [1].

## Prevalence

0.7–15% of all liver biopsies contain hepatic granulomas [2], but in many cases they are not accompanied by hepatitis, and no specific disease is detected during the course of further investigations.

## Genes

There is substantial evidence from epidemiological and twin studies that host genetic factors are important in determining susceptibility to infections with Mycobacteria and the subsequent development of granulomas. Case-control (association) studies pointed to several gene variants contributing to tuberculosis risk, including HLA haplotypes, macrophage receptor mannose-binding lectin (MBL2), a pattern recognition molecule of the innate

immune system, natural resistance associated macrophage protein-1 (SLC11A2), the vitamin D receptor (VDR), IFN-γ and the IL-1 gene cluster; however, together these only account for a small proportion of the genetic component suggested by familial aggregation and twin studies.

Similar to tuberculosis (and leprosy), sarcoidosis shows family clustering and genetic factors appear to contribute to the multifactorial pathogenesis. Association studies indicate that allelic variants at the HLA class I (HLA-A1 and B8) and II loci (HLA-DRB*1101 and DPB1*0101) are genetic risk factors. Up to now, only few non-HLA susceptibility genes such as angiotension-converting enzyme (ACE) and IFN-α have been identified. Recently genetic variants of the costimulatory molecule butyrophylin-like protein 2, which modulates the activation of T cells and is encoded by the TTNL2 gene, were demonstrated to be associated with sarcoidosis and to contribute 34% of the population-associated risk [3].

In PBC, HLA polymorphisms do not seem to be a major determinant of susceptibility and clinical expression, with several studies reporting primarily weak associations with HLA-DR8 [4]. This may indicate that antigen presentation through the HLA class II pathway is not of paramount importance in PBC pathogenesis. However, other association studies indicated that polymorphisms within the cytotoxic lymphocyte associated protein-4 (CTLA4), a critical surface molecule for conditioning of T-cells and dendritic cells, MBL2, SLC11A2, VDR, IL-10 and the IL-1 gene cluster are associated with susceptibility to PBC, whereas polymorphisms within the caspase 8 gene and the apolipoprotein E4 isoform might affect disease progression [4].

## Molecular and Systemic Pathophysiology

Granulomatous hepatitis is usually part of a generalized disease (Table 1) and represents a chronic inflammatory response to antigenic stimuli (e.g., infections, drugs).

Primary biliary cirrhosis (PBC), sarcoidosis, tuberculosis, schistosomiasis, drugs and AIDS account for the majority of all cases. The presence of clinical or laboratory signs of portal hypertension (cytopenias, esophagogastric varices, ascites) should be considered suspicious for schistosomiasis, sarcoidosis, or PBC. In addition to the infections listed in Table 1, hepatic granulomas can be associated with viral hepatitis, Crohn's disease, Whipple's disease, atypical mycobacteriosis, yersiniosis, listeriosis, tularemia, psittacosis, leishmaniasis as well as various helminths and other rare infections [1,2]. Drugs that cause granulomatous hepatitis include allopurinol, carbamazepine, phenylbutazone, phenytoin, α-methyldopa, quinine/quinidine, sulfonamides, glibenclamide, and diltiazem. There is a small subgroup of patients in whom granulomatous hepatitis of unknown origin is the cause of general symptoms (fever, fatigue, abdominal pain, weight loss) and liver dysfunction.

In PBC and sarcoidosis, hepatic granulomas are often found near portal tracts. Hepatic granulomas have a common histological pattern (Fig. 1) but differ in composition and size (50–300 μm).

The reaction is usually not liver-specific except when a definite antigen (e.g., Schistosoma ova) can be identified. Sarcoidosis type granulomas (Table 1, Fig. 1) are characteristically tight, well formed and non-caseating. Older granulomas are often surrounded by a fibrous reaction consisting of proliferating fibroblasts and extracellular matrix. Pseudotuberculosis type granulomas display a purulent centre infiltrated by neutrophils and surrounded by epitheloid cells.

The formation of granulomas results from the complex interaction of macrophage activation, $CD4^+$ T-helper cell response, Th1 type cytokines mediators (IFN-γ, IL-2), B-cell overactivity, and circulating immune complexes [2]. $CD4^+CD28^+$ T-cells in the central part of the granuloma are the major source of IFN-γ and TNF-α. Loss of immunoregulation by CD1d-restricted natural-killer T-cells could contribute to the amplified and persistent T-cell reactivity that characterizes sarcoidosis. Macrophages are activated by persistent antigens, proliferate and undergo transformation into epitheloid cells, which secrete catabolic enzymes (proteases, elastases, collagenases). Stimulated by cytokines and complement factors, macrophages and epitheloid cells may fuse to syncytial (giant) cells. Granuloma formation involves not only macrophages but also chemokine-regulated migration of circulating lymphocytes and dendritic cells to portal tract-associated lymphoid tissue [5]. Lymphotoxins and lysosomal enzymes can result in formation of central caseating necrosis (absent in sarcoidosis). The resolution of granulomas is associated with an influx of $CD8^+$ lymphocytes and secretion of IL-10, whereas cytokines associated with chronic disease and fibrosis include IL-8, IL-12, and TNF-α.

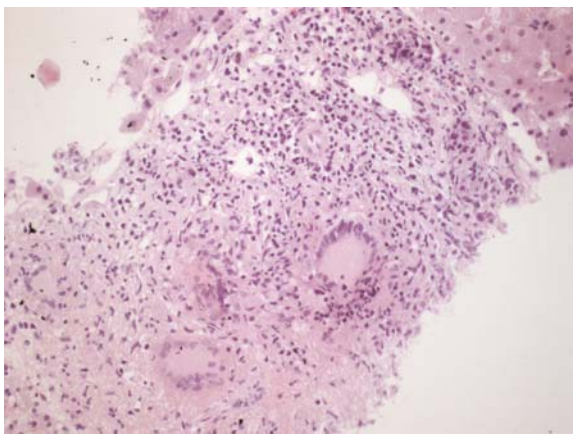
## Diagnostic Principles

Liver biopsy confirms the diagnosis of granulomatous hepatitis. Specific stains, culture biopsies and PCR for acid-fast bacilli or other pathogens (CMV, EBV, fungi, Brucella abortus, Tropheryma whipplei, Bartonella henselae) should be performed in cases of granulomatous hepatitis of unknown origin, but the sensitivity of many tests is low.

Liver chemistry tests may be moderately increased (e.g., transaminases, γ-glutamyl transpeptidase, alkaline phosphatase). Serum ACE activity and soluble IL-2 receptor concentrations are often increased. On contrast-enhanced CT scans, patients with granulomas 5 mm or greater in size might display multiple, small

**Hepatitis, Granulomatous. Table 1** Hepatic granulomas

| | Etiology | Characteristics of granulomas |
|---|---|---|
| Sarcoidosis type | | |
| Sarcoidosis | Unknown | Epitheloid and giant cells flower-like |
| | | Centripetal hyaline fibrosis |
| | | Clusters of granulomas |
| Primary biliary cirrhosis | Unknown | |
| Toxoplasmosis | Toxoplasma gondii | Small granulomas |
| | | Rare irregular giant cells |
| Tuberculosis type | | |
| Tuberculosis | Mycobacterium tuberculosis | Central caseating (fibrillogranular) necrosis with destruction of the reticulin framework |
| | | Epitheloid and ordered giant cells peripheral lymphocytes |
| Leprosy | Mycobacterium leprae | Central necrosis |
| | | Foam cells |
| Syphilis | Treponema pallidum | Central necrosis |
| | | Peripheral plasma cells |
| Pseudotuberculosis type | | |
| Q fever | Coxiella burnetii | Central lipid vacuole surrounded by granulocytes, epitheloid cells, lymphocytes and fibrin ring (doughnut granuloma) |
| Brucellosis | Brucella abortus | Mixed granuloma with plasma cells |
| Cat-scratch disease | Bartonella henselae | Central purulent necrosis |
| Schistosomiasis | Schistosoma spp. | Central necrosis with eosinophils peripheral fibrosis |
| | | Schistosoma ova and finely granular, black schistosomal pigment |
| Cryptococcosis | Cryptococcus neoformans | Mixed granuloma |
| Histoplasmosis | Histoplasma capsulatum | Central fibrillogranular necrosis with granulocytes hyaline fibrosis and focal calcification |
| Coccidiomycosis | Coccidioides immitis | Central fibrillogranular necrosis with granulocytes calcification |



**Hepatitis, Granulomatous. Figure 1** Sarcoidosis type granulomas.

low-attenuation areas; caseating granulomas may appear as hyper- or hypointense foci on T1-weighted MRI images [2].

## Therapeutic Principles

Treatment of hepatic granulomas depends on the assigned etiology. Specific infections are treated with antibiotics or antifungal agents. The effect of ursodeoxycholic acid, which shows favorable effects on PBC progression, on hepatic granulomas has not yet been reported [2]. Sarcoidosis and idiopathic granulomatous hepatitis may subside spontaneously or regress with corticosteroid treatment; patients not responding to steroids may benefit from other immunsuppressive therapies (e.g., azathioprine or methotrexate) or anti-inflammatory treatment (e.g., indometacin) [2].

## Synonyms

Hepatoma; Liver cancer; Primary liver cancer; Liver cell carcinoma; Primary liver cell carcinoma; HCC

## Definition and Characteristics

Hepatocellular carcinoma (HCC) is a malignant liver tumor that arises from parenchymal epithelial liver cells (hepatocytes). HCCs have a generally very poor prognosis with a 5-year survival rate of <5% in symptomatic patients. Furthermore, these tumors have been shown to be quite resistant to chemotherapy. The natural course of the disease and the median survival of patients with HCC depend on the stage of the disease at the time of diagnosis. In patients with CLIP score O or Okuda stage I (see below) the median survival is in the range of 23–69 months, while in patients with CLIP score 3–5 or Okuda stage III median survival is only 1–14 months [1]. The staging system is clinically most important for the appropriate choice of the therapeutic strategy for individual patients. Cirrhotic patients developing a HCC during the last 5 years of surveillance survived longer than previously, due to improved management of the tumor and of the complications of cirrhosis. Importantly, however, in a population-based study in the US underutilization of potentially curative therapies even among patients with favorable HCC features is a problem that needs to be addressed.

## Prevalence

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors worldwide and has been recently reviewed [1,2]. The incidence ranges from <10 cases per 100,000 population in North America and Western Europe to 50–150 cases per 100,000 population in parts of Africa and Asia where HCC is responsible for a large proportion of cancer deaths. However, a rise in the incidence of and mortality from HCC, most likely reflecting the increased prevalence of hepatitis C virus (HCV) infection, has recently been observed in most industrialized countries.

## Genes

Central to the concept of molecular carcinogenesis are mutations of oncogenes and tumor suppressor genes as well as genetic instability, including mismatch repair deficiency and impaired chromosomal segregation. As for most cancers, hepatocarcinogenesis is a multistep process involving different genetic alterations that ultimately lead to the malignant transformation of the hepatocyte [3]. While significant progress has been made in recognizing the sequence of events involved in other forms of cancer, most notably in colorectal cancer and certain hematopoietic malignancies, the molecular contribution of the multiple factors and their interactions in hepatocarcinogenesis are still poorly understood. HCCs are phenotypically (morphology, microscopy) and genetically very heterogenous tumors, possibly reflecting in part the heterogeneity of etiologic factors implicated in HCC development, the complexity of hepatocyte functions and the late stage at which HCCs usually are detected. Malignant transformation of hepatocytes may occur regardless of the etiologic agent through a pathway of increased liver cell turnover, induced by chronic liver injury and regeneration in a context of inflammation, immune response and oxidative DNA damage. This may result in genetic alterations, such as the activation of cellular oncogenes, the inactivation of tumor suppressor genes, possibly in cooperation with genomic instability, including DNA mismatch repair defects and impaired chromosomal

segregation, overexpression of growth and angiogenic factors, and telomerase activation. Chronic viral hepatitis B, C and D, alcohol, metabolic liver diseases such as hemochromatosis and alpha-1-antitrypsin deficiency as well as non-alcoholic fatty liver disease may act predominantly through the pathway of chronic liver injury, regeneration, and cirrhosis. The major clinical risk factor for HCC development, therefore, is liver cirrhosis that coexists in 70–90% of HCCs. Most HCCs occur after many years of chronic hepatitis that provides the mitogenic and mutagenic environment to precipitate random genetic alterations resulting in the malignant transformation of hepatocytes and HCC development.

There is evidence that HBV – and possibly also HCV – may under certain circumstances play an additional direct role in the molecular pathogenesis of HCC. Finally, aflatoxins have been shown to induce mutations of the p53 tumor suppressor gene, thus pointing to the contribution of an environmental factor to tumor development at the molecular level. Further, in a transgenic mouse model it has been shown that chronic immune-mediated liver cell injury without environmental or infectious agents is sufficient to cause HCC and that inhibition of cytotoxic T lymphocyte-induced apoptosis and chronic inflammation by neutralization of the Fas ligand prevents HCC development in this model. In addition, also in a transgenic mouse model it has been demonstrated that NF-kappaB may be the link between inflammation and HCC development. Finally, individual polymorphisms of drug metabolizing enzymes, e.g., various cytochrome P450 oxidases, *N*-acetyltransferases and glutathione-*S*-transferase, may contribute to the genetic susceptibility to HCC development.

## Molecular and Systemic Pathophysiology

The molecular pathogenesis of HCC is very complex and involves alterations in the structure or expression of several tumor suppressor genes, oncogenes and, possibly, mechanisms leading to genetic instability due to mismatch repair deficiency or chromosomal instability and aneuploidy due to defective chromosomal segregation.

The HCC risk in patients with liver cirrhosis depends on the activity, duration and the etiology of the underlying liver disease. In general, HCCs are more frequent in males than in females. Major HCC risk factors are chronic hepatitis B, C and D, toxins (e.g., alcohol, tobacco, aflatoxins), hereditary metabolic liver diseases (e.g., hereditary hemochromatosis, alpha-1-antitrypsin deficiency, autoimmune hepatitis and states of insulin resistance, e.g., overweight in males, diabetes mellitus as well as non-alcoholic steatohepatitis (NASH) or non-alcoholic fatty liver disease (NAFLD). Clinical and biological variables (age, anti-HCV positivity, PTT and platelet count) allow to further identify a subset of cirrhotic patients with the highest HCC risk. While in HBsAg positive patients the level of serum hepatitis B virus (HBV) DNA seems to correlate with the risk to develop a HCC, also in HBeAg negative patients with normal liver function tests. Also occult HBV infection (anti-HBc and HBV DNA positive only) carries a significant HCC risk. Coexistence of etiologies, e.g., HBV and HCV infection, HBV infection and aflatoxin B1, HBV or HCV infection and alcohol or diabetes mellitus, HCV infection and liver steatosis, environmental factors, e.g., alcohol as well as diabetes mellitus, obesity and tobacco increase the relative risk of HCC development. The contribution of tobacco use is controversial, however, while coffee consumption appears to reduce the HCC risk.

## Diagnostic Principles

Diagnosis is based on laboratory tests and imaging analyses, including histopathology. Apart from laboratory parameters defining the etiology, grade and stage of the underlying liver disease, an elevated alpha-fetoprotein (AFP) level strongly suggests a HCC (sensitivity 40–60%, specificity 80–90%). Two additional tumor markers, des-gamma-carboxyprothrombin (DCP) and the lens culinaris agglutinin-reactive fraction of AFP (AFP-L3), seem to add to HCC detection [4] but are not routinely used in clinical practice. The most widely used imaging analysis is abdominal ultrasound complemented by color duplex sonography and contrast media. Further imaging analyses that are particularly important for the selection and monitoring of therapeutic strategies are dynamic spiral computed tomography (CT), angio-CT and lipiodol-CT as well as magnetic resonance imaging (MRI). In patients with low or moderate AFP elevations and a liver lesion detected by imaging analyses biopsy and histopathological examination is recommended.

For the staging of HCCs seven systems have been proposed to assess the extent and of the prognosis of the disease: the Okuda staging system, the TNM classification and its modification by the "Union Internationale contre le Cancer (UICC)," the "Barcelona Clinic Liver Cancer (BCLC)" classification, the "Cancer of the Liver Italian Program (CLIP)" score, the "Japan Integrated Staging (JIS)" score, the Groupe d'Etude de Traitement du Carcinome Hépatocellulaire (GRETCH) score and the Chinese University Prognostic Index (CUPI).

## Therapeutic Principles

Therapeutic options for HCCs fall into five categories: surgical interventions (tumor resection and liver transplantation, LTx), percutaneous interventions (e.g., ethanol or acetic acid injection, radiofrequency thermal ablation), transarterial interventions (embolization, chemoperfusion, or chemoembolization), radiation and drugs.

To date, surgical, percutaneous and transarterial interventions, including systemic internal radiotherapy (SIRT), have not systematically been compared in randomized controlled trials. In selected patients, tumor resection and LTx result in 5-year survival rates of 60–70%, with LTx being the best treatment for patients with single lesions and advanced liver disease, e.g., decompensated cirrhosis, or multicentric small tumors. Percutaneous interventions, again in selected patients, result in 5-year survival rates of 40–50%. In the following, the different therapeutic options as well as primary and secondary HCC prevention will be discussed in some detail.

In patients without coexisting liver cirrhosis (5% in Western countries, 40% in Subsaharan Africa and Asia) HCC resection is the treatment of choice with low rates of life-threatening complications. By comparison, in the majority of patients with cirrhosis, strict selection is required to avoid resection-related complications, especially postoperative liver failure. Resection-related mortality should be <1–3%, and the 5-year survival rates should be >50%. LTx is in principle the optimal therapeutic option for HCCs because it simultaneously removes the tumor and the underlying cirrhosis, including the risk of HCC recurrence.

Percutaneous interventions are the best options for small unresectable HCCs. Tumor ablation can be achieved chemically by percutaneous ethanol injection (PEI) or acetic acid injection (PAI) or thermally by radiofrequency thermal ablation (RFA), microwave-heat induced thermotherapy (HiTT), laser induced thermotherapy (LiTT), or cryoablation. Apart from an US- or CT-guided percutaneous approach, these techniques can also be applied laparoscopically or at laparotomy. PEI was the technique most widely used. It is safe, easy to perform, inexpensive and achieves complete tumor response rates of 90–100% in HCCs <2 cm in diameter, 70% in HCCs <3 cm diameter and 50% in HCCs <5 cm in diameter. Patients with liver cirrhosis Child-Pugh stage A with complete responses can achieve 5-year survival rates of 50% and more. Therefore, PEI was the procedure of choice for patients with a single HCC lesion <5 cm in diameter or with up to three lesions <3 cm in diameter. Survival is predicted by the initial response to PEI. In recent years, however, RFA was used more frequently than PEI, primarily because of patient comfort, requiring a single intervention only in most patients.

Transarterial chemoperfusion (TAC), embolization (TAE) and chemoembolization (TACE) are the most widely used treatment modalities for HCCs that are unresectable or cannot be treated by percutaneous interventions. Embolization agents may be administered alone (TAE) or after selective intra-arterial chemotherapy (generally doxorubicin, mitomycin or cisplatin mixed with lipiodol) without (TAC) or with subsequent embolization (TACE). Transarterial interventions yield partial responses in 15–55% of patients, delay tumor progression and vascular invasion and result in a survival benefit compared with best supportive care (BSC). The most important aspect is the selection of patients, i.e., patients should have preserved liver function (liver cirrhosis Child-Pugh stage A) and asymptomatic multinodular tumors without vascular invasion or extrahepatic spread. In patients with advanced liver disease (Child B or C) treatment-induced liver failure may offset the antitumor effect or the survival benefit from the intervention. In a randomized controlled clinical study the combination of TACE and PEI improved the survival of patients with HCC Okuda stage I, as compared to TACE alone. Further, postoperative adjuvant TACE may improve survival in patients with risk factors for residual tumor.

While radiotherapy has played a minor role in HCC treatment in the past, selective intra-arterial injection of $^{131}$iodine-labeled lipiodol has been performed in some patients but needs further clinical evaluation before a recommendation can be made. Further, high dose proton beam radiotherapy and modulated external beam radiation as well as Yttrium-90 microsphere treatment have been recently studied in clinical trials in patients with unresectable HCC. These strategies will certainly be further explored in clinical studies and may become a treatment option in the future.

A number of systemic chemotherapies, hormonal and other drugs have been evaluated in clinical trials. While most chemotherapeutic agents, tamoxifen, octreotide and interferon-alpha have not been shown to be effective in randomized controlled clinical trials. A number of substances may deserve further clinical evaluation alone or in combination with other drugs, e.g., gemcitabine, thymostimulin, alpha-1-thymosin, pravastatin, thalidomide and megestrol acetate as well as several antiangiogenic small molecules, e.g., erlotinib, sorafenib, gefitinib, as well as antiangiogenic monoclonal antibodies, e.g., bevacizumab or cetuximab, Cox-2 inhibitors in combination with capecitabine, pamidronate and others. To date, however, none of these drugs can be recommended outside of clinical studies.

In view of the limited therapeutic options for advanced HCCs a number of experimental strategies are being evaluated, incl. gene and immune therapies based on suicide, cytokine and antiangiogenic genes or DNA vaccination with tumor-specific genes, oncolytic viruses as well as novel drugs, e.g., 3-bromopyruvate.

Apart from exploring new and refining existing HCC treatment strategies, primary prevention is of major importance. After successful surgical or non-surgical HCC treatment, secondary HCC prevention of local recurrence or new HCC lesions is central to the improvement of disease-free and overall patient survival. Based on rapid scientific advances, molecular diagnosis,

gene therapy and molecular prevention are becoming increasingly part of our patient management and will eventually complement and in part replace existing diagnostic, therapeutic and preventive strategies.

Enlarged liver; Liver enlargement

## Definition and Characteristics

Hepatomegaly is the enlargement of the liver beyond its normal size. Hepatomegaly is a non-specific medical condition with a broad range of possible causes. These may be divided into infectious (hepatitis A, hepatitis B, cytomegalovirus, infectious mononucleosis, malaria, amoeba infection, hydatid cyst, schistosomiasis, leptospirosis, leishmaniasis/Kala-Azar, actinomycosis, liver abscess); neoplastic (giant hemangioma, focal nodular hyperplasia, adenoma, hepatocellular carcinoma, leukemia, lymphoma, myeloma, tumor metastases, neuroblastoma); toxic (alcohol, vitamin A overdose, toxins, drugs such fibrates, procainamide, pyrazinamide, retrovir, zidovudine); metabolic (steatosis, hemochromatosis, protein malnutrition, diabetes mellitus, Wilson's disease, amyloidosis, Gaucher disease, Niemann-Pick disease, hereditary fructose intolerance, glycogen storage diseases, jejuno-ileal bypass) and miscellaneous other causes (sarcoidosis, sclerosing cholangitis, primary biliary cirrhosis, autoimmune hepatitis, Budd-Chiari syndrome, hemolytic-uremic syndrome (HUS), congestive heart failure, Reye's syndrome, and hemolytic anemia). Clinically, hepatomegaly presents as an abdominal mass and may present along with jaundice.

## Prevalence

The most common cause of hepatomegaly may be schistosomiasis, which affects over 200,000,000 people worldwide. In western countries, (non)-alcoholic steatohepatitis (NASH/ASH) due to obesity, type II diabetes and alcohol consumption is the most frequent reason for hepatomegaly [1].

## Genes

Hepatomegaly is a regular feature of several metabolic diseases as already mentioned. In these cases, liver enlargement may be attributed to defects in single genes. Examples are (chromosomal location in brackets): hemochromatosis – HFE gene (6p21.3), Hemojuvelin (1q21), Hepcidin (19q13.1) or Transferrin Rezeptor 2 (7q22); Wilson's disease – ATPase7B (13q14.3–q21.1), Niemann-Pick disease – sphingomyelinase (18q11–q12), hereditary fructose intolerance – fructose-1-phosphate aldolase deficiency (9q22.3), glycogen storage diseases type I – glucose-6-phosphatase (17q21), Gaucher's disease type I – glucocerebrosidase (1q21), etc.

Several animal models have been described with hepatomegaly as a prominent feature, highlighting the involvement of the respective genes. Examples are the sterol 27-hydroxylase (knock out) [2], the oncogenic form of beta-catenin (transgenic) [5] or overexpression of a constitutively active Akt [3].

The development of hepatomegaly due to infectious causes may also be determined by genes of the host. For example, the development of hepatomegaly in mice with leishmania infections was linked to a subset of 17 "leishmania-responsive" genes [4].

## Molecular and Systemic Pathophysiology

The reason for hepatomegaly may be an increase in cell number as in neoplastic or infectious forms of

hepatomegaly, with neoplastic or inflammatory cells invading the liver. In addition, inflammation may cause interstitial edema and cell swelling.

An increase in the size of individual cells may also cause enlargement of the liver and may be due to the retention and deposition of un-metabolized intermediates. These metabolites may include fat/triglycerides (NASH, ASH), nascent proteins (ASH), glycogen (glycogen storage diseases), and glycosphingolipids, glucocerebrosides or mucopolysaccharides in lysosomes (lysosomal storage diseases). In amyloidosis liver enlargement is caused by the deposition of insoluble proteins within the extracellular space.

## Diagnostic Principles

Hepatomegaly may readily be diagnosed on physical examination. It may be suspected on plain X-ray films (elevation of the right hemi-diaphragm) and can easily be quantified on abdominal ultrasound or CT scans. Both imaging techniques may provide first clues for the diagnosis of the underlying disease. Criteria are: masses within the liver (solid, cystic, homogeneous); density (hypo- or hyperdense)/echogenicity (hypo- and hyperechoic) and texture (homogeneous, inhomogeneous) of the liver; vascular abnormalities (e.g., dilatation of hepatic veins, clotted hepatic veins, and signs of portal hypertension). Because numerous causes may lead to hepatomegaly, definite diagnosis is based on the synopsis of the patient's history, general and specific laboratory tests, imaging techniques and possible liver biopsy.

## Therapeutic Principles

Due to the heterogeneity of the causes of hepatomegaly, there is no common therapeutic procedure for liver enlargement. An indication for surgical treatment may arise from symptoms due to mass effects (abdominal pain, abdominal distension, dyspnoea). This may be the case in large benign or malignant liver tumors, (complicated) liver cysts or polycystic liver disease.

## Synonyms

Congestive hepatomegaly; Cardiac cirrhosis; Shock liver; Nutmeg liver

## Definition and Characteristics

Congestive hepatopathy is caused by passive hepatic congestion in patients with right sided heart failure of any origin such as constrictive pericarditis, tricuspid regurgitation, mitral stenosis, cor pulmonale, and cardiomyopathy. Liver fibrosis or cardiac cirrhosis may result from prolonged or recurrent congestive heart failure. Most such patients have either constrictive pericarditis or mitral valve disease and secondary tricuspid insufficiency. Patients with congestive hepatopathy uncommonly develop variceal bleeding but coagulation factors and albumin may be decreased. In patients with coexisting reduced cardiac output liver perfusion may be impaired leading to ischemia-reperfusion injury. Ischemic hepatitis (hypoxic hepatitis, shock liver) frequently manifests as asymptomatic elevation of the serum aminotransferase levels after an episode of hypotension. In most cases, congestive hepatopathy and ischemic hepatitis do not have major clinical impact. However, acute liver failure may occur in patients with preexisting cirrhosis, severe chronic heart failure, or sustained hepatic ischemia. The prognosis in patients with congestive hepatopathy is determined mostly by the severity of the underlying heart disease.

## Prevalence

Mild hyperbilirubinemia and elevated transaminases are frequent findings in patients with right side heart failure. In a prospective series of 1,800 consecutive cardiac surgical cases 20 patients developed hypoxic hepatitis with ALT levels above 500 U/l [1]. These patients had higher mortality than matched control patients with cardiac surgery.

## Molecular and Systemic Pathophysiology

On pathological examination congested liver presents as "nutmeg liver" with reddish central areas (representing sinusoidal congestion and bleeding into atrophic regions surrounding enlarged hepatic veins) and contrasting yellowish areas that represent either normal liver tissue or fatty liver. The central veins are enlarged and fatty change or hemorrhagic necrosis in the zone 3 (pericentral region around the central veins) of the hepatic acinus may be present. Severe congestion leads to excess fluid in the space of Disse and fluid exudes from the surface of the liver into the peritoneal space, leading to the high-protein ascites characteristic for congestive heart failure [2]. Chronic congestion leads to accumulation of reticulin and collagen and eventually causes fibrous bands originating from the central vein and sparing the periportal areas. This histologic pattern is distinct from other forms of liver fibrosis and cirrhosis.

Passive congestion by itself does not appear to be sufficient to cause significant hepatic necrosis and there is no clear correlation between the degree of congestion as assessed by right atrial pressure and pericentral necrosis. However, reduced cardiac output in addition to congestion is the critical factor promoting pericentral necrosis. Passive congestion and reduced cardiac output coexist in most patients with hypoxic hepatitis or shock liver [3,4].

In shock syndromes such as sepsis there is a compensatory decrease in peripheral and splanchnic blood flow. The decrease in hepatic blood flow may result in hepatocellular hypoxia, especially in the pericentral zone 3 [2]. Reperfusion injury appears to account for most of the histologically apparent damage. It is mediated by generation of reactive oxygen species once ischemic hepatocytes are reexposed to oxygen. The mechanisms of ischemia-reperfusion injury include: cell injury by lipid peroxidation; Kupffer cell induction producing cytokines such as tumor necrosis factor alpha, which triggers the recruitment and activation of polymorphonuclear leukocytes; production of superoxide and hydrogen peroxide from accumulated xanthine by xanthine oxidase; induction of multiple genes in the hepatocyte via the transcription factors heat-shock factor and nuclear factor kappa B.

## Diagnostic Principles

Patients with mild to moderate hepatic congestion are usually asymptomatic and may only present with elevated liver enzymes on laboratory testing. Symptomatic patients may present with jaundice, hepatomegaly, right upper quadrant discomfort due to stretching of the liver capsule and ascites. In patients with constrictive pericarditis hepatic vein pressures are generally higher than those seen in patients with right-sided heart failure. Hepatomegaly, a pulsatile liver, massive ascites, and peripheral edema are common. Important clinical signs are elevated jugular venous pressure, Kussmaul's sign (a rise in the jugular venous pressure on inspiration), a pericardial knock, and pericardial calcification on chest radiograph.

The most common liver biochemical abnormality in congestive hepatopathy is a mild elevation in the serum bilirubin level, which occurs in up to 70% of the patients [2]. The total serum bilirubin is usually less than 3 mg/dl, most of which is unconjugated. Serum aminotransferase levels are elevated in about one third of patients but typically no more than 2–3 times the upper limit of normal. Elevations in aminotransferases exceeding 1000 U/l may be seen in patients with hypotension due to heart failure and may cause confusion with viral hepatitis [5]. Liver biopsy is infrequently necessary, but may reveal the characteristic histological findings of liver congestion and pericentral necrosis

## Therapeutic Principles

Congestive hepatopathy is treated by management of the underlying heart disease and usually responds to diuretics and medications improving cardiac output. Early pericardiectomy is curative in constrictive pericarditis.

# Hepatopulmonary Syndrome

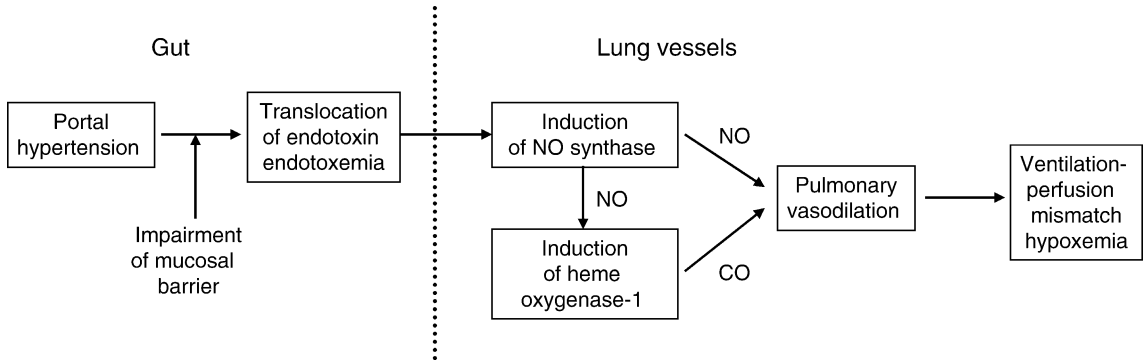
Matthias Wettstein
Internal Medicine I, Passau Hospital, Passau, Germany

## Synonyms

Orthodeoxia-platypnea syndrome; HPS

## Definition and Characteristics

The hepatopulmonary syndrome (HPS) is defined as a triad of liver diseases or extrahepatic portal hypertension, an arterial $pO_2$ lower than 80 mmHg in the absence of



**Hepatopulmonary Syndrome. Figure 1** Putative pathophysiological mechanism of hepatopulmonary syndrome.

heart or lung disease and intrapulmonary vascular dilatations. Manifestations include cyanosis, orthodeoxia and platypnea. Patients with HPS have more cutaneous spiders, finger clubbing and dyspnea compared to liver cirrhotics without HPS.

## Prevalence

Data on the prevalence of HPS in liver cirrhotics vary between 5 and 30%. In a study with 80 candidates for liver transplantation, evidence of a hepatopulmonary syndrome was found in 18%. In 54 consecutive patients with liver cirrhosis and 50 patients with extrahepatic portal venous obstruction, the prevalence of HPS was 11 and 2%, respectively [1].

## Molecular and Systemic Pathophysiology

HPS is characterized by intrapulmonary shunting with subsequent ventilation-perfusion mismatch. Shunting is due to intrapulmonary vasodilatation preferentially localized in the basal lung areas expressing orthodeoxia. Experimental data indicate that the induction of nitric oxide and carbon monoxide synthesis by bacterial endotoxin is the major pathophysiological mechanism for the intrapulmonary vasodilatation (Fig. 1).

Portal hypertension promotes translocation of bacteria and toxins from the gut by affecting the mucosal barrier. In rats with prehepatic portal hypertension, an increased expression of inducible nitric oxide synthase and heme oxygenase-1 mRNA and protein were detectable [2]. The iNOS expression was localized in the vascular endothelium and activation of guanylate cyclase was demonstrated. In rats, development of HPS was shown following common bile duct ligation with elevated exhaled NO levels, increased pulmonary iNOS expression and improvement of HPS, following administration of the NO synthase inhibitor L-NAME [3]. Antibiotic therapy with norfloxacin decreased the bacterial translocation of gram-negative bacteria to 0% and decreased intrapulmonary shunting and iNOS expression in these rats. In cirrhotic rats upregulation of heme oxygenase-1 in the lung is mediated by NO [4].

However, in a recent study in patients with HPS selective inhibition of pulmonary NO production with nebulized N-nitro-l-arginine, methyl ester had no effect on intrapulmonary shunting and arterial deoxygenation, pointing to pulmonary vascular remodeling rather than ongoing vasodilator effect of NO [5].

## Diagnostic Principles

Pulse oximetry or arterial $pO_2$ determination in the supine and upright position are symptoms for HPS. Contrast-enhanced echocardiography is the method of choice for the detection of intrapulmonary shunting. Lung scanning following injection of technetium-marked macroaggregates is a more specific and sensitive test. Pulmonary angiography may show a spongy pattern of dilated pulmonary blood vessels or, less commonly, discrete arteriovenous communications amenable to embolization.

## Therapeutic Principles

There is no general recommendation for medical treatment. Based on the concept of bacterial translocation induced by portal hypertension with consecutive induction of pulmonary vasodilators, preliminary data indicate improvement of HPS following oral application of antibiotics. Application of methylene blue, a potent guanylate cyclase inhibitor, via a pulmonary artery catheter also improved hypoxemia and hyperdynamic circulation in patients with HPS. Patients with HPS may benefit from reduction of portal hypertension by shunt procedures. In 80–90% of the patients, improvement of oxygenation follows liver transplantation.

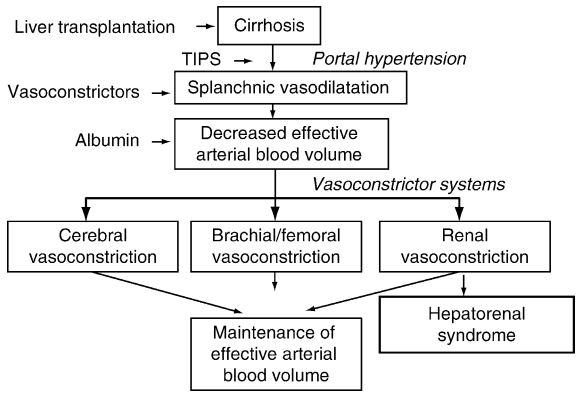
# Hepatorenal Syndrome

Mónica Guevara, Pere Ginès
Liver Unit, Hospital Clinic and University of Barcelona, IDI BAPS, CIBERHED, Barcelona, Spain



**Hepatorenal Syndrome. Figure 1** Treatment of Type-1 HRS.

## Synonyms

Functional renal failure

## Definition and Characteristics

Hepatorenal syndrome estimated by a level of serum creatinine >1.5 mg/dL, occurring in a patient with advanced liver disease and portal hypertension, is characterized by a marked decrease in glomerular filtration rate (GFR) and renal plasma flow (RPF) in the absence of other identifiable causes of renal failure.

Hepatorenal syndrome (HRS) is classified as type-1 and type-2, according to both the intensity and progression of renal failure. These types exhibit different prognosis and survival. Type-1 HRS is characterized by a severe and rapidly progressive renal failure defined as doubling of serum creatinine, reaching a level greater than 2.5 mg/dl in less than two weeks. Patients with type-1 HRS usually have severe liver failure as indicated by jaundice, encephalopathy and coagulopathy. If there is the complication of cirrhosis with the poorest prognosis, the median survival is only 2 weeks. Type 2 HRS is characterized by a moderate and stable renal failure. It is associated with relatively preserved liver function. The main clinical consequence of type 2 HRS is refractory ascites. Median survival is approximately 6–12 months.

## Prevalence

The annual incidence of patients with ascites is approximately 8%.

## Molecular and Systemic Pathophysiology

Currently, the Vasodilation Theory is the most accepted theory to explain the pathogenesis of HRS [1] (Fig. 1). According to this theory, portal hypertension is the initial event in the pathogenesis of HRS, inducing arterial vasodilation by mechanisms not completely known, but probably related to increased levels of vasoactive mediators such as nitric oxide, carbon monoxide, cytokines and others vasodilators. Arterial vasodilation occurs mainly in splanchnic circulation. Vasodilation induces decreased effective arterial blood volume and increased activity of vasoconstrictor systems. In the early stages of the disease, the increased activity of vasoconstrictors is enough to compensate the arterial vasodilation. As the disease progresses, the activation of the vasoconstrictor system further increases, leading first to sodium and water retention and ascites formation and then severe renal vasoconstriction with HRS in the late stage of the disease.

## Diagnostic Principles

The diagnosis of HRS is based on the demonstration of a marked reduction in GFR and exclusion of other types of renal failure. In 1996, the International Ascites Club recommended the following criteria for the diagnosis of HRS.

*Major Criteria*: All the following major criteria must be present:

1. Chronic or acute liver disease with advanced hepatic failure and portal hypertension
2. Low glomerular filtration rate, as indicated by serum creatinine of >1.5 mg/dL or 24-h creatinine clearance <40 mL/min
3. Absence of shock, ongoing bacterial infection, fluid losses and current or recent treatment with nephrotoxic drugs
4. No sustained improvement in renal function (decrease in serum creatinine to 1.5 mg/dL or less or increase in creatinine clearance to 40 mL/min or more) following diuretic withdrawal and expansion of plasma volume with 1.5 L of isotonic saline
5. Proteinuria <500 mg/day
6. No ultrasonographic evidence of obstructive uropathy or parenchymal renal disease

## Therapeutic Principles

Liver transplantation is the treatment of choice for patients with HRS. Patients with HRS who undergo transplantation have more complications, spend more days in the intensive care unit, and have a higher in-hospital mortality rate than patients transplanted without HRS. However, long-term survival is only moderately reduced compared with patients transplanted without HRS. Nevertheless a significant number of these patients die while in the waiting list. Therefore, it is important to improve renal function and reduce mortality while awaiting transplantation.

Several studies have shown that the administration of vasoconstrictor drugs, analogues of vasopressin, and albumin is effective in patients with HRS. The mechanism of action of terlipressin is vasoconstriction of splanchnic circulation, which is associated with an improvement in systemic hemodynamics and a decrease in vasoconstrictor systems, with consequent enhancement in renal hemodynamics. The administration of vasopressin analogues plus albumin is following by a marked improvement in renal function in most of the patients with HRS. This improvement commonly occurs several days after the initiation of therapy. The concurrent systemic vasoconstriction may potentially cause ischemic side effects; however, their appearance is infrequent and is reversed after stopping the treatment. The reversal of HRS is associated with an improvement in survival allowing that a significant number of patients may reach liver transplantation. Catecholamines (midodrine and norepinephrine) are also reported to be effective in the treatment of HRS. However, more studies should be performed confirming their efficacy before recommending them.

Transjugular intrahepatic portosystemic shunt (TIPS) seems to be useful as a treatment for HRS. In patients with HRS, renal function improves within 1–4 weeks after TIPS placement. However, TIPS is contraindicated in patients with severe liver failure or severe hepatic encephalopathy because of the risk of inducing irreversible liver failure or chronic disabling hepatic encephalopathy. It should be considered for patients who cannot receive vasoconstrictor drugs.

Haemodialysis is not effective in the treatment of HRS. It should be used only if patients have specific clinical indications (hypervolemia, tubular acidosis, or hyperkalemia).

Recently, extracorporeal albumin dialysis (MARS), a system that uses an albumin-containing dialysate that is recirculated and perfused trough a charcoal and anion-exchanger columns, has been shown to improve renal function in a small series of patients with type-1 HRS. However, the results of this only study should be confirmed.

Treatment of type 2 HRS. Management of these patients should be focused on the treatment of refractory ascites, which is usually associated with this condition.

## Hermansky-Pudlak Syndrome

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

H

### Synonyms

Albinism with hemorrhagic diathesis and pigmented reticuloendothelial cells; δ-storage pool disease; HPS

### Definition and Characteristics

Rare autosomal recessive disease involving subcellular organelles of many tissues, including melanosomes, platelet δ-granules, and lysosomes. HPS is characterized by tyrosinase-positive oculocutaneous albinism, a bleeding diathesis, and lysosomal storage disease [1].

### Prevalence

Rare in the general population but more frequent in isolated populations including Puerto Rico (northwest region) (prevalence 1:1,800 and carriership in 1:21 persons) and a village in the Swiss Alps.

### Genes

Hermansky-Pudlak syndrome (HPS) can be caused by mutation in one of several genes: HPS1, HPS3, HPS4, HPS5, and HPS6. HPS2, which includes immunodeficiency in its phenotype, is caused by mutation in the AP3B1 gene. HPS7 is caused by mutation in the Gene map locus 22q11.2-q12.2, 11p15-p13, 10q24.32, 10q23.1, 3q24.

DTNBP1 gene [2]. The majority of patients have mutations in the *HSP1* gene.

*Mouse Model*: Several different mouse strains have a HPS phenotype, each related to a different gene. In mice, at least 16 loci are associated with HPS, including "sandy" (sdy). The sdy mutant mouse expresses no dysbindin protein due to a deletion in the Dtnbp1. A

mutation of dysbindin causes the sdy phenotype and that dysbindin is important for normal platelet-dense granule and melanosome biogenesis. Dysbindin is a component of the biogenesis of lysosome-related organelles complex-1 (BLOC1), including the proteins pallidin, muted, and cappuccino, all of which are associated with HSP in mice [2,3].

## Molecular and Systemic Pathophysiology

To date, 18 mutations in the HSP1 gene have been reported. Half of these affect exons 5 and 11, suggesting two mutational hotspots. A database with mutations related to albinism is being updated regularly [4].

The basic defect in HPS remains unknown. A combination of defective calcium uptake and low activities for membrane-associated thioredoxin reductase has been demonstrated in HPS. In platelets from a patient with HPS, a deficiency in a granule membrane protein similar to synaptophysin was found. Further studies showed a reduced level of CD63 (a membrane protein) and granulophysin, possibly identical proteins that are normally present in platelet-dense granules and lysosomes or melanosomes. However, there are no indications for mutations in CD63 as causal factor of HPS [5]. In the absence of dense bodies in platelets, the bleeding tendency is complex. Literature data suggest that many patients are at risk of severe and potentially life-threatening bleeding; however, the mechanisms are still not fully understood. Changes in platelet aggregation are not consistently found, and secretion of dense granule contents may not be essential for platelet function [5]. Thus, thrombocytopathy is not a cardinal feature. A recent study in albino patients showed lower levels of vWF both in platelets and to a lesser extent in plasma, but the relation with bleeding risk also is not clear.

HPS is characterized by tyrosinase-positive oculocutaneous albinism, a bleeding diathesis, and ceroid-lypo fuscin lysosomal storage defects. The latter is thought to be responsible for progressive pulmonary fibrosis and granulomatous colitis. In general, patients have a severe bleeding tendency, but severity may be highly variable. In women, menometrorrhagia and bleeding after delivery is common. In general, spontaneous mucocutaneous bleeding occurs in up to 40% of cases and can be life-threatening.

## Diagnostic Principles

Platelet function tests including bleeding time and aggregation studies are abnormal in most but not all patients with HPS. Platelet and plasma levels of vWF may be diminished. The number of δ granules as well as the membrane protein granulophysin is markedly lowered in HPS.

## Therapeutic Principles

Treatment is usually supportive with regard to bleeding. Formerly, cryoprecipitate has been successfully applied, and more recently, DDAVP was used to correct a prolonged bleeding time and could be applied as prophylaxis for minor surgical procedures. Oral vitamin E has been reported to reduce pulmonary bleeding [5].

# Hernia, Indirect Inguinal

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Childhood inguinal hernia

## Definition and Characteristics

The hallmark of an indirect inguinal hernia is an intermittent bulge in the groin, scrotum, or labia (Fig. 1) [1]. The bulge is most apparent during periods of

**Hernia, Indirect Inguinal. Figure 1** A 6-year-old boy with a left indirect inguinal hernia.

increased intra-abdominal pressure such as crying, straining or coughing. The condition is often asymptomatic [1]. However, the hernia may become incarcerated and the patient may present with vomiting, abdominal distention, and a painful mass that is irreducible. The overlying skin may be erythematous. An incarcerated hernia occurs most often during the first 6 months of life [1]. Occasionally, strangulation may occur, and infarction of the small bowel, testis, or ovary may result.

## Prevalence

The incidence of indirect inguinal hernia in term infants is 1–2% [1]. The male to female ratio is 9:1 [1]. The incidence is higher in premature infants and those with connective tissue disorders, bladder exstrophy, and increased intra-abdominal pressure. There is a familial tendency for hernia formation.

## Molecular and Systemic Pathophysiology

During the last few weeks of gestation or shortly after birth, the layers of the processus vaginalis normally fuse together and obliterate the entrance to the inguinal canal in the vicinity of the internal inguinal ring. An indirect hernia results from a failure of fusion of the processus vaginalis. The bowel subsequently descends through the inguinal canal and results in hernia formation. It has been hypothesized that calcitonin gene-related peptide (CGRP) induces an increased hepatocyte growth factor expression (HGF) [2]. HGF secreted by fibroblasts binds to the epithelial cells in the processus vaginalis to induce fusion of the processus vaginalis [2]. In a subset of patients, deficient endogenous CGRP may account for the patency of the processus vaginalis [2].

## Diagnostic Principles

The diagnosis is a clinical one [3]. A bulge may be detected. The cranial extension prevents the examiner from getting around the top of the bulge [3]. If no mass can be identified, an older child should stand and perform a Valsalva maneuver whereas a younger child may be allowed to cry to provoke an inguinal bulge to appear [3]. The spermatic cord on the ipsilateral side is often thickened ("silk string" sign or "silk glove" sign). The differential diagnosis includes a direct inguinal hernia, communicating hydrocele, inguinal adenopathy, and undescended testis. A direct inguinal hernia is rare in children and results from an inherent weakness in the abdominal musculature. In contrast to an indirect inguinal hernia, a direct inguinal hernia arises medial to the inferior epigastric vessels.

## Therapeutic Principles

Surgical repair of the hernia should be carried out electively shortly after diagnosis. Unless the child appears toxic or shows signs of peritonitis, a manual reduction of the incarcerated hernia with the child sedated should be attempted. Immediate surgery is indicated if the incarcerated hernia is irreducible manually. There is controversy about whether the contralateral groin should be explored. Most surgeons do not routinely perform a contralateral exploration unless a contralateral inguinal hernia or patent processus vaginalis can be demonstrated either by preoperative ultrasonography or intraoperative laparoscopy [4]. Laparoscopic inguinal repair has become an alternative to the conventional "open" procedure [5].

# Herpes Gestationis

►Pemphigoid Gestationis

# Herpes Stomatitis

Ulrich Heininger
University Children's Hospital (UKBB), Basel, Switzerland

## Synonyms

Stomatitis aphthosa; Gingivostomatitis

## Definition and Characteristics

An infectious disease caused by primary infection with herpes simplex virus type 1 (HSV-1) which occurs mainly in children less than 3 years of age. It is characterized by multiple painful vesicular lesions surrounded by erythema around the mouth, on the lips, gingiva, and anterior parts of the tongue and palate. The affected mucosa is usually swollen and ulcerated. The child is febrile and sick with significant discomfort, and it has difficulties to swallow fluids and eat. New superficial lesions evolve over 3–5 days and resolve over a further 6–7 days without scarring. Later in life, some individuals will suffer from periodic endogenous virus reactivation triggered by febrile illnesses, immunosuppression, menstruation in females, and intense exposure to sunlight, typically presenting as vesicles on the lips (herpes labialis = "cold sores" or "fever blisters") or elsewhere in the face or on the skin at any other site of the body.

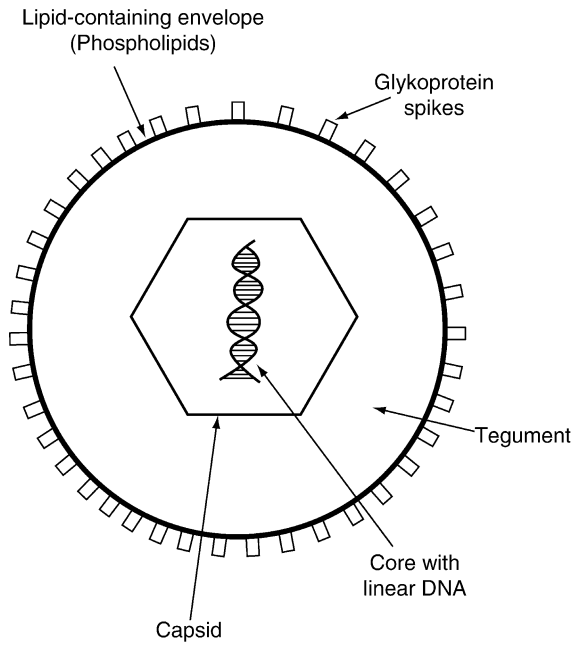
## Prevalence

HSV-1 IgG antibody seroprevalence as an indicator for previous infection varies widely between different populations but usually is around 30–50% in young children and 40–90% in adolescents and adults [1]. The great majority of primary infections are asymptomatic; symptomatic herpes stomatitis is estimated to affect less than 5% of individuals with primary HSV-1 infection.

## Molecular and Systemic Pathophysiology

Like other herpesviruses, HSV-1 is built up of a core of double-stranded DNA enclosed by a protein capsid, a protein tegument, and an envelope consisting of glycoproteins and phospholipids (Fig. 1).

Glycoproteins B and D allow the virus to attach and penetrate the host target cells; glycoprotein C binds to the C3b component of complement and can block complement-mediated neutralization; glycoproteins E and I are targets for attachment of the Fc part of the host's immunoglobulines. The HSV ligands for the host cell receptors are glycoproteins B and C for heparan sulfate and glycoprotein D for the protein receptors and specific sites in heparan sulfate generated by certain 3-*O*-sulfotransferases [2].



**Herpes Stomatitis. Figure 1** Structure of herpes simplex virus.

All viral glycoproteins are major targets of the host's humoral immune response following viral invasion. After penetration of the cell, the virion expresses a cascade of genes: early α genes promote transcription of viral genes and also interfere with the host's immune response, early β genes will transcribe regulatory proteins and DNA replication enzymes, and late γ genes which encode the viral structural proteins. These gene products will then form new virions which get released from the infected cell via lysis or direct spread to neighboring cells. The inflammatory host responses, initiated by Toll-like receptor (TLR) 2 [3], induce intercellular edema causing local tenderness, burning sensations and itching. A few hours later, vesicles will erupt at the site of virus replication. Initially, the vesicles contain clear fluid, which changes to purulent appearance within 2–3 days due to invasion of leukocytes. Finally, after approximately a week, the host's innate and adaptive immune responses will terminate the process of viral replication and its associated symptoms. Although humoral and cellular immune responses develop, the host is not able to clear infection definitely. HSV possesses specific mechanisms to avoid detection by the host's immune system. An immediate early protein, ICP47, is able to block presentation of viral peptides to MHC class I-restricted cells. ICP47 has selected the transporter associated with antigen processing (TAP) as the target for immune evasion in that, after binding of ICP47 to TAP, class I molecules are retained in the endoplasmic reticulum and peptide translocation into the endoplasmic reticulum is prevented [4].

The interference of ICP47 and TAP prevents recognition of peptides by class I MHC and ultimately recognition of HSV-infected cells by cytotoxic T-lymphocytes. By this mechanism, HSV effectively evades the host immune response and manages to survive within the host.

Finally, HSV-1 establishes latent infection via retrograde travel along peripheral sensory nerves from where the virus reaches the cervical, trigeminal, or – less commonly – lumbosacral and other spinal ganglia [5]. The molecular basis of this characteristic development is yet unknown. During latency the patient is asymptomatic. Recurrent reactivation is not inhibited by acquired immunity and commonly affects the identical site of primary infection. Reactivation is mediated by anterograde transport of the virions along the sensory nerve axons to mucocutaneous sites where they again replicate and cause formation of contagious vesicles. Recurrent disease usually is less severe than that during primary infection.

### Diagnostic Principles

The diagnosis can usually be made on the typical clinical presentation. When in doubt, HSV-1 can be isolated from lesions by tissue culture (gold standard) and distinguished from other herpesviruses by specific antiserum or monoclonal antibodies. Further, presence of HSV-1 can be demonstrated in specimens taken from vesicles by direct immunofluorescence or by specific primers applied to a polymerase chain reaction assay. Finally, serological tests (mainly enyzme-linked immunosorbent assays) can measure IgM antibodies and/or seroconversion of IgG antibodies in paired serum specimens. However, antibodies may cross-react with HSV-2.

### Therapeutic Principles

Treatment with oral acyclovir for 7–10 days initiated within 48–72 h of appearance of lesions will shorten duration of illness, ameliorate symptoms and decrease viral shedding [6]. Further, symptomatic treatment consisting of analgetics and rehydration is recommended. For recurrent herpes labialis, topical and – preferably – oral acyclovir is helpful, too.

## Herpes Zoster Oticus

Markus Pfister, Hans-Peter Zenner
Department of Otolaryngology and Head and Neck Surgery, University of Tuebingen, Tuebingen, Germany

H

### Definition and Characteristics

Herpes zoster oticus is a viral infection of the inner, middle and external ear. Zoster oticus manifests most often as severe otalgia and associated cutaneous vesicular eruption. When associated with facial paralysis, the infection is called Ramsay Hunt syndrome.

### Prevalence

The annualized incidence of herpes zoster is about 1.5 to 3.0 cases per 1000 persons.

### Molecular and Systemic Pathophysiology

Reactivation of the varicella zoster virus (VZV) along the distribution of the sensory nerves innervating the ear, which usually includes the geniculate ganglion, is responsible for zoster oticus. Symptoms such as hearing loss and vertigo are thought to occur as a result of transmission of the virus via direct proximity of cranial nerve (CN) VIII to CN VII at the cerebellopontine angle or via vasa vasorum that travel from CN VII to other nearby cranial nerves. Incidence in males and females is equal and increases significantly in patients older than 60 years.

### Diagnostic Principles

Patients often present with severe otalgia that can be associated with painful blisters around the ear, on the face, in the mouth and/or on the tongue. Additional symptoms might be vertigo, nausea, vomiting and/or hearing loss, hyperacusis, tinnitus and lacrimation. Paralysis of the facial nerve including dysgeusia may be present.

Laboratory studies should include blood urea nitrogen (BUN), creatinine, blood cell counts and electrolytes as well as neurotropic viral titers.

### Therapeutic Principles

High dose acyclovir (800 mg PO five times daily for 7 days), famciclovir (500 mg PO three times daily for 7 days) or valacyclovir (1 g PO three times daily for 7 days) plus a tapering 6-day course of prednisone beginning usually at 1 mg/kg PO are administered for acute treatment of herpes zoster oticus. The hearing loss, vertigo and facial weakness slowly improve over weeks to several months.

## Hiatus Hernia

Marcus Schmitt
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

### Definition and Characteristics

Hiatus hernia refers to herniation of elements of the abdominal cavity through the esophageal hiatus of the diaphragm. Different types of hernia can be distinguished.

Sliding axial hiatal hernia (95%; type I) and paraesophageal hernias (5%; type II, III, and IV) can be distinguished.

## Prevalence

Epidemiologic data is rare because of the more general definition of hiatus hernia. Moreover, most hiatal hernias show no symptoms. Hiatus hernia is common in adults with increasing occurrence in older people. Barium meal studies of the year 1968 demonstrated an incidence in 30–33% of adults. There was no difference in incidence between an asymptomatic population (33%) and patients with gastrointestinal symptoms (30%) [1]. Estimates of prevalence vary from 10 to 80% (North America).

## Genes

The affected gene(s) are unknown.

## Molecular and Systemic Pathophysiology

The main pathogenetic factor of hiatal hernia is a change of the anchor of the distal end of the esophagus to the diaphragm, which is built up by the phrenoesophageal membrane. The membrane itself is formed by the fused endothoracic and endoabdominal fascia. This elastic membrane inserts circumferentially into the esophageal musculature. The lower esophageal sphincter and the squamocolumnar junction are located in this area.

Sliding hernia or type I hernia is characterized by widening of the muscular hiatal tunnel and circumferential laxity of the phrenoesophageal membrane leading to upward herniation of a part of the gastric cardia.

Type II, III, and IV hernias are paraesophageal hernias.

A type II hernia results from a defect in the phrenoesophageal membrane, thus the gastric fundus is the leading point of herniation in the thoracic space.

Type III hernias are a combination of type I and type II whereas type IV involves herniation of organs other than stomach in the thoracic space through a large defect of the phrenoesophageal membrane.

Molecular causes of a hiatal hernia have not been detected so far, but few twin studies and family studies suggest heritability for hiatus hernia in an autosomal dominant manner [2]. Moreover, the very rare Galloway-Mowat syndrome, which is also known as microcephaly-hiatal hernia-nephrotic syndrome, is a genetic disorder characterized by an autosomal recessive trait.

## Diagnostic Principles

Diagnosis is based on barium contrast radiography or endoscopy for detecting the herniation. Only a small number of patients report symptoms: classical symptoms are acid reflux, dysphagia, heartburn, regurgitation, postprandial fullness, substernal fullness, or nausea.

## Therapeutic Principles

Major goals of therapy in hiatal hernia are decreasing symptoms and therapy of ►gastroesophageal reflux disease (GERD).

*Drug Therapy*: Drug therapy with proton pump inhibitors (PPI) is applied in patients with hiatal hernia and GERD.

*Surgery*: For type I hiatal hernia, surgery is rarely indicated. The risk of complications by enlarging in the thoracic space indicates surgical treatment for paraesophageal hernias of type II, III, and IV.

Surgical techniques include reduction of the herniated stomach into the abdomen, herniotomy (excision of the hernia sac), herniorraphy (closure of the hiatal defect), and gastropexy (attachment of the stomach subdiaphragmatically).

# Hibernation

Arend F. L. Schinkel[1], Don Poldermans[1], Jeroen J. Bax[2]
[1]Thoraxcenter, Department of Cardiology, Erasmus Medical Center Rotterdam, Rotterdam, The Netherlands
[2]Department of Cardiology, Leiden University Medical Center, Leiden, The Netherlands

## Definition and Characteristics

Hibernating myocardium is characterized by an impaired contractile function in the setting of a chronically reduced coronary blood flow [1,2]. Restoration of blood flow by coronary revascularization may improve contractility of dysfunctional but viable tissue [1,2].

## Prevalence

In ~70% of patients with heart failure, left ventricular dysfunction is caused by chronic coronary artery disease, referred to as ischemic cardiomyopathy. Recent data indicate that in more than 50% of patients with ischemic cardiomyopathy, a clinically significant amount of dysfunctional but viable myocardium is present.

## Molecular and Systemic Pathophysiology

Clinical observations have led to the concept that myocardial hibernation is the result of a patho-physiological

down-regulation of contractile function, which may be an adequate response to myocardial ischemia to protect myocytes from irreversible damage [3]. Biopsy samples obtained during coronary bypass surgery show that hibernating myocardium is characterized by a loss of contractile proteins, whereas cell membrane and cellular metabolism remain intact.

## Diagnostic Principles

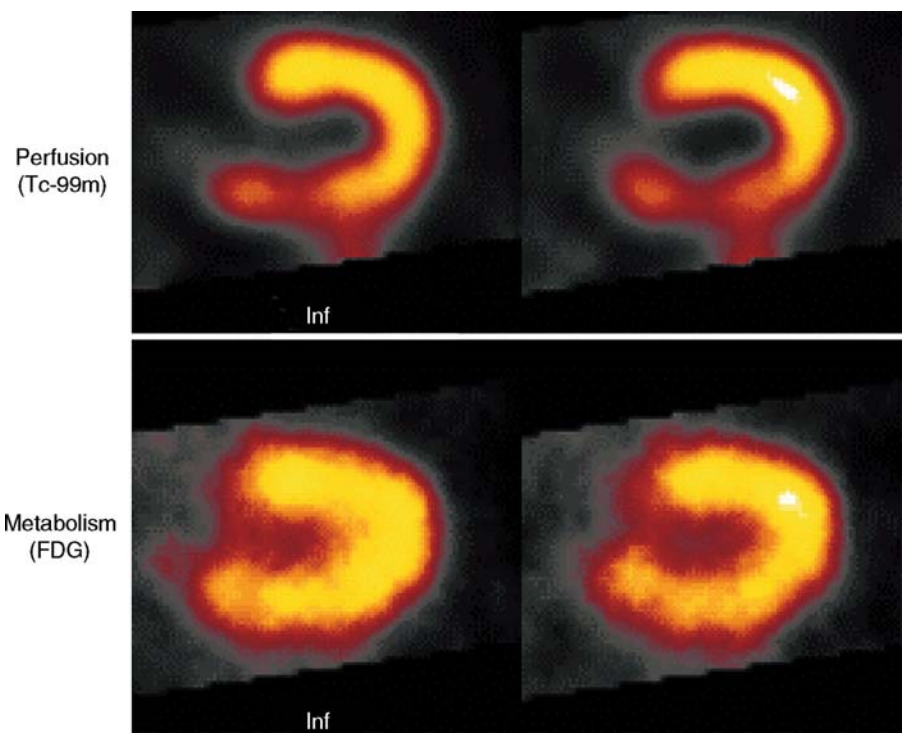
Currently, a range of techniques is available to evaluate myocardial viability, including dobutamine stress echocardiography (DSE), nuclear imaging with positron emission tomography (PET) and single photon emission computed tomography (SPECT), as well as magnetic resonance imaging (MRI). These modalities probe different characteristics of viable myocardium [4,5].

DSE is a relatively simple, inexpensive and widespread method to assess myocardial viability. The hallmark of viability on DSE is the improvement of wall motion during low-dose dobutamine infusion (contractile reserve). Moreover, a low-high-dose DSE protocol allows assessment of stress-induced ischemia.

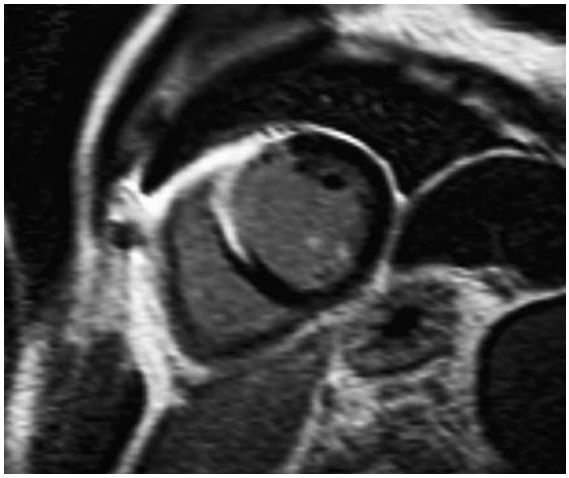
PET is a quantitative technique with a high spatial resolution, and good correlation with outcome after coronary revascularization, and is often considered the reference technique for viability assessment. Generally, glucose utilization is evaluated with the glucose analog FDG and compared to regional perfusion using N13-ammonia, Rubidium-82, or O15-labeled water. Hibernating myocardium is characterized by a reduced perfusion with normal or enhanced FDG uptake (mismatch pattern). Alternatively, PET can be combined with C11-acetate to evaluate residual oxidative metabolism, or Rubidium-82 to evaluate perfusion and cell membrane integrity.

Thallium-201 SPECT, with a stress-redistribution-reinjection or rest-redistribution protocol, allows assessment of regional blood flow and myocardial viability. Delayed thallium-201 uptake indicates an intact sodium-potassium pump and cell membrane, which suggest cellular viability. Technetium-99m SPECT is nowadays acquired with ECG-gating, for simultaneous evaluation of regional perfusion, mitochondrial integrity, and contractile function. FDG SPECT (Fig. 1) using dedicated collimators is an interesting alternative for FDG PET metabolic imaging, and has a similar diagnostic performance.

Dobutamine MRI is used to assess contractile reserve, in a comparable way as DSE. The major advantage of MRI over DSE is the higher resolution, and quantitative assessment of wall thickening. Contrast-enhanced MRI using gadolinium-based agents (Fig. 2) has an excellent spatial resolution, which is particularly useful for the visualization of subendocardial scar tissue.



**Hibernation. Figure 1** Dual isotope simultaneous acquisition SPECT scan (horizontal long axis slices) showing a perfusion–metabolism mismatch in the inferior wall, indicating viable myocardium.



**Hibernation. Figure 2** Example of a contrast enhanced MRI study showing transmural antero-septal infarction (hyperenhancement, white tissue).

### Therapeutic Principles

Considerable improvement in the management of ischemic cardiomyopathy has been reached with medical therapy. Heart transplantation is associated with a favorable survival, but the availability of donor hearts is limited. Coronary revascularization may be a good alternative treatment for selected patients with a substantial amount of hibernating myocardium. Clinical management and outcome are determined by multiple factors, including left ventricular ejection fraction, coronary anatomy, amount of viable tissue, presence and extent of scar tissue, ventricular remodeling, and concomitant valvular disease.

## High Altitude Pulmonary Edema

Heimo Mairbäurl, Peter Bärtsch
Department of Internal Medicine VII, Division of Sports Medicine, Medical University Clinic, Heidelberg, Germany

### Synonyms

HAPE; HAPO

### Definition and Characteristics

HAPE is a non-cardiogenic form of pulmonary edema that occurs within 2–4 days at altitudes above 3,000 m after rapid ascent of non-acclimatized individuals. It is often associated with severe exercise during ascent [1]. Chest radiographs and CT scans show a patchy predominantly peripheral distribution of edema (Fig. 1).

HAPE is preceded by exaggerated pulmonary artery hypertension and increased pulmonary capillary pressure, whereas wedge pressure is normal. An inflammatory response might be the consequence of persisting pulmonary edema. Decreased alveolar fluid clearance could also be a pathophysiological mechanism [1].

### Prevalence

No one should be considered resistant to HAPE. If one goes high enough and fast enough, HAPE is almost inevitable [2]. Prevalence is 0.2 (pre-acclimatized) to 6% (rapid ascent) in an unselected population at ~4,559 m, 2–15% at ~5,500 m, 60–70% in individuals with a history of HAPE. These values can be decreased with proper acclimatization and slow ascent. The risk might be increased by infections of the upper respiratory tract. In Himalayan mountaineers mortality was estimated to be around 50% when no treatment was available.

## Genes

A history of HAPE correlates with the probability of developing this condition upon return to high altitude which indicates a genetic pre-disposition. Unfortunately, little can be concluded on heritability because of small sample sizes. Polymorphisms of genes controlling vascular reactivity such as NOS3, ACE and ET-1, as well as ventilation (tyrosine hydroxylase), alveolar function (surfactant protein A1), and hypoxia-induced gene expression (HIF-1α and dependent genes) have been studied but results are unclear or even contradictory and thus allow no conclusion on the influence of genetic background on HAPE [3].

## Molecular and Systemic Pathophysiology

Exaggerated pulmonary hypertension, increased alveolar permeability, and inhibition of alveolar reabsorption seem to be the major pathophysiologic mechanisms that cause HAPE because these mechanisms disturb the interstitial and alveolar fluid balance. An increased alveolar fluid volume will exaggerate alveolar hypoxia and amplify these mechanisms (Fig. 1). Hypoxic pulmonary arterial vasoconstriction has been observed in many species including man. It most likely includes a so far not identified mitochondrial oxygen sensor and oxygen and redox-sensitive Kv1.5 channels [4]. The mechanism of exaggerated pulmonary vasoconstriction associated with HAPE is not known. The fact that Ca-antagonists and stimulators of the NO-system are preventive may point to dysfunction of the vasodilating NO-cGMP-axis in individuals susceptible to HAPE. In early HAPE increased alveolar permeability also increasing the rate of fluid filtration into the alveolar space might be due to the increased capillary pressure and ruptures (stress failure); in late HAPE also inflammatory responses seem to contribute as indicated by elevated IL-6 and CRP {2; 7208/id}. Hypoxia inhibits alveolar Na- and fluid reabsorption by decreasing activity, membrane surface expression and protein expression of epithelial Na-channels (ENaC) and Na/K-ATPase, which has been observed in cultured alveolar epithelium and animal models, but also in airway epithelium of HAPE-susceptible individuals [5].

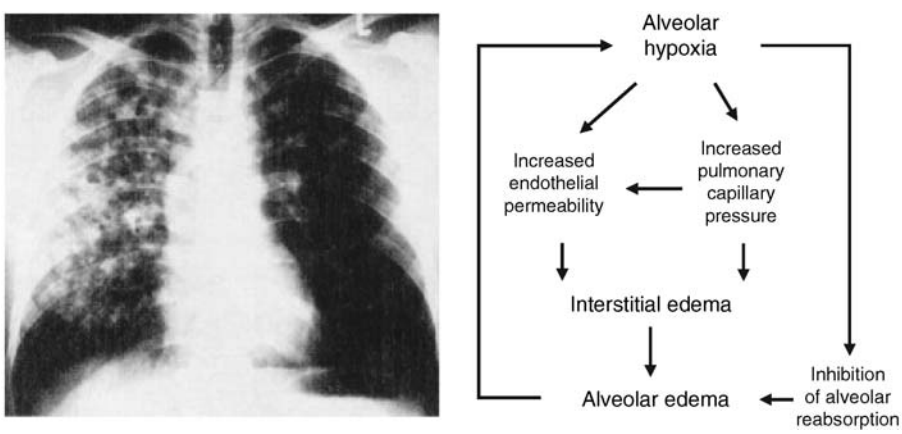
## Diagnostic Principles

HAPE is associated with cyanosis, tachypnea, tachycardia, and elevated body temperature (up to 38.5°C). Rales can be observed over the middle lung fields. In advanced cases, signs of concomitant cerebral edema, such as ataxia and decreased levels of consciousness, are frequent findings. In early cases, $PO_2$ values of ~30 mmHg and $SaO_2$ of ~70% were observed at 4,559 m. Chest radiographs and CT scans of early HAPE show a patchy, peripheral distribution of edema, whereas in advanced cases the radiographic appearance is more diffuse.

## Therapeutic Principles

The treatment of choice is immediate improvement of oxygenation. Without medical care this can only be achieved by descent. Breathing with low-flow oxygen (2–4 l/min) should keep arterial oxygen saturation above 90%. An alternative is a portable hyperbaric chamber.

Without descent and supplemental oxygen treatment is directed against exaggerated pulmonary hypertension. Nifedipine (20 mg slow release formulation every 6 h) should be given until descent is possible. Alternatively PDE-5 inhibitors can be used (e.g., sildenafil: 3 × 40 mg/day; tadalafil: 2 × 10 mg/day). Prophylactic intake of these drugs has been shown to prevent HAPE. Dexamethasone (2 × 8 mg/day for 3 days) had a similar effect and also reduced the risk of acute mountain sickness, but the optimal dose with regard to its side effects has not been evaluated. Prophylactic inhalation of β2-adrenergic agents also reduced the risk of HAPE.



**High Altitude Pulmonary Edema. Figure 1** Left: Patchy distribution of alveolar and interstitial infiltrates in HAPE. Right: Schematic overview of the major hypothetical pathways that might cause interstitial and alveolar edema in hypoxia.

With improvement of oxygenation relief of symptoms is achieved within hours and complete clinical recovery usually occurs within 2–3 days. Severe cases need to be evacuated and may require hospitalization.

## Hirschsprung's Disease

Ralf Kubitz, Georg H. Merker, Dieter Häussinger
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

### Synonyms

Congenital intestinal aganglionosis

### Definition and Characteristics

Hirschsprung's disease (HD) is a disorder of gut motility. It is due to the absence of neurons from the submucosal and myenteric plexuses as a consequence of incomplete neuronal cell migration during early embryogenesis. These neurons belong to the intrinsic parasympathetic ganglion cells, which mediate relaxation of gut segments. Accordingly, absence of these neurons causes functional obstruction. Involvement of the rectum is characteristic, and most cases (80%) are limited to the rectosigmoid. However, HD may involve the whole colon (total colonic aganglionosis) and even the small bowel (total intestinal aganglionosis).

### Prevalence

The prevalence of Hirschsprung's disease is ≈1:5,000 live births [2] with an ethnicity-dependent variability (Asians > Afro-Americans > Caucasians). In short segment HD male children are 3–4 times more often affected than female children.

### Genes

Mutations of several genes may cause HD. The gene most often affected is the RET proto-oncogene. Apart from RET, other genes account for up to 5% of HD cases (endothelin 3, endothelin receptor B) or for single cases only (endothelin converting enzyme, glial-cell-line-derived neurotrophic factor and neurturin (both are ligands for RET), transcription factor SOX10 and SIP1) [1,2].

At least 20 different mutations of the RET proto-oncogene are known, which account for 50% of familial and 20% of sporadic cases. In long segment HD, RET mutations are frequent. The RET protein belongs to the family of receptor tyrosine kinases. It is operational in neuronal cells from the neural crest.

In approx. 40% of familial cases and 20% of sporadic cases HD is associated with other chromosomal abnormalities and syndromes. Up to 10% of HD patients suffer from Trisomy 21 (with a male:female ration of 5 to10). Other associated syndromes are septal

heart defects, multiple endocrine neoplasia type 2 (which is also linked to mutations in RET), and the Waardenburg syndrome (pigment disturbances and deafness).

### Molecular and Systemic Pathophysiology

In Hirschsprung's disease the craniocaudal migration of neuroblasts from the neural crest during early embryogenesis (first 12 weeks of gestation) is impaired. Another hypothesis proposes a defect in the differentiation of neuroblasts into ganglion cells in the intestinal wall.

Patients with HD may present during neonatal period with the universal symptoms of distal intestinal obstruction: vomiting, obstipation, abdominal distension, and crampy pain (becoming evident by repetitive crying). In less severe cases of HD most prominent symptoms are chronic constipation and failure to thrive. However, first symptoms may also arise from life-threatening enterocolitis, with fever, vomiting and diarrhea. Enterocolitis may also develop after surgery, especially in long-segment HD or when a stricture of the anastomosis develops.

Mutations in the RET proto-oncogene have also been associated with the development of thyroid cancer and neuroblastomas. Hence, these two neoplasias more often develop in patients with HD compared to the general population.

### Diagnostic Principles

The diagnosis of HD may be suspected when the first stools (meconium) appear with a delay of more than 48 h after birth. Rectal examination may temporarily release the obstruction in short segment HD, resulting in an explosive evacuation of bowels (Blast sign).

When HD is suspected due to the clinical presentation, anorectal manometry (absent reflective anal relaxation after balloon dilatation of the rectum), an abdominal X-ray film (absent gas in rectum, dilated bowels proximal from the aganglionic segment) or a contrast enema ("transition zone" with a caliber shift from normal to aganglionic bowel) may support the diagnosis. The diagnosis is confirmed by a rectal biopsy which must contain a part of the muscularis mucosae, therefore a suction biopsy or full thickness biopsy is necessary. Suggestive histological features are thickened nerve fibers or increased amounts of acetylcholine-esterase, while the absence of ganglion cells is diagnostic for HD.

### Therapeutic Principles

HD is treated by bowel surgery. In principal, the aganglionic segment is resected and the unaffected bowel is connected close to the anal sphincter in order to ensure continence. Although contrast enema is only moderately sensitive for the diagnosis of HD it is useful to determine the extent of affected bowel preoperatively.

## Hirsutism

Percy Chiu, Richard S. Legro
Department of Obstetrics and Gynecology, College of Medicine, Pennsylvania State University, Hershey, PA, USA

### Definition and Characteristics

Condition of unwanted excess facial and body hair in females similar to that of male-pattern predominantly midline hair growth. Commonly affected sites are the face, neck, extremities, trunk, breasts, linea alba, lower back, upper pubic triangle, and upper inner thighs. Unwanted hairs in hirsutism tend to be dark, coarse, long, terminal hairs. It should be distinguished from hypertrichosis, which is a generalized increase in fine, downy, vellus hair.

### Prevalence

In the general population, the prevalence of hirsutism is ~2–8%. Hirsutism is frequently found in women with polycystic ovary syndrome, a condition characterized by excess circulating androgen levels and chronic anovulation. PCOS is found in 4–5% of the population [1].

### Molecular and Systemic Pathophysiology

The pilosebaceous unit (PSU) is the common skin structure that gives rise to both hair follicles and sebaceous glands and are found everywhere on the body except the palms and soles. Before puberty the body hair is primarily fine unpigmented vellus hair. After puberty and stimulated by increased androgens, some of these hairs (mainly midline hair) are transformed into coarser pigmented terminal hairs. Although hirsutism can be drug-induced (ex. progesterone, glucocorticoids, and anabolic steroids), the condition is most commonly associated with endogenous excess androgens that can stimulate increased transformation of the vellus hair to the thickened terminal hair. Hypertrichosis is associated with a number of medications such as phenytoin, penicillamine, diazoxide, minoxidil, or cyclosporine. Normally, sex hormone binding globulin (SHBG) is

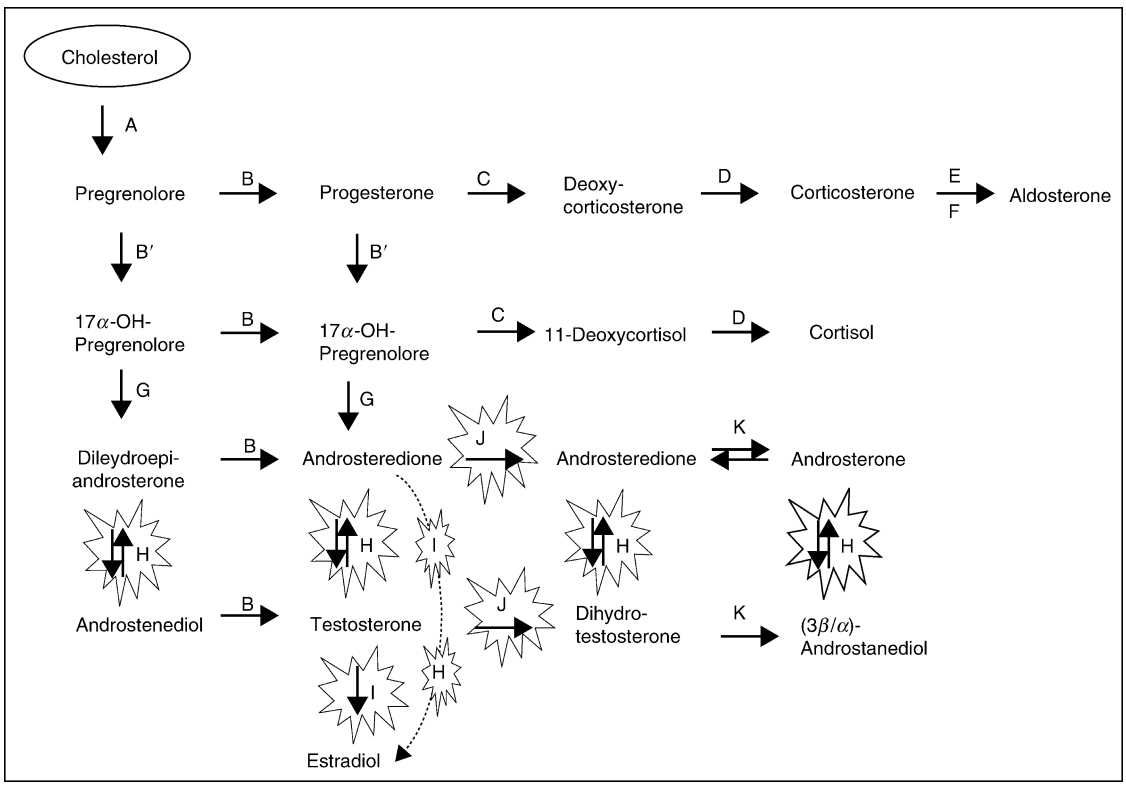
present in abundance to regulate the amount of androgens that are available to the PSU to stimulate hair growth. Both androgen excess and hyperinsulinemia/insulin resistance suppress SHBG leading to a greater pool of bioavailable androgens [2].

Androgen excess leading to hirsutism may both be due to a relative increase in the production of androgens by the androgen secreting glands, the adrenal and the ovary, as well as to an increased peripheral sensitivity to androgens, presumably mediated through "intracrine" production of more potent growth promoting androgens by the hair follicle. Hyperinsulinemia can also stimulate the pilosebaceous unit both directly, and indirectly by acting as a co-gonadotropin in the ovary to stimulate thecal and stromal androgen production and further suppress SHBG. The most potent androgens involved in hair growth are the 17β-hydroxysteroids: androstenediol, testosterone, dihydrotestosterone (DHT), and the androstanediols. The increase in potent androgens is thought to be mainly mediated by the intracellular actions of enzymes 17-hydroxysteroid dehydrogenase (also referred to as 17-ketosteroid reductase), which converts androstenedione to testosterone, and 5α-reductase, which converts testosterone to DHT [3]. Other dysfunctions in the enzyme steps, viewed in (Fig. 1), involved in the balance of androgens may also contribute to the excess of androgens.

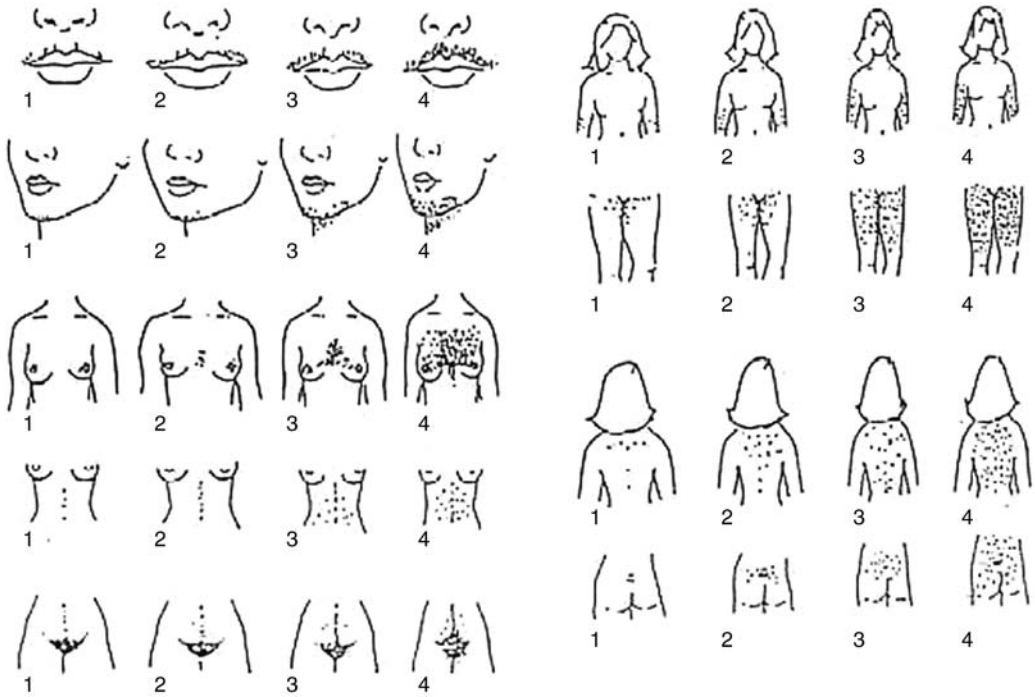
Aspects such as the potency of the androgen produced (DHT > testosterone > androstenedione > dehydroepiandrosterone (DHEA)), the amount of androgen that is free or weakly bound in serum and thus bioavailable (SHBG preferentially binds more potent androgens), and the peripheral metabolism of androgens (primarily the intracellular production of DHT from precursors) all factor in the phenotype of hirsutism.

## Diagnostic Principles

Diagnosis is based on detection of excess terminal hairs in a masculine pattern upon physical examination. Often accompanying symptoms or conditions include polycystic ovary syndrome, acanthosis nigricans, obesity, acne, alopecia, adrenal hyperplasia, seborrhea, virilization, and Cushing's syndrome. Additional laboratory testing used to assess the cause of androgen



**Hirsutism. Figure 1** Any disruption or imbalance of the enzyme steps involved in the formation of androgens can lead to androgen excess. (Adapted from [5]) *Enzyme Steps*: A = $C_{20-22}$ "Desmoiase"; B = $\Delta^5$-3β-hydroxysteroid dehydrogenase (3β-OL); B' = 17α-Hydroxylase; C = 21-Hydroxylase; D = 11β-Hydroxylase; E = 18-Hydroxylase; F = 18-OH-Oxidase; G = $C_{19-20}$ Lyase; H = 17-hydroxysteroid dehydrogenase; I = Aromatase; J = 5α-Reductase; K = 3-hydroxysteroid dehydrogenase ✵ = Indicates major step whose disruption may lead to excess androgens and hirsutism ..... = Indicates alternate pathway to estrogen.



**Hirsutism. Figure 2** Ferriman-Gallwey score. (Adapted from [5].)

excess include testosterone levels, dehydroepiandrosterone sulfate levels, and androstenedione levels. Severity of hirsutism is measured using the Ferriman and Gallwey Score, a quantitative scale for assessment of the severity of hirsutism (Fig. 2). There are nine locations of assessment, ranging from 0 to 4, for a total possible score of 36. A score greater than 8 indicates the presence of androgen excess.

## Therapeutic Principles

Nonpharmacological therapy is available such as:

- Shaving or mechanical hair removal – does not increase follicle number or hair shaft diameter, but the thicker diameter of the shaft at the skin level may give the perception of "thicker" hair.
- Chemical depilatories & bleaching – topical chemicals that dissolve the hair shaft and lighten the color of the hair. Can cause skin sensitivity or rashes.
- Electrolysis – an epilator, a thin probe delivering heat, is inserted into the hair follicle alongside the hair. The nourishing cells found beneath the root of the hair are destroyed permanently, either by heat (thermolysis), chemical action (galvanic) or, in some methods, by both at the same time (blend). Hirsutism recurs in many women.
- Plucking/waxing.
- Laser – hair is damaged using the principle of selective photothermolysis with wavelengths of light well absorbed by follicular melanin and pulse durations that selectively thermally damage the target tissue without damaging surrounding tissue. Less effective in individuals with darker skin pigmentation.

As far as pharmacological therapy is concerned, the following options are available:

- Oral contraceptives (estrogen-progestin combinations) – increases estrogen levels leading to increases in SHBG and less bioavailable androgen. This reduction in androgens may slow hair growth and produce lighter, finer hairs. Oral contraceptives also inhibit luteinizing hormone (LH) secretion causing a decrease in ovarian androgen production and an inhibition of adrenal androgen production.
- Hormone replacement – increases estrogen levels in perimenopausal or menopausal women leading to increased SHBG levels.
- Gonadotropin-releasing hormone agonist – luteinizing hormone is reduced, which lowers ovarian testosterone and androstenedione.
- Glucocorticoid therapy – adrenal androgen secretion is reduced although it is not highly efficacious for hirsutism [4].
- Anti-androgens: Androgen receptor antagonists (spironolactone, flutamide, cyproterone acetate) – prevent the binding of androgens to their receptors.
- 5-α-reductase inhibitors (finasteride) – prevent the conversion of testosterone to dihydrotestosterone, a more potent androgen.

Also, dietary therapy is available:

- Weight loss – obesity is linked to excess androgens and insulin. Weight loss can reduce insulin levels and potentially androgen levels, thus improving hirsutism.

Novel treatments include:

- Eflornithine (Vaniqa) – topical drug that inhibits ornithine decarboxylase, an enzyme necessary for the production of polyamines, which stimulate follicular cell division.
- Ketoconazole – inhibitor of the P450 enzyme system and thus inhibits androgen biosynthesis. Can cause hepatotoxicity.
- Insulin-sensitizing agents – improves insulin sensitivity that can raise SHBG and thus lower bioavailable androgens. Troglitazone, a thiazolidinedione has been shown to improve hirsutism in a dose response fashion.

# Histaminic Cephalgia

►Cluster Headache

# Histidinuria

William L. Nyhan
Department of Pediatrics, University of California San Diego, La Jolla, CA, USA

## Synonyms

Increased urinary excretion of histidine; Impaired intestinal absorption of histidine

## Definition and Characteristics

Histidinuria is a rare disorder of histidine transport, in which blood levels of histidine are not elevated [1,2].

There may be no other abnormalities, but four of the patients reported had some abnormality of the central nervous system [2–5]. The criterion for diagnosis is an elevated level of excretion of histidine in the urine. Our patient excreted 276 mmol/mol creatinine, which was approximately twice the upper limit of normal for our laboratory. In another patient [3] the level was 1.5 times the upper limit of normal and 2.5 times the control mean. In the others, the data reported were of 24-h excretion at 2–3 times the control mean. In contrast patients with histidinemia excrete seven times the control mean.

Patients with histidinuria tend to have low but normal concentrations of histidine in plasma. In patients reported [2–5] plasma concentrations ranged from 64 to 87 μmol/l. In our laboratory the normal range is 50–100 μmol/l. Histidine concentration in the cerebral spinal fluid was normal in the patient in whom it was measured [2].

Intestinal absorption of histidine is low in patients with histidinuria.

Oral loading with histidine revealed our patient to have a peak level that was lower and achieved later than a control boy of similar age.

Our patient [2] was moderately developmentally delayed and had bilateral neural hearing loss. He also had a history of neonatal hypoglycemia. Two reported [5] sensoring siblings had mild retardation. Another [3] was severely retarded and had microcephaly and spastic diplegia. An intellectually normal boy developed myoclonic seizures at the age of 13 years [4]. It appears unlikely that any of these abnormalities are consequences of abnormal transport of histidine. They appear rather to represent bias of ascertainment.

## Prevalence

Only four patients have been reported. Others may well have been missed for current convention is to assay for amino acids only in blood.

## Genes

Recessive inheritance seems likely. Parents have all been normal, and there were affected siblings. The four patients reported were all male. Therefore, X-linked inheritance is a possibility, but it could be an autosomal gene. The consistent occurrence of abnormality of the central nervous system could represent the possibility of deletion of adjacent closely linked genes, or the pleiotropic effects of a single gene.

## Molecular and Systemic Pathophysiology

The molecular basis of disease is clearly a histidine transporter expressed in the renal tubular and intestinal

cells. Neither the gene nor the protein is known. It seems unlikely that the loss of histidine in the urine and its limited absorption are responsible for any of the clinical manifestations seen in any of the patients. Plasma levels have been well preserved in every patient.

### Diagnostic Principles

Quantitative analysis of the amino acids of the urine is a requirement for diagnosis.

### Therapeutic Principles

Treatment is not indicated for this abnormality in transport. Dietary sources of histidine are adequate.

## Hodgkin Lymphoma

Sandeep S. Dave
Department of Medicine, Oncology Division, Institute for Genome Sciences and Policy, Duke University, Durham, NC, USA

### Synonyms

Hodgkin's disease

### Definition and Characteristics

Hodgkin lymphoma (HL) is a malignancy derived mostly (over 95% of the cases) from B cells. The hallmark of HL is that the neoplastic cells, Reed-Sternberg (RS) cells and their variants usually constitute a minority of cells in the tumor-bed, which is primarily composed of inflammatory cells.

Hodgkin lymphoma comprises two biologically and clinically distinct diseases: classical HL and nodular lymphocyte predominance HL (NLPHL) [1].

### Prevalence

In the United States, there are approximately 150,000 men and women who have a history of Hodgkin lymphoma.

### Genes

The search for mutations in oncogenes and tumor-suppressor genes in HL has been hampered by the rarity of malignant cells. A relatively few number of genes have been analyzed for mutations in RS cells. Mutations in BCL2, p53 and CD95 have been identified in only a small number of cases.

### Molecular and Systemic Pathophysiology

In nearly half of the cases of classical HL, the malignant cells (RS) are infected with the Epstein-Barr virus (EBV). EBV infection can immortalize B cells and the EBV-encoded protein LMP1 is oncogenic, it is possible that EBV is involved in the pathogenesis of HL in the EBV-positive cases.

The hallmark of RS cells appears to be constitutive action of the nuclear factor-κB (NF-κB) signaling pathway. NF-κB signaling, which plays an important role in the survival of B cells. Notably, amplifications of the c-REL oncogene, a member of the NF-κB family occur in nearly a third of the cases of classic HL. Further, inactivating mutations in NF-κB inhibitors IκBα and IκBμ occur in an additional third of the cases. NF-κB can also be activated by the stimulation of CD40 by CD40 ligand-expressing T-cells in the microenvironment, or by stimulation of CD30 which is universally expressed on RS cells. Thus, diverse genomic aberrations and micro-environment interactions contribute to the constitutive activation of the NF-κB pathway in HL.

In addition to the constitutive activation of NF-κB in HL, a number of other oncogenic signaling pathways are active in HL [2]. The Jak-STAT pathway, a primary mediator of cytokine signaling is deregulated in a number of HL cell lines, with constitutive activation of STAT3 and STAT6 transcription factors. STAT6, in particular, appears to be down-stream of IL13, inhibition of which leads to reduced proliferation of HL cell lines. Similarly, Notch1, which is not normally expressed on normal B cells is highly expressed on RS cells. Activation of the Notch1 with the Notch1 ligand Jagged1 induces strong proliferation in RS cells.

Several receptor tyrosine kinases have been found to be aberrantly expressed and activated in HL. This feature appears to be unique to HL among lymphomas and suggests that it might contribute to HL pathogenesis.

**Hodgkin Lymphoma. Table 1** Subclassification of Hodgkin lymphoma

| | Pathology features | Additional features | Surface markers present | Surface markers absent |
|---|---|---|---|---|
| Classical HL | | | | |
| Lymphocyte rich classic HL | Nodular pattern with remnants of germinal centers. Background is predominantly lymphocytes with rare or no eosinophils | Increased frequency of early stage disease. Male predominance (75%). Frequent sparing of mediastinum | CD15, CD30 | CD45, CD19, CD20, CD22, CD79a |
| Nodular Sclerosis HL | Nodular pattern, fibrous bands | Variant associated with large mediastinal masses and poor prognosis | | |
| Mixed Cellularity HL | Diffuse pattern. No sclerosis | | | |
| Lymphocyte Depleted HL | Hypocellular with paucity of inflammatory cells | May be difficult to distinguish from anaplastic large cell lymphoma | | |
| Nodular lymphocyte predominant HL | Partially nodular growth pattern; RS cells lack classic morphology | Male predominance (75% male), usually spares mediastinum. | CD45, CD19, CD20, CD22, CD79a | CD15, CD30 |

## Diagnostic Principles

HL has a bimodal distribution in age, with one peak occurring in the 20s and a second peak over the age of 50. The majority of patients present with an asymptomatic enlarged lymph node or mass on X-ray. The most common involved site is the neck, with the mediastinum being the next most common site of involvement. A significant number of patients develop systemic symptoms prior to the discovery of lymphadenopathy. These symptoms, called B symptoms, include fever, night sweats, and weight loss. Pruritus and fatigue are also observed. The signs and symptoms may be non-specific and more suggestive of infection rather than malignant disease.

Diagnosis is established by tissue biopsy, preferably a lymph node biopsy. The diagnosis of HL is made primarily by light microscopy. Immunophenotype for classic HL includes the presence of Reed Sternberg cells, which are large, bilobed or multiple nuclei and a prominent nucleolus. These cells are typically CD15 and CD30 positive and lack pan-B and pan-T cell antigens. The pathologic features and surface markers that characterize the subgroups of HL are summarized in Table 1.

Radiologic imaging should include a chest X-ray and computed tomography.

## Therapeutic Principles

Therapy and prognosis are based upon the stage of the disease. Standard care currently provides a number of treatment options for patients with early stage, favorable prognosis Hodgkin's disease. The preferred option is the use of combination chemotherapy and radiation therapy. Among patients with stage I-II disease, the treatment of HL is so effective that the mortality rate from reasons other than HL exceed that caused by the disease [3]. Second malignancies and cardiac complications are the most frequent causes of morbidity and mortality in the survivors of early stage HL.

In patients with advanced stage HL, combination chemotherapy is the standard of care. With standard regimens (e.g., ABVD), up to 40% of patients will relapse. Recurrent disease is usually treated with high dose chemotherapeutic approaches combined with stem cell support. The relative efficacy of such approaches is under active investigation.

# Hodgkin's Disease

►Hodgkin Lymphoma

# Holt-Oram Syndrome

Jürgen Kohlhase
Center for Human Genetics, Freiburg, Germany

## Synonyms

Hand-heart syndrome; HOS

## Definition and Characteristics

Holt-Oram syndrome (HOS) is characterized by the combination of radial upper limb defects in combination with congenital heart defects and cardiac conduction defects. The limb defects may be uni- or bilateral, symmetric or asymmetric. They include triphalangeal thumbs, hypoplastic or aplastic thumbs, shortening and/or fusion of carpal bones and thenar bones, and at the minimum a missing carpal bone. The radius can be hypoplastic or aplastic, with concomitant involvement of the ulna. The humeri may be shortened. Sloping shoulders with limited movements of the shoulder joints are common. Heart defects (in 75% of patients) most commonly include ostium secundum atrial septal defect (ASD) and ventricular septal defect (VSD), especially those occurring in the muscular trabeculated septum, but can also be complex like tetralogy of Fallot. Cardiac conduction disease may present at birth as sinus bradycardia and first-degree atrioventricular (AV) block. The conduction defects can progress to a higher grade including complete heart block with and without atrial fibrillation.

## Prevalence

Holt-Oram syndrome (HOS) is inherited in an autosomal dominant fashion. About 85% of cases represent de novo mutations. HOS occurs with an estimated frequency of 1 in 100,000 births.

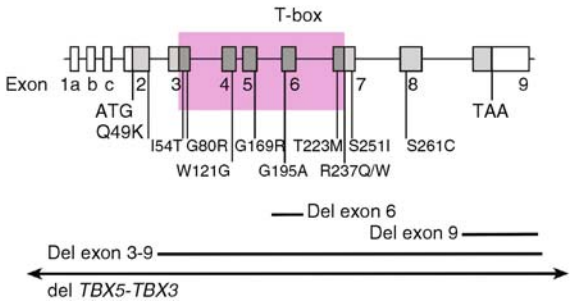
## Genes

HOS is caused by mutations in the gene TBX5 on chromosome 12q24. The TBX5 protein is a member of the T-Box family of transcription factors sharing similarity with the Brachyury or T-protein. Only 30–35% of patients with the clinical diagnosis HOS, but 74% if meeting strict diagnostic criteria (i.e., presence of typical malformations of hands and heart but no involvement of other organs or tissues) carry mutations in the TBX5 gene. Of typical patients, 3–5% is expected to carry single- to multiexon or complete gene deletions. Most mutations in TBX5 are private mutations, only found in single families, and a few are recurrent. Apart from TBX5, the combination of heart defects and radial upper limb malformations can rarely also be caused by mutations in the gene SALL4. However, about 20% of cases are likely to result from mutations in yet unidentified genes.

## Molecular and Systemic Pathophysiology

The TBX5 gene (Fig. 1) consists of nine (eight coding) exons. Most HOS-causing mutations in the TBX5 gene are nonsense, frameshift, or splice mutations, which lead to transcripts carrying a premature stop codon. Those transcripts are in most instances rapidly degraded, and therefore these mutations are a priori likely to cause HOS via TBX5 haploinsufficiency. In agreement with this, large deletions including the complete gene or single exons were also reported in HOS cases. Pathogenic missense mutations are often found, mostly positioned in the DNA-binding T-box, and those interfere with the DNA-binding capacity of the protein. Earlier reports suggested that missense mutations may lead to more severe phenotypes, however, such genotype–phenotype correlations could not be confirmed in later studies.

The TBX5 protein functions as a transcription factor important in heart and limb development. In the upper limbs, TBX5 is required for forelimb specification and outgrowth. The similarity of HOS and Okihiro syndrome with respect to the forelimb malformations is reflected by the fact that Tbx5 regulates Sall4 (and Sall1a in Zebrafish) expression in the mouse and zebrafish forelimb. In heart development, TBX5 interacts with the cardiac transcription factors NKX2.5 and GATA4. The similarity of the cardiac phenotypes caused by TBX5 or SALL4 mutations is represented by the regulation of Sall4 by Tbx5 in the heart, and by the synergistic action of both proteins on the Gja5 promotor. Atrial septal defects are more typical for Holt-Oram syndrome, while SALL4 mutations less



**Holt-Oram Syndrome. Figure 1** Schematic representation of the TBX5 gene. The gene consists of nine (eight coding) exons. The T-Box is encoded by exons 3–7. Loss of function mutations have been found in all coding exons (not shown). Missense mutations (some are indicated as examples) were also detected in all coding exons, but cluster within the T-box. Recurrent missense mutations are T223M and R237Q/W. The horizontal bars mark some of the detected deletions involving exons 6, 9, 3–9, or the whole gene (including the neighboring gene TBX3).

often cause heart defects and rather lead to ventricular septal defects. These differences in cardiac defects might result from a different action of both genes on the NPPA gene. Cardiac arrhythmias, common with TBX5 mutations, are not frequently associated with SALL4 defects, and are reflecting the importance of Tbx5 function for the development of the cardiac conduction system, in which regulation of Id2 gene expression by Tbx5 together with Nkx2–5 appears crucial.

## Diagnostic Principles

Holt-Oram syndrome (HOS) is diagnosed clinically based on the presence of typical radial ray malformations of the upper limbs in combination with congenital heart defects, especially atrial septal defects, and/or cardiac conduction defects. The presence of other malformations, for example, of ulna (predominantly), lower limbs, kidneys, genitourinary system, vertebrae, cranium, auditory or ocular systems, mental retardation, and strong facial dysmorphisms typically exclude the diagnosis. Very rarely, preaxial polydactyly of the hands or eye malformations were seen in patients with TBX5 mutations. The main differential diagnoses are Okihiro syndrome (almost the same spectrum of radial upper limb and cardiac malformations, but typically involving other organs as well), Fanconi anemia (an autosomal recessive disease affecting many organs with predisposition to leukemia and bone marrow failure), Thrombocytopenia Absent-Radius syndrome (TAR), where the radii are always absent but thumbs preserved and other organs usually affected, and the other heart–hand syndromes.

## Therapeutic Principles

At present, there is no specific gene therapy available for HOS. Therapeutic strategies focus on surgical correction of the observed malformations of the upper limbs and heart as well as on treatment of the cardiac conduction defects. When the diagnosis is suspected based upon presence of typical limb malformations, physical examination is required to rule out differential diagnoses. Upper limb and hand radiographs can be performed to detect subtle anomalies of the carpal bones. Early cardiac evaluation is obligate to detect and treat cardiac disease. Chest radiographs may demonstrate enlarged pulmonary arteries due to pulmonary hypertension or cardiomegaly. Evidence of congestive heart failure may be present. Echocardiography is needed to define the presence of septal defects or other cardiac anomalies. Further tests are required to rule out the main differential diagnosis, for example, for Okihiro syndrome renal ultrasound and ophthalmological examination.

The management of individuals with HOS should involve specialists in medical genetics, cardiology, and orthopedic (hand) surgery. A cardiologist will determine the need for antiarrhythmic medications and surgery. Pacemaker implantation may be indicated for individuals with severe heart block. The hand surgeon will help individuals in making decisions regarding surgery for improved upper limb and hand function. Patients born with severe hand malformations (radial club hand, thumb aplasia) may be candidates for "pollicization" (creation of a thumb-like digit by moving another digit into the thenar position), for improved hand function. Affected children with severe limb shortening may benefit from prostheses. Many affected individuals will likely also benefit from physiotherapy.

# Homocysteine: Plasma Levels and Genetic Basis

Arne W. J. H. Dielis, Hugo ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Departments of Internal Medicine and Biochemistry, Maastricht University, Maastricht, The Netherlands

## Synonyms

Elevated plasma levels of homocysteine: hyperhomocysteinemia; Cubilin gene (CUBN) mutation: hereditary megaloblastic anemia 1 (Imerslund-Gräsbeck syndrome); Cystathionine beta-synthase (CBS) deficiency: homocysteinuria

## Definition and Characteristics

Homocysteine is formed during metabolization of methionin, and most of it is linked to plasma albumin (80%) or

cysteine (20%). Only trace amounts of free homocysteine are found in plasma [1].

Reported reference values for total plasma homocysteine levels in healthy individuals range between 4.9 and 13.6 μmol/L, generally regarding concentrations of <10 μmol/L to be optimal. Homocysteine levels increase with age and are elevated at low plasma vitamin concentrations (folic acid, vitamin $B_6$, and vitamin $B_{12}$). Males have higher plasma homocysteine levels (approximate difference is 2 μmol/L), although this may be related to vitamin status [2].

Hyperhomocysteinemia has been associated with an increased risk for carotid artery stenosis, stroke, dementia, Alzheimer's disease, hip fracture, congestive heart failure, and thrombosis, although data are conflicting.

Homocysteinuria is characterized by elevated homocysteine plasma levels, lens dislocation (ectopia lentis), skeletal changes (osteoporosis, scoliosis, arachnodactyly), and mental retardation.

## Prevalence

The leading cause of hyperhomocysteinemia is vitamin deficiency (especially folic acid), either due to reduced intake, reduced gastrointestinal absorption, or drug interactions.

Homozygosity for MTHFR gene mutations is seen in 15% of Western populations, heterozygosity in 30–40%. The prevalence of cysteinuria is unknown, but estimated at about 1 in 7,000 in the general population.

## Genes

Elevated plasma levels result from polymorphisms in genes encoding homocysteine-metabolizing enzymes: 5,10-methylenetetrahydrofolate reductase (MTHFR gene), human intrinsic factor-vitamin $B_{12}$ receptor (cubilin; CUBN gene), cystathionine beta-synthase (CBS gene), and possibly folate-binding protein (FOLR1 gene). The MTHFR gene contains 11 exons on chromosome 1p36.3, at a mass of 74.6 kDa. A loss of function mutation in exon 4 at the folate binding site (MTHFR 677C- > T) decreases enzyme activity by 65% in fibroblasts of homozygous subjects. Another polymorphism in exon 7 in the regulatory domain (MTHFR 1298A- > C) decreases enzyme activity by 60%, but is not related to increased homocysteine levels. The CUBN (alternatively: MGA1) gene coding region encompasses 10,864 bp on chromosome 10p12.1. Two mutations (CUBN 3916C- > T; in-frame insertions of 126 and 66 bp) are found in hereditary megaloblastic anemia 1 patients, and are designated as FM1 and FM2, respectively. The FOLR1 gene contains seven exons on chromosome 11q13.3-q13.5, encompassing 6.8 kb. Knocking out the FOLR1 gene is lethal in homozygous mice, whereas in heterozygous mice, homocysteine plasma levels are elevated after a low-folate diet. However, no human functional defects are yet described [3]. The most common CBS gene mutation out of 130 known mutations is the CBS 278I- > T substitution, located on chromosome 21q22.3.

## Molecular and Systemic Pathophysiology

Homocysteine is formed during the metabolism of methionine, present in a diet containing proteins of animal origin. Homocysteine can be metabolized through three pathways: (i) homocysteine is remethylated to methionine by betaine-homocysteine methyltransferase (in the liver and kidney); (ii) homocysteine is remethylated to methionine by methionine synthase (in most other tissues; vitamin $B_{12}$ dependent) with 5-methyltetrahydrofolate as the methyl donor. MTHFR catalyzes the formation of 5-methyltetrahydrofolate; and (iii) homocysteine is transsulphurated to cysteine (vitamin $B_6$ dependent) through CBS.

Mutations in the MTHFR gene decrease MTHFR activity and reduce 5-methyltetrahydrofolate synthesis, and thereby decrease remethylation of homocysteine to methionine. As a result, homocysteine levels increase. Disruption of metabolism of vitamins $B_6$ and $B_{12}$ (e.g., CUBN gene mutation, CBS gene mutation) and vitamin deficiencies reduce remethylation and transsulphuration of homocysteine leading to an increased level.

Homocysteine induces endothelial dysfunction leading to endothelial injury (probably through increased oxidative stress and reduced release of vasodilating NO), platelet activation and aggregation, tissue factor upregulation, and coagulation factor VII activation, and it also influences other coagulation factors and inhibitors. These changes may lead to hypercoagulability and increased inflammatory responses and might explain the association between hyperhomocysteinemia and stroke, thrombosis, congestive heart failure, and carotid artery stenosis [1]. Vascular dysfunction may link homocysteine and dementia and Alzheimer's disease.

## Diagnostic Principles

Fasting homocysteine can be measured in plasma via immunofluorescence methods. Alternatively, an oral methionine loading test can be performed before plasma homocysteine measurement.

## Therapeutic Principles

Since folic acid and vitamin $B_6$ and $B_{12}$ deficiencies are the most common causes of hyperhomocysteinemia, the primary therapy is supplementation. Although supplementation causes a decrease in plasma homocysteine, conflicting data exist on whether the risk of cardiovascular diseases, thrombosis, and dementia is decreased [4].

The treatment of cysteinuria consists of urine dilution and alkalization, and lowering of free cysteine in urine.

# Homocystinuria due to Cystathionine Beta-Synthase Deficiency

S. Harvey Mudd
NIHM/DIRP/LMB, National Institutes of Health, Bethesda, MD, USA

## Synonyms

CBS deficiency; Cystathionine beta-synthase deficiency

## Definition and Characteristics

Deficient activity of cystathionine beta-synthase (CBS) leading to abnormal elevations of homocysteine (and its disulfide derivatives) and of methionine due to increased remethylation of homocysteine (Fig. 1).

## Prevalence

In screening of newborns for elevated methionine, CBS deficiency has been detected worldwide at rates of 1:200,000 to 1: 350,000 [1], but many cases are being missed and the true prevalence is higher (possibly by an order of magnitude) [1–3].

## Genes

In the gene that encodes CBS 139 disease-associated mutations have been identified. Most common are I278T and G307S (see: http://www.uchsc.edu/cbs).

## Molecular and Systemic Pathophysiology

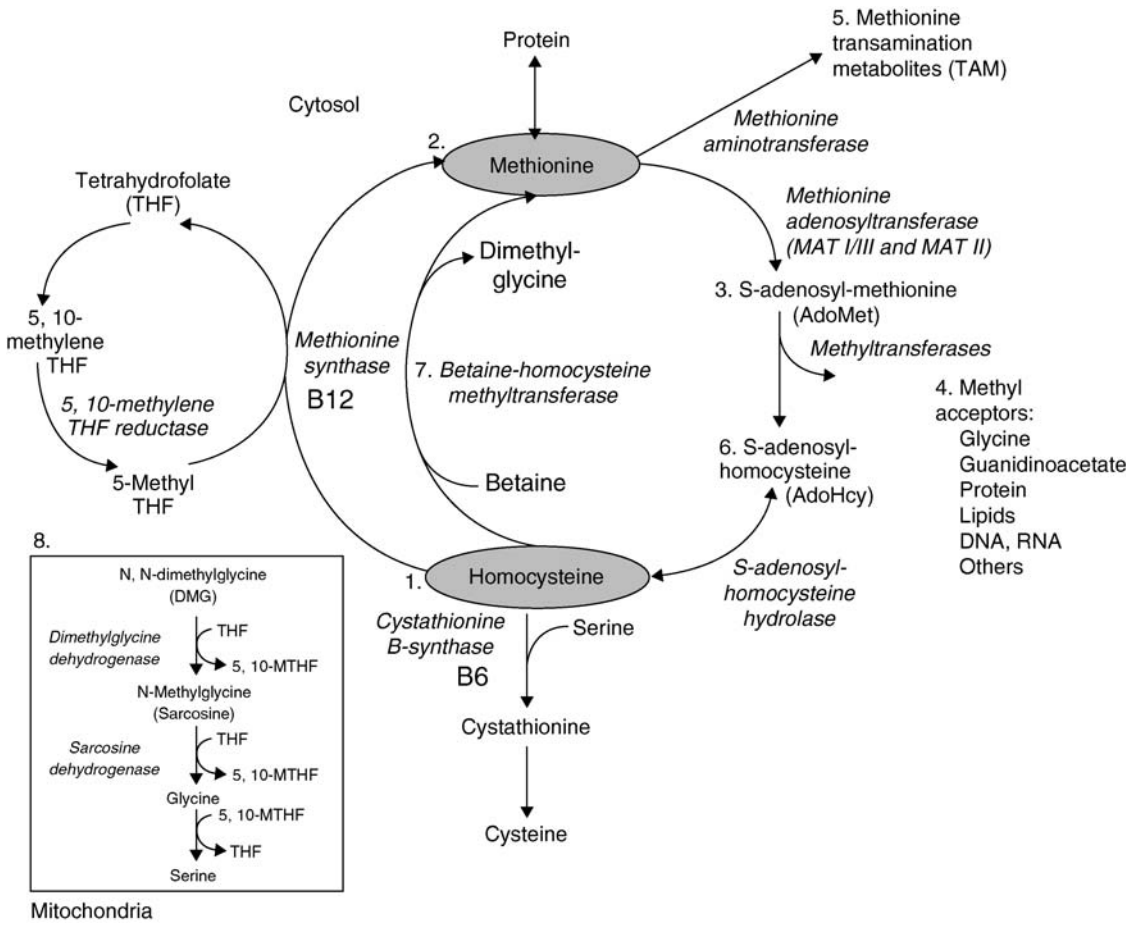
CBS catalyzes the synthesis of cystathionine from serine and homocysteine, an obligatory step in the transsulfuration pathway that converts the sulfur of methionine to that of cysteine. Homocysteine arises by the hydrolysis of *S*-adenosylhomocysteine, a product of each of the 39, or more, *S*-adenosylmethionine-dependent methyltransferase reactions that occur in mammals. When CBS activity is deficient, homocysteine and its disulfide derivatives (usually assayed together by modern techniques, and termed total homocysteine (tHcy)) accumulate abnormally in tissues, plasma, and urine (homocystinuria) [1]. Alternatively, homocysteine may be methylated to reform methionine. Either 5-methyltetrahydrofolate and/or betaine provides the methyl group. Therefore, in CBS deficiency methionine also tends to be abnormally high (Fig. 1). The major adverse clinical effects of CBS deficiency are dislocation of the optic lenses, mental retardation and seizures, osteoporosis and other skeletal abnormalities, and early thromboembolic events. These become manifest at various times after birth. Approximately 50% of clinically diagnosed CBS-deficient patients respond to administration of high-dose vitamin B6 with marked reductions in the elevations of tHcy and methionine, whereas the remaining patients are not responsive. The responsiveness is a function of the specific mutation(s) underlying the CBS deficiency – for example, homozygotes for I278T are almost always responsive, but G307S homozygotes are not [1]. Clinical abnormalities tend to be less severe and to become manifest later in B6 responders [1]. Dislocation of the optic lenses may be due to breakage by homocysteine of disulfide bonds in fibrillin, a glycoprotein of the suspensory ligaments that hold the lens in place. Bony abnormalities have been suggested to be due to similar disruption of collagen. The pathophysiologies of the mental retardation and the vascular events (in spite of many experimental investigations) remain uncertain [1].

## Diagnostic Principles

Diagnosis may be based upon the presence of severe hyperhomocysteinemia (i.e., plasma tHcy of 100–150 μM, or more) accompanied by elevation of plasma methionine. Abnormally low CBS activity is present in cultured skin fibroblasts or lymphocytes [1]. Alternative causes of hyperhomocysteinemia affecting the 5-methyltetrahydrofolate-dependent methylation of homocysteine (cobalamin metabolic defects; 5,10-methylenetetrahydrofolatae reductase deficiency; methionine synthase deficiency (Fig. 1)) do not have hypermethioninemia. If an alternative cause of hypermethioninemia is suspected, CBS deficiency may be confirmed by assay of plasma cystathionine that is low in CBS deficiency [4].

## Therapeutic Principles

Therapy seeks to mitigate the elevation of tHcy. When initiated early in life, dietary methionine restriction has proven to be effective in preventing mental retardation, postponing or preventing optic lens dislocation and osteoporosis, and decreasing the frequency of thromboembolic episodes [1]. B6 treatment for responders has



**Homocystinuria due to Cystathionine Beta-Synthase Deficiency. Figure 1** Metabolic relationships of methionine and homocysteine.

been validated as effective in preventing thromboembolic episodes in late-detected responders [1]. Late-detected B6-nonresponders present the most difficult therapeutic challenge because they often do not accept strict dietary methionine restriction. In such cases, administration of betaine (often accompanied by B6, vitamin B12, and folic acid) has been used. Plasma tHcy is usually lowered, often accompanied by rises in plasma methionine, and the rate of vascular episodes has been markedly decreased (e.g., from an expected 112 events without treatment to 17 events on treatment [5]).

## HPV-associated Laryngeal Cancer

Christian Simon
Department of Otolaryngology – Head and Neck Surgery, Ruprecht-Karls-University, Heidelberg, Germany

### Definition and Characteristics

Head and neck cancer is the sixth most common cancer in humans with around 13,000 patients annually in Germany [1]. Smoking and alcohol consumption are the major risk factors for the development of squamous cell carcinomas of the head and neck (HNSCC) [1]. Zur Hausen, Zenner, and Winkler first described in 1986 the presence of HPV 16 DNA in carcinomas of the larynx [2]. Since then evidence accumulated suggesting a significant role of infections with HPV 16 as an independent risk factor for the development of squamous cell carcinomas of the oropharynx, larynx, and oral cavity [3].

### Prevalence

In the year 2002, 13,400 patients with head and neck cancers were counted by the Robert-Koch Institute. Three-thousand three-hundred patients suffered from cancer of the larynx. Nearly 25% of squamous cell

carcinomas of the larynx are HPV positive [3]. In about 70%, HPV 16 DNA is detected [3]. The highest rate of HPV infections, however, is found in squamous cell carcinomas of the oropharynx (35–50%) [3].

### Molecular and Systemic Pathophysiology

Little is yet known about the mechanisms of HPV-related tumorigenesis in HNSCCs. It has been speculated that as in cervical cancer interaction among viral early proteins (E6, E7), p53, and Rb contributes to tumorigenesis. Differences between both cancer entities, however, exist that include a high percentage of episomal viral DNA in contrast to cervical cancers. The presence of HPV DNA is associated with a better prognosis and decreased recurrence rate [4].

### Diagnostic Principles

Diagnostic procedures follow the guidelines for any HNSCC:

- Otolaryngologic examination
- Examination under anesthesia and biopsy
- CT scan of the neck and chest X-ray, for advanced stage disease – chest CT, ultrasound of the abdomen, and bone scintigraphy
- HPV testing is not yet considered a standard diagnostic procedure

### Therapeutic Principles

The principles of therapy follow the guidelines for the treatment of HNSCCs that is currently independent of the HPV status. Therapy consists of single modality treatment (surgery, radiation therapy) for early lesions and multimodality treatment (surgery followed by radiation or chemoradiation) for advanced lesions. Certain centers (i.e., USA, UK) favor combined chemoradiation for advanced lesions for larynx preservation [5].

HBoV

## Definition and Characteristics

Human Bocavirus (HBoV) was described by Tobias Allander and co-workers [1] in 2005. The virus was identified retrospectively in specimens from pediatric patients with respiratory tract infection (RTI). HBoV-DNA was identified in 17 out of 540 nasopharyngeal aspirates (NPA). Fourteen of 17 HBoV-positive symptomatic patients proved to have no viral co-infection, thus showing a significantly high occurrence in samples without previous detection of a pathogen. Viral coinfection was found in 3 patients. All 14 children without coinfection had been admitted to an inpatient medical treatment center having presented symptoms of cough and fever during the past 1–4 days. Seven children had a history of recurring bronchial obstruction/asthma bronchiale and four out of seven had been hospitalized due to exacerbation of RTI at least once before. Two patients suffered from chronic lung disease (CLD) following positive pressure ventilation in neonatal treatment. Interstitial bilateral infiltrates were reported in six of seven patients, in whom a chest radiograph (CXR) was performed. Hitherto, according to all published studies until March 2007, the application of Koch's revised postulates on HBoV remains still incomplete, since neither a method for virus culture nor an animal model has been established; in addition, HBoV has not been isolated from airway tissues to get histologic evidence of the infection. Nevertheless, the significantly higher occurrence of HBoV-DNA in respiratory secretions of symptomatic patients, the correlation of the severity of the clinical status of the patient and the detected viral load in respiratory specimens and a significantly higher rate of virus shedding in patients during the acute phase of infection suggest the role of HBoV as a real pathogen in RTI. HBoV has frequently been associated with RTI in infants and young children. Children older than 6 months seem to face the highest risk. To this point there have only been very few reports of HBoV-infection in adults. However, due to the high frequency of coinfections it is not fully clear whether bocavirus is a serious pathogen or an innocent bystander in respiratory tract infections, although there is increasing evidence for the latter.

## Prevalence

The hitherto published reports on bocavirus suggest that the virus occurs worldwide. Based on phylogenetic analysis it can be assumed that the virus forms two major lineages that co-circulate. Choi et al. [2] (Korea 2000–2005) reported a relatively high occurrence of HBoV in the mild months of late spring and early summer. The prevalence of HBoV-infection, i.e. the proportion of respiratory specimens from symptomatic patients with detection of HBoV-genome, among hospitalized children with RTI ranged between 1.5% and 18.3%. Most children with HBoV-infection were younger than 24 months.

## Genes

Sequence analysis revealed that the most closely related viruses were members of the genus *Bocavirus* (family: Parvoviridae, subfamily: Parvovirinae), namely bovine parvovirus and canine minute virus. Thus, the first member of this virus genus infecting humans was termed human bocavirus (HBoV). Phylogenetic analyses revealed that two genetically distinguishable clusters cocirculate. The genome length of known bocaviruses is 5,090–5,520 nucleotides. Their genomes contain three open reading frames (ORFs) with the two major ORFs encoding a nonstructural protein (NS1) and two viral capsid proteins (VP1 and VP2). The function of the NS1 protein is still unknown. An additional ORF encodes a nonstructural protein (NP-1).

## Molecular and Systemic Pathophysiology

Less is known about the molecular pathophysiology of bocavirus infections and most is a matter of speculation. As a matter of fact bocavirus DNA can be detected from nasopharyngal samples and nasal swabs, sputum, from blood samples during the acute phase of respiratory disease, and from stool samples. The latter suggests viral replication not only in the airways but also in gut;

also despite more detailed investigations and in lack of an animal model this remains a hypothesis.

## Diagnostic Principles

Until now no cell culture system permissive for human bocavirus was published. As with other viruses from the parvovirus family it can be assumed that the viral life cycle is dependent on distinct but hitherto unknown conditions, thus virus isolation in its classical sense remains impossible. This major difficulty in bocavirus research and diagnostics consequently led to the development of several PCR-based amplification and detection protocols for the laboratory diagnosis of bocavirus. It is noteworthy that there is a trend to real-time PCR protocols in the most recent literature, although (i) the additional information on the viral load in the clinical specimen has no implications on the therapy nor (ii) is reliable as it strongly depends on the procedure of harvesting of the clinical specimen by the individual physician. Based on earlier experiences with other pathogens it can be estimated that further diagnostic procedures that also cover serological aspects like peptide-based ELISAs or similar methods are already under development and will be available soon.

In addition to specimens derived from respiratory tract HBoV DNA could be detected in serum particularly during acute HBoV infection. However, the potential role of viremia in HBoV pathogenesis remains to be investigated. In autopsy tissues HBoV DNA could not yet be detected. HBoV DNA was also detected in stool samples derived from children with acute gastroenteritis, indicating an alternative route of viral transmission. This is not surprising since it has been documented that the bovine parvovirus is able to induce gastroenteritis in young calves.

## Therapeutic Principles

Yet there were no studies on benefits of particular treatments in HBoV-infected children. Most hospitalized patients receive intravenous antibacterial chemotherapy, may be explained by the high rate of radiologically confirmed pneumonia (70%) in patients "without a detected pathogen." The uncertainty concerning the etiology of the severe RTI may explain the "uncritical application" of antibiotics to HBoV-positive patients.

## Synonyms

hMPV

## Definition and Characteristics

Human metapneumovirus (hMPV) was first described by Van den Hoogen et al. in 2001, after they isolated it from nasopharyngeal aspirates of young children [1]. However, it is not a new pathogen; serological studies have shown its presence in the Netherlands dating from 1958 [1]. HMPV is a pleomorphic, enveloped RNA virus with mean diameter of spherical particles of 209 nm [2]. According to its morphological, biochemical, and genetic features, hMPV is assigned to the Paramyxoviridae family, Pneumovirinae subfamily, Metapneumovirus genus. It causes acute respiratory infections (ARI) in individuals of all ages [2] with hMPV primary infections occurring in early childhood [3] and reinfections or acquisition of new genotypes throughout life. Clinical manifestations range from rhinopharyngitis to bronchitis and pneumonia [4]. In young children, signs and symptoms of hMPV infection resemble those induced by respiratory syncytial virus (RSV) infection, hMPV being preceded only by RSV as the main cause of bronchiolitis in this population. It can also cause acute otitis media, bronchitis, pneumonitis, and asthma exacerbation in children, while in healthy adults it is more often associated with the common cold and flu-like syndrome [2]. A more severe clinical outcome of hMPV infection is reported in infants and young children, elderly people, immunocompromised patients, and those with concomitant or underlying disease.

## Prevalence

Reported incidence of hMPV infection in patients with ARI varies from 1.5 to 25%. In hospitalized children hMPV is generally found in 5–10% ARI cases, while in asymptomatic children hMPV positive rate is <1%. Rate of hMPV infection in asymptomatic young and elderly adults is 4.1% [2].

## Genes

HMPV genome consists of a single-stranded negative-sense RNA of ~13Kb containing eight genes coding for nine different proteins: the nucleoprotein (N),

phosphoprotein (P), matrix protein (M), fusion protein (F), transcription elongation factor (M2.1), RNA synthesis regulatory factor (M2.2), small hydrophobic protein (SH), major attachment glycoprotein (G), and major polymerase subunit (L), in the order 3′-N-P-M-F-M2.1-M2.2-SH-G-L-5′ [2]. On the basis of nucleotide sequence analysis, hMPV isolates can be divided into two major genetic groups (A and B) and at least four subgroups (A1, A2, B1, and B2) [2].

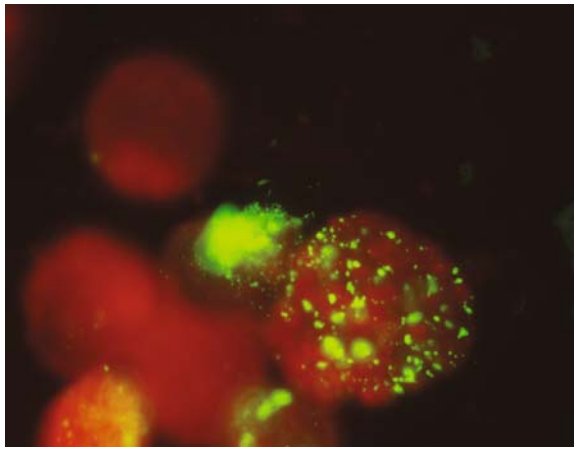
## Molecular and Systemic Pathophysiology

HMPV primarily affects airway epithelium. Findings in bronchoalveolar lavage in the children infected with hMPV include respiratory epithelial cell degeneration and/or necrosis with ciliacytophthoria and round red cytoplasmic inclusions, in a background of hemosiderin-laden macrophages, abundant neutrophils, and prominent mucus [5]. Lung biopsies have shown that later stages of diseases include expansion of peribronchiolar lymphoid tissue, squamous metaplasia, hemosiderin, and accumulation of intraalveolar foamy macrophages, indicating chronic/healing airway inflammation with a degree of concomitant airway obstruction and impairment of the mucociliary escalator that is in correlation with bronchiolitis and wheezing noted clinically [5].

## Diagnostic Principles

HMPV is relatively difficult to isolate because of its long-lasting and fastidious growth in cell culture. Its cytopathic effect (CPE) consists of granular rounded cells, small syncytia and cell destruction in tMK (tertiary monkey kidney), and LLC-MK2 (rhesus monkey kidney) cells. It can replicate with poor or no CPE in HEp-2 (human laryngeal carcinoma), Vero (African green monkey kidney), and human bronchial epithelial cells. Replication of hMPV in cell culture without showing CPE, as well as hMPV antigen in nasopharyngeal secretions of infected persons, can be proven by immunofluorescent technique (e.g., indirect immunofluorescent assay – IFA) (Fig. 1).

HMPV growth can be detected or confirmed in supernatant of cell culture using reverse transcription polymerase chain reaction (RT-PCR). RT-PCR performed on clinical specimen is the method of choice for the diagnosis of acute hMPV infection. Amplification and detection of different hMPV genes by RT-PCR based on real-time polymerase chain reaction is very rapid, sensitive, and probably the most cost effective method for detection of hMPV. Due to existence of two significantly different hMPV genetic lineages, appropriate primers should be used to prevent underestimation of hMPV infection [4]. Serological tests using IFA or enzyme-linked immunoabsorbent assay could be done. Findings of IgM antibodies, seroconversion or fourfold increase/decrease in IgG antibody titers must be demonstrated to confirm acute or recent infection.



**Human Metapneumovirus. Figure 1** Viral inclusions in infected LLC-MK2 cells recognized by monoclonal antibodies directed to hMPV nucleoprotein shown by IFA, (Suncanica Ljubin Sternak).

## Therapeutic Principles

Ribavirin (nucleoside analog of guanosine) and a polyclonal intravenous immunoglobulin preparation show in vitro antiviral activity against hMPV, but at the moment there are no clinical studies to confirm these observations in vivo. Given the well-known limitations of these medications (i.e., side effects, difficult administration, and high costs) they should be used with caution and considered for treating immunocompromised or patients with severe hMPV disease [4]. To prevent the spreading of hMPV in communities or hospitals, large droplets precaution measures should be taken according to the similarity in biological properties and clinical features of hMPV and RSV infection. There have been many attempts in developing efficient and safe hMPV vaccine. There are a few different live attenuated vaccines for intranasal administration, developed by reverse genetics, and evaluated in experimental animals that seem like good candidates for immunization, but clinical trials on hMPV vaccines are required.

Painful plantar warts or vegetative warts; Common warts; Filiform warts; Mosaic lesions; Plane warts; Epidermodysplasia verruciformis; Condylomata accuminata; Butcher's warts; Focal epithelial hyperplasia (Heck's disease); Bowenoid papulosis; Cervical cancer; Keratoacanthoma; Bowen's disease; HPV

## Definition and Characteristics

Identification of more than 100 different HPV types so far. Close phylogenetic relationship of cutaneous types (β/γ-HPVs) with the rabbit papilloma virus (shope virus) and Mastomys coucha (MnPV1, McPV2). Genital low-risk α-HPV types (e.g., HPV 6 and HPV 11) are associated with benign tumors and high-risk types (e.g., HPV 16, 18, 31, 33, 35, and 45) are associated with malignant diseases.

## Prevalence

Between 5 and 25% of the world's female population have detectable genital HPV DNA in the cervix increasing worldwide with the highest rates in women between 20 and 30 years [1]. Incidence shows a maximum in the second decade and a second increase in women older than 65 years [2]. Persistence of HPV in subclinical lesions is associated with an increased risk for cervical cancer, anogenital cancers and possible non-melanoma skin cancers [3].

## Molecular and Systemic Pathophysiology

HPV particles are small, have a mean diameter of 46–54 nm and consist of an outer protein envelope (capsid, contains 72 subunits of L1 and L2) covering the virus genome. Its double-stranded DNA contains 7,200–8,000 base pairs. The genomic organization of all HPV types consists of three different regions:

1. Non-Coding Region (NCR), containing regulatory sequences for transcription and viral-replication.
2. The early region, consisting of the open reading frames (ORF, E1–E7), necessary for viral and cellular regulatory processes, DNA-replication, and cell transformation.
3. The late region, encodes for two proteins, L1 and L2, which self assembles to viral capsids.

**Human Papilloma Virus. Table 1** HPV types and corresponding virus diseases

| Clinical findings | HPV-type | Oncogenetic risk |
|---|---|---|
| Painful plantar warts or vegetative warts | 1, 2, 4, 60, 63 | ø |
| Common warts, filiform warts, mosaic lesions | mainly 2, 27, 57 | ø |
| Plane warts, sometimes associated with Epidermodysplasia verruciormis | 3, 10, 28 | ++ |
| Maculous or slightly raised lesions above the skin surface (patients with Epidermodysplasia verruciformis) | 5, 8, and other β-HPV types | +++ |
| Epidermal malignancies of immunocompromised patients | mainly β-HPV types | +++ |
| Condylomata accuminata c-Buschke-Lowerstain tumor | 6, 11 | + |
| Butcher's warts | 7 | ø |
| Focal epithelial hyperplasia (Heck's disease) | 13 and possibly 32 | ø |
| Bowenoid papulosis | 16, 18 | +++ |
| Cervical cancer | 16 (50%), 18 (20%) | +++ |
| Keratoacanthoma | 35 | + |
| Bowen's disease | 16, 18 | +++ |

+ low risk ++ intermediate risk +++ high risk.

The viral oncogenes E6 and E7 of high-risk α-HPV types are consistently expressed in genital lesions, immortalize keratinocytes causing genomic instability. The low-risk types HPV 6 and 11 are mainly associated with Condylomata acuminata and the high-risk types HPV 16 and 18 with invasive cancers (e.g., cervical-, penile-, anal- cancer) and their precursors (e.g., cervical intraepithelial neoplasia, CIN).

HPV are mainly host specific and can be transmitted from humans to humans as well as from animal to animal (e.g., cattle, horse, dog or cat) and a interspecies transmission can not be excluded. The incubation period ranges between weeks and years. The virus enters the skin and the mucosa via micro-lesions and causes an increased cell-growth leading to benign tumor (acanthopapilloma). Only in differentiated keratinocytes (stratum granulosum and stratum corneum) infectious viral particles can be produced and released (mostly in benign lesions but normally not in malignant carcinomas), which can lead to new HPV infections.

### Diagnostic Principles

*Southern Blot Hybridization and Sequencing*: Both techniques are the gold standard for the detection of known and novel HPV types.

*Hybrid Capture HPV DNA Assay Second Generation (HC2)*: Validated in large trials. This technique allows differentiating between both genital groups the low-risk and high-risk α-HPV types. The sensitivity of HC2 is approximately $10^4$ viral genome copies, and thus less sensitive than the polymerase chain reaction (PCR).

*PCR Based Methods*: Amplification allows detection of small amounts of HPV DNA, 10–1,000 copies depending of the virus type. Sensitivity and specificity mainly depend on the primer sets and the size of the PCR product [4].

### Therapeutic Principles

Pharmacological therapy including cytotoxic agents (i.e., podophyllin, trichloroacetatic acid), 5-Fluorouracil (5-FU), immunotherapy, interferons, immunomodulators (i.e., Imidazoquinolones, Cimetidine), therapeutic vaccination, antiviral therapy, retinoids, Cidovir, dietary therapy (indole-3-carbinol, aconstituent of cruciferous vegetables) and (depending on the infected area): local destruction (i.e., cryotherapy, laser vaporization), excision (e.g., cold-knife cone biopsy in cervical CIN 2/3), photodynamic therapy (PDT), homeopathy, suggestion, hypnosis [5].

Common warts have a high rate of spontaneous regression. (i.e., 63% within 2 years).

►Respiratory Syncytial Virus

## Human Transmissible Spongiform Encephalopathies

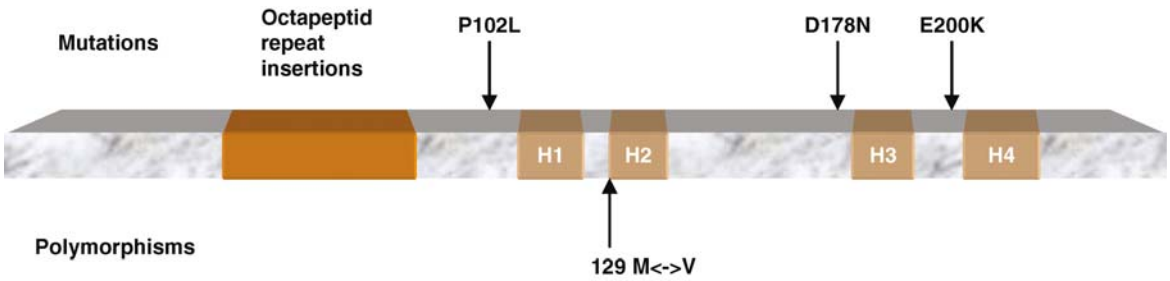
Inga Zerr, Mathias Bähr
Department of Neurology, National Reference Center for TSE Surveillance, Georg-August University, Goettingen, Germany

### Synonyms

Creutzfeldt-Jakob disease; CJD, prion diseases; Spongiform encephalopathies

### Definition and Characteristics

The unique nature of human prion diseases includes their pathogenesis, mode of transmission and neuropathology. In humans, the disease is characterized by a long incubation time, rapid and dramatic evolution of the clinical disease course and always a lethal outcome. The most common form of the human prion diseases is sporadic Creutzfeldt-Jakob disease (sCJD), which is generally regarded as a spontaneous neurodegenerative illness, arising either from a spontaneous *PRNP* somatic mutation or a stochastic PrP protein structural change. Acquired TSE (kuru due to cannibalism, variant CJD due to BSE or iatrogenic (dura mater-, hGH- and neurosurgery-related CJD) are known. Autosomal dominant familial/genetic prion diseases are associated with mutations or insertions in the prion protein (PrP) gene in 5–15% of all prion disease cases. They are classified according to the changes in the prion protein gene (*PRNP*) or according to the phenotypes as familial Creutzfeldt-Jakob



**Point mutations:**

P102L, P105L, A117V, G131V, I138M, G142S, Y145s, Q160s, D178N-129V, D178N-129M, V180I, V180I+M232R, T183A, H187R, T188R, T188A, T188K, E196K, F198S, E200K, D202N, V203I, R208H, V210I, E211Q, Q212P, Q217R, M232R, M232T, P238S

**Insertions:**

24bp, 48bp, 96bp, 120bp, 144bp, 168bp, 192bp, 216bp

**Human Transmissible Spongiform Encephalopathies. Figure 1** Frequent mutations and polymorphisms in the human prion protein gene.

**Human Transmissible Spongiform Encephalopathies. Table 1** Molecular subtypes of sporadic CJD (clinical and pathological characteristics and diagnostic tests)

| | Molecular disease subtype | Median age at onset | Median duration months (range) | Most prominent clinical signs/syndrome | Neuropathological features |
|---|---|---|---|---|---|
| Frequent | MM1/MV1 | 65 (31–82) | 4 (1–18) | Dementia, cortical anopsia, myoclonus | Prominent involvement of occipital cortex, "synaptic type" PrP staining |
| | MV2 | 64 (53–76) | 12 (4–27) | Ataxia, dementia, extrapyramidal | Similar to VV2, focal involvement of the cortex, amyloid-kuru plaques in the cerebellum, plaque-like focal PrP deposits |
| | VV2 | 61 (40–76) | 7 (3–18) | Ataxia at onset, late dementia | Prominent involvement of subcortical, including brain stem nuclei, spongiosis often limited to deep cortical layers, plaque-like PrP staining, prominent perineuronal staining |
| Rare | MM2-T | 52 (36–71) | 16 (8–24) | Insomnia, dysautonomia at onset, later ataxia and cognitive impairment | Atrophy of the thalamus and inferior olive, spongiosis may be absent or focal |
| | MM2-C | 64 (49–77) | 16 (9–36) | Progressive dementia for several month | Large confluent vacuoles with perivacuolar PrP staining |
| | VV1 | 44 (19–55) | 21 (17–42) | Dementia at onset, later ataxia and extrapyramidal | Severe pathology in the cerebral cortex and striatum with sparing of brain stem nuclei and cerebellum |

disease, Gerstmann-Sträussler-Scheinker syndrome (GSS) or fatal familial insomnia (FFI) (see Fig. 1).

The most prominent and striking feature of the disease is a gradual decline in memory and loss of higher cognitive functions within several weeks or months (Table 1).

On autopsy, spongiform degeneration, neuronal loss and gliosis are typical neuropathological changes of the affected brain regions. The detection of abnormally folded proteinase K resistant prion protein ($PrP^{Sc}$, Sc = scrapie) is required for the diagnosis. In sCJD, the pathology is restricted to the brain. In vCJD, there is also an involvement of the lymphoreticular tissue. The abnormal folding and change of the secondary structure of the host derived $PrP^{c}$ (c = cellular) is regarded as a key event in the pathological process.

One of the unique features of all TSE is their transmissibility; sporadic, but also acquired and

genetic forms are transmissible via intracerebral, intraperitoneal, intramuscular and oral routes within the same and between species.

## Prevalence

sCJD represents the most common human prion disease form. The annual incidence of sCJD ranges between one and two cases per million per year worldwide. The disease is rare in young people and the peak incidence is seen in the seventh decade [3]. The median age at onset is 65 years and the median disease duration is 6 months.

## Genes

The sequence of 254 amino acids of the human prion protein is encoded by a gene, which is located on the short arm of chromosome 20. It consists of two exons and one intron of 13 kbp in length. The entire protein coding part of the gene *(open reading frame)* is located in exon 2. All prion protein genes analyzed in mammals so far display a similar structure. There is a high degree of homology between the prion protein sequences in man and other mammalian species (primates 93–99%, rodents 91–92% at the amino acid level). The prion protein is modified posttranslationally by cleavage of N-terminal signal peptide and a C-terminal signal sequence and addition of two or three sugar chains.

More than 20 point mutations and insertions that inherited prion diseases are known to date. These point mutations cluster in the central and in the more C-terminal part of PrP. In other families, one allele of PRNP has an extended coding region and the synthesized PrP molecules carry insertions of various lengths (multiples of an octapeptide) in the N-terminal part [2].

Besides the mutations, several polymorphisms have been described, the most important one being the methionine/valine polymorphism at codon 129. Homozygosity at codon 129 is considered to be a susceptibility factor for sporadic disease and influences the incubation time in acquired cases (shorter in homozygous patients) and the survival in sCJD (longer in heterozygous).

## Molecular and Systemic Pathophysiology

Distinct clinicopathological phenotypes are defined by molecular characteristics such as codon 129 genotype of the *PRNP* and type of proteinase K resistant core of the prion protein ($PrP^{Sc}$, either as type 1 or type 2) [4]. The most frequent subtypes of sCJD are designated as MM1/MV1, VV2 and MV2. MM2 and VV1 subtypes are rare. In MM2 subtype, a cortical and a thalamic form are distinguished (MM2-cortical, MM2-thalamic) (Table 1).

## Diagnostic Principles

The definite diagnosis of CJD requires autopsy or brain biopsy and $PrP^{Sc}$ detection. Electroencephalogram (EEG), magnetic resonance imaging (MRI) and cerebrospinal fluid (CSF) tests support the clinical diagnosis (Table 2).

High signal changes on the MRI in various cortical and subcortical regions are detected using special

**Human Transmissible Spongiform Encephalopathies. Table 2** Typical alterations in diagnostic procedures for various CJD types

| TrueTypical tests | | Sporadic | | | | | Genetic | | | Acquired | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | MM1/MV1[a] | MM2[b] | MV2[c] | VV1[d] | VV2[d] | GSS | FFI | fCJD | VCJD[e] | iCJD |
| CSF | 14-3-3 | + | – | + | + | + | (+) | – | + | (+) | + |
| EEG | PSWCs | + | – | – | – | – | – | – | (+) | – | (+) |
| MRI | Basal ganglia | + | – | + | (+) | + | – | – | ? | (+) | + |
| | Cortex | + | (+) | + | + | ? | ? | ? | ? | ? | + |
| | Thalamus | – | – | + | (+) | ? | ? | ? | ? | + | (+) |
| | Hippocampus | – | – | ? | + | ? | ? | ? | ? | ? | + |
| SPECT PET | Hypoperfusion/hypometabolism | + | + | + | + | ? | ? | + | ? | ? | ? |

[a]Corresponds to classic sCJD with a rapid disease course.
[b]The "thalamic type" shows affection of the thalamus at least on SPECT/PET during the later disease course.
The "cortex type" may show affection of the cortex on MRI.
[c]The MRI may resemble vCJD. The 14-3-3 protein may be negative in around 20% of cases.
[d]Only limited data available.
[e]"pulvinar sign" in the MRI: hyperintensity of the pulvinar compared to the anterior putamen.
EEG may become positive during the later disease stage.
(+) = Reported but not frequent, ? = No sufficient data.
Abnormal $PrP^{Sc}$ can be detected in the tonsils by biopsy. Tonsil biopsy is only recommended in suspected vCJD with no pulvinar sign in the MRI.

techniques such as FLAIR (fluid attenuated inversion recovery) and DWI (diffusion weighted imaging). Hyperintense basal ganglia are reported in two thirds of all patients. Recent results indicate that the alteration of particular brain regions might vary between molecular subtypes, thus allowing an early differential diagnosis (see Table 2) [1].

Cerebrospinal fluid (CSF) analysis plays an important role in the clinical diagnosis of CJD. Routine tests are normal without any signs of an inflammatory response. CSF levels of brain derived proteins such as 14-3-3, tau, phosphorylated tau, neuron specific enolase and S100b are extremely high, thus allowing the differential diagnosis between sCJD and other dementias. Among biochemical markers, only 14-3-3 has become part of the criteria because of high sensitivity (95%) and specificity (90% in the differential diagnosis of dementia) [5].

## Therapeutic Principles

Given the wide range of symptoms and signs in CJD and current limitations of causal therapy, symptomatic treatment becomes extremely important. Many CJD patients suffer from psychiatric symptoms such as depression, anxiety, psychosis and hallucinations. Symptomatic treatment spans over a wide range of anxiolytic and antipsychotic drugs such as benzodiazepines or neuroleptics. Because muscle rigidity and akinesia are frequent in the middle and advanced disease stages, atypical neuroleptics should be used to minimize the adverse effects. A symptomatic therapy exists for CJD-typical myoclonus, that responds well to clonazepam or valproate. Recent data indicate an effect of doxycyline, which results in increased survival and delay of disease progression.

# Hungry Bone Syndrome

Nicole Stankus
Department of Nephrology, University of Chicago, Chicago, IL, USA

## Definition and Characteristics

Hungry bone syndrome is distinguished by a severe and prolonged hypocalcemia despite normal or even elevated levels of PTH due to a rapid increase of bone formation to bone resorption ratio which causes augmented requirements of calcium.

It usually develops after parathyroidectomy for either primary [1] or secondary hyperparathyroidism. Severe hypocalcemia results from the sudden drop of PTH secretion in the setting of a pre-existing severe bone resorption due to high levels of PTH. In a similar fashion a "chemical" parathyroidectomy can be induced by treating secondary hyperparathyroidism with calcium-sensing receptor modulators [2]. Hungry bone syndrome may complicate thyroid surgery due to parathyroid gland trauma, devascularization, accidental removal of the glands or reversal of thyrotoxic osteodystrophy [3]. It can manifest in prostate cancer with osteoblastic metastases to the bones after treatment with estrogens [4]. A less common cause of hungry bone syndrome is an overly rapid correction of the renal tubular acidosis with alkali due to rapid remineralization of the bone.

## Prevalence

Hungry bone syndrome complicates about 12% of parathyroidectomies. Permanent hypoparathyroidism happens in 0.4–13.8% of surgical thyroidectomies and temporary hypocalcemia occurs in 2–53%. Patients with Grave's disease and a long duration of uncontrolled thyrotoxicosis are at increased risk. Hypocalcemia is observed in 20% of metastatic prostate cancer patients with osteoblastic bone lesions treated with estrogenic agents.

## Molecular and Systemic Pathophysiology

After parathyroidectomy PTH is no longer maintaining calcium levels via usual regulatory mechanisms such as bone resorption, increased renal resorption of calcium and stimulation of active 1,25 vitamin D production (via activation of 1-α hydroxylase). Serum calcium flux into and from bone is no longer in equilibrium, osteoblastic activity exceeds osteoclastic resorption, resulting in symptomatic and severe prolonged hypocalcemia.

Pathophysiology of hungry bone syndrome following thyroid surgery is not well understood. Perhaps it is due to reversible ischemic injury to the parathyroid

glands or possibly due to the release of endothelin, which is known to suppress PTH production. Calcitonin, which is produced by the thyroid and inhibits bone breakdown, has effects on the calcium metabolism that oppose the effects of PTH. Severely hyperthyroid patients are in accelerated bone breakdown state. When the stimulus for breaking down the bone is removed, calcitonin is acutely released and bone, "hungry" for calcium, increases its uptake from serum resulting in severe hypocalcemia.

There is marked increase in serum alkaline and acid phosphatase and PTH, decreased serum phosphorus and magnesium, marking positive calcium balance and active bone formation. Estrogens reduce resorption of normal bone, initiating "hungry bone" phenomenon, maintained by active osteoblastic metastases which act like a "calcium sink."

PTH levels are increased in patients with renal tubular acidosis and normalize with gradual alkali repletion. Overly rapid correction, rarely, can result in magnesium and calcium depletion, manifesting as hungry bone syndrome in the milieu of rapid bone remineralization.

### Diagnostic Principles

Patients at highest risk for hungry bone syndrome are the ones with uncontrolled hyperthyroidism; severe osteitis fibrosa cystica; parathyroid adenomas larger than 0.5 cm, elevated serum calcium and alkaline phosphatase, very high serum PTH and age over 60 years.

1. Persistently low ionized serum calcium following parathyroidectomy, thyroid surgery, treatment of metastatic osteoblastic lesion in prostate cancer, or sudden correction of renal tubular acidosis
2. Low urinary calcium excretion
3. Increased serum alkaline phosphatase
4. Low serum phosphorus (more common in primary hyperparathyroidism)
5. Hypomagnesemia (more common in primary hyperparathyroidism)

### Therapeutic Principles

After parathyroidectomy calcium is replaced intravenously using a rapid 10% calcium gluconate infusion. Oral calcium carbonate supplementation 4–8 g daily should be initiated as soon as the patient is able to swallow, together with calcitriol, 2–4 μg daily. Hypomagnesemia is best treated with intravenous administration of magnesium sulfate, 6–8 g per day. Importantly, up to 70% of parentally administered magnesium will be excreted by the normally functioning kidneys. Prevention of hungry bone syndrome includes successful pre-operative treatment of hyperthyroidism, administration of vitamin D, early diagnosis of hyperparathyroidism and possibly pre-operative administration of bisphosphonate.

### Synonyms

Huntington's chorea; Chorea maior; Saint Vitus' dance; Westphal variant; Juvenile-Onset HD

### Definition and Characteristics

Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder; the eponyme honors the precise description of its core features by George

Huntington in 1872. Clinically HD is characterized by a progressive movement disorder, a progressive impairment of cognitive functions as well as psychopathological symptoms and signs. The movement disorder presents as an excess of involuntary movements (chorea, athetosis), impaired voluntary movements (bradykinesia) and an impaired regulation of posture (dystonia). As the disease progresses, choreatic movements increase in amplitude and spread from distal to proximal extremities finally involving the trunk thus impairing the ability to sit or stand stably, to walk, to speak, chew and swallow; the physical impairment results eventually in a state of complete dependence on assistance. In addition to the motor signs patients show a decline in cognitive functions including apathy, declining executive prefrontal and memory functions, impaired motor learning, a reduced ability to recognize emotional facial expressions and identifying odors, leading to dementia. Psychopathology tends to vary more than cognitive and motor signs and include depression, anxiety, aggressive and compulsive behavior, addictions (alcoholism, drug abuse, gambling) and delusional and paranoid psychosis. The mean age of onset for HD is between 35 and 50 years; about 10% of patients have a disease onset before the age of 20, representing the juvenile form of HD. The first symptoms can be either cognitive and emotional (depression, anxiety, paranoia, forgetfulness, impaired judgement, irritability, mood swings, and social withdrawal) and/or an impairment in motor skills. Juvenile HD patients display a rigid-dystonic phenotype, tremors, and myoclonic jerks and seizures. Survival from the onset of motor signs is on average 21 years for adult onset HD and probably somewhat shorter for juvenile HD. Death most often occurs as a result of the ensuing physical disability resulting in choking, aspiration pneumonia or other infections.

## Prevalence

5–10:100,000 in North America and Europe. Prevalence is thought to be lower in African and Asian populations.

## Genes

The HD (or IT 15) gene on chromosome 4p16.3 contains 67 exons encoding for huntingtin (htt), a multifunctional 364 kD protein [1]. Physiological functions of htt include a role in transcriptional regulation and vesicle trafficking. HD is caused by a triplet repeat expansion mutation: a moderate expansion of a polymorphic CAG triplet repeat in exon 1 of the IT15 gene results in an extended stretch of uninterrupted polyglutamines (polyQs) thought to induce misfolding of the mutant htt [1]. The age of onset of clinically definite HD is inversely correlated to the number of CAG repeats: most HD patients with adult onset have CAG repeat expansions in the range of 40–55 repeats. Like in other triplet repeat disorders the number of CAG repeats is unstable and may increase in successive generations, in particular with paternal transmission, thus providing a mechanism for the genetic anticipation (progressively younger age of onset in subsequent generations) observed in HD families. CAG repeat expansions of ≥40 repeats are fully penetrant whereas repeat expansions between 36 and 39 are associated with reduced penetrance. Unaffected individuals have 35 or less CAG repeats. CAG repeat sizes of more than 26 are thought to be unstable and to be prone to further expansions thus representing a risk for developing HD de novo once the threshold of 35 repeats is exceeded.

## Molecular and Systemic Pathophysiology

Despite the widespread expression of htt in both non-neuronal and neuronal cells, HD presents phenotypically as a central nervous system disorder. The expanded polyQ stretch changes the conformational structure of mutant htt and renders mutant htt prone for aggregation. Fragments of mutant htt form intranuclear and cytoplasmic aggregates. The causal relationship between aggregation and cellular dysfunction is still a matter of debate. Htt is predominantly found in the cytoplasmatic compartment and can be detected in the nuclear compartment as well. Htt is part of a complex network of proteins; these htt-interacting proteins represent scaffolding, nuclear, transcriptional, membrane and signaling proteins suggesting that htt is involved in numerous cellular processes, e.g., endocytosis, vesicle transport and transcription [2]. Due to the multitude of interactions of htt in the cellular context, several cellular pathways are altered in HD and have been proposed to underly cell dysfunction and cell death: transcriptional dysregulation, impaired proteasomal degradation, abnormal mitochondrial energy metabolism, calcium dysregulation and excitotoxicity. Neuropathologically HD is characterized by a generalized forebrain atrophy particularly prominent in the striatum and a loss of medium spiny neurons in the striatum [3]. The cause of this selective cell loss is still not well-understood.

## Diagnostic Principles

Most people affected by HD have a positive family history consistent with an autosomal dominant pattern of inheritance and full penetrance. New mutations are rare but do occur, mostly in patients presenting late in life with symptoms and signs of HD and typically small CAG repeat expansions. In the presence of symptoms and signs suggestive of HD, (independent of a positive family history) confirmatory genetic testing is performed. For genetic testing DNA from the patient's blood is isolated and the number of CAG repeats within the IT15 gene is determined using PCR with appropriate size markers or sequencing. In homozygotes, Southern Blotting may be required.

Presymptomatic genetic testing is available and requires genetic counseling according to international guidelines [4]. HD must be differentiated from other disorders associated with chorea including other triplet repeat disorders (e.g., spinocerebellar ataxia 17 (SCA-17), dentato-rubro-pallido-lyusian atrophy (DRPLA)), neuroacanthocytosis associated syndromes (McLeod, choreoacanthocytosis), autoimmune disorders and drug-induced disorders like tardive dyskinesia.

### Therapeutic Principles

Currently, no curative treatment able to fully arrest the progression of HD or able to prevent the emergence of symptoms and signs of HD is known. However, the functional impairment and the symptoms and signs of HD can be reduced or alleviated through pharmacotherapy and appropriate care including physiotherapy, occupational and speech therapy. Ensuring adequate nutrition is an important part of the care for HD sufferers; in more advanced stages caloric needs are increased to 2–3 times the requirements of an average person to maintain body weight.

A pharmacotherapy is available to help control chorea; compounds include dopamine D2 receptor antagonists like haloperidol, sulpride or tiapride or dopamine depleting agents blocking vesicular dopamine transporters like tetrabenazine. Antichoreic treatment may have the side effect of aggravating bradykinesia or dystonia or of inducing akathesia. Therefore, these compounds should be used with caution and should be given at the lowest possible dose. Other standard treatments to alleviate symptoms like depression, apathy and aggression include the use of selective serotonin (e.g., sertraline and paroxetin) and combined serotonin and noradrenaline reuptake inhibitors (e.g., venlafaxine), sedatives and antipsychotics (e.g., olanzepine) [5].

Experimental disease modifying treatments target the expression of htt (gene silencing using siRNA), the proteolytic processing of htt, the modulation of misfolding by the induction of chaperones, the degradation of mutant htt through autophagy or proteosomal pathways, the reversal of transcriptional dysregulation by e.g., histone deacetylase inhibitors, mitochondrial dysfunction (e.g., Coenzyme Q10) or the loss of neurotrophic factors (e.g., BDNF) and the modulation of the activity of glutamate receptors. In addition, restorative approaches including the striatal transplantation of fetal neuronal tissue and the stimulation of neuroneogenesis are currently explored.

## Hurler Syndrome

►Mucopolysaccharidoses

## HUS

►Hemolytic Uremic Syndrome

## Hutchinson Gilford Progeria Syndrome

Jonas Denecke
Department of Pediatrics, University of Rostock, Rostock, Germany

### Synonyms

Progeria; HGPS (#176670) chromosome 1q21.2-1q21.3

### Definition and Characteristics

Accelerated phenotypical ageing and a dramatic shortening of life span are key features of the Hutchinson Gilford progeria syndrome. Children are normal at birth but develop first signs of the disorder within the first year of life. Growth retardation, loss of hair and prominent scalp veins are initial signs of the disorder. Gradually a sharp nose and a loss of subcutaneous fat with lipodystrophy, dry and thin skin and stiff joints underline the progeria phenotype. Osteoporosis and arteriosclerosis and sometimes cardiomyopathy develop later on. Patients reach a median age of 13.4 years before dying from sequels of arteriosclerosis or cardiomyopathy. While HGPS patients show several problems affecting connective tissue ageing, other typical disorders generally associated with ageing are not common: the incidence of cancer and dementia is not increased.

## Prevalence

1:8,000,000.

## Genes

In the early history of HGPS an autosomal dominant trait of the disorder was already proposed. Due to the nature of the disorder with death in childhood almost every case of HGPS is due to a new mutation, single cases of typical HGPS patients might be due to a germ line mutation associated with the risk of inheritance. In 2003 two groups independently revealed the molecular basis of HGPS [1,2]. A mutation in one codon of the LMNA gene activates a cryptic splice-site in exon 11 (p.G608G) resulting in a deletion of 50 amino acids of the lamin A protein. The LMNA gene contains 12 exons and is located on chromosome 1q21.2-q21.3. Two distinct proteins are coded by the gene, lamin A and lamin C that are products of different splicing. Lamin A and C share 566 amino acids, while lamin A has a unique 98 amino acid c-terminus and lamin C has a distinct 6 amino acid carboxyl tail. Interestingly, mutations in other parts of the gene result in at least seven further distinct disorders with partly overlapping phenotypes. This fact leads to the term "laminopathy" for the group of disorders caused by mutations of the LMNA gene or affecting the lamin A and lamin C proteins.

HGPS is a disorder affecting the specific c-terminus of lamin A while the synthesis of lamin C, coded by the common 566 amino acids is generally not affected.

## Molecular and Systemic Pathophysiology

Mutations causing HGPS generally affect the lamin A splice variant of the LMNA gene. Lamin A is an inner nuclear lamina protein forming homodimers and multimers with other lamin proteins. Many interactions of the lamin A protein with other proteins and DNA are known, including transcription factors, components of chromatin, histones, the splicosome, emerin and other structural proteins and the p53 signaling pathway implicating a fundamental regulative role of the protein. The nuclei of HGPS cells show gross changes with abnormal shape, blebs and herniation of the nuclear envelope, thickening of the nuclear lamina, loss of peripheral heterochromatin and clustering of nuclear pores underlining not only a functional but also a mechanical influence of the LMNA mutation in HGPS.

The lamin A protein undergoes a multistep post-translational modification resulting in temporary farnesylation of the protein and finally cleavage of the farnesylated C-terminus releasing mature lamin A (Fig. 1). Mutations resulting in HGPS predominantly cause a deletion of the cleavage site for the last processing step. Thus in HGPS a lamin A protein with a deletion of 50 amino acids and a C-terminal elongation of 15–18 amino acids containing a farnesyl residue is synthesized. Due to the heterozygosity of the disorder normal lamin A proteins and mutated lamin A proteins called progerin coexist within the nucleus [3].

Knockout mice for the lamin A and lamin C gene are not viable emphasizing the vital role of the LMNA gene. However, knockout mice solely lacking the lamin A protein are healthy and have a normal live span implicating that lamin A is not necessary for viability and health in mice [4]. Mice harboring the HGPS mutation show a progeria phenotype but do not develop arteriosclerosis. ZMPSTE24 knockout mice, in which lamin A processing is abolished, also develop a severe progeria phenotype underlining the role of incompletely processed and farnesylated lamin A for the progeria phenotype and less the specific role of progerin. This appreciation is underlined by mutations of a single patient combining a homozygous null mutation in the ZMPSTE24 gene with a heterozygous C-terminal stop mutation in LMNA also showing a HGPS phenotype without presence of progerin [5]. Breeding ZMPSTE24 knockout mice with lamin A knockout mice showed that a decreased amount of lamin A ameliorates the progeria phenotype in case of a lamin A processing defect [4].

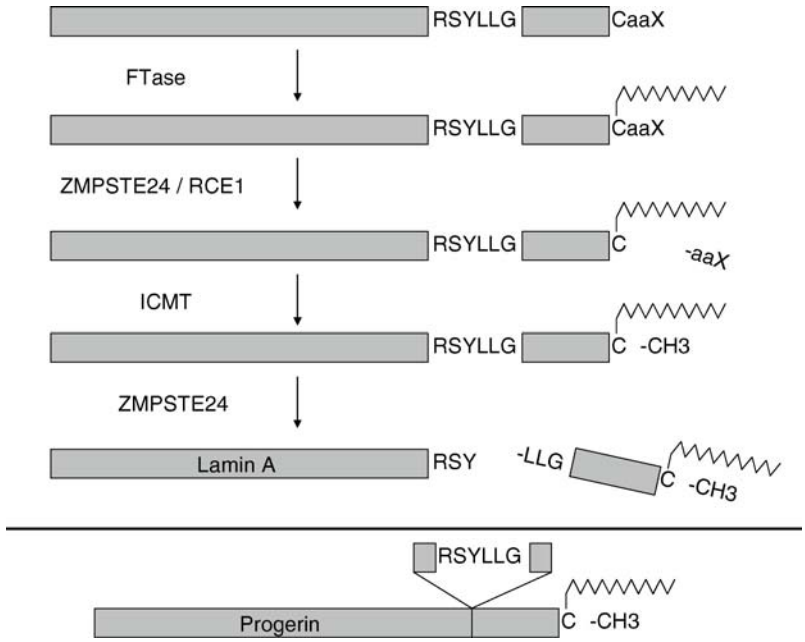
To sum up, animal models and the existence of single patients with complex mutations implicate that not the lack of lamin A but the presence of farnesylated lamin A protein or lamin A protein variants seem to cause HGPS.

Two major models are proposed for the progeria phenotype in patients with LMNA mutations. The genomic instability model proposes impairment of the specific role of an intact nuclear matrix for chromatin condensation, gene regulation and DNA reparation for the phenotype and decreased live span of HGPS patients while the mechanical model focuses on the decreased stability of the nucleus to mechanical stress that might explain the fact that connective tissue is mainly affected in HGPS.

## Diagnostic Principles

The definitive diagnosis of HGPS is made by the molecular proof of a heterozygous mutation in codon 608 of the LMNA gene. In case of typical clinical signs of HGPS without a mutation in codon 608 the whole LMNA gene should be sequenced since the clinical picture of other disorders caused by mutations of the LMNA gene might be similar to HGPS and other disorders of the laminopathy group or a HGPS variant should be considered as a differential diagnosis. In addition to the molecular diagnosis and especially if no mutation is found in the LMNA gene, fibroblasts of the patient should be analyzed using immunofluorescence analysis with antibodies to lamin A and lamin C and western blot analysis of lamin A and lamin C proteins which can detect lamin A processing defects that in rare cases might cause a classical HGPS phenotype.

Radiological findings include osteopenia, joint deformation and osteolytic lesions of the clavicle.



**Hutchinson Gilford Progeria Syndrome. Figure 1** Lamin A is firstly synthesized as a precursor (prelamin A) with a c-terminal CaaX motif, a consensus site for farnesylation. After farnesylation of the cysteine by the cytosolic enzyme protein farnesyltransferase, endoproteolysis of three terminal amino acids is performed by ZMPSTE24 or maybe by RCE1 and terminal cysteine is methylated by the ER protein isoprenylcysteine methyltransferase (ICMT). Finally additional 15 c-terminal amino acids are cleaved by ZMPSTE24 cutting a specific cleavage site releasing the mature lamin A protein. Deletion of 50 amino acids including the second ZMPSTE24 cleavage site results in a farnesylated and methylated incompletely processed protein called progerin.

## Therapeutic Principles

In vitro transfection of morpholino oligos specific to the cryptic splice site generated in HGPS patients and RNA interference specific for mutated LMNA mRNA showed a significant reduction of mRNA coding for progerin and a significant amelioration of misshapen nuclei and cellular senescence. Comparable results were seen when HGPS cells were treated with farnesyltransferase inhibitors (FTI) decreasing farnesylation of prelamin A but also of other proteins. Although the decrease of farnesylated prelamin A was slight, normalization of the nuclear shape was observed in many cells. Accordingly, feeding progeria mice with FTI significantly restored most of the misshaped nuclei, increased body weight and prolonged but did not normalize life span. If the effect of FTI is due to a direct influence on progerin farnesylation or due to decreased farnesylation of other proteins like lamin B or RAS remains to be elucidated. Clinical trials using FTI in HGPS patients are being planned (www.progeria-research.org/).

# Hyalinosis Cutis et Mucosa

►Lipoid Proteinosis

# Hydrocele

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

A hydrocele refers to a collection of fluid within a processus vaginalis and often presents in the male as a cystic scrotal mass that transilluminates brightly (Fig. 1) [1]. In the female, it may present as a cystic mass in the inguinal area [2]. A hydrocele can be communicating or non-communicating. A communicating hydrocele fluctuates in size, being smaller when the patient is recumbent. Gentle pressure or squeezing reduces the fluid from the scrotum into the peritoneal cavity [3]. Typically, the fluid reappears when there is increased intra-abdominal pressure (e.g. crying, straining). A non-communicating hydrocele, on the other hand, is of stable size although the size may increase slowly. An abdominoscrotal hydrocele is an hourglass-shaped hydrocele that extends from the scrotum to the retroperitoneum but has no demonstrable communication with the peritoneal cavity. Pressure on the abdominal mass often causes enlargement of the scrotal component [3].

**Hydrocele. Figure 1** A 3-year-old boy with a left-sides hydrocele. Note the transillumination.

## Prevalence

Hydrocele is very common in male infants, although the exact incidence is not known. The incidence in children older than 1 year is probably less than 1% [3]. The condition is rare in girls.

## Molecular and Systemic Pathophysiology

The processus vaginalis is a tubular extension of the peritoneal sac that develops ventral to either the gubernaculum or round ligament. During the last few weeks of gestation or shortly thereafter, the layers of the processus vaginalis normally fuse together and obliterate the entrance to the inguinal canal. A hydrocele results from a failure of fusion of the processus vaginalis with accumulation of fluid inside the processus vaginalis. It has been hypothesized that calcitonin gene-related peptide (CGRP) induces an increased hepatocyte growth factor expression (HGF) [4]. HGF secreted by fibroblasts binds to the epithelial cells in the processus vaginalis to induce fusion of the processus vaginalis [4]. In a subset of patients, deficient endogenous CGRP may account for the patency of the processus vaginalis [4].

## Diagnostic Principles

A hydrocele can be distinguished clinically by its cystic nature, transillumination, and characteristic location. Ultrasonography may be useful in doubtful cases as well in the confirmation of an abdominoscrotal hydrocele.

## Therapeutic Principles

Most hydroceles will disappear by the end of the first year of life and surgery can be avoided within the first 2 years of life unless a hernia cannot be excluded [5]. A communicating hydrocele may need to be operated earlier [5]. A high ligation of the patent processus vaginalis should be performed and the fluid in the sac should be emptied [5]. Treatment of an abdominoscrotal hydrocele consists of complete excision of all components of the hydrocele sac to prevent recurrence [3].

# Hydrocephalus due to Stenosis of the Aqueduct of Sylvius

Shoichi Katsuragi
National Kikuchi Hospital, Kumamoto, Japan

## Synonyms

CRASH syndrome; HSAS

## Definition and Characteristics

HSAS is an X-linked recessive neurological disorder characterized by hydrocephalus, mental retardation, adducted thumbs, and spastic quadriplegia. HSAS is usually diagnosed at birth or antenatally by sonographic survey. Mutations in the gene encoding L1 cell adhesion molecule (L1CAM) are involved in HSAS [1]. Four X-linked neurological abnormalities with an overlapping clinical spectrum (HSAS, MASA syndrome, X-linked complicated spastic paraplegia type 1, and X-linked agenesis of the corpus callosum) were initially reported as distinct clinical entities, but can now be included in CRASH syndrome caused by the L1CAM gene mutations [2]. CRASH is an acronym derived from the five main clinical features as follows: *C*orpus callosum hypoplasia, mental *R*etardation, *A*dducted thumbs, *S*pastic paraplegia, and *H*ydrocephalus. Therefore, HSAS is one phenotype of CRASH syndrome in which hydrocephalus is the most dominant symptom.

## Prevalence

About 1–30,000 male births.

## Genes

L1 Cell Adhesion Molecule (L1CAM) gene located on chromosome Xq28.

## Molecular and Systemic Pathophysiology

L1CAM is a transmembrane glycoprotein, composed of 1,256 amino acids, belonging to the immunoglobulin superfamily. The protein has a motif of six repeating immunoglobulin domains followed by five repeating fibronectin type III-like domains, a single-pass transmembrane domain, and a cytoplasmic C-tail [3,4]. L1CAM is expressed on outgrowing axons and growth cones of post-mitotic nerve cells in the central nervous system and in the peripheral nervous system (PNS) and on Schwann cells in the PNS. L1CAM plays an important role in guidance of neurite outgrowth in development, neural cell migration, axon bundling, synaptogenesis, myelination, neuronal cell survival, and long-term potentiation.

The mutations are dispersed throughout the L1CAM gene and no hot spot has been identified. Mutations affecting the key residues in either the immunoglobulin or fibronectin type III-like domains were more likely to produce a phenotype with severe hydrocephalus, adducted thumbs, and life span less than 1 year compared with mutations affecting surface residues.

HSAS was first described by Bickers and Adams as a new clinical entity based on observations of a British family where male sibs died at birth from congenital hydrocephalus. The aquedutal stenosis or narrowing was initially assumed as the cause of hydrocephalus. However, a neuroradiological study showed patency of the aqueduct in 80% of the patients [5] and the developmental outcome was shown to be very poor in surgically treated survivors. Postmortem examinations did not always reveal obstruction or narrowing of the aqueduct. This evidence suggests that the pathogenesis of HSAS is not ventricular dilatation due to aqueduct stenosis. It is speculated that the compression of dilated ventricles might produce the aqueduct stenosis. Spastic quadriplegia and adducted thumbs found in most HSAS patients are considered to be caused by hypoplasia of the corticospinal tract.

## Diagnositic Principles

Detection of L1CAM gene mutations is essential for precise diagnosis in male patients with congenital hydrocephalus. Prenatal diagnosis is made by the identification of L1CAM mutations in the fetus by amniocentesis or chorionic villus sampling in families with HSAS.

## Therapeutic Principles

Gene therapy is not available. Pharmacological therapy is not available. Dietary therapy is not available. Developmental outcome after Shunt operation for hydrocephalus is poor.

## Hyper IgE Syndrome

Bodo Grimbacher[1], Cristina Woellner[1], Steven Holland[2]
[1]Department of Immunology and Molecular Pathology, Royal Free Hospital & University College Medical School, London, UK
[2]National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, USA

### Synonyms

Job syndrome; Hyper-IgE recurrent infection syndrome; Buckley syndrome; HIES

### Definition and Characteristics

Hyper-IgE syndrome (HIES, Mendelian Inheritance in Man #147060, #243700) is a primary immunodeficiency characterized by recurrent staphylococcal skin abscesses, pneumonias with pneumatocele formation, extreme elevations of serum IgE, and eosinophilia.

Although most of the cases are sporadic, an autosomal dominant and an autosomal recessive trait of inheritance have been described. The autosomal dominant form [1] shows distinct abnormalities of the connective tissue, skeleton, and dentition, whereas the autosomal recessive variant is characterized by an extreme hypereosinophilia, susceptibility to *molluscum contagiosum*, CNS involvement, a not well characterized T cell defect, the lack of pneumatocele-formation, and a high mortality [2].

### Prevalence

HIES is a very rare disease with an incidence of less than one in a million live-births. However, more than 200 cases have been reported in the literature.

### Genes

About 65% of HIES patients with an autosomal dominant phenotype were found to harbor heterozygous mutations in the Signal Transducer and Activator of Transcription 3 (STAT3; chromosome 17q21) [3,4] and one HIES patients with an autosomal recessive phenotype has been described to carry a homozygous mutation in the receptor associated tyrosine kinase Tyk2 (Chromosome 19p13) [5].

### Molecular and Systemic Pathophysiology

In 2006 Minegishi et al reported the first monogenetic defect in a single patient from consanguineous parents with clinical features of autosomal recessive HIES. The patient had a homozygous defect in the receptor-associated cytoplasmic tyrosine kinase *Tyk2*. Subsequently it has been shown that Tyk2 deficiency is

not a common cause of the autosomal recessive HIES [6]. This notion is supported by atypical features in the clinical history of the patient described by Minegishi et al, such as a BCG lymphadenitis and a non-typhi salmonella infection.

STAT3 is part of one of the JAK-STAT signaling pathways, which play a critical role in the signal transduction of cytokines from the cell surface into the nucleus. Cytokines bind to their specific receptors on the surface and prompt those to multimerise. Consequently, the receptor associated JAK-molecules cross-phosphorylate each other and then the respective receptor. This serves to recruit STATs and other signaling molecules. JAKs also phosphorylate and activate STATs, which, once phosphorylated, dissociate from the receptors, form dimers, translocate to the nucleus and enhance the expression of their target genes. Heterozygous mutations in the *STAT3*-gene do not totally abrogate the activity of the protein; however, theoretically, those mutations lead to the formation of 50% heterozygous STAT3 dimers, 25% of homozygous mutated and 25% of homozygous unaffected wild-type dimers, since mutant STAT proteins can still interact with wild-type STAT proteins; nevertheless both homozygous mutated and heterozygous STAT3 dimers in HIES patients will result in a faulty STAT3 function. Obviously, one unaffected allele and the existence of 25% of properly working STAT3 dimers cannot compensate the loss of function of the mutated STAT3 allele, but may prevent the patients from early embryonic death as observed in STAT3 knock-out mice.

Given the pivotal role of STAT3 in a broad range of signaling pathways including the IL-6-, IFN- and IL-2-signalling, its reduced activity may influence the development and functions of multiple organ systems, thereby resulting in the combined clinical manifestations in HIES. STAT3 has been shown to be critical for the differentiation of both osteoblasts and osteoclasts, and mice deficient for STAT3 in osteoblasts reveal an osteoporotic phenotype. This may point to the skeletal and dental abnormalities observed in HIES patients. Despite severe pneumonia or skin infections, HIES patients are often afebrile and feel well. This lack of classic inflammatory reactions in HIES patients may be explained by a defective signaling of proinflammatory cytokines including IL-6. At least in mice it is well known, that liver-specific inactivation of STAT3 leads to an impaired acute-phase response due a faulty IL-6 signaling.

STAT3 plays a vital role in the development of TH17 cells, which release IL-17, a cytokine boosting the host defense against extracellular bacteria, and IL-22, which stimulates cells of the skin and the respiratory systems to produce beta-defensins. It has been shown that STAT3-deficient HIES patients lack TH17 cells whereas STAT3 wild type HIES patients have reduced but still detectable numbers of IL-17 producing cells (Milner et al 2007). This defect in the TH17 cell development and IL-22 signaling may account for the increased susceptibility to bacterial infections of the skin and lung due to *S. aureus*.

So far, the causes of some of the clinical features such as the high palate and the elevated IgE levels in the patients are still unclear and remain to be elucidated.

To date no genotype-phenotype correlation has been identified.

## Diagnostic Principles

HIES is a mutisystemic disease and therefore difficult to diagnose. A group at the National Institutes of Health (NIH) defined the most widely used diagnostic approach in 1999 (Grimbacher et al 1999b). This NIH scoring system was used to assess HIES patients until recently because no definitive diagnostic test was available. Since, in 2007 mutations in STAT3 were shown to be cause of HIES this knowledge has been used to re-visit the scoring system and to develop diagnostic guidelines for HIES.

Based on data from a multicenter cohort, following diagnostic guidelines for *STAT3*-mutant HIES/Job's syndrome have been proposed:

- *Possible: IgE ≥1,000 IU/mL plus a weighted score of clinical features > 27.76 based on recurrent pneumonia, newborn rash, scoliosis, pathologic bone fractures, characteristic face, and high palate (see Table E4 in the Online Repository).*
- *Probable: Above plus lack of Th17 cells or a family history for definitive HIES.*
- *Definitive: Above plus a dominant-negative heterozygous mutation in STAT3.*

## Therapeutic Principles

Aggressive skin care and prompt treatment of infections are the main pillars of HIES management. Anti-Staphylococcal antibiotic treatment and antiseptic treatments, in association with topical moisturizing creams and topical steroids, are an essential part of management of abscesses, dermatitis, and eczema in HIES. Skin abscesses may require incision and drainage.

The role of prophylactic antibiotics has not been rigorously investigated in this setting, but there is general consensus in favor of their use.

The use of oral antifungals, such as the triazoles, is recommended for mucocutaneous candidiasis in HIES.

High-dose intravenous antibiotics for a prolonged course are required for eradication of infection and to prevent bronchopleural fistula formation and bronchiectasis. Empirical acute coverage should consider *S. aureus, H. influenzae*, and *S. pneumoniae*. The former two organisms account for the majority of acute infections. One of the typical features of HIES is that following the resolution of acute pneumonias pulmonary cysts form. These pneumatoceles then serve

as the focus for colonization with *pseudomonas aeruginosa, aspergillus* and other fungal species. These superinfections are the most difficult aspect of longterm management of HIES. Potential management strategies include prophylactic itraconazole or voriconazole, aerosolized colistin, or aerosolized aminoglycosides.

Lung abscesses may require thoracotomy for adequate drainage or resection. However, thoracotomy and lung resection are more difficult in HIES. Surgery often results in a need for very prolonged chest tube drainage, thoracoplasty, or pneumonectomy along with intensive parenteral antibiotic treatment. Therefore, pulmonary surgery in HIES should be performed at a center with experience with the disease where possible.

# Hyperaldosteronism, Primary

Christian A. Koch
Division of Endocrinology, Diabetes and Metabolism, University of Mississippi Medical Center, Jackson, MS, USA

## Synonyms

Conn's syndrome

## Definition and Characteristics

Normal or elevated aldosterone levels and decreased plasma renin activity levels (plasma aldosterone/renin activity ratio >30), leading commonly to hypertension, hypokalemia (only in about 50% of patients), and metabolic alkalosis. Overactivity of amiloride-sensitive sodium channels in the distal renal tubule and collecting duct of the kidney. Clinical hallmark is salt sensitivity, i.e. improvement by salt restriction and aggravation of hypertension by high-salt diet.

## Prevalence

Estimated to affect 8% of the hypertensive population. Familial hyperaldosteronism type I is estimated to affect 1% of all patients with hyperaldosteronism [1,2].

## Genes

In FH I, autosomal dominantly inherited chimeric gene defect in CYP11B1/CYPB2. In FH II, the responsible gene is still unknown, although it has recently been linked to 7p22 [3].

## Molecular and Systemic Pathophysiology

Usually, aldosterone secretion is mainly stimulated by hyperkalemia and angiotensin II. An increase of serum K of 0.1 mmol/L increases aldosterone by 35%. Excess aldosterone secretion leads to increased renal tubular sodium reabsorption with water retention keeping the serum sodium concentration normal. The electrochemical gradient generated by sodium retention causes K and H loss in the distal tubule. Ammonia synthesis by the kidney increases in parallel with hypokalemia, contributing to alkalosis. Inappropriate urinary K excretion continues. Plasma renin activity is suppressed. In FH I, a hybrid gene leads to aldosterone synthase activity in the zona fasciculata which responds to ACTH. Thus, maneuvers leading to ACTH stimulation (e.g. orthostasis) will subsequently cause aldosterone production/secretion. Such production/excretion is much higher than the one seen with ordinary aldosterone-producing adenomas.

Sporadic aldosterone-producing adrenal adenoma, aldosterone-producing adrenocortical carcinoma, unilateral adrenal cortex hyperplasia, bilateral zona glomerulosa hyperplasia, familial hyperaldosteronism type I and type II

(FH I, FH II). 11beta – hydroxysteroid dehydrogenase deficiency (inherited and acquired) do lead to mineralocorticoid excess but not to hyperaldosteronism per se and thus will not be discussed here.

## Diagnostic Principles

Unsuppressible aldosterone levels and low plasma renin activity after intravenous saline (overnight fast, 2 l normal saline over 4 h: positive test, if plasma aldosterone is >10 ng/dl) or oral salt loading (4 days high salt diet, then 24 h urine collection: if urinary aldosterone is >10 mcg when urinary sodium is >200 mEq, unsuppressibility of aldosterone is documented). To clinically distinguish hyperplasia from unilateral adenoma, imaging with computed tomography and MRI are helpful but adrenal venous sampling with cosyntropin infusion often is essential: cutoff for unilateral adenoma >4 "cortisol-corrected" aldosterone ratio (adenoma side aldosterone/cortisol: normal adrenal aldosterone/cortisol); cutoff for bilateral hyperplasia <3 "cortisol-corrected" aldosterone ratio (high-side aldosterone/cortisol: low-side aldosterone/cortisol). In FH I or glucocorticoid-remediable aldosteronism, urinary 18-oxocortisol and 18-hydroxycortisol are 30-fold higher than in sporadic aldosteronomas [4].

The diagnosis of FH I can be confirmed by testing for the hybrid gene on chromosome 8 (i.e. by Southern Blot) [5].

Dexamethasone suppression testing 0.5 mg q6h for 48 h results in a fall in aldosterone to nearly undetectable levels (below 4 ng/dl) in contrast to adenomas.

## Therapeutic Principles

Adrenalectomy or adenomectomy for adenomas, adrenal carcinomas, and in rare circumstances for unilateral hyperplasia. In cases of bilateral hyperplasia, medical treatment with glucocorticoids in the smallest effective dose to suppress aldosterone. Spironolactone 25–50 mg bid upward, amiloride 5–15 mg bid, diet with <2 g Na/day.

# Hyperaldosteronism, Secondary

Christian A. Koch
Division of Endocrinology, University of Mississippi Medical Center, Jackson, MS, USA

## Synonyms

Secondary aldosterone excess; Secondary aldosteronism

## Definition and Characteristics

Elevated plasma aldosterone and renin levels in response to disease states associated with reduced effective circulating blood volume, decreased hepatic aldosterone meta-/catabolism, or renin-secreting tumors, renal artery stenosis, malignant hypertension, salt-wasting nephropathies, Bartter's or ►Gitelman's syndrome.

Etiology includes congestive heart failure, cirrhosis of the liver, nephrotic syndrome and other hypoalbuminemic states, defective renal tubular function due to mutations in genes coding for electrolyte transport (for instance Na-K-2Cl cotransporter).

## Prevalence

1.2 per million for Bartter's and Gitelman's syndrome; otherwise depending on the prevalence of congestive heart failure, nephrotic syndrome, (over)use of diuretics, (over)use of laxatives, renovascular hypertension/renal artery stenosis, liver cirrhosis.

## Genes

In ►Bartter syndrome I-V, missense or frameshift mutations in the renal Na-K-2Cl cotransporter gene, potassium channel genes for ROMK and RACTK, chloride channel gene CLCKNKB, at chromosomes 15 and 1p; in Gitelman's syndrome, mutations in the thiazide sensitive renal Na-Cl cotransporter gene at 16q13; point mutation in the angiotensin II type 1 receptor.

## Molecular and Systemic Pathophysiology

Usually, aldosterone secretion is mainly stimulated by hyperkalemia and angiotensin II. An increase of serum K of 0.1 mmol/L increases aldosterone by 35%. Excess aldosterone secretion leads to increased renal tubular sodium reabsorption with water retention. In states with low effective circulating volume (due to low oncotic pressure), renin increases and subsequently aldosterone, without causing hypertension. Renin stimulation or production by a tumor or renal artery stenosis, however, leads to hypertension. In Bartter's and Gitelman's

syndrome, hypertension is uncommon. Defects in the renal tubular reabsorption system may lead to failure of sodium and chloride absorption with subsequent water loss, stimulation of the RAAS, and other abnormalities such as hypo- or hypercalciuria and magnesium loss (depending on the location of the renal tubular defect).

### Diagnostic Principles

After discontinuation of possible interfering medications such as ACE-inhibitors and diuretics, measurement of plasma aldosterone, renin, potassium, chloride, magnesium, and sodium concentrations, as well as urinary chloride, calcium, prostaglandin (hyperprostaglandinuria in Bartter's). Depending on the level of clinical suspicion based on physical examination and history, initiation of imaging studies including abdominal CT/MRI, ultrasonography, or renal artery angiography. In children, growth delay and impaired intellectual development as well as nephrolithiasis and nephrocalcinosis due to hypercalciuria may point to the diagnosis Bartter's syndrome which begins in childhood. Ionized calcium is decreased, serum parathyroid hormone is increased. In Gitelman's syndrome, hypocalciuria is common, ionized calcium is normal, and serum parathyroid hormone decreased, possibly because of hypomagnesemia. Patients with Bartter's or Gitelman's syndrome are usually normotensive.

### Therapeutic Principles

Reversal or inhibition of the underlying metabolic and electrolyte disturbance; aldosterone antagonists such as spironolactone, potassium-sparing diuretics such as thiazide diuretics (Gitelman's), potassium and magnesium supplementation, nonsteroidal antiinflammatory drugs, treatment of underlying problem such as heart failure, hypoalbuminemia, renal artery stenosis (angioplasty), renin-secreting tumor (extirpation), low sodium diet.

## Hyperammonemia

Michael T. Geraghty
Children's Hospital of Eastern Ontario, Ottawa, ON, Canada

H

### Synonyms

Urea cycle disorders; UCD (include deficiencies of the following enzymes: *N*-acetylglutamate synthetase; NAGS; Carbamyl phosphate synthetase; CPS; Ornithine transcarbamylase; OTC; Argininosuccinic acid synthetase; ASS; Argininosuccinic acid lyase (ASAL) and arginase (ARG1) and deficiencies of two mitochondrial membrane transporters: Citrin (SLC25A13) and ORNT1 (SLC25A15))

### Definition and Characteristics

Normal plasma ammonium levels are <35 μmol/L. Plasma ammonium levels of >500 μmol/L are associated with coma and death. Hyperammonemia can result primarily from urea cycle disorders (UCD), but also secondarily from certain dibasic acidurias, organic acidemias, fatty acid oxidation defects, lactic acidosis, viral disease, liver disease, porto-systemic shunts, valproic acid and chemotherapy.

### Prevalence

Data derived from the NeoGen screening program (www.neogenscreening.com) suggest an incidence of Citrullinemia (ASS deficiency) of 1/186,000 and 1/700,000 for argininosuccinic aciduria (ASAL deficiency). While prevalence is unknown an overall incidence of 1/8,200 for UCD has been estimated.

### Genes

With the exception of NAGS the genes encoding all of the enzymes and transporters have been identified, mapped and characterized (www3.ncbi.nlm.nih.gov/Omim/). Clinical mutation analysis is available for many of these disorders (www.geneclinics.org).

### Molecular and Systemic Pathophysiology

Pathogenic mutations have been described for all of the UCD except NAGS deficiency. Ammonium appears to be the major cause of acute encephalopathy. Several studies strongly suggest that this is mediated by excess glutamine synthesis in perivascular astrocytes leading to an increased osmotic effect and

| Enzyme/transporter | Map (OMIM) |

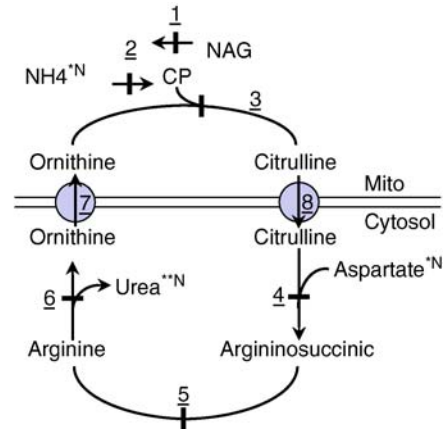
| 6 Arginase | 6q23 (207800) |
| 7 Mitochondrial ornithine transporter (ORNT1) | 13q14 (238970) |
| 8 Citrin (SLC25A13) | 7q21.3 (603471) |



**Hyperammonemia. Figure 1** The urea cycle.

cerebral edema. High levels of citrulline, ASA and arginine and also deficiency of arginine may play a role chronically in the poor neurological outcome of these patients. It has been suggested that nitric oxide production is adversely affected by these changes. Finally it has been suggested that deficiency of oxaloacetate may account for liver disease seen in ASAL deficiency (Fig. 1).

## Diagnostic Principles

UCD can present in the neonatal period with severe hyperammonemia, encephalopathy and respiratory alkalosis. Late onset is seen at all ages with a variety of presentations including recurrent encephalopathy, developmental delay, recurrent vomiting, failure to thrive and protein aversion. Episodes are often precipitated by metabolic stress. Arginase present with a progressive spastic diplegia associated with other neurological findings. Citrin deficiency is usually of adult onset but may present as intrahepatic cholestasis in infancy. When hyperammonemia is suspected initial investigations should include plasma ammonium, blood gases, electrolytes and liver function tests, plasma amino acids, plasma carnitine and acylcarnitine profile and urine organic acids and urine orotic acid. UCD are associated with respiratory alkalosis and the precise site of the enzymatic blockage can be inferred from the amino acid pattern and the presence or absence of orotic aciduria. Metabolic acidosis +/− lactic acidosis, increased anion gap and hypoglycemia are generally not found in UCD and indicate possible disorders of organic acid, fatty acid or energy metabolism.

## Therapeutic Principles

Therapy consists of stopping protein intake, preventing catabolism and correcting fluid and acid-base disturbances. IV arginine should be given to correct deficiency and may correct hyperammonemia in ASAL deficiency. IV sodium benzoate and sodium phenylacetate allow alternate waste nitrogen excretion and may restore euammonemia especially in intercurrent disease. Hemodialysis is the treatment of choice for acute severe hyperammonemia and if not responding to the above measures. Chronic management of patients with UCD requires a low protein diet perhaps supplemented with essential amino acids. Oral citrulline (CPS, OTC) or arginine (ASS, ASAL) are needed. Oral sodium benzoate or sodium phenylbutyrate provide an alternate pathway for waste nitrogen excretion. Liver transplantation has been successfully reported in CPS, OTC, ASS, ASAL deficiencies but may not correct all the metabolic disturbances or reverse neurological abnormalities. Comprehensive long-term reports are needed for this intervention.

## Synonyms

Jaundice

## Definition and Characteristics

Yellow discoloration of skin and sclera. In jaundice due to cholestasis, patients produce dark urine and light-colored stools. In jaundice due to hemolysis, stool color is normal.

## Prevalence

Jaundice is a common symptom of liver disease and also occurs in diseases of the bile ducts and pancreas. It can be the result of severe hemolysis. Neonatal jaundice is very common.

Jaundice because of ▶Gilbert's syndrome is common (about 6% of the population). Jaundice due to ▶Crigler Najjar syndrome is rare (less than one per million).

## Genes

In Crigler Najjar syndrome types I and II, UGT1A1 encoded by the UGT1 gene on chromosome 2q37 carries mutations; in case of Gilbert's syndrome the defect is in the TATA box of the promoter region of UGT1A1, it contains 7TA's in stead of the usual 6TA repeats. In Dubin-Johnson syndrome the defect lies in the ABCC2/MRP2 gene on chromosome 10q24.

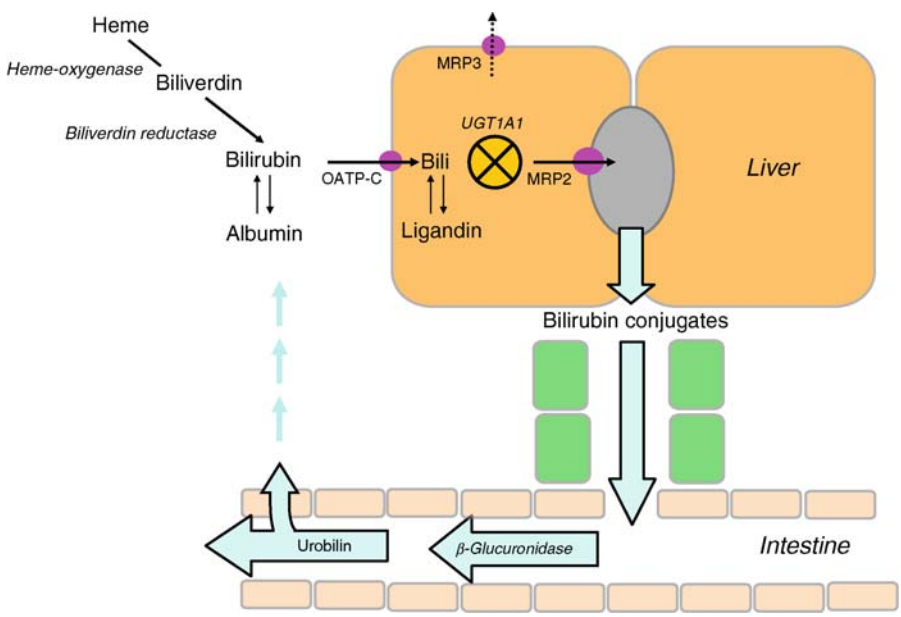
## Molecular and Systemic Pathophysiology

Hyperbilirubinemia is a symptom rather than a disease on its own. A basal understanding of liver physiology is needed to explain the causes of jaundice. Bilirubin is produced from heme in senescent erythrocytes. In the spleen heme is transformed to biliverdin by the enzyme heme-oxygenase and biliverdin is rapidly converted to bilirubin by biliverdin reductase. Unconjugated bilirubin is taken up by the liver (Fig. 1).

In hemolysis there is an overproduction of bilirubin and if this occurs to a degree that exceeds the capacity of the liver, jaundice ensues. In neonates the various transport and conjugation systems are not fully developed. Therefore the physiological hemolysis in neonates often leads to more or less severe jaundice that lasts for a few days up to a week. During hemolysis in adults serum bilirubin level does not exceed 60–70 micromol/l (3.5–4.0 mg/dl) unless hepatic bilirubin clearance is impaired [1].

The sinusoidal membrane contains a transport protein, in humans called OATP-2/OATP-C (organic anion transport protein) that is responsible for the hepatic uptake of bilirubin [2]. In the circulation bilirubin is firmly bound to albumin. In the liver, bilirubin is efficiently removed from its albumin bond. It is the free unbound bilirubin that is taken up in the liver. The exact mechanism of hepatic bilirubin uptake is incompletely understood.

In the endoplasmic reticulum of hepatocytes, unconjugated bilirubin is converted predominantly to bilirubin diglucuronide by the enzyme UDPglucuronosyltransferase UGT1A1 [3]. Gilbert's syndrome and Crigler Najar



**Hyperbilirubinemia. Figure 1** Heme is converted to biliverdin and this is changed to bilirubin. This mainly occurs in the spleen. Bilirubin in the circulation is bound to albumin. In the liver bilirubin is taken up into the hepatocyte, albumin stays in the circulation. OATP-C is the uptake carrier responsible for the hepatic uptake of bilirubin. In the liver bilirubin is bound to ligandin and is converted to bilirubin mono- and diglucuronide by the enzyme UDPglucuronosyltransferase 1A1. Bilirubin mono- and diglucuronide are transported into the bile by MRP2 (ABCC2) a member of the ABC transporter superfamily. Bilirubin conjugates is excreted with the bile into the intestine where they are subject to further bacterial degradation. Urobilin is reabsorbed into the circulation and is excreted by the urine.

syndrome result from partial or complete genetic defects of conjugation. After conjugation, bilirubin-glucuronides are secreted into the bile. Secretion from hepatocyte to bile is mediated by an ATP-dependent transport protein called MRP2 (Multidrug Resistance-associated Protein–2) [4,5]. ►Dubin-Johnson syndrome results from a genetic defect of MRP2.

Most causes of jaundice are due to post- or intrahepatic bile secretion problems. Possible causes are bile duct obstruction due to stones or tumors, viral or autoimmune hepatitis, drug-induced cholestasis, advanced stages of primary biliary cirrhosis and primary sclerosing cholangitis and numerous other genetic or acquired diseases. When bilirubin cannot be secreted from hepatocyte to bile, it has to exit the hepatocyte via the sinusoidal membrane and is returned to the blood. There is an interesting regulatory mechanism at work under these conditions: MRP3, a transport protein in the sinusoidal membrane that is lowly expressed under normal conditions, is greatly up-regulated during cholestasis or other causes of reduced bilirubin clearance. This protein helps the transport of bilirubin conjugates across the sinusoidal membrane. During cholestasis, tubular MRP2 expression in the kidneys is maintained and this protein actively helps the removal of conjugated bilirubin via the urine.

### Diagnostic Principles

Serum conjugated and unconjugated bilirubin can be measured by various laboratory techniques. Post-hepatic obstruction can be diagnosed by endoscopy and retrograde imaging of the bile ducts, magnetic resonance, CT-scanning or ultrasonography.

For intrahepatic causes of jaundice often a liver biopsy is required.

Hemolysis, Gilbert's syndrome and Crigler Najjar syndrome are characterized by unconjugated hyperbilirubinemia. Dubin-Johnson syndrome, diseases of the liver and the bile ducts by conjugated hyperbilirubinemia wherein the ratio of conjugated/unconjugated bilirubin differs with the highest ratio in bile duct obstruction.

### Therapeutic Principles

Therapy depends on the cause of the jaundice.

## Hyperbradykininism

►Orthostatic Hypotensive Disorder, Familial, Streeten Type

## Hypercalcemia

Robert P. Whitehead
Division of Hematology/Oncology, University of Texas Medical Branch, Galveston, TX, USA

### Synonyms

Elevated serum calcium; Elevated blood ionized calcium

### Definition and Characteristics

Increased levels of total serum calcium above the normal range of 9–10.5 mg/dL when corrected for any abnormal level of serum albumin, (although limits of normal can vary depending upon the laboratory), or increased levels of blood ionized calcium above the normal range of 4.5–5.6 mg/dL [1]. Patients may have multiple manifestations of illness depending upon the calcium level, but may include altered mental status, fatigue, nausea, anorexia, constipation, polyuria, shortened QT interval, or cardiac arrhythmias. Severely elevated calcium levels may lead to coma or cardiac arrest. Lower levels that persist for long periods may lead to kidney stones, peptic ulcers and bone resorption. The most common causes are primary hyperparathyroidism or malignancy, but other causes include therapy with lithium, increased vitamin D or A intake, sarcoidosis or other granulomatous diseases, hyperthyroidism, thiazide diuretics, immobilization, or renal failure [2]. Other more rare causes of hypercalcemia are listed in reference [3].

## Prevalence

The most common cause, hyperparathyroidism has an estimated prevalence of 1%. Many of these cases may be unrecognized and patients are asymptomatic. Hypercalcemia may occur in up to 30% of cases of malignancy at some time during the course of the disease. Malignant diseases are the second most common cause of hypercalcemia [2,4].

## Genes

The normal parathyroid hormone gene is located on the short arm of chromosome 11. Several genetic defects can result in hypercalcemia. Increased secretion of parathyroid hormone in primary hyperparathyroidism is due to a single abnormal gland in 80% of the cases, usually a benign adenoma but rarely a parathyroid carcinoma. Hereditary hyperparathyroidism may be part of a multiple endocrine neoplasia (MEN) syndrome with tumors of the pituitary and pancreas (Type I) or pheochromocytoma and medullary carcinoma of the thyroid (Type II A). The MEN syndromes are inherited in an autosomal dominant manner. In MEN I, there is a mutation in the MENIN gene locus on chromosome 11q13. The MENIN locus on chromosome 11 is deleted in about 20% of cases of sporadic parathyroid adenomas also. In 40% of cases of sporadic parathyroid adenomas, a mutation occurs in a gene mapped to chromosome 1p, and a gene mapped to chromosome Xp11is involved in patients with secondary hyperparathyroidism from renal failure who develop monoclonal outgrowths from hyperplastic glands. The RB gene, a known tumor-suppressor gene on chromosome 13q14 shows an allelic deletion in parathyroid carcinomas and 10% of parathyroid adenomas. The chromosome 1q21-q31 region is involved in the rare hyperparathyroidism jaw tumor syndrome with benign jaw tumors and parathyroid adenoma or carcinoma, and the syndrome of familial isolated primary hyperparathyroidism which can be caused by parathyroid carcinoma. In up to 15% of parathyroid adenomas, there may be a reciprocal translocation involving chromosome 11 that places the PTH gene promoter upstream of a cyclin D protein, PRAD-1 that plays a role in normal cell division. In MEN II, a mutated protooncogene RET coding for a tyrosine kinase-type receptor leads to constitutive activity of the receptor. In hypercalcemia of malignancy due to tumors other than those of the parathyroid glands, parathyroid hormone-related peptide (PTHrP) produced by the tumor cells is the most common cause. The gene for PTHrP is different from that of parathyroid hormone and is located on the short arm of chromosome 12 [2,5].

## Molecular and Systemic Pathophysiology

Serum calcium levels are normally maintained within a narrow range of 9–10.5 mg/dL by a balance between absorption of ingested calcium from the gut as well as secretion into the intestinal lumen, deposition and release of calcium from bone, and renal excretion of calcium. About 50% of calcium in the blood is ionized, the remainder is bound to negatively charged proteins, predominantly albumin and immunoglobulins, but also phosphate, citrate, sulfate or other anions. The ionized calcium concentration in the blood is normally controlled by adjusting the rates of the movement of calcium across the intestine and kidney epithelial cells. These adjustments are mediated mainly by changes in the blood levels of PTH and $1,25(OH)_2D$. PTH is an 84 amino acid peptide. In hypocalcemia, predominantly ionized calcium interacts with a calcium sensor, a G protein coupled receptor which is present in the parathyroid glands, brain, kidney and other sites. This results in the release of preformed PTH but also causes increased transcription of PTH messenger RNA, and chronically can cause cell division leading to gland hyperplasia. PTH is broken down in the liver and kidney at a rate that does not seem to be related to calcium levels. Both PTH and parathyroid hormone-related protein (PTHrP), the hormone responsible for most of the cases of hypercalcemia of malignancy, bind to a 500 amino acid receptor, the PTH/PTHrP receptor, also known as PTH-1 receptor. After hormone binds to the extracellular region of the receptor, intracellular receptor segments bind G protein subunits and stimulate second messengers resulting in tissue specific cellular responses. $1,25(OH)_2D$ is synthesized in the kidney from metabolites of vitamin D by the enzyme 25(OH)D-1α-hydroxylase in the proximal convoluted tubule cells. This enzyme is stimulated by PTH and inhibited by calcium and its own product, $1,25(OH)_2D$. The effects of $1,25(OH)_2D$ are mediated by binding to the vitamin D receptor, a nuclear receptor. The vitamin D receptor binds to DNA sequences as a heterodimer with the retinoid X receptor, recruiting coactivators that result in target gene expression. It can cause repression of target genes by interfering with activating transcription factors or by recruiting proteins that cause transcriptional repression. 1, $25(OH)_2D$ through the vitamin D receptor induces genes in the small intestine for calcium binding proteins and calcium transporters of the intestinal epithelia cells increasing the efficiency of intestinal calcium absorption. The vitamin D receptor can inhibit proliferation of parathyroid gland cells and suppress transcription of the PTH gene. The vitamin D receptor can regulate the expression of genes in osteoblasts and 1,25 $(OH)_2D$ and PTH can induce the expression of receptor activator of nuclear factor κB (RANK) ligand which can increase osteoclast activity and promote osteoclast differentiation. When calcium intake is not enough to replace obligate losses, increased blood levels of PTH and 1, $25(OH)_2D$ activate osteoclast bone resorption to maintain normal levels [2,6].

## Diagnostic Principles

When high serum calcium levels are found, it is necessary to be sure it is not just a false positive laboratory test but true hypercalcemia. False positive tests occur from hemoconcentration or elevation in serum proteins. When true hypercalcemia is confirmed, it is important to determine the underlying cause. Some are listed above in the characteristics section and in reference 2. The two most common causes are primary hyperparathyroidism and hypercalcemia of malignancy. An elevated immunoreactive PTH level establishes a diagnosis of primary hyperparathyroidism. Most of these patients are asymptomatic with relatively low levels of elevated calcium. Serum phosphate is usually low but may be normal. In hypercalcemia of malignancy, often symptoms of the tumor are present. Most commonly, the tumor secretes PTHrP and serum levels can be measured by immunoassay, confirming the diagnosis. In normal individuals, levels of PTHrP are usually undetectable. Direct bone invasion by tumor and activation of osteoclasts by tumor secretion of interleukin 1 or tumor necrosis factor may also cause hypercalcemia in patients with malignancies [2].

## Therapeutic Principles

In cases of hyperparathyroidism, where calcium levels are severely elevated, surgical resection of the abnormal parathyroid gland is required. In asymptomatic hyperparathyroidism, the consensus is that for patients less than 50 years of age or who are unlikely to have consistent long term follow-up, surgery should be done. Patients over age 50 who meet other criteria (listed in reference 2) may be closely followed and undergo surgery if further indications develop. In hypercalcemia of malignancy, treatment of the malignancy should be done whenever possible. For treating severe hypercalcemia, hydration with saline and forced diuresis with a loop diuretic should be done. Treatment with a biphosphonate which inhibits osteoclast bone resorption is usually helpful for chronic treatment. Treatment with calcitonin can produce rapid lowering of calcium over a period of hours in a symptomatic patient [2].

# Hypercalcemia, Familial Hypocalciuric

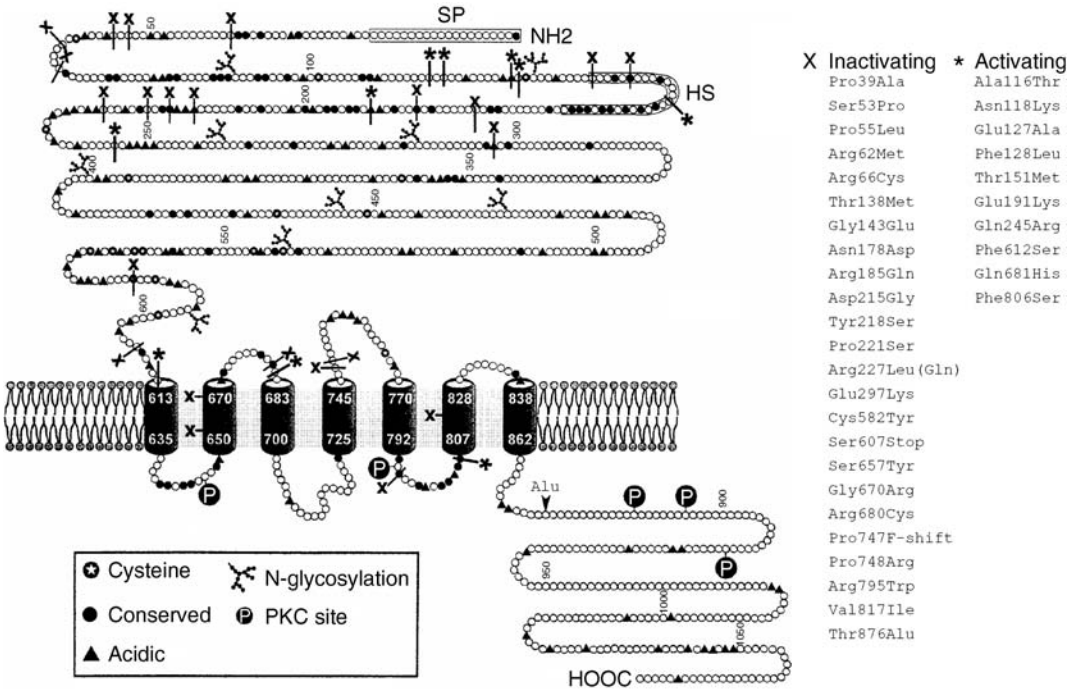
Edward M. Brown, Mei Bai
Division of Endocrinology, Diabetes and Hypertension, Brigham and Women's Hospital, Boston, MA, USA

## Synonyms

FHH; Familial benign hypocalciuric hypercalcemia, FBHH; Familial benign hypercalcemia; FBH

## Definition and Characteristics

FHH is an autosomal dominant disorder caused, in most cases, by heterozygous inactivating mutations in the gene encoding the extracellular calcium-sensing receptor (CaR or CaSR) (Fig. 1) [1]. It is a generally benign condition in which the system governing extracellular calcium homeostasis is reset upward (see below), producing mild to moderate hypercalcemia (i.e., 2.6–2.9 mmol/L) accompanied by absolute or relative (e.g., inappropriately normal in the setting of hypercalcemia) hypocalciuria [2]. Other biochemical findings include generally normal levels of serum PTH and phosphate, and serum magnesium concentrations that are in the upper part of the normal range or are mildly elevated. Bone mineral density is usually normal, although markers of bone turnover may be modestly elevated. Persons with this condition are often asymptomatic and exhibit none of the usual signs and symptoms of hypercalcemia, such as mental clouding, gastrointestinal complaints, kidney disorders (e.g., stones) and skeletal complications (i.e. bone loss or fractures). Occasional families, however, exhibit more substantially elevated serum calcium concentrations (e.g., 3.0–3.5 mmol/L), and hypercalciuria and renal stone disease has been described in one family. Thus there is some phenotypic heterogeneity in this condition. Neonatal severe hyperparathyroidism (NSHPT), in contrast, is a much more severe disorder, which can be fatal in its most severe forms if untreated and is the clinical expression of homozygous or compound heterozygous inactivating mutations of the CaSR gene. NSHPT presents in the neonatal period as severe hypercalcemia (viz., 3.75–6.25 mmol/L) accompanied by marked biochemical hyperparathyroidism and hyperparathyroid bone disease, which can cause multiple fractures and resultant skeletal deformities. Occasional patients homozygous for inactivating



**Hypercalcemia, Familial Hypocalciuric. Figure 1** Schematic view of the structure of the CaR, showing the large extracellular aminoterminal domain, the seven membrane spanning helices and the cytoplasmic carboxyterminus. SP refers to signal peptide and HS to hydrophobic segment. Also illustrated are the locations of representative FHH mutations, which are indicated by X. * denotes activating mutations, which produce a hypocalcemic disorder, autosomal dominant hypoparathyroidism, in which hypocalcemia is accompanied by low-normal or frankly low PTH levels and relative or absolute hypercalciuria (for additional details, see [4,5]).

mutations of the CaR have presented in a largely asymptomatic state in adulthood, apparently because the functional defect in the mutant CaR was not severe enough to cause overt NSHPT. Some infants present with hyperparathyroid bone disease but less severe hypercalcemia (2.75–3.0 mmol/L) a condition that has been termed neonatal hyperparathyroidism (NHPT). In several cases, these infants have harbored heterozygous inactivating CaR mutations; the factors causing some newborns heterozygous for inactivating CaR mutations to present with FHH and some with NHPT are not fully understood, but in some cases the mutant CaR may exert a dominant negative action on the wild type CaR present in wild type-mutant heterodimers, since the CaR functions as a dimer (see below).

## Prevalence

Although precise estimates are unavailable, FHH is thought to have a prevalence about 100-fold lower than that of the more common disorder, primary hyperparathyroidism [2], which is caused by mutations in genes other than the CaR, which in several cases have been shown to activate oncogenes or to inactivate tumor suppressor genes. Primary hyperparathyroidism has a prevalence on the order of 1:1,000, suggesting that the prevalence of FHH is about 1:100,000.

## Genes

The CaR gene (band q21–24) is the major locus for FHH. The Mendelian in Man nomenclature refers to this locus as HHC1. In single families, a condition phenotypically similar to FHH has been associated with two currently unknown genes on the short and long arms of chromosome 19 (19p13.3 and 19q13, respectively). These latter two loci are referred to as HHC2 and HHC3, respectively. Well over a hundred inactivating mutations of the CaR gene have been described, including missense, splice site, deletion, insertion, and truncation mutations (for an up to date summary, see http://www.casrdb.mcgill.ca/). These mutations reduce the receptor's activity by interfering with its biosynthesis and cell surface expression, reducing its affinity for $Ca^{2+}_o$ and/or interfering with its signal transduction. In addition to the reduction in CaR signaling in FHH resulting from the loss of one normal CaR allele, some mutant receptors exert a dominant negative action on the normal CaR when present within wild type-mutant heterodimers, thereby likely contributing to the more severe phenotype observed in some FHH kindreds, as noted above.

## Molecular and Systemic Pathophysiology

The CaR is a G protein-coupled receptor expressed in the parathyroid glands, kidney and various other

tissues whose principal function is to set the level of the blood calcium concentration ($Ca^{2+}_o$) at its normal level (Fig. 1) [3]. It functions as a disulfide-linked dimer and regulates a variety of signaling pathways, including activating phospholipases $A_2$, C and D, various mitogen activated protein kinases (MAPK) (ERK1/2, p38 and JNK) and phosphoinositide-3 and -4 kinases, and inhibiting adenylate cyclase. It plays key roles in maintaining the near constancy of $Ca^{2+}_o$ by sensing perturbations in the level of $Ca^{2+}_o$ and producing changes in parathyroid and kidney function designed to normalize the blood calcium concentration. For example, a reduction in $Ca^{2+}_o$ increases PTH secretion, which stimulates the release of calcium from bone, reduces urinary calcium excretion, and enhances renal synthesis of the active form of vitamin D (1,25-dihydroxyvitamin $D_3$), thereby increasing gastrointestinal absorption of calcium. In addition to the indirect, PTH mediated action of the change in $Ca^{2+}_o$ to reduce calcium excretion in the kidney, calcium receptors in the kidney directly modulate tubular reabsorption of calcium – increasing it when $Ca^{2+}_o$ is low and reducing it when $Ca^{2+}_o$ is high. The loss of one allele of the CaR in FHH renders the parathyroid glands and kidneys mildly to moderately resistant to the usual effects of $Ca^{2+}_o$, thereby resetting the level of serum calcium upward and that of urine calcium downward. The mildly elevated level of $Ca^{2+}_o$ combined with the low urinary calcium excretion and generally normal level of PTH spares individuals with FHH the renal and skeletal complications of hypercalcemia and hyperparathyroidism. In NSHPT, in contrast, the lack of any normal CaRs leads to severe resistance of parathyroid and kidney to $Ca^{2+}_o$ resulting in marked parathyroid enlargement, very high levels of serum calcium and PTH and often severe hyperparathyroid bone disease.

## Diagnostic Principles

In most cases the diagnosis of FHH can be established by documenting the presence of autosomal dominant inheritance of mild, PTH-dependent hypercalcemia in an asymptomatic individual with relative or absolute hypocalciuria (a calcium to creatinine clearance ratio of <0.01). If needed, DNA sequencing can be carried out to document the presence of mutations in the CaR gene, which are present in the coding region in about two-third of cases.

## Therapeutic Principles

The lack of symptoms and the generally benign clinical course of patients with FHH obviates the need for parathyroid surgery in the great majority of persons with this condition, who can simply be followed expectantly. In contrast, in NSHPT due to homozygous or compound heterozygous mutations in the CaR gene, total parathyroidectomy is recommended if aggressive medical management does not improve the patient's condition substantially. The less severe neonatal hyperparathyroidism that can occur in occasional infants with FHH does not, in most cases, require surgery but can be managed medically by ensuring adequate hydration and, if needed, administering a bisphosphonate to reduce bone resorption. These patients often revert over time to a clinical picture of FHH.

# Hypercalcemia of Malignancy

T. John Martin
St. Vincent's Institute of Medical Research, Melbourne, VIC, Australia

## Definition and Characteristics

Hypercalcemia occurring in patients with cancer, whether solid tumors or with or without bone metastasis, or hematological malignancies. Clinical features consist of thirst and polyuria, nausea and anorexia, constipation, mental confusion, which can lead to stupor and coma in severe states. Symptoms in cases of mild hypercalcemia can resemble those of the underlying condition and its treatment, so awareness of this possible complication is important. Hypercalcemia in malignancies is often progressive, and can be subject to rapid deterioration with provocations such as restricted fluid intake, fluid loss through vomiting or diarrhea, or intercurrent infections or treatment-related events. Hypercalcemia can occur in patients with cancer without evident bone metastasis, the "humoral hypercalcemia of malignancy," in those with lytic bone metastasis from solid cancers, or in some hematological malignancies.

## Prevalence

Patients with cancer provide the commonest source of hypercalcemia in a general hospital population. The annual incidence of hypercalcemia of malignancy in the entire population is 150 per million per year, with all causes of hypercalcemia at 250 per million per year. Hypercalcemia is not distributed evenly throughout the cancer population. Primary cancers of lung, breast, head and neck, kidney and ovary have a higher incidence than other cancers.

The humoral hypercalcemia of malignancy (HHM) syndrome is most commonly associated with squamous cell cancers of the lung, head and neck and esophagus, as well as with renal cortical carcinoma. Hypercalcemia occurs in 30–40% of patients with breast cancer at some stage of the disease, usually in association with bone metastases. Up to 1/3 of patients with multiple myeloma develop hypercalcemia, it is common in adult T cell leukemia/lymphoma, and occurs sporadically in those with Hodgkin's and non-Hodgkin's lymphoma.

## Molecular and Systemic Pathophysiology

The term HHM describes those patients with cancers (epithelial, renal cortical carcinoma etc) and not necessarily with bone metastases, in whom the blood calcium is elevated, phosphorus decreased and nephrogenous cAMP is increased, often with mild hypokalemic hyperchloremic alkalosis. It is due to the production by those cancers of parathyroid hormone-related protein (PTHrP) which acts generally upon the skeleton to promote osteoclast formation and bone resorption and upon the kidney to decrease calcium and phosphorus excretion and increase cAMP formation and excretion. In some of these patients tumors might also produce other bone-resorbing cytokines (e.g. IL-6, IL-1) that add to the effects of PTHrP upon the skeleton.

In 80–90% of hypercalcemic patients with unselected solid tumors, irrespective of whether bone metastases are present, there is evidence of an underlying humoral mechanism. Hypercalcemia in association with bone metastasis most commonly occurs in patients with breast cancer and lytic bone metastases, but the extent of metastatic bone disease correlates poorly with both the occurrence and degree of hypercalcemia. In two thirds of hypercalcemic breast cancer patients with bone metastases, plasma PTHrP levels are elevated. In the case of breast cancer, PTHrP production might also contribute to the ability of those cancers to grow as bone metastases. There is pre-clinical and clinical evidence in support of this, but PTHrP is the most extensively studied of the bone-resorbing cytokines in this process, and other factors could contribute also, such as IL-6, IL-11, IL-1, TNFα. Clearly the ability of tumors to grow as metastases in bone depends on their ability to promote osteoclast formation locally and thereby allow the tumor to advance.

Hypercalcemia occurs in approximately one third of patients with multiple myeloma, with the lytic lesions in that disease showing active osteoclasts in the areas near myeloma cells. Several cytokines can contribute to the process as plasma cell products, among them IL-1, TNFβ, IL-6 and PTHrP. Recent evidence shows that RANK ligand (RANKL) is produced by myeloma cells, and could provide for the direct stimulation of osteoclast formation at sites of myeloma deposits in bone, as well as circulating activity, if the extracellular component of RANKL is shed by the myeloma cells. Of other hematological neoplasms, adult T cell leukemia/lymphoma, a malignancy associated with human T cell leukemia virus type 1 infection, is frequently associated with a syndrome very similar to HHM. The HTLV-1 infected T-cells have been shown to produce PTHrP. Hypercalcemia is relatively uncommon in both non-Hodgkin's and Hodgkin's lymphoma.

## Diagnostic Principles

The hypercalcemia may be the first diagnostic hinting prompting the search for the tumor.

## Therapeutic Principles

Since the high plasma calcium concentration in cancers is due ultimately to increased bone resorption, resulting from increased generation of active osteoclasts, specific treatment requires inhibition of bone resorption. This can be achieved with bisphosphonates, which inhibit osteoclast activity, and to some extent their formation. In patients with the HHM syndrome there is a significant renal component to the hypercalcemia, evident to a lesser extent in many patients with solid tumors metastatic to bone but with evidence also of some humoral contribution. In those patients, in whom renal calcium conservation is particularly marked through the action of PTHrP on the kidney to restrict calcium excretion, the efficacy of bisphosphonate in lowering the blood calcium may be reduced. There are no drugs available to counter the renal effect.

Efforts continue to discover new approaches to treatment of the increased bone resorption that leads to hypercalcemia in cancer, and to the development of drugs that could possibly be used as adjuvant therapies in those patients considered most at risk. Osteoprotegerin (OPG) is a secreted member of the TNF receptor family which acts as a "decoy" receptor for RANKL, thereby preventing osteoclast formation. It is very effective in preventing and treating the hypercalcemia of malignancy in animal models of the condition, and approaches through that pathway may be of value. Several other inhibitors are at various stages of development.

# Hypercalciuria

Joaquin Escribano[1], Victor M. Garca Nieto[2]
[1]Pediatric Nephrology Unit, Hospital Universitari Sant Joan, Reus, Spain
[2]Pediatric Nephrology Unit, Hospital Ntra. Sra. de Candelaria, Santa Cruz de Tenerife, Spain

## Synonyms

Idiopathic hypercalciuria; Absorptive hypercalciuria; Renal hypercalciuria, Primary hypercalciuria

## Definition and Characteristics

Idiopathic hypercalciuria (IH) is an inherited metabolic abnormality characterized by excessive amounts of calcium excreted into the urine in patients with normal serum levels of calcium. The morbidity of hypercalciuria is related to two separate factors: kidney stone disease and bone demineralization leading to osteopenia and osteoporosis. Hypercalciuria contributes to kidney stone disease in adults and children. Patients with hypercalciuria form renal stones of oxalate and calcium phosphate. In some cases crystallized calcium can be deposited in the renal interstitium causing nephrocalcinosis. In children, hypercalciuria can cause a wide variety of symptoms, the most common of which is recurrent hematuria (macroscopic or microscopic), but can also produce frequency-dysuria syndrome, urinary tract infection and abdominal and lumbar pain [1,2].

## Prevalence

Prevalence rates in the healthy population have been reported to be between 2.9 and 6.5%. About 80% of all kidney stones contain calcium, and at least 40–60% of all idiopathic calcium nephrolithiasis (ICN) formers are found to have hypercalciuria when tested.

## Genes

Between 16% and 50% of calcium-stone patients have a family history of IH and ICN and findings suggest that this is caused by a genetic predisposition. A monogenic disorder could not be demonstrated. It was hypothesized that IH have a heterogeneous genetic milieu and develop as the final effect of a mosaic of susceptibility genes in many different possible combinations [3].

## Molecular and Systemic Pathophysiology

Hypercalciuria is a multisystemic disease that is arbitrarily divided into four overlapping categories according to the primary or predominant disturbance. The primary disturbance occurs in one of the three calcium homeostasic organs: kidney, gut or bone. In each instance, secondary compensatory changes involve multiple hormones such us parathyroid hormone and 1,25-dihydroxy-vitamin D3. The most common subtypes of IH are absorptive, renal leak, resorptive, and renal phosphate leak. The main physiopathological mechanisms respectively implied are: (i) an increase in, the intestinal reabsorption of calcium secondary to high levels of, or hypersensitivity to, calcitriol; (ii) reduction in the tubular reabsorption of calcium, with the emergence of compensatory hyperparathyroidism; (iii) imbalance between bone formation and reabsorption; (iv) renal loss of phosphates with secondary increased synthesis of calcitriol and intestinal hyperabsorption.

Weissinger has postulated a theory that tries to explain the different mechanisms described [4]. Blood monocytes isolated from IH tend to produce significantly more of some cytokines, such as interleukin-1, granulocyte-macrophage colony-stimulating factor or tumor necrosis factor-[alpha], that would increase osteoclastic activity, and produce a reduction in bone mineral density. IL-1 would stimulate the production of prostaglandin E2 and this, in its secondary form, increases the production of calcitriol. Hypercalciuria would, therefore, mainly originate from bone resorption and intestinal hyperabsorption.

## Diagnostic Principles

Hypercalciuria is defined as urinary excretion of more than 250 mg of calcium per day for women or more than 275–300 mg of calcium per day for men while on a regular, unrestricted diet. It can also be defined as the excretion of urinary calcium in excess of 4 mg/kg of body weight per day in children. Idiopathic hypercalciuria has not be shown to have secondary causes, such as primary hyperparathyroidism, renal tubular acidosis, malignancy, vitamin D intoxication, immobilization, hyperthyroidism and Bartter's syndrome.

## Therapeutic Principles

No gene therapy is available. When there is no lithiasis, nephrocalcinosis or macroscopic haematuria, dietary

treatment should include an increase in the consumption of water, fruit, vegetables, blue fish, and wholemeal cereals, along with a moderate reduction in dairy products salt and red meat. Several pharmacological treatments have been described that can decrease levels of calciuria or its index of urinary crystallization. Thiazides have demonstrated to reduce calciuria and stone rate formation, increasing the number of patients free of calculi [5]. Potassium citrate could be added to the thiazides therapy to prevent hypokalemia and to increase urinary citrate levels. Orthophosphates lower serum calcitriol levels and reduce calcium excretion.

### Definition and Characteristics

Familial hypercholesterolemia, (FH), is an autosomal co-dominant disorder categorized clinically by a selective elevation in the plasma level of low density lipoprotein cholesterol (LDL-C), deposition of LDL derived cholesterol in tendons (xanthomas) and in arteries (atheromas) causing premature coronary artery atherosclerosis [1]. Cholesterol is usually elevated at birth. Generally, triglycerides and high density lipoprotein cholesterol (HDL-C) concentrations are normal in heterozygous FH. HDL-C is frequently decreased in homozygous FH. The Fredrickson phenotype is IIa (IIb is rare). In heterozygous FH, in which the number of functional LDL receptors is halved, LDL-C is elevated by two-fold (usually 5.2 mmol/L–10.4 mmol/L), symptomatic coronary artery heart disease typically develops after age 35 years (on average at about age 45 years in an untreated man and age 55 years in an untreated women). Among people in North America and Western Europe who have a myocardial infarction before age 60 years, about 5% are from FH heterozygotes. In FH homozygotes in which functional LDL receptors are absent, LDL-C is elevated six to eight times (usually 13 mmol/L–26 mmol/L). Death from myocardial infarction can result before puberty. Untreated, receptor negative patients with homozygous FH rarely survive beyond the second decade. Patients with LDL receptor defects have a better prognosis but almost invariably develop significant atherosclerotic vascular disease by age 30.

### Prevalence

The prevalence of heterozygotes among Europeans, North Americans and Japanese populations is about one in 500 persons, placing this disease amongst the most

common inborn errors of metabolism. The homozygous form occurs in only one in one million. Molecular diagnosis can be made through linkage analysis in families. However, in some inbred populations, a small number of mutations predominate, and screening at a DNA level is feasible. These populations include Ashkenazi Jews of Lithuanian ancestry living in South Africa, Afrikaners in South Africa, Christian Lebanese in Lebanon and Syria, French Canadians in Quebec Province, and the Finns. The prevalence of heterozygous FH is increased in some of these groups: one in 67 among the Ashkenazi Jews, one in 100 among the Afrikaners, one in 170 among the Christian Lebanese, and one in 270 among the French Canadians.

## Genes

Brown and Goldstein demonstrated that in FH there is a defect in the gene controlling the LDL receptor protein [2]. The LDL receptor gene has 18 exons. Exon 1 localizes the receptor to the endoplasmic reticulum. Exons 2–6 code the ligand-binding region. There are 5 broad classes of mutation of the LDL receptor: Class 1 affects the synthesis of the receptor in the endoplasmic reticulum, Class II interferes with the transport to the Golgi body, Class III stops the binding to LDL, Class IV affects the internalization of the receptor-ligand complex, and Class V interferes with the receptor recycling [2].

## Molecular and Systemic Pathophysiology

Brown and Goldstein demonstrated that in FH there is a defect in the gene controlling the LDL receptor protein [2]. The elevated LDL-C levels of FH are due to delayed catabolism of LDL and its precursor particles from the blood secondary to more than 750 mutations in the LDL receptor gene. There is a major gene dose effect in that individuals with two mutated LDL receptor alleles, (FH homozygotes) are much more affected that those with one mutant allele (FH heterozygotes) [1]. Mutations in the LDL receptor gene may result in complete loss of activity in cultured fibroblasts or result in 2–25% residual LDL receptor function. Located on the surfaces on most body cells, the LDL receptor normally binds LDL and facilitates its cellular uptake and delivery to lysozymes, where the LDL is degraded and its cholesterol is released for use in its synthesis of cell membranes (most cell types), steroid hormones (adrenocorticoid cells), and bile acids (liver cells). The deficiency of LDL receptors in patients leads to a decreased rate of removal of LDL from plasma, and the plasma LDL level rises inversely to the reduction in LDL receptors. The excess plasma LDL is deposited in scavenger cells and other cell types, producing xanthomas and atheromas. Atherosclerosis often develops first in the aortic root and can cause aortic valvular or supra-valvular stenosis and then extends into the coronary ostia. Carotid and femoral disease develops later in life. Female FH heterozygotes develop atherosclerosis disease on average 10 years later than male counterparts. This may be secondary to the enhanced production of LDL receptors by estrogen [3].

## Diagnostic Principles

Clinical diagnosis may be established by LDL-C above the 90th percentile in two or more first-degree relatives and in persons with tendinous xanthomas within the kindred. Typically, most patients with homozygous FH present in childhood with manifestations including cholesterol ester deposits on the Achilles tendons and the extensor tendons of the hands, wrists, elbows, knees and heels. Xanthomas in the palpebral fissure are also common, where they are called xanthelasmas. In the homozygous form, "buttery" xanthomas may be present over the thighs and buttocks. Another characteristic finding in FH is premature corneal arcus. Widespread severe early atherosclerosis, including aortic stenosis, is usual in homozygotes. The diagnosis of homozygous FH can be confirmed by obtaining a skin biopsy and measuring LDL receptor activity in cultured skin fibroblasts, or by quantifying the number of LDL receptors on the surfaces of histiocytes using cell – sorting technology. FH heterozygous can be difficult to diagnose; the differential diagnosis should include familial defective Apo B-100, familial combined hyperlipidemia, hypothyroidism, nephrotic syndrome, and cholestatic liver diseases such as primary biliary cirrhosis. Heterozygotes have elevated cholesterol levels from birth, but the onset of the cutaneous manifestations of xanthelasmas, xanthoma and premature coronary artery disease are variable and usually not apparent until adulthood. The family history is usually positive for premature coronary artery disease on one side of the family. No definite diagnostic test available for heterozygous FH. Although FH heterozygotes have reduced LDL receptor number in skin fibroblasts, there is significant overlap with the levels of normal fibroblasts.

## Therapeutic Principles

Treatment for a heterozygous and homozygous individual should be directed at lowering the plasma level of LDL. Diet and correction of co-existing cardiovascular risk factors remain crucially important. Inevitably FH heterozygous require lipid-lowering pharmacotherapy, and availability of the HMG-CoA reductive inhibitor has revolutionized this treatment [4]. Hypercholesterolemia in most heterozygotes can now be controlled by statin monotherapy or by statin-ezetimibe combination drug therapy [5]. Therapy

for homozygotes can be difficult because the condition is usually diet and drug resistant, although some benefits from a statin-ezetimibe combination has been recently been reported. FH homozygotes and heterozygotes can also be treated with LDL aphoresis. Liver transplantation, portocaval shunting, genetic inhibition of Apo B production and gene therapy remain experimental.

## Hyperekplexia, Hereditary

Angelika F. Hahn
Department of Neurology, University of Western Ontario, London Health Science Centre, London, ON, Canada

### Synonyms

Familial startle disease; Stiff-baby syndrome

### Definition and Characteristics

This is an autosomal dominant, recessive or sporadically occurring neurological disorder characterized by excessive startle responses, hypertonia and apneic spells in the neonatal period, nocturnal myoclonus, startle-induced falls and accumulation of injuries.

### Prevalence

Hereditary hyper ekplexia has been identified in over no pedigrees of many different nationalities.

### Genes

Genetic heterogeneity is confirmed with documented mutations affecting either subunit or the anchoring proteins of the human inhibitory glycine receptor (GlyR) complex (Table 1) [1].

Hereditary hyperekplexia is typically caused by mutations in GLRA1 encoding the ligand-binding GlyR α1 subunit, less frequently by mutations in GLRB encoding the GlyR β-subunit, or in GPHN encoding gephyrin or ARHGEF9 encoding collybistin, both proteins that are involved in the clustering and anchoring of GlyRs at postsynaptic membranes. Mutations in SLC6A5 encoding the presynaptic glycine transporter 2 (GlyT2) also cause hyperekplexia [2].

### Molecular and Systemic Pathophysiology

The human inhibitory GlyRs are hetero-pentameric, ligand-gated chloride channels that are composed of three ligand-binding α1 subunits and two β-subunits. Association of the β-subunit with gephyrin/collybistin coaggregates results in clustering of GlyRs at the postsynaptic membranes and in their anchoring to the microtubule scaffolding (schematic illustration in Fig. 1); inhibitory $GABA_A$ receptors ($GABA_A$Rs) are often co-expressed [3].

GlyRs facilitate the fast-response, inhibitory glycinergic neurotransmission in the brainstem and spinal cord. Patients with hereditary hyperekplexia exhibit a pathological exaggeration of the physiological startle reflex occurring in response to unexpected auditory or

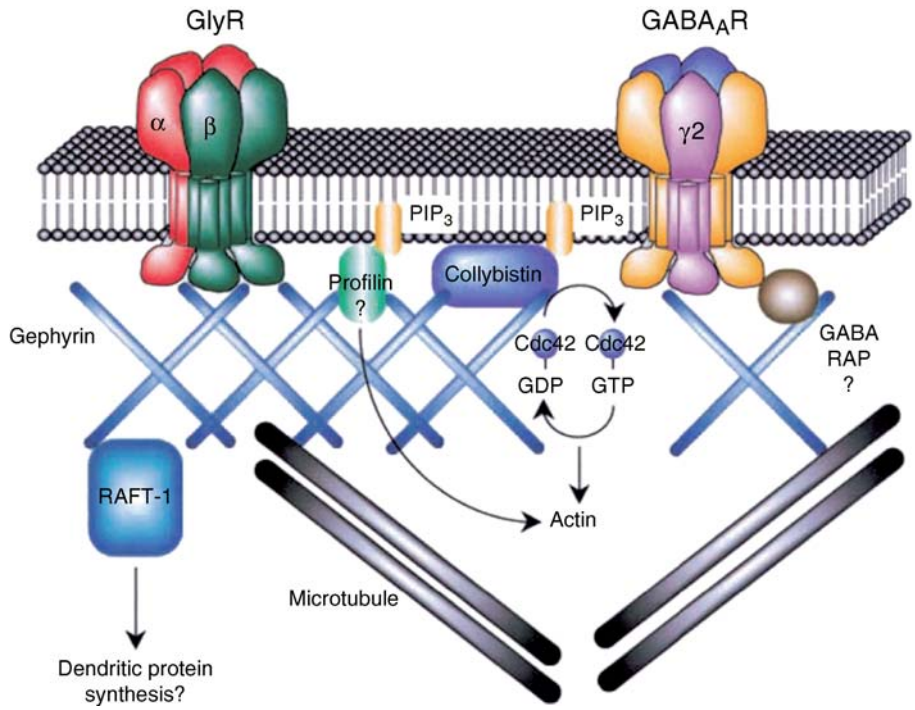
somesthetic stimuli. The auditory startle reflex originates in the caudal brainstem, specifically in the bulbopontine reticular formation, a region rich in GlyRs. In hyperekplexia, the abnormal startle is characterized by a lower threshold, shorter latency, greater extent and resistance to habituation. Neurophysiological observations indicate a bulbospinal origin [4], and are in keeping with impaired glycinergic synaptic function.

## Diagnostic Principles

Symptoms are present from birth, as infants display muscular rigidity, which increases with handling and disappears during sleep. It may lead to potentially fatal spells of apnea (sudden-infant death). The diagnosis is clinically confirmed by demonstrating an exaggerated head-retraction reflex in tapping the infant's nose-bridge or chin. Muscular hypertonia



**Hyperekplexia, Hereditary. Figure 1** Schematic representation of the pentameric glycine receptors (GlyRs), which are composed of 3 ligand-binding α-subunits and 2 β-subunits and are often co-expressed in CNS postsynaptic membranes together with $GABA_A$ receptors. Gephyrin, a membrane protein crucial for clustering of GlyRs at the inhibitory synapses, binds to the β-subunit and to microtubules, thereby anchoring the receptor to the postsynaptic scaffold. Gephyrin also binds to PIP3 (phosphatidylinositol 3)-binding protein involved in actin dynamics and downstream signaling proteins such as profilin and collybistin. Gephyrin interacts with RAFT1 (rapamycin and FKBP12 target protein), a candidate regulator of dendritic protein synthesis. It was proposed that $GABA_A$ receptors might interact with gephyrin via the tubulin-binding protein GABARAP. However, it is not involved in $GABA_A$ receptor anchoring at the synapse. From [3] with permission of the Birkhauser Verlag, Basel.

decreases gradually during the first year of life. Even so, affected young children and adults tend to walk stiff-legged, with a mildly wide-based gait, but without signs of spasticity. The head-retraction response continues to be readily elicited.

Other clinical features are periodic limb movements in sleep and hypnagogic myoclonus. The hallmark is the excessive startling in response to unexpected stimuli, which results in short-lasting generalized stiffness causing the patient to fall forwards "as stiff as a stick" while fully conscious but unable to protect himself. This may result in serious injuries.

## Therapeutic Principles

Clonazepam is the treatment of choice, which potentiates the inhibitory transmitter GABA [5]. $GABA_A$Rs and GlyRs show widespread co-localization in the central nervous system. During the first year of life infants need to be fitted with an apnea monitor.

## Synonyms

Hypereosinophilic syndrome; IHES; Eosinophilia; Lymphocytic hypereosinophilic syndrome; Myeloproliferative eosinophilia; Overproduction of eosinophils

## Definition and Characteristics

Hypereosinophilic syndrome is a rare hematological disorder characterized by sustained overproduction of eosinophils in the bone marrow without any underlying cause, resulting in eosinophilia, tissue infiltration, and multiple organ damage. Hardy and Anderson first described it in 1968 [1]. Later in 1975, Chusid et al. [2] defined the term idiopathic hypereosinophilic syndrome characterized by the following three criteria:

1. Peripheral blood eosinophil count (AEC) greater than 1500 cells/μl persisting longer than six months
2. End organ (heart, brain, lung, skin, etc.) involvement with eosinophil tissue infiltration and injury
3. Exclusion of known other causes for the eosinophilia such as parasitic infections and bone marrow/blood diseases

The presentation of clinical symptoms varies according to the organ damage (Table 1). Heart is the most common organ involved with thromboembolic complications leading to multisystem disease.

**Hypereosinophilic Syndrome, Idiopathic. Table 1** Common clinical manifestations associated with idiopathic hypereosinophilic syndrome

| System | Abnormalities/symptoms |
|---|---|
| Neurological | Seizures, stroke, peripheral neuropathies, mononeuritis multiplex, muscle atrophy |
| Cardiac | Thrombosis, valvular disease, endocardial fibrosis, restrictive endomyocardopathy |
| Skin | Rashes, pruritus, urticaria, dermatographism, angioedema, erythematous papules, plaques, and nodules |
| Musculoskeletal | Myalgia, arthralgia, arthritis |
| Psychiatric | Depression, irritability, fatigability |
| Pulmonary | Cough, dyspnoea, pleural effusions |
| Others | Fever, fatigue, anorexia, weight loss |

## Prevalence

Till date, there is no published data on epidemiology of this rare disorder. Because of its rarity and a diagnosis of exclusion makes it difficult to estimate its prevalence. It is a predominantly male disorder with an estimated male to female ratio of 9:1 and is commonly seen in patients with age group of 20–50. No racial predilection is documented.

## Genes

Recent reports [3] suggest that the condition is caused by fusion of the FIP1L1 (Fip1-like1) gene to the PDGFRA (platelet-derived growth factor receptor alpha chain) gene. Both FIP1L1 and PDGFRA genes are located on chromosome 4q12; the FIP1L1–PDGFRA fusion results from an apparent interstitial deletion that links FIP1L1 to exon 12 of PDGFRA.

## Molecular and Systemic Pathophysiology

Several mechanisms have been explained for the dysregulated overproduction of eosinophils in IHES and their role in tissue toxicity. The most common explanation is the cytokines induced overproduction of eosinophils. Interleukin-5 (IL-5) is the most important and specific cytokine that is responsible for eosinophilia; others include IL-3 and granulocyte-macrophage colony-stimulating factor (GM-CSF). It has been also postulated that abnormal clones of T-cells [4], a defect in the cytokine receptor or a signal transduction may play a pivotal role in IL-5 overproduction in IHES. This stimulates, in turn, sustained overproduction of eosinophils, and these may survive for longer periods in tissues causing increased amount of damage.

Eosinophils exert nonspecific toxic effects that induce tissue damage to host tissues. Eosinophils also

store toxic cationic proteins in their granules. These include major basic protein, eosinophil peroxidase, eosinophil-derived neurotoxin, and eosinophil cationic protein. These toxins are the primary mediators of tissue damage. Other mechanisms include direct tissue infiltration and antibody-dependent cellular cytotoxicity. The most commonly damaged tissues are cardiac and neural tissues.

### Diagnostic Principles

Diagnosis of the IHES is mainly on the aforementioned diagnostic criteria. There are many conditions that are associated with blood or tissue eosinophilia, and these needs to be distinguished with IHES on clinical and pathologic grounds. Other than blood and bone marrow examination, bronchoalveolar lavage for eosinophils is also required in patients with pulmonary involvement. A molecular abnormality like fusion of the FIP1L1–PDGFRA on chromosome 4q12 is also observed [3]. Further, an abnormal clone of cells can be identified by standard flow cytometry for analysis of peripheral T lymphocytes. Other laboratory and imaging studies are required depending on the organ damage and system involved.

### Therapeutic Principles

IHES is not a completely curable disease, so the goal of the treatment is to prevent or control organ damage by suppressing the eosinophil count. Till now, the most effective drug used is the corticosteroids, which inhibit the synthesis of eosinophil production. Other treatment modalities include chemotherapeutic agents (hydroxyurea), cyclosporine, alpha-interferon, monoclonal antibodies, and recently imatinib [3] is also used. Valve replacement and endomyocardectomy is done whenever required for patients with cardiac involvement.

## Hyperhomocysteinemia

►Homocysteine: Plasma Levels and Genetic Basis

## Hyperhomocysteinemia: Genetic Basis and Arterial Thrombosis

Hugo ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

### Definition and Characteristics

Homocysteine is a thiol-containing amino acid and an intermediate product from the metabolism of methionine from dietary protein [1]. Metabolism takes place in every cell, and two metabolic pathways are involved. First, a vitamin B6 (pyridoxine)-dependent transsulfuration to form cysteine, second a resynthesis to methionine in a folate- and vitamin B12-dependent pathway. Homocysteine is metabolized to methionine by the enzyme methionine synthase that uses 5-MTHF as methyl donor. Transfer of the methyl group results in tetrahydrofolate, which is involved in DNA synthesis. Deficiencies in folate or vitamin B12 impair remethylation. Thus, deficiencies of any of the vitamins B6, B12, or folate may result in disturbed homocysteine metabolism resulting in homocysteine accumulation and hyperhomocysteinemia.

### Prevalence

Classic homocysteinuria is a rare disorder. Mild hyperhomocysteinemia occurs in about 5% of the normal population. In 25% of elevated homocysteine levels the most relevant causal factor is a homozygous 677TT variant in MTHFR.

### Genes

Homocysteine is influenced by genetic and metabolic factors. Classical homocysteinuria is an inborn error of metabolism associated with a high risk of venous thrombosis and atherosclerosis. Homozygous homocysteinuria is caused by CBS of MTHFR deficiency or cobolamin C/D defects [2]. Moderate hyperhomocysteinemia is a mild risk factor for atherothrombotic disease, but this risk has not been confirmed in all prospective studies [3]. The MTHFR C677T polymorphism has been studied extensively in association with disease.
*Gene Map Locus*: Two genes are involved in metabolism of homocysteine: 1p36.3 5,10-αMETHYLENETETRAHYDROFOLATE REDUCTASE (MTHFR) and 21q22.3 CYSTATHIONINE BETA-SYNTHASE (CBS).

### Molecular and Systemic Pathophysiology

Specific mutations can be screened using PCR-based analysis.

The nature of the detrimental effects of homocysteine cannot be directly linked to a single biological action. Rather, the cumulative data from several in vitro and animal experiments showing reduced bioavailability of nitrous oxide linked to endothelial cell dysfunction, altered oxidant stress, uncoupling of nitrous oxide, reduced expression of anticoagulant molecules and so on point to unfavorable effects of elevated homocysteine concentrations. Part of these effects, such as disturbed vasomotor functions can be restored with folic acid supplementation, and the question of causality of homocysteine correction versus folate supplementation per se remains unsolved.

*Clinical Features*: In a recent meta-analysis of >17,000 patients with coronary, cerebrovascular, or peripheral vascular disease, the MTHFR C677T mutation increases the risk of ischemic stroke (OR 1.46, 95% CI 1.19- 1.79) but not for myocardial infarction (OR 1.05, 95% CI 0.86-1.27). The risk for peripheral arterial vascular disease could not be established. When the data from all studies are pooled and the risk determined in individuals <55 years, the OR for the MTHFR mutation remains modest but statistically significant (OR 1.41, 95% CI 1.13- 1.76) [3].

## Diagnostic Principles

Hyperhomocysteinemia can be diagnosed either by determining a fasting homocysteine level or by also adding a post-methionine loading homocysteine level. Methionine loading detects a subset of patients with a high normal fasting homocysteine level, but in the absence of accepted criteria for interpreting post-methionine loading levels its use should not be recommended for routine purposes. Mostly used methods are HPLC with electrochemical or fluorescence detection. Alternatively, immunoassays, ion exchange chromatography, gas chromatography, mass spectrometry, and radioenzymatic assays can be employed.

## Therapeutic Principles

As stated by den Heijer: "The clinical relevance of the finding that hyperhomocysteinemia is a risk factor for venous thrombosis depends mainly on its treatability by vitamin supplementation" [2]. So far, no evidence from randomized controlled trials is available to support the use of vitamin supplements for correcting hyperhomocysteinemia in relation the cardiovascular disease [1]. In the absence of any negative effects of vitamin supplementation and with the potential benefit in terms of arterial vascular disease reduction, vitamin administration is encouraged in all individuals with hyperhomocysteinemia.

H

## Definition and Characteristics

Homocysteine is a thiol-containing amino acid and an intermediate product from the metabolism of methionine from dietary protein [1]. Metabolism takes place in every cell, and two metabolic pathways are involved. First, a vitamin B6 (pyridoxine)-dependent transsulfuration to form cysteine, second a resynthesis to methionine in a folate- and vitamin B12-dependent pathway. Homocysteine is metabolized to methionine by the enzyme methionine synthase that uses 5-MTHF as methyl donor. Transfer of the methyl group results in tetrahydrofolate, which is involved in DNA synthesis. Deficiencies in folate or vitamin B12 impair remethylation. Thus, deficiencies of any of the vitamins B6, B12, or folate may result in disturbed homocysteine metabolism resulting in homocysteine accumulation and hyperhomocysteinemia.

## Prevalence

Classic homocysteinuria is a rare disorder. Mild hyperhomocysteinemia occurs in about 5% of the normal population and in approximately 10% of patients with venous thromboembolism. In 25% of elevated homocysteine levels the most relevant causal factor is a homozygous 677TT variant in MTHFR.

## Genes

Homocysteine is influenced by genetic and metabolic factors. Classical homocysteinuria is an inborn error of metabolism associated with a high risk of venous thrombosis and atherosclerosis. Homozygous homocysteinuria is caused by CBS of MTHFR deficiency or cobolamin C/D defects [2]. Moderate

hyperhomocysteinemia is a mild risk factor for venous thrombosis, but the risk has not been consistently matched with the presence of gene mutations. Gene defects in MTHFR and CBS, involved in intracellular homocysteine metabolism, may result in enzyme deficiency and hyperhomocysteinemia. A MTHFR 677 C-T polymorphism is associated with reduced enzyme activity and a mild to moderate hyperhomocysteinemia, but is disputed as an independent risk factor of thrombosis. Compound heterozygosity of MTHFR 677 C-T with MTHFR 1298 A-C also results in increased homocysteine levels due to reduced enzyme activity, but the role of this combined defect as a risk factor for thrombosis needs further study [3]. A 68-bp insertion in the CBS gene (844ins68) is another frequent mutation, but it is not associated with elevated homocysteine levels. In association with the MTHFR 677 C-T mutation a thrombotic risk factor may exist.

*Gene Map Locus*: Two genes are involved in metabolism of homocysteine: 1p36.3 5,10-αMETHYLENETETRAHYDROFOLATE REDUCTASE (MTHFR) and 21q22.3 CYSTATHIONINE BETA-SYNTHASE (CBS).

## Molecular and Systemic Pathophysiology

The specific mutations can be screened by routine PCR analysis.

The nature of the detrimental effects of homocysteine cannot be directly linked to a single biological action. Rather, the cumulative data from several in vitro and animal experiments showing reduced bioavailability of nitrous oxide linked to endothelial cell dysfunction, altered oxidant stress, uncoupling of nitrous oxide, reduced expression of anticoagulant molecules and so on point to unfavorable effects of elevated homocysteine concentrations. Part of these effects, such as disturbed vasomotor functions can be restored with folic acid supplementation, and the question of causality of homocysteine correction versus folate supplementation per se remains unsolved.

*Clinical Features*: The first prospective study to link homocysteine with venous thrombosis was the Physicians' Health Study [4] showing a relative risk of 1.6 (95% CI 0.8–3.3) for first time all cause venous thrombosis at a cut-off level of the 95th percentile. The risk was higher in patients with idiopathic thrombosis (relative risk 3.4). In a second prospective study the relative risk of hyperhomocysteinemia defined as the upper versus the lower quintile was 1.55 (95% CI 0.93–2.58) [2]. These figures are lower than those in several retrospective cohort studies [2]. The risk or recurrent thrombosis associated with elevated homocysteine levels is 2.0 in one study (95% CI 1.5–2.7) and 2.7 in another trial (95% CI 1.3–5.8) (reviewed in 1). The risk associated with the MTHFR 677TT genotype and thrombosis showing an increased risk as compared with the CC genotype of 1.29 (95% CI 1.08–1.54). A second meta-analysis showed a pooled odds ratio of 1.2 for the TT genotype versus the CC and CT genotypes (95% CI 1.15–2.22) [2].

## Diagnostic Principles

Hyperhomocysteinemia can be diagnosed either by determining a fasting homocysteine level or by also adding a post-methionine loading homocysteine level. Methionine loading detects a subset of patients having a high normal fasting homocysteine level, but in the absence of accepted criteria for interpreting post-methionine loading levels its use should not be recommended for routine purposes 95). Mostly used methods are HPLC with electrochemical or fluorescence detection. Alternatively, immunoassays, ion exchange chromatography, gas chromatography, mass spectrometry, and radioenzymatic assays can be employed [5].

## Therapeutic Principles

As stated by den Heijer: "The clinical relevance of the finding that hyperhomocysteinemia is a risk factor for venous thrombosis depends mainly on its treatability by vitamin supplementation" [2]. So far, no published studies have demonstrated any beneficial effect of vitamin supplementation on the risk of (recurrent) thrombosis, whereas several studies have clearly shown that hyperhomocysteine levels are fully corrected with vitamin supplementation, even in individuals without demonstrable vitamin B6, B12, or folate deficiencies [2]. In the absence of negative effects of vitamin supplementation and with the potential benefit in terms of arterial vascular disease reduction, vitamin administration is encouraged in all individuals with hyperhomocysteinemia.

# Hyper-IgE Recurrent Infection Syndrome

►Hyper IgE Syndrome

# Hyper-IgM Syndrome

Raffaele Badolato
Clinica Pediatrica, Universita' di Brescia, Brescia, Italy

## Synonyms

Immunodeficiency with hyper-IgM

## Definition and Characteristics

The term hyper-IgM syndrome identifies a heterogeneous group of genetically inherited disorders that are characterized by susceptibility to opportunistic infections and decreased serum levels of IgG and IgA, but normal or elevated IgM.

## Prevalence

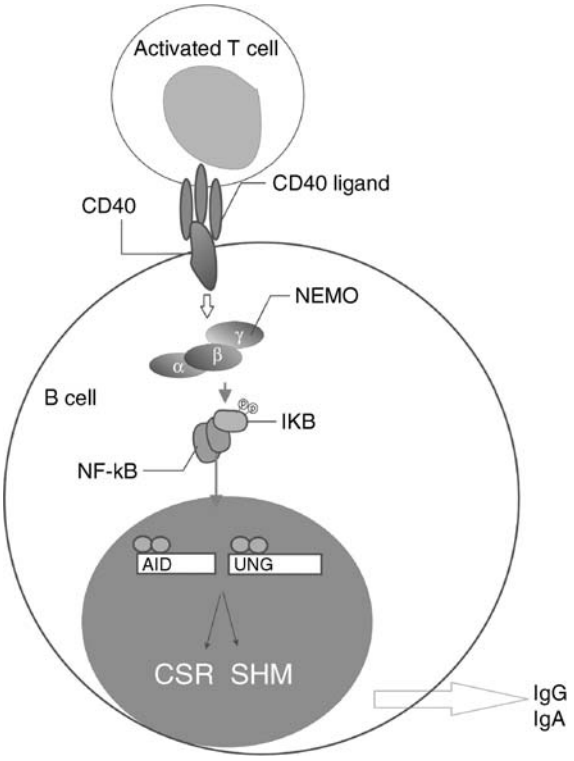
The prevalence of X-linked hyper-IgM is 1/1 million live births in males. Investigation of the five molecular defects that lead to hyper-IgM in a large cohort of 140 patients has shown that the majority of them (up to 70%) carried mutations of CD40L. In the remaining subjects, AICDA mutations were described in four patients, UNG mutations were detected in one patient, a patient with hypohidrotic ectodermal dysplasia carried a NEMO mutation, while a genetic cause was not identified in 33 patients. CD40 mutations were only identified in HIGM patients living in the Mediterranean region.

## Genes

Hyper-IgM type 1 (HGM1 or X-linked HIGM) and the hyper-IgM syndrome associated with hypohidrotic ectodermal dysplasia, which are transmitted as X-linked disorders, are caused by mutations of the genes encoding for CD40 Ligand (CD40L) and Nuclear factor kB Essential Modulator (NEMO), respectively. All the other forms, including HIGM2, due to Activation Induced Cytidine Deaminase (AICDA) mutations, HIGM3, caused by CD40 mutations and HIGM5, due to Uracil-DNA Glycosylase (UNG) mutations, are autosomal recessive. The term HIGM4 identifies a novel clinical entity, which remains genetically undefined.

## Molecular and Systemic Pathophysiology

The hyper-IgM syndromes are caused by the inability of B-lymphocytes to undergo immunoglobulin isotype switching. Class switch recombination consists in the replacement of the μ heavy chain by a downstream heavy chain, including Cγ, Cα or Cε, and subsequent synthesis of IgG, IgA and IgE that share the same variable regions. Germinal center B-cells are also subjected to somatic hypermutation, a process consisting in the introduction of point mutations in variable (V) regions of immunoglobulin genes, which results in additional expansion of antibody repertoires. Cognate interactions between B- cells and T-cells are required for induction of an antigen dependent secondary antibody repertoire and for selection of high affinity antigen specific antibodies. In this process, expression of CD40L by activated T-cells is essential for triggering isotype switching in B-cells that constitutively express the counter-receptor CD40 (Fig. 1).



**Hyper-IgM Syndrome. Figure 1** Representation of molecular defects leading to hyper IgM syndromes.

H

CD40 cross-linking on B-cells by CD40 ligand leads to phosphorylation of IkB, a cytoplasmic NF-kB inhibitor, by the IkB kinase (IKK) complex and to subsequent release of a functionally active form of NF-kB. Mutations of NEMO, which is a component of the IKK complex and is also designated IKK-γ, prevent NF-kB activation and interfere with the signaling events that are required for transcription of the multiple components of B-cell machinery involved in generation of antibody diversity. Specifically, translocation of NF-kB complex from cytoplasm to nucleus activates transcription of many genes required for CSR and SHM that are expressed by germinal center B-cells, including AID and UNG. The enzyme AID catalyses deamination of cytosine to uracil in single stranded DNA, thereby leading to generation of DNA breaks which are required for isotype switching as well as for somatic hypermutation. This process takes place during transcription of the switch region at the growing end of RNA:DNA hybrid by the action of AID and leads to the formation of uracil residues, which are subsequently removed by the enzyme UNG. Uracil excision results in the creation of an abasic site that will become the target of apyrimidinic endonucleases leading to DNA nicks. The downstream process of non-homologous end joining requires a series of molecular events that are not characterized at the molecular level, but involve enzymes required for DNA repair.

In HIGM1, HIGM3 and NEMO-HIGM, hypogammaglobulinemia, which is observed in all HIGM patients, is associated to susceptibility to intracellular pathogens, including Pneumocystis carinii and Cryptosporidium. The defective T-helper function that is observed in these patients is probably related to the role of CD40-CD40L interactions in promoting maturation of dendritic cells and thereby secretion of cytokines, such as IL-12, which are essential for activation of the T-cell mediated response against these opportunistic microorganisms.

## Diagnostic Principles

Diagnosis should be considered in children with recurrent or severe infections and low IgG and IgA, but normal or elevated IgM. HIGM1 and HIMG3 usually present with a more severe course of the disease with Pneumocystis infection, while HIGM patients with intrinsic B-cell defect (HIGM2, HIGM4, HIGM5) present with recurrent infections and lymph node hyperplasia. Mycobacterial infections can be observed in NEMO-HIGM patients. A decrease in the number of memory B-cells (CD27+) and switched memory B-cells (CD27 + /sIgD-) are usually observed in all variants of the disease. Molecular diagnosis is confirmed by demonstration of mutations in one of the genes associated with HIGM syndrome.

## Therapeutic Principles

The long established treatment for hyper-IgM has been the administration of prophylactic intravenous immunoglobulins at doses of 400–600 mg/kg per month. Children affected by type 1 and type 3 hyper-IgM should be considered for hematopoietic stem cell transplantation to prevent late complications of the disease, including Cryptosporidium enteritis. For prophylaxis of infection by this opportunistic parasite, HIGM1 and HIGM3 children should use boiled or filtered water. Gene therapy is currently unavailable for these diseases.

# Hyperinsulinemic Hypoglycemia

►Persistent Hyperinsulinemic Hypoglycemia

# Hyperinsulinism of Infancy

Benjamin Glaser
Endocrinology and Metabolism Service, Internal Medicine Division, Hebrew University-Hadassah Medical School, Jerusalem, Israel

## Synonyms

Persistent hyperinsulinemic hypoglycemia of infancy; PHHI; Nesidioblastosis; Congenital hyperinsulinism; CHI; Beta-cell dysmaturation syndrome; Persistent neonatal hyperinsulinism; PNH

## Definition and Characteristics

HI can be defined as a syndrome caused by the unregulated secretion of insulin causing hypoglycemia. Although typically appearing soon after birth, some forms may present later in infancy or early childhood. Discrete, insulin producing adenomas or carcinomas (insulinoma), which are exceedingly rare in the newborn, are not considered part of this entity. As described below, the syndrome is caused by a failure of suppression of insulin secretion in the face of hypoglycemia and is thus characterized by inappropriately elevated insulin levels during spontaneous or induced hypoglycemia. In many cases, the precise molecular genetic defect can now be identified. Mutations in either of the 2 subunits of the beta-cell KATP channel can cause either focal or diffuse disease, depending on the precise genetic defect (see below). Mutations in glutamate dehydrogenase can cause the Hyperammonemia-Hyperinsulinism syndrome (HI-HA), which appears to be associated with increased risk of epilepsy. Thus, it is desireable, when possible, to precisely define the genetic classification in a given patient, since this may have important clinical ramifications.

## Prevalence

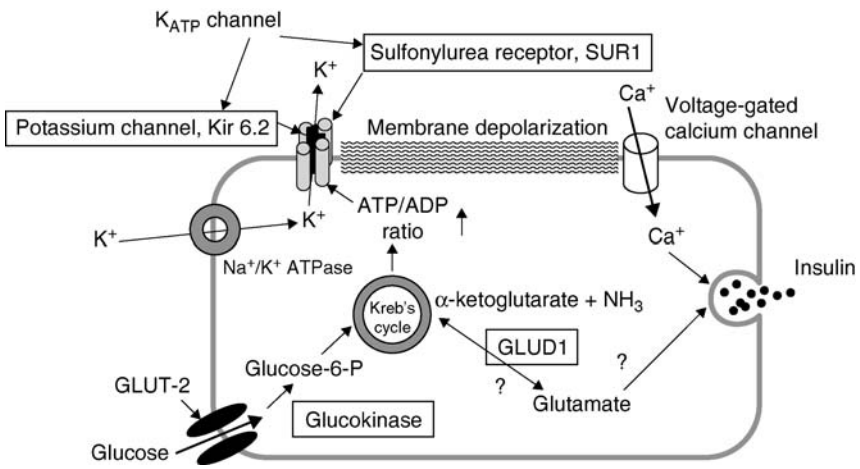
HI has been reported in most ethnic groups in the world. In out-bred populations the incidence is approximately 1:50,000, however in some in-bred populations an incidence up to 1:2,500 has been reported. There is an apparent increased incidence of disease in the Ashkenazi Jewish population, where the majority of disease can be traced to two major founder mutations.

## Genes

HI may be caused by mutations in at least 5 different genes. The most common form is due to mutations in either of the 2 subunits of the beta-cell KATP channel: ABCC8 (SUR1) or KCNJ11 (Kir6.2). Mutations in these gene lead to defective channel activity (KATP-HI). Mutations in any of 3 different beta-cell enzymes have also been reported to cause HI: Glucokinase (GK-HI), Glutamate Dehydrogenase (GLUD1-HI) or Short Chain Hydroxysteroid Dehydrogenase (SCHAD-HI).

## Molecular and Systemic Pathophysiology

The molecular etiology of HI is very complex and dysregulation of insulin secretion can be caused by abnormalities in any of several regulatory steps within the beta-cell (Fig. 1).



**Hyperinsulinism of Infancy. Figure 1** Schematic representation of major steps in the regulation of insulin secretion. Mutations in the genes marked in boxes have been shown to be associated with hyperinsulinism of infancy. GLUD1 = glutamate dehydrogenase. The mechanism by which activating mutations in gene cause hyperinsulinism is still controversial.

An understanding of the basic mechanisms responsible for regulation of insulin secretion is needed to appreciate the pathophysiology of various forms of HI.

The resting β-cell membrane is maintained in a hyperpolarized state by the $Na^+$-$K^+$-ATPase pump and open, ATP-sensitive potassium channels ($K_{ATP}$). Under these conditions, the voltage-gated calcium channels are closed and insulin secretion is inhibited. Plasma glucose enters the β-cell through the membrane-bound, high Km glucose transporter – GLUT-2. It is then phosphorylated by the enzyme glucokinase and metabolized, resulting ultimately in the phosphorylation of ADP to ATP, increasing the ATP/ADP ratio. This change in metabolic state is sensed by the nucleotide binding domains on SUR1, and Kir6.2 causing the $K_{ATP}$ channels to close. This, in turn results in depolarization of the cell membrane, opening of voltage-dependent $Ca^{2+}$ channels, and a rise in the free intracellular $Ca^{2+}$ concentrations. Rising intracellular $Ca^{2+}$ concentrations activate the insulin secretory mechanisms. Thus, the $K_{ATP}$ channel complex "senses" the intracellular metabolic state by reacting to changes in the ATP/ADP ratio and uses this information to regulate insulin secretion.

In at least 50% of cases, HI appears to be caused by beta-cell $K_{ATP}$ channel defects that result in unregulated membrane depolarization and insulin secretion. These channels are hetero-octomers made up of four molecules of the inward-rectifying potassium channel Kir6.2 which create the ion-specific channel, and four molecules of the sulfonylurea receptor SUR1, which is responsible for regulation of channel activity in response to changes in the ATP/ADP ratio within the cell. The detailed structure of the channel has recently been described. Over 100 $K_{ATP}$ channel mutations have been reported to cause HI [1]. These include missense, non-sense, splice-side, deletion and insertion mutations. Most are located in the coding region of SUR1, although several Kir6.2 gene mutations have also been reported. The majority of these mutations are recessive, meaning that affected individuals must carry disease-causing mutations on both alleles, however dominant SUR1 mutations have recently been described and it is likely that dominant Kir6.2 mutations are also present.

Some HI patients have discrete, focal regions of beta-cell hyperplasia. These are not true adenomas and are now known to be caused by a unique sequence of genetic events [2]. Patients must inherit a SUR1 or Kir6.2 mutation from their fathers. At some point in early development, a beta-cell precursor undergoes a second, somatic, genetic event in which the maternal allele of chromosome 11p is lost. Thus the progeny of this precursor carry only a mutant SUR1 or Kir6.2 allele. In all cases, the mutation is on the paternal allele, and the maternal allele is lost, implying that the resultant defect is caused by genomic imprinting. Neither SUR1 nor Kir6.2 are imprinted, however several adjacent genes are, including genes known to be important for the regulation of cell proliferation. Thus Focal-HI is caused by a unique "double hit" process in which a patient inherits a germline $K_{ATP}$ channel gene mutation and undergoes a somatic loss of the maternal chromosome 11p gene. The risk of a patient with a paternal mutation developing focal-HI is not known, but must be small, since the vast majority of siblings of HI patients are asymptomatic, even though 1/3 of them carry paternally inherited $K_{ATP}$ channel gene mutations.

Other genetic defects may cause hyperinsulinism. Some patients with HI have simultaneous mild to moderate hyperammonemia. This hyperammonemia is asymptomatic and will be missed unless specifically tested for. Many of these patients have dominant, activating mutations in the glutamate dehydrogenase gene (GLUD-1), the gene responsible for the reversible conversion of a glutamic acid to alphaketogluterate [3]. The precise mechanism by which this causes hyperinsulinism is still controversal. Typically, these patients have milder disease that presents after the new-born period, and is responsive to diazoxide treatment.

Rarely, HI may be caused by a dominant, activating mutations in the glucokinase gene [4]. This form of the disease (GK-HI) was previously thought to be characterized by relatively mild, diazoxide-sensitive hyperinsulinism that may present as either fasting of post-prandial hypoglycemia. However, recently, severe mutations in this gene have been reported to result in severe, diazoxide-unresponsive disease clinically indistinguishable from severe KATP-HI.

Very recently, a small number of patients have been reported with hyperinsulinemic hypoglycemia associated with a spectrum of other clinical signs and symptoms and not caused by mutations in the genes described above. Despite this, in as many as 40–45% of patients no mutation can be identified in any of the genes described, and the genetic etiology of disease in these patients is still unknown.

## Diagnostic Principles

The primary clinical feature of HI is hypoglycemia which may be difficult to diagnose in the new-born period, since presenting symptoms may be non-specific. Once hypoglycemia is identified, it must be treated aggressively to prevent irreversible brain damage. Other causes of hypoglycemia such as defects in glucose production or counter-regulatory hormone deficiency must be excluded. During the initial treatment, hyperinsulinism may be suspected when glucose requirement to prevent hypoglycemia is greater than the normal glucose requirement for the age of the

patient (8 mg $kg^{-1}$ $min^{-1}$ for the newborn). This finding suggests increased glucose utilization, as opposed to inadequate production as can be seen in a wide variety of metabolic and endocrine disorders. Unless a highly sensitive insulin assay is used, it may be difficult to document inappropriately elevated insulin levels. Surrogate measurements of insulin action, including suppressed ketone body production, glycemic response to glucagon and glucose requirement to prevent hypoglycemia may be particularly useful in making the diagnosis. A systematic approach to the diagnosis of HI has been recently reviewed in detail [5].

## Therapeutic Principles

The primary goal of treatment must be aimed at preventing hypoglycemia, since it is the persistent and severe hypoglycemia that may cause irreversible brain damage. Initial treatment consists of a bolus of intravenous glucose followed by an infusion at a rate sufficient to prevent hypoglycemia. Since total glucose requirement may be extremely high, central venous access is typically required. After stabilization, medical therapy may be attempted, and includes diazoxide, somatostatin analog, glucagon and nifedipine. A recommended, therapeutic protocol has recently been published [5]. If adequate glycemic control can be attained, long-term management may be attempted. Management appears to become easier with time as beta-cell function appears to decrease. When glycemic control cannot be attained using medical therapy, a more radical approach must be considered. Most centers opt of near-total pancreatectomy, a procedure that is associated with a high rate of success in terms of control of hypoglycemia. However, many, if not all of these patients will develop insulin-requiring diabetes. The risk of persistent hypoglycemia and of diabetes appear to be related to the degree of pancreatectomy, with less than 80% pancreatectomy associate with a very high incidence of persistent, severe hypoglycemia and 95% pancreatectomy being associated with insulin-requiring diabetes. Recently it was documented that focal-HI can be cured by resection of the focal lesion only, a procedure that appears to carry little if any risk of diabetes. However, identifying patients with focal disease, and then identifying the lesion in those that have it, has proven extremely difficult. Selective portal vein sampling for insulin appears to be both sensitive and specific, but it is difficult to perform and requires maintaining the child in a state of mild to moderate hypoglycemia for several hours. Other techniques such as selective arterial calcium infusion and acute insulin response to tolbutamide are being developed but their utility appears to be limited. Recently it was shown that positron emission tomography (PET) with 18F-Dopa is both sensitive and specific for the diagnsosis and localization of focal disease [6]. Although availability is still limited to a few specific centers, this is currently the best method for pre-operative localization of focal lesions.

# Hyperinsulinism of Infancy and Childhood

►Persistent Hyperinsulinemic Hypoglycemia

# Hyperinsulinism/Hyperammonemia Syndrome

►Leucine Sensitivity

# Hyperkalemia

Ruth Schreiber, Daniel Landau
Department of Pediatrics, Soroka University Medical Center, Beer Sheva, Israel

## Definition and Characteristics

Hyperkalemia, serum potassium ($K^+$) concentration higher than 5.5 mEq/L, is a rare occurrence in normal subjects, due to cellular and renal adaptations preventing significant accumulation of $K^+$ in the extracellular fluid. Clinical consequences of hyperkalemia are related to the adverse electrophysiologic effects of an altered transmembrane $K^+$ gradient on excitable tissues, reducing the resting membrane potential, initially enhancing but ultimately suppressing tissue excitability ("depolarizing block").

Cardiac arrhythmias (potentially fatal) generally develop when the plasma $K^+$ concentration rises above 7 mEq/L, however, adverse effects may be seen with lower plasma levels if hyperkalemia has developed acutely or with other metabolic derangements such as acidosis or hypocalcemia. Neuromuscular system manifestations include skeletal muscle weakness, paresthesias, and ascending flaccid paralysis.

The major three etiological categories include: high $K^+$ intake, movement of $K^+$ from cells to the extracellular fluid, but mostly impairment in urinary $K^+$ excretion [1].

## Prevalence

Hyperkalemia has been reported in 1.1–10% of all hospitalized patients.

## Genes

Genes associated with hyperkalemia are summarized in the Table 1 below.

## Molecular and Systemic Pathophysiology

Although small amounts of $K^+$ are lost each day in stool and sweat, the kidney plays the major role in the maintenance of $K^+$ balance. Roughly 98% of the body $K^+$ is located in the cells. Ingestion of a $K^+$ load leads to the uptake of most of the excess $K^+$ by the cells, a process regulated by insulin and β-2-adrenergic receptors, by increasing the activity of the Na-K-ATPase pump in the cell membrane, and by $K^+$ itself. This prevents a potentially serious elevation in the plasma $K^+$ concentration until the excretion of the excess $K^+$ in the urine, mediated by aldosterone. The net effect is that most of the $K^+$ load is excreted in 6–8 h. Metabolic acidosis, insulin deficiency diabetes

**Hyperkalemia. Table 1** Genes associated with hyperkalemia

| Mutated gene | Chromosomal location/heredity | Cell involved | Phenotype | Special features |
|---|---|---|---|---|
| CYP11B2 (aldosterone synthase) | 8q21/AR | Adrenal | Hypoaldosteronism | Congenital adrenal hyperplasia leading to reduced or absent aldosterone |
| CYP11B1(11-β hydroxylase) | 8q21/AR | Adrenal | | |
| CYP21A2(21 hydroxylase) | 6p21.3/AR | Adrenal | | |
| ENaC | 16p13-p12 | CCD | Pseudohypoaldosteronism (PHA type I) | Loss-of-function mutation. Severe phenotype. Multi organ involvement |
| | 12p13/AR | | | |
| MLR (mineralocorticoid receptor) | 4q31.1/AD | CCD | | Mild/transient renal phenotype |
| WNK4 | 17q21/AD | DCT | Gordon syndrome (PHA type II) | Low renin hypertension. Gain-of-function missense mutations. An additional locus referred to as PHA IIA, has been mapped to 1q |
| WNK1 | 12p/AD | DCT | | |
| KCNJ1 (ROMK) | 11q24/AR | TAL or DCT | Antenatal Bartter syndrome | Transient hyperkalemia (and not hypokalemia, as usually seen in this syndrome) in the neonatal period [2] |
| SCNA4 | 17q23AD | Skeletal muscle | Hyperkalemic periodic paralysis | Point mutations encoding skeletal muscle sodium channel |

mellitus, β blockers, tissue catabolism and severe exercise lead to a transcellular shift of $K^+$ out of the cells causing hyperkalemia. In hyperkalemic periodic paralysis, continuous $Na^+$ channel activity results in episodes of hyperkalemia either due to $K^+$ release from skeletal muscle cells or to an inability of ingested $K^+$ to enter the cells.

The main nephron site where $K^+$ secretion is regulated is in the cortical collecting duct (CCD), where reabsorption of $Na^+$ occurs via the ENaC channel in the luminal membrane of principal cells (and can be blocked by K-sparing diuretics such as amiloride) and $K^+$ secretion occurs through several K+ channels including ROMK (KCNJ1).

Aldosterone is released from the adrenal gland in response to a low effective circulating volume mediated via the renin-angiotensin system or directly by hyperkalemia. In adults hyporeninemic hypoaldosteronism and primary adrenal insufficiency are the most common reasons for hypoaldosteronism. The hereditary adrenal enzyme deficiencies and type 1 pseudohypoaldosteronism begin in infancy or childhood. A rise in serum $K^+$ concentration directly stimulates aldosterone and $K^+$ secretion. The net effect is that the rise in the serum $K^+$ concentration is generally small in patients with normal renal function. However, in advanced renal failure, impaired $K^+$ excretion due to hyporeninemic hypoaldosteronism, a decreased distal flow and a reduced cellular uptake, lead to hyperkalemia.

Potassium secretion via the colon becomes physiologically important in patients with end-stage renal failure on chronic dialysis, in whom enhanced fecal losses may account for the excretion of as much as 30–50% of dietary $K^+$ intake.

### Diagnostic Principles

Investigation includes urine and plasma electrolytes and osmolality, blood gases and ECG. Calculation of the transtubular $K^+$ gradient (TTKG) [$=(U_K \times P_{osm})/(P_K \times U_{osm})$] can estimate the degree of aldosterone action. A value below 7, and particularly below 5 is highly suggestive of aldosterone deficiency or resistance [2].

### Therapeutic Principles

The treatment of hyperkalemia is divided into three general categories: (i) antagonism of the cardiac effects of hyperkalemia with intravenous calcium; (ii) rapid reduction in serum $K^+$ by redistribution into cells with β2 –agonists and insulin, and sodium bicarbonate when metabolic acidosis exist; (iii) removal of $K^+$ from the body with diuretics, cation exchange resins and dialysis [3].

Keiya Tada[1], Yoichi Matsubara[1,2]
[1]Department of Pediatrics, Tohoku University School of Medicine, Sendai, Japan
[2]Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan

### Definition and Characteristics

This is an extremely rare disorder resulting in failure to thrive, progressive mental deterioration, convulsions, and intermittent dehydration and dyspnea. The reported patients showed mild to moderate elevation of plasma

leucine and isoleucine and normal plasma valine and metabolic acidosis without ketosis.

## Prevalence

There is only one report of two affected French siblings presenting at 2–3 months of age [1].

## Genes

Unknown.

## Molecular and Systemic Pathophysiology

Two different branched chain amino acid transferases, BCT1 and BCT2, are known to catalyze the transamination of branched chain amino acids (leucine, isoleucine and valine). It has been suggested that the transamination of valine may be distinct from that of leucine and isoleucine.

## Diagnostic Principles

The diagnosis is based on characteristic aminochromatogram in plasma, namely the increase of leucine and isoleucine without the increase of valine.

## Therapeutic Principles

Unknown. Low leucine/isoleucine diet failed to improve the clinical condition in the reported cases.

# Hyperlipidemia

Goo Taeg Oh
Laboratory of Cardiovascular Genomics, Ewha Womans University, Seoul, Korea

## Synonyms

Hypercholesterolemia; Hyperlipoproteinemia; Hypertriglyceridemia; Dyslipidemia

## Definition and Characteristics

Hyperlipidemia is a metabolic complex disease characterized by abnormally elevated levels of lipids in the plasma.

All hyperlipoproteinemias are characterized by hyperlipidemia, which refers to elevated plasma cholesterol or triglyceride levels or both. The primary causes of hyperlipoproteinemia are hypercholesterolemia, hypertriglyceridemia, and mixed hyperlipoproteinemia, while secondary causes include diabetes mellitus, pancreatitis, renal disease, and hypothyroidism. Many studies have shown that there is a direct correlation between the presence of hyperlipidemia and the development of coronary heart disease (CHD) [1].

Hypercholesterolemia is the term for high cholesterol levels in the blood. Hypertriglyceridemia refers to high triglyceride levels in the blood.

Mixed hyperlipoproteinemia is the concomitant hypercholesterolemia and hypertriglyceridemia seen in two disorders, namely, familial combined hyperlipidemia and dysbetalipoproteinemia.

## Prevalence

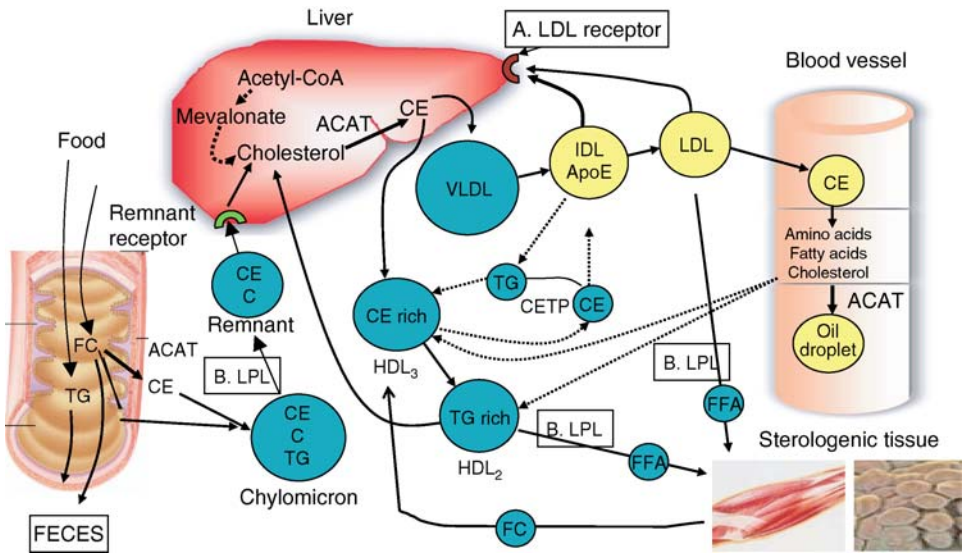
The National Cholesterol Education Program (NCEP) has estimated that more than 100 million American adults have total cholesterol levels above 200 mg/dL, and more than 40 million have cholesterol levels above 240 mg/dL [2].

## Genes

1. Low density lipoprotein receptor (LDLR) (19p13.3): more than 200 different mutations, autosomal dominant disorder, familial hypercholesterolemia, familial defective ApoB100
2. Lipoprotein lipase (LPL) (8p22): autosomal recessive disorder, familial LPL deficiency, familial apoprotein CII deficiency
3. Apolipoprotein E (APOE) (19q13.2): homozygosity apo E2, the binding defective form of apoE, dysbetalipoproteinemia

## Molecular and Systemic Pathophysiology

The major lipoproteins are classified according to their relative densities and composition [3]. They are essential for many cellular processes, including the production and storage of energy, the synthesis of steroid hormones, and the maintenance of cell membrane integrity. Cholesterol homeostasis is maintained through an intricate system of enzymes and cell surface receptors, and the liver is the primary organ responsible for regulating this process. If intracellular cholesterol levels decrease, specific receptors that bind circulating lipoproteins are up-regulated, resulting in enhanced



**Hyperlipidemia. Figure 1** Schematic depiction of the transport of lipids and the cyclic movement of several apoproteins. After meals, serum triglycerides may be elevated primarily due to the presence of chylomicrons. In the fasting state, however, chyromicrons are not usually present. Instead, the liver can synthesize cholesterol and triglycerides and package them together in the form of a VLDL, which is then secreted into the circulation. VLDL is converted to LDL, which is the predominant carrier of cholesterol in the plasma. While VLDL and LDL carry cholesterol and triglycerides from the liver to the periphery, HDL appears to serve the opposite purpose. (a) Mutations in the LDL receptor can cause familial hypercholesterolemia and familial defective ApoB100. (b) Mutations in LPL can cause familial apoprotein CII deficiency. *ACAT* Acyl-CoA: cholesterol acyltransferase; *CETP* cholesterol ester transfer protein; *CE* choleteryl ester; *FC* free cholesterol; *FFA* free fatty acid; *TG* triglyceride; *LDL* low-density lipoprotein; *HDL* high-density lipoprotein; *VLDL* very low-density lipoprotein; *IDL* intermediate-density lipoprotein.

removal and degradation of lipoproteins in the blood. Alterations in the number or function of these receptors can lead to marked elevations in lipids, such as those seen in patients with familial hypercholesterolemia [3]. In the homozygous form of this genetic disorder, the patients lack functional LDL receptors (A in Fig. 1) and typically present with extremely elevated plasma levels of cholesterol and LDL.

Most of these patients develop CHD at an early age. The inhibition of lipoprotein lipase and triglyceride lipase can also decrease the clearance of triglyceride-rich lipoproteins (B in Fig. 1). Other factors such as peripheral insulin resistance, carnitine deficiency, and hyperthyroidism may contribute to lipid abnormalities. The association between high cholesterol levels and the development of CHD has been extensively investigated over the past decades. In particular, LDL appears to play an integral role in the pathophysiology of atherosclerosis. Since LDL and cholesterol are directly involved in the development of atherosclerotic plaques, elevated LDL and cholesterol levels increase the risk of developing CHD and are therefore considered positive risk factors for CHD. On the other hand, since HDL is involved in removing cholesterol from the periphery, it may help prevent the progression (or facilitate the regression) of atherosclerotic lesions. Elevated HDL levels have been shown to be protective against the development of CHD and are therefore considered a negative risk factor, while low levels of HDL are considered a positive risk factor. Unlike the other lipid parameters, the role that triglycerides play in the development of CHD is still controversial.

## Diagnostic Principles

As hyperlipidemia is not generally associated with symptoms, a blood test is needed to diagnose it. According to the National Cholesterol Education Program Guidelines, healthy adults should be tested once every five years starting at age 20. People with a family history of high cholesterol or other risk factors may need earlier or more frequent testing. Most blood tests measure levels of LDL cholesterol, HDL cholesterol, total cholesterol, and triglycerides. To have a low risk of heart disease, the desirable lipid levels are: LDL less than 130 mg/dL, HDL greater than 40 mg/dL (men) or 50 mg/dL (women), total cholesterol less than 200 mg/dL, triglycerides less than 200 mg/dL.

## Therapeutic Principles

Hyperlipidemia is treated by lifestyle change (i.e., diet, weight loss and exercise). If necessary, physicians may

consider adding medications to lifestyle change. There are medications that can lower LDL cholesterol and triglycerides, or raise HDL cholesterol. Statins are the most effective agents available for reducing LDL and total cholesterol. All work by competitively inhibiting HMG-CoA reductase, the enzyme that catalyzes the rate-limiting step in cholesterol biosynthesis. Statins also cause variable reductions in triglycerides, as well as modest increases in HDL. Fibrates and niacin are used to lower triglycerides and raise HDL cholesterol. Bile acid sequestrants (BAS) are resins that bind to bile acids by exchanging them for an anion, thus interrupting the normal enterohepatic recycling. Inhibitor of the microsomal triglyceride transfer protein can be used to reduce the LDL cholesterol levels in patients with homozygous familial hypercholesterolemia, as it reduces apo B production.

# Hyperlipidemia, Combined

Carla Van Der Kallen
Laboratory of Metabolism and Vascular Medicine, University of Maastricht, Maastricht, The Netherlands

## Synonyms

Familial combined hyperlipidemia; FCHL

## Definition and Characteristics

FCHL is the most common inherited lipid disorder in humans, characterized by a variable pattern of elevated levels of plasma cholesterol (Chol) and/or triglycerides (TG), elevated apolipoprotein (apo) B levels, and increased numbers of small, dense low-density lipoprotein (LDL) particles.

## Prevalence

FCHL is affecting 1–2% of the adult population, and 10–20% of premature coronary artery disease patients.

## Genes

Although FCHL was delineated about 30 years ago [1], until now the genetic background, including the number of genes involved, has been unknown. The mode of inheritance of FCHL is complex and heterogeneous. Furthermore, environmental factors and possible gene–environment interactions are also involved in the development of the FCHL. In the last few years, considerable progress in dissecting the genetics of FCHL has identified several loci involved in FCHL. The most prominent loci are 1q21-23, 11p14.1-q12.1, and 16q22-24.1 [2,3]. A recently identified important candidate gene is upstream stimulatory factor 1 (USF1), which is located in the 1q21-23 region [4]. Allelic associations of the at-risk USF1 haplotype were found with TG, apoB, Chol, and LDL peak particle size, supporting the concept that USF1 affects the complex lipid phenotype of FCHL.

## Molecular and Systemic Pathophysiology

FCHL is associated with abnormalities in lipoprotein metabolism, including hepatic hypersecretion of apoB-containing lipoproteins (very low-density lipoproteins (VLDL)), and delayed clearance of atherogenic TG-rich lipoprotein remnants, such as VLDL remnants (intermediate-density lipoproteins) and chylomicron remnants. Increased hepatic VLDL secretion contributes to elevated plasma TG and Chol. In addition to abnormalities in lipid metabolism, insulin resistance of adipose tissue and muscle, fatty liver, hypertension, low HDL, and a prothrombotic state have been documented as well. The presence of insulin resistance and obesity further contributes to the expression of the hyperlipidemia [5]. Recently, it has been recognized that (genetic) overlap with metabolic syndrome exists.

## Diagnostic Principles

At present, there is no complete consensus on diagnostic criteria for FCHL, in large part due to the unknown basic biochemical defect. Since there is no specific (diagnostic) marker, slightly different criteria have been used. The diagnosis is based on clinical criteria and family anamnesis. First, a patient is marked with primary hyperlipidemia, i.e., hypercholesterolemia (hyperChol), hypertriglyceridemia (hyperTG), or both. Subjects with secondary hyperlipidemia, due to, e.g., obesity and/or type 2 diabetes are excluded. Next, a positive family history of premature coronary heart disease has to be present and at least one first degree relative has to have a different hyperlipidemia than the initially identified patient.

### Therapeutic Principles

Together with lipid-lowering drug therapy and management of other cardiovascular risk factors, life style intervention that includes physical activity and diet should be undertaken. Which approach should be used depends to some extent on the primary manifestation (hyperChol, hyperTG, or both). Statins are commonly used to control hyperChol. Statins target and inhibit 3-hydroxy-3-methylglutaryl-coenzyme A (HMGCo-A) reductase that is necessary for the production of Chol in the liver thereby reducing the synthesis of LDL Chol and increasing its catabolism. Fibrates are used to treat hyperTG and mixed hyperlipidemia. Fibrates are peroxisome proliferator-activated receptor (PPAR) alpha agonists that lead to expression of multiple genes involved in lipoprotein metabolism. They stimulate apo A-I and A-II synthesis, decrease synthesis of TG, and enhance catabolism of TG-rich particles. Therefore, fibrates lower TG and increase HDL Chol. Niacin effectively treats the common lipid abnormalities. Niacin binds to its G-coupled protein receptor, highly expressed in adipose tissue. Subsequently, it activates a G-protein signal, which reduces cAMP concentrations and inhibits lipolysis. Therefore, niacin reduces the production of free fatty acids by adipose tissue, which results in a reduced availability of substrate for VLDL synthesis in the liver.

## Hypermagnesemia

Joel Michels Topf[1], Patrick Murray[2]
[1]Chronic Kidney Disease Clinics, Detroit, MI, USA
[2]St. John Hospital and Medical Center, University of Chicago, Chicago, IL, USA

### Synonyms

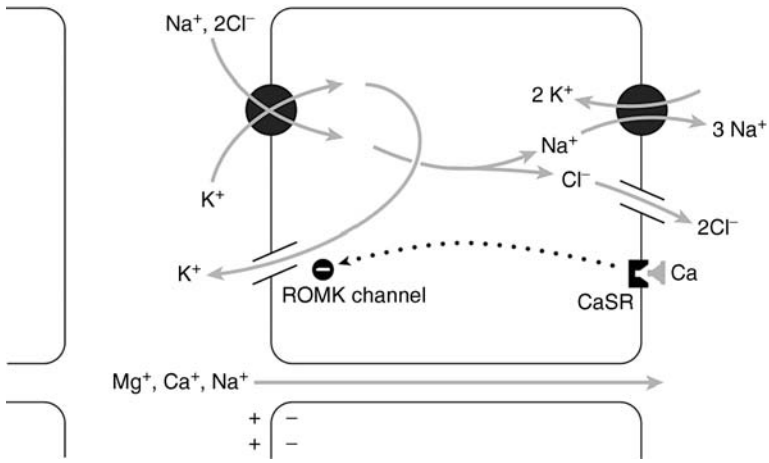
Hypermagnesemia; Familial hypocalciuric hypercalcemia; Magnesemia

### Definition and Characteristics

Hypermagnesemia is characterized by a serum magnesium level greater than 0.95 mmol/L (2.3 mg/dL), but symptoms are uncommon until magnesium rises above 2–3 mmol/L. Magnesium can block synaptic transmission of nerve impulses. Increasing magnesium levels can sequentially cause loss of deep tendon reflexes, flaccid paralysis and apnea. Other complications include bradycardia, hypotension and heart block.

### Prevalence

Like hypomagnesemia, hypermagnesemia is almost always of environmental origin, with genetic causes being unusual. Unlike hypomagnesemia, however,



**Hypermagnesemia. Figure 1** Activation of the CaSR in the thick ascending limb of the Loop of Henle decreases the conductance of the ROMK channel. Slowed conductance in the ROMK channel prevents the creating of a positive potential difference, essential for efficient paracellular Mg, Na and Ca reabsorption.

symptomatic hypermagnesemia is very rare. In a study of nearly 20,000 magnesium measurements, levels high enough to cause symptomatic hypermagnesemia were found in only eight patients [1]. No formal prevalence data is available for genetic causes of hypermagnesemia.

## Genes

Familial hypocalciuric hypercalcemia (FHH) and neonatal severe hyperparathyroidism (NSHPT) both result from inactivating mutations of the Ca sensing receptor [2]. The heterozygote form is FHH and is autosomal dominant. The homozygous condition is NSHPT and is autosomal recessive. The CaSR is a seven-transmembrane-spanning, G-protein-coupled receptor located at 3q13.3-21. Several missense mutations have been associated with both disorders.

## Molecular and Systemic Pathophysiology

The CaSR normally regulates calcium and magnesium reabsorption in the thick ascending limb of the loop of Henle (TAL). Activation of CaSR inhibits the ROMK channel reducing the positive potential difference in the tubule. The loss of polarization decreases the driving force for paracellular magnesium and calcium reabsorption. Defective CaSR prevents this and patients have unregulated reabsorption of magnesium and calcium at the TAL (Fig. 1).

## Diagnostic Principles

The primary consideration in looking for genetic causes of hypermagnesemia is to differentiate it from the more common environmental causes and primary hyperparathyroidism, which presents similarly to FHH. Environmental causes of hypermagnesemia are associated with either excessive magnesium ingestion (parenteral, oral or colonic have all been reported) in association with decreased renal function. In the largest series of environmental causes of hypermagnesemia the average Cr was 422 mmol/L (4.8 mg/dL) [1]. In diagnosing FHH most of the diagnostic work-up is focused on differentiating FHH from primary hyperparathyroidism. In both conditions calcium and PTH plasma concentrations are increased. The primary differentiator would be a family history of hypercalcemia and a paucity of symptoms in FHH. Importantly, patients with primary hyperparathyroidism do not have hypermagnesemia.

## Therapeutic Principles

Patients with FHH are typically asymptomatic. Despite elevated calcium and magnesium levels they have few of the symptoms usually associated with these anomalies. It is thought that the abnormal CaSR that causes the condition also protects them from most of the symptoms. The primary therapeutic goal is not to misdiagnose primary hyperparathyroidism and send the patient for parathyroidectomy. A benign course is not the case for NSHPT, which presents with severe hypercalcemia and hyperparathyroidism during infancy. These patients require parathyroidectomy to prevent hypercalcemia and skeletal demineralization [3].

# Hypermethioninemia due to Methionine Adenosyltransferase I/III Deficiency

S. Harvey Mudd
NIHM/DIRP/LMB, National Institutes of Health, Bethesda, MD, USA

## Definition and Characteristics

Deficient activity of methionine adenosyltransferase I/III (MAT I/III) leads to persistent hypermethioninemia without elevation of plasma *S*-adenosylmethionine (AdoMet).

## Prevalence

About 70 patients known, mostly heterozygotes for R264H.

## Genes

Defect of MAT1A encoding methionine adenosyltransferase I/III (MAT I/III).

## Molecular and Systemic Pathophysiology

Methionine adenosyltransferase (MAT) catalyzes the conversion of methionine to *S*-adenosylmethionine (AdoMet), the methyl group donor in the 39, or more, AdoMet-dependent methyltransferase reactions occurring in humans (see Fig. 1 in the chapter ►Homocystinuria due to Cystathionine Beta-Syntase Deficiency). Humans possess two genes, MAT1A and MAT2A, located, respectively on chromosomes 10q22 and 2p11.2, and encoding catalytically active subunits of forms of MAT. The encoded subunits have 84% identical amino acid sequences. Those encoded by MAT1A form either tetrameric (MAT I) or dimeric (MAT III) enzymes. Those encoded by MAT 2A occur in MAT II. MAT1A is expressed in liver post-natally. MAT2A is expressed in all tissues, including fetal liver and, to a small extent, adult liver [1]. Inactivating mutations in MAT1A produce MAT I/III deficiency, so termed because the effects on MAT I and MAT III have usually not been separately defined. MAT I/III-deficient individuals have been ascertained during the past approximately 35 years, predominately by findings of elevated blood methionine in newborn screening programs seeking hypermethioninemia as an indicator of possible cystathionine beta-synthase (CBS) deficiency. Thus, most known MAT I/III-deficient patients are as yet relatively young and the longer-term prognosis remains uncertain. Molecular genetic studies have identified at least 27 inactivating mutations in MAT1A. Most behave as Mendelian recessive traits, but one, R264H, behaves as a Mendelian dominant leading to mild hypermethioninemia. Although individuals with point mutations with some residual MAT I/III activity have usually been clinically normal, three of the five known patients with the most severe losses of activity (due to truncating mutations or a splicing defect) have developed brain demyelination and/or severe mental deficits [1]. Although the evidence is suggestive, a cause-and-effect relationship between MAT I/III deficiency and these neurological effects has not been rigorously established, and the possible pathophysiologic connection between failure to synthesize AdoMet in the liver and brain damage remains unclear. Synthesis of AdoMet by MAT II (normal in MAT I/III-deficient individuals) almost surely provides some protection against the adverse effects of MAT I/III deficiency [1].

## Diagnostic Principles

Persistent hypermethionemia is usually the initial metabolic finding consistent with MAT I/III deficiency. This may be severe, ranging up to as high as 2,500 μM (normal < 35 μM), although in MAT1A R264H heterozygotes the mean has been 188 μM (range 45–400 μM). Given the presence of persistent hypermethioninemia, it is necessary to assess whether this is due to CBS deficiency or some other cause. In MAT I/III deficiency amino acid chromatography does not reveal elevated plasma homocystine, ruling out CBS deficiency. However, with the use of more sensitive methods that assay total homocysteine (tHcy), it turns out that in severe cases of MAT I/III deficiency plasma tHcy may be slightly elevated (up to 40–50 μM; 5–14 μM) [2]. This may cause misdiagnosis of MAT I/III deficiency as CBS deficiency. A useful addition is assay of plasma cystathionine, a metabolite that will be low or undetected in CBS deficiency, but normal or slightly elevated in MAT I/III deficiency [2]. To further substantiate MAT I/IIII deficiency in cases with hypermethioninemia not due to CBS deficiency the most useful additional tool is assay of plasma AdoMet. In spite of the hypermethioninemia, this compound is not elevated in MAT I/III deficiency, although it is in normals with hypermethioninemia due to a methionine load [1], or in individuals with more rare genetic causes of hypermethioninemia such as glycine *N*-methyltransferase deficiency [3] or *S*-adenosylhomocysteine hydrolase deficiency [4]. Hypermethioninemia may occur also in intensive care unit/very low birth weight babies, in some infants receiving excess dietary methionine [5], in tyrosinemia 1 [1] and (usually to only a slight extent) in liver disease [3].

## Therapeutic Principles

Because of the paucity of experience, little has been proven with respect to effective therapy in MAT I/III

deficiency. Dietary methionine restriction, at least for individuals with some residual MAT I/III activity, is not advised. In one girl, brain demyelination was mitigated during administration of oral AdoMet. In the pregnancies followed in a homozygote for a point mutation in MAT1A, eggs were ingested as a supplemental source of phosphatidylcholine and three normal babies were born [6].

# Hypermetropia

Jaime Tejedor
Department of Ophthalmology, Hospital Ramón y Cajal, Madrid, Spain

## Synonyms

Hyperopia; Farsightedness

## Definition and Characteristics

The eye has insufficient refractive power for its axial length. The far point of the eye, conjugate to the sharp retinal image with accommodation relaxed, i.e., from which light rays focus on the retina, is placed behind the eye. Hypermetropia may be axial (axial length too short for the relatively low refractive power of the eye) or refractive (*index* – anomalous refractive indices of one or more media, *curvature* – increased radius of curvature in any refractive surface, or *anterior chamber*–decreased anterior chamber depth – *hyperopia*); physiological (each component of refraction lies within the normal distribution) or pathological (lies outside the limits of normal biological variation, typically with reduction of axial length by a space-occupying lesion); and, with regard to the action of accommodation, total hyperopia may be divided into latent (uncovered by cycloplegic refraction) and manifest (maximum positive lens that provides the best distance visual acuity), and the latter may be subdivided into absolute (not compensated for by accommodation, exceeds the amplitude of accommodation) and facultative (masked by accommodation at the patient's will).

## Prevalence

Seventy percent of all adult eyes studied in large-scale surveys fall into the range of hypermetropia up to + 2.00 D, and 40% are hypermetropes over + 1.00 D. Hypermetropia over + 1.00 D to + 8.00 D in worse eye affects 47.4% of total sample in surveys of ophthalmic prescribing. Neonate eyes are found to be hypermetropic up to + 4 D about 57%, and beyond this degree up to + 12 D a further 18% (25% are myopic). The mean spherical refractive error is slightly negative at age 3 months, + 0.50 D at age 1 year, and maintained till age 8 years when it moves toward myopia again. Since then, there is a trend toward myopia until 20–30 years of age, and toward hyperopia beyond that age [1].

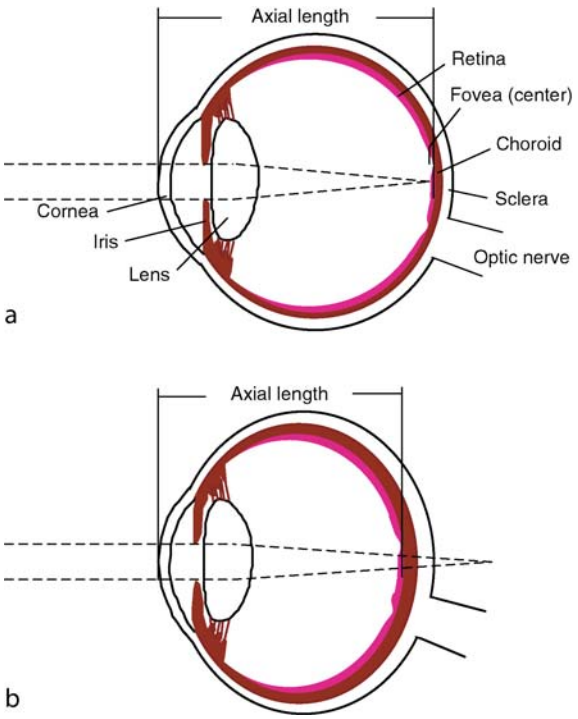
## Genes

In general, inheritance of hyperopia is considered to be polygenic. Genetic linkage of extreme axial hyperopia (without structural ocular abnormalities, nanophthalmos) to 11q23.3 has been described, particularly a 13-exon gene encoding MFRP, a protein related to the Frizzled family [2], expressed prominently only in the eye (RPE and ciliary body). Microphthalmos (reduced eye volume due to growth failure, with structural abnormalities) is rarely caused by gene mutations in PAX6, SOX2, CHX10, and MFRP.

## Molecular and Systemic Pathophysiology

Humans are born with a wide variety of refractive errors that resemble a Gaussian distribution with some skew toward hyperopia. Axial elongation of the eye is regulated, during development, through a vision-dependent process, known as emmetropization, by matching the axial length of the eye to the optical power. Genetic factors and, to a lesser extent, environmental risk factors, in association, are supposed to

induce hyperopia by failure of the emmetropization process. Hyperopia has been associated with poor reading ability, lower intelligence test scores relative to myopic children, learning difficulties, delay in visual perceptual skills, amblyopia, and strabismus. In animal studies, transient hyperopia occurs in some species after form deprivation, and hyperopia has been induced by dark rearing and fitting positive lenses to emmetropic eyes [3], indicating that myopic defocus generates a stop signal for growth. Detecting the sign of defocus and controlling eye growth involves local intraocular mechanisms. Presumably, signals pass from the retina (and retinal pigment epithelium) to the choroid, on their way to the sclera. Upregulation of the expression of early intermediate genes ZENK and fos, and glucagon synthesis, in glucagon-containing amacrine cells, is found under conditions that suppress eye growth causing hyperopia [4], like positive lenses. Increased retinoic acid synthesis in the choroid (which decreases the rate of scleral glycosaminoglycan synthesis) [5] and decreased retinoic acid synthesis in the retina are also associated with conditions that suppress eye growth. Basic fibroblast growth factor (bFGF) may act as a stop signal in the sclera, although it stimulates growth of scleral chondrocytes and fibroblasts (Fig. 1).



**Hypermetropia. Figure 1** In emmetropia, the overall dioptric power of the eye is adequate to focus rays on the retina (a), whereas in axial hyperopia, the most frequent type of hyperopia, the power of the eye is normal, but the axial length is short and the retina lies in front of the posterior focal plane. In cases of extreme axial hyperopia (nanophthalmos), the sclera is thicker than normal, the choroidal vascular bed expands, and the anterior chamber angle of the eye (between iris and cornea) is narrow (b).

## Diagnostic Principles

Retinoscopy under cycloplegia is mandatory, particularly in children, to uncover latent hypermetropia. Use of duochrome test (green is seen better), phoropter (or trial lenses), keratometer, cross cylinders, and astigmatic dial (fogging) with optotype charts may be of use in subjective refining of hyperopic refractive error.

## Therapeutic Principles

Correction with positive lenses moves the far point of the eye to infinity. Keratorefractive surgery corrects hyperopia by sculpting the cornea or implanting an IOL into the eye. Keratomileusis corrects hyperopia when a lamellar section is removed, frozen, shaped on a cryolathe, and replaced in stromal bed. In epikeratophakia, epithelium is removed and a lathed donor lenticule is placed to correct hyperopia. Laser in situ keratomileusis (combination of corneal flap created with microkeratome or femtolaser and laser ablation with excimer argon fluoride laser) induces steepening of the optical zone when tissue is ablated in the surrounding treated zone. It enables correction of low to moderate hyperopia. In thermokeratoplasty, thermal energy is applied to the peripheral cornea in a ring pattern by radiofrequency energy or noncontact holmium:yttrium-aluminum-garnet, to steepen the central cornea and correct low to moderate hyperopia. Pharmacological therapy of hypermetropia will probably be used in the future, but has not yet been established.

## Synonyms

Joint hypermobility syndrome; JHS; Benign joint hypermobility syndrome; BJHS; Generalized joint hypermobility; GJH; Articular hypermobility; Joint laxity

## Definition and Characteristics

In the early seventies, musculoskeletal complaints in association with joint hypermobility were labeled as hypermobility syndrome [1]. Later, after the recognition of the benign prognosis of this disease in terms of life-threatening complications, the term benign joint hypermobility syndrome (BJHS) or joint hypermobility syndrome (JHS) was used [2]. This condition features multitude of musculoskeletal, visceral, and psychological problems along with joints that easily move beyond the normal range expected for a particular joint (Fig. 1). These loose joints give rise to soft tissue injuries, pain, strains, dislocations, and osteoarthritis. Recently, associated neurophysiological abnormalities producing chronic pain, psychological distress, autonomic dysfunction, and joint proprioceptive impairments have been observed in BJHS. The spine is particularly susceptible for lumbar disc prolapse, pars interarticularis defects, and spondylolisthesis. An increased frequency of osteoarthritis, epicondylitis, and plantar fasciitis is also observed. The prevalence of both urinary and anal incontinence appears to be significantly higher in women with BJHS. This condition closely resembles the Ehlers-#x2013;Danlos syndrome hypermobility type (formerly EDS type-III) and it should be differentiated from other heritable disorders of connective tissue (HDCTs) such as Marfan syndrome (MFS), osteogenesis imperfecta (OI), and the Ehlers-Danlos syndromes (other than type-III).

**Hypermobility Syndrome. Figure 1** A patient with BJHS opposing the thumb to volar aspect of forearm.

## Prevalence

It was reported that the number of positive hypermobility tests in hypermobility syndrome was age- and sex-related; the younger the children the higher the score and it was estimated that 10–15% of normal children have hypermobile joints. Women had higher scores than age matched men. An increased prevalence of hypermobility was reported in certain racial groups and in ballet dancers. Reports suggested that increased prevalence was observed in Igloolik Eskimos compared with Native Americans and no difference seen between Caucasian and Maori individuals. The prevalence for Chinese children and adults also seems to be increased when compared with Caucasians. The literature also supports a decreasing prevalence with aging as well as race-related differences.

## Genes

There is a tendency of the condition to run in families. Autosomal dominant is the predominant mode of proposed inheritance. It is felt that certain genes are inherited that predispose to the development of hypermobile joints. Whether any mutations in different types of collagen are involved in pathology of BJHS remains obscure. Segregation analysis excluded COL3A1, COL5A2 and COL6A3 as causative genes for joint hypermobility in two large families with BJHS. Recently, mutations in a noncollagenous molecule, tenascin-X, have been identified in a subset of patients with JHS [3].

## Molecular and Systemic Pathophysiology

It is presumed that the clinical findings in BJHS arise due to excessively lax and nonsupporting ligaments and capsule due to defective collagen and associated proteins. Ultrastructural abnormalities of collagen fibrils have been observed in many diseases characterized by increased joint laxity including EDS, OI, and

BJHS. Some patients carry mutations of tenascin-X (see above), which is a large extracellular matrix glycoprotein, belonging to the family of tenascins. In developing rats, tenascin-X is expressed in tendon sheaths, ligaments, synovium, muscle, and in blood vessel adventia. Other candidate genes for BJHS are those involved in collagen fibrillogenesis such as the family of small leucine-rich proteoglycans (SLRPs). Their importance in regulating fibrillogenesis has become clear from studies of SLRP-deficient mice, some of which have phenotypes resembling EDS [4]. However, thus far no mutations have been identified in any of the SLRPs in BJHS.

## Diagnostic Principles

When a patient presents with a history of joint hypermobility with other clinical symptoms of other connective tissue diseases causing hypermobility, such as EDS, marfans, and OI, those conditions are to be ruled out with clinical evaluation. At present, BJHS is diagnosed with revised Brighton's 1998 criteria [2]. According to this, the presence of two major criteria or one major and two minor criterion or four minor criteria, two minor criteria will suffice where there is an unequivocally affected first degree relative for the diagnosis of BJHS. The scoring for joint hypermobility is done with nine-point Beighton scoring system (Table 1).

*Major Criteria:*

- A Beighton score of 4/9 or greater (either currently or historically)
- Arthralgia for longer than 3 months in four or more joints

*Minor Criteria:*

- A Beighton score of 1, 2, or 3/9 (0, 1, 2, or 3, if aged 50+)
- Arthralgia (≥3 months) in one to three joints or back pain (≥3 months), spondylosis, spondylolysis/spondylolisthesis

**Hypermobility Syndrome. Table 1** Nine-point Beighton hypermobility score [5]

| Ability to do | Right | Left |
|---|---|---|
| More than 10° hyperextension of the elbows | 1 | 1 |
| More than 10° hyperextension of the knee | 1 | 1 |
| Oppose the thumb to the volar aspect of the ipsilateral forearm (Fig. 1) | 1 | 1 |
| Passively dorsiflex the fifth metacarpophalangeal joint to ≥90° | 1 | 1 |
| Place the hands flat on the floor without bending the knees | 1 | |
| Total score | 9 | |

- Dislocation/subluxation in more than one joint, or in one joint on more than one occasion
- Soft tissue rheumatism. ≥3 lesions (e.g., epicondylitis, tenosynovitis, bursitis)
- Marfanoid habitus (tall, slim, span/height ratio >1.03, upper: lower segment ratio less than 0.89, arachnodactily (positive Steinberg/wrist signs))
- Abnormal skin: striae, hyperextensibility, thin skin, papyraceous scarring
- Eye signs: drooping eyelids or myopia or antimongoloid slant
- Varicose veins or hernia or uterine/rectal prolapse

## Therapeutic Principles

The main aim of therapy in BJHS is to improve the quality of life in these patients. This is achieved by advising the patients with proper rehabilitation measures. Proper posture at work and during activities, prevention of soft tissue injuries, isometric strengthening exercises, and counseling is advised. Drugs and use of physical modalities are required when there is a pain and psychological disturbances.

### Synonyms

Morgagni-Stewart-Morel syndrome; Metabolic craniopathy; Endostosis crani; Enostosis cranii; Endocraniosis; Hyperostosis calvaria interna; HCI; Hyperostosis calvariae diffusa; HCD; HFI

### Definition and Characteristics

Hyperostosis frontalis interna (HFI) is a condition involving progressive symmetric irregular cortical thickening (Fig. 1) of inner table of the frontal bone of human skull by smooth, rounded exostosis covered by dura projecting into the cranial cavity.

These exostoses are generally less than 1 cm thick and extend to parietal bones, orbital roofs and may involve both tables of the skull by sparing areas occupied by superior sagittal sinus and venous channels. Even in severe cases, HFI does not cross suture lines and there would be clear boundary along the middle meningeal artery [1].

**Hyperostosis Frontalis Interna. Figure 1** A woman with HFI having depression in the midline of frontal bone.

Morgagni and Santorini first described HFI in 1769 in an obese female patient during autopsy that had hirsutism and thickening of inner table of skull. In 1928, Stewart added neuropsychiatric problems. The first living case was reported by Morel in 1930 leading to the use of the labels Morgagni-Stewart-Morel syndrome. The condition is predominantly found in females >35 years, and is thought to be the result of a more generalized disorder of bone metabolism. The symptoms of HFI (Table 1), obesity, virulism, neuropsychiatric, endocrinal, and vascular symptoms are referred to as Morgagni-Stewart-Morel syndrome. The variant of the HFI is called hyperostosis calvariae diffusa (HCD), which causes diffuse thickening of the vault in both the sides.

## Prevalence

The finding is observed with many clinical conditions and reported with several theories like metabolic and hereditary causes for the disease. Reports estimate that the prevalence of HFI could be in between 5 and 12%. It is more commonly observed in elderly patients, postmenopausal women and especially when there is obesity. The prevalence also varies according to the amount of adipose tissue present in the body and also observed lowest prevalence in thin people.

## Genes

The condition is reported as autosomal dominant [2] and has been observed in families and in archeological remains affecting mostly females.

## Molecular and Systemic Pathophysiology

The pathogenesis behind skull thickening is still not clear. Till now, two mechanisms have been explained, i.e., hormonal theory and vascular theory. Hormonal mechanism for HFI is suggested due to its high prevalence in women and a common association with obesity and endocrinal abnormalities [3]. There are studies, which explain that HFI could be related to adiposity due to increased production or altered metabolism of estrogens by adipose tissue. Prolonged estrogen stimulation at the primary ossification centers of the frontal bone reactivates them and cause abnormal bone growth [1]. Few other reports link the levels of estrogen, leptin, androgens, prolactin, and progesterone for the development of HFI. The vascular mechanism for HFI is explained by the rich and special vascular supply to frontal bone and the adherence of the dura to its inner surface.

**Hyperostosis Frontalis Interna. Table 1** Common clinical features associated with HFI [5]

| System | Abnormalities/symptoms |
|---|---|
| Endocrine | Obesity, hirsutism, galactorrhoea, menstrual disorders, hypogonadism, atrophied testis, hypetrichosis, diabetes mellitus |
| Neurological | Headache (migraines), seizures, cranial nerve palsies, transitory hemiplegias, muscle weakness |
| Psychiatric | Depression, irritability, fatigability |
| ENT | Hearing impairment, vertigo |

## Diagnostic Principles

It is typically an incidental finding in skull X-rays and should be differentiated with meningioma and posttraumatic subdural and dural calcifications. The radiographic criterion for diagnosis is at least 1 cm thickness of the respective cranial bones on a 24 × 30 cm roentgenogram (Fig. 2), Bone scintigraphy, which reflects the vascularity and increased metabolic state of the lesion, is more sensitive.

The imaging finding should be correlated with clinical symptoms mentioned in Table 1 and clinical examination. Accordingly, further hormonal evaluation is required.

## Therapeutic Principles

Surgical treatment is of benefit in cases in which patients present with high intensity headache [4]. Weight reduction by physical exercises and psychological counseling are effective in patients who do not require surgical intervention [4]. Other than these medications are also required for neuropsychiatric symptoms.

**Hyperostosis Frontalis Interna. Figure 2** Lateral skull radiograph showing, thicking of the inner and outer table of the skull vault in the region of frontal bone. Note : Inner table is showing the undulations.

## Synonyms

Caffey disease; Caffey-Silverman disease; ICH

## Definition and Characteristics

Infantile cortical hyperostosis (ICH) is an inherited disorder characterized by hyperirritability, acute inflammation of soft tissues, and massive subperiosteal formation of the underlying bones typically involving the diaphyses of the long bones, mandible, clavicles, or ribs [1]. It is inherited as autosomal dominance with incomplete penetrance and variable expression [2]. A sporadic case of ICH has also been described. The bone changes typically appear before 5 months of age and resolve spontaneously by 2 years of life. Recurrent episodes of cortical hyperostosis are uncommon. It is usually benign and self-limited [1]. However, there are few reports describing the sequelae of the hyperostotic lesions including short stature and persistence of bony deformities. Short stature may be partly due to progressive height loss from scoliosis, compression fractures of the spine, and genu varus [3].

## Prevalence

ICH is a rare condition. It was first reported by Caffey and Silverman in 1945. The prevalence is difficult to estimate since the clinical manifestations are variable. The diagnosis could have been missed in subtle cases. In addition, there are several conditions causing cortical bone lesions in infants mimicking ICH including prolonged prostaglandin infusion, hypervitaminosis A, and hyperphosphatemia [2,4]. After the gene responsible for ICH was identified in 2005, there have been at least four unrelated families with clinically and molecularly confirmed ICH, two from Canada, one from Australia, and one from Thailand [2,3].

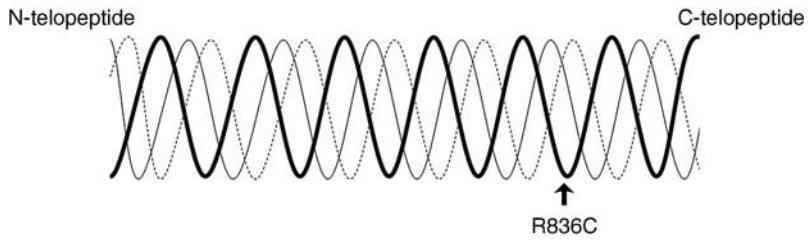
## Genes

ICH is caused by a heterozygous missense mutation in the gene encoding the α1 chain of type 1 collagen (COL1A1) located on chromosome 17q21 [2]. This particular mutation (3040C→T) in a CpG dinucleotide of exon 41 of COL1A1 results in the substitution of an arginine by a cysteine at position 836 (R836C) within the helical domain of the chain. The fact that all four unrelated kindreds from Australia, Canada, and Thailand with an autosomal dominant form of ICH harbor a similar mutation suggests the recurrent nature of the mutation. This indicates that the involved CpG dinucleotide is a mutational hot spot in COL1A1.

Different mutations in COL1A1 have been found in osteogenesis imperfecta and Ehlers-Danlos syndrome (EDS). Interestingly, some of the clinical features of EDS such as hyperextensible skin and joint hyperlaxity were found in some patients affected with ICH. It was shown that the R134C found in EDS and the R836C found in ICH gave a similar effect on synthesis and function of the collagen fibrils [2].

## Molecular and Systemic Pathophysiology

The clinical and radiographic features suggest that a local inflammation is likely one of the major mechanisms underlying ICH. This hypothesis is further supported by a finding of cortical hyperostosis in infants with prostaglandin E administration [4]. There are other possible mechanisms by which the R836C mutation in COL1A1 could lead to the cortical hyperostosis. Arg836 is located within the carboxy-terminal cyanogen bromide peptide 6 (CB6) of the α1(I) chain (Fig. 1), which has been shown to bind with high affinity to IL-2 and to the amyloid protein precursor (APP). Biochemical studies in cultured dermal fibroblasts from an affected individual revealed an abnormal disulfide-bonded α1(I) dimer. Ultrastructural studies of the patient's dermis also showed abnormal collagen fibril architecture. Increased disulfide cross-linking, either within or between mutant collagen fibrils or between the mutant collagens and



**Hyperostosis, Infantile Cortical. Figure 1** Scheme of the collagen fibril reveals the approximate location of the R836C mutation within the triple-helical domain of the α1(I) chain.

other cystein-containing proteins, may be responsible for the alterations in collagen architecture [2].

The fact that hyperostotic lesions in ICH occur mostly during infancy led to the hypothesis that periosteum detachment facilitated with the R836C mutation in COL1A1 would be a key pathological process as the periosteum is loosely attached to the underlying bone structure in infants. In addition, the intrinsic differences in periosteal bone formation in infants and adults may explain the absence of hyperostotic lesions in adults with the R836C mutation.

## Diagnostic Principles

The diagnosis is often made during infancy. The clinical features of painful, soft tissue swelling with the radiographic features of subperiosteal formation of the underlying bones suggest a diagnosis of infantile cortical hyperostosis. Family history may reveal the inherited form. Detection of 3040C→T in exon 41 of COL1A1 confirms the diagnosis.

## Therapeutic Principles

ICH is usually self-limited with symptoms lasting from 2–3 weeks to 2–3 months. The inflammatory nature as well as the bone changes similar to those induced by administration of prostaglandin in infants led to the treatment trials with anti-inflammatory agents [5]. Treatment with indomethacin was able to reduce the symptoms and resulted in a progressive decrease in soft tissue swelling in 1 week.

# Hyperoxalurias, Primary

Bernd Hoppe[1], Albrecht Hesse[2]
[1]University Children's Hospital, University of Cologue, Cologue, Germany
[2]Department of Urology, University of Bonn, Bonn, Germany

## Synonyms

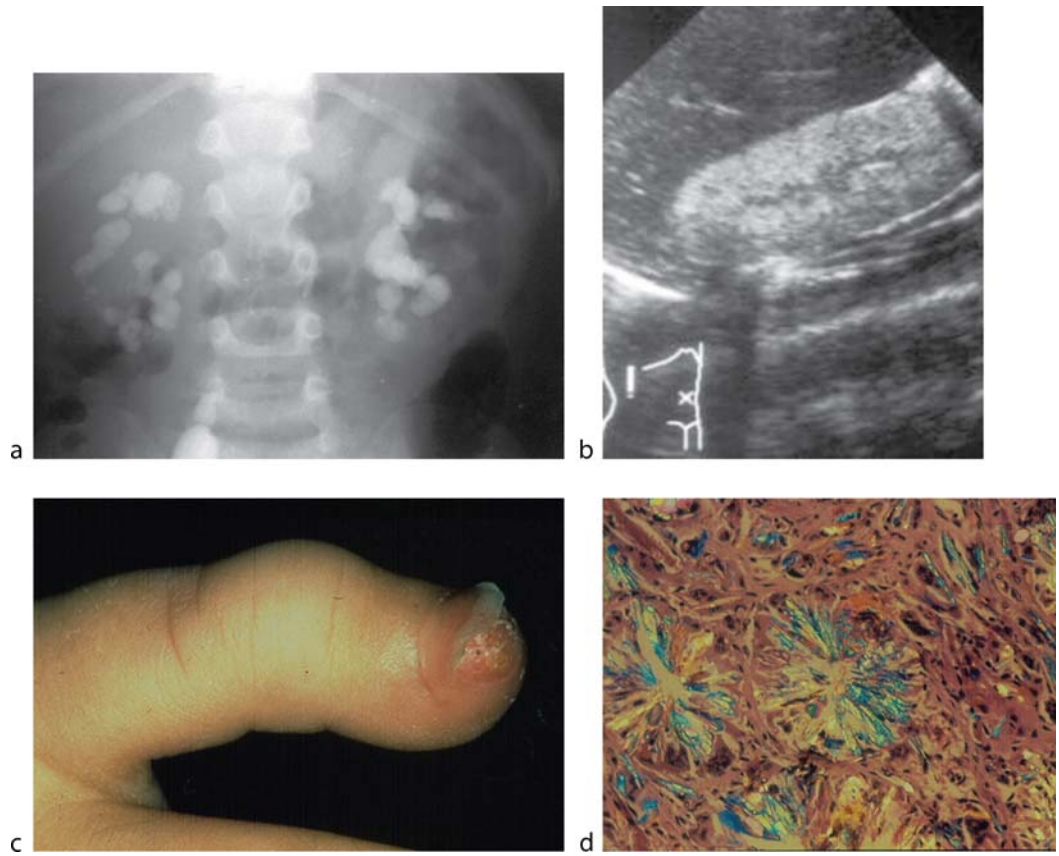
Primary hyperoxaluria types I and II (PH I, OMIM: 259900 and PH II, OMIM: 260000)

## Definition and Characteristics

Autosomal recessive inherited diseases of the glyoxylate metabolism. Lack of or mitochondrially mistargeted liver-specific peroxisomal alanine:glyoxylate aminotransferase (AGT) in PH type I and lack of ubiquitous glyoxylate reductase (GR) in PH type II is leading to endogenous overproduction of oxalate and thus to extreme hyperoxaluria, which is more pronounced in patients with PH type I (>1.0 mmol/1.73 $m^2$/24 h, normal <0.5). In addition, most of the patients with PH type I express an elevated urinary glycolate excretion and those with PH type II have an elevated urinary excretion of L-glyceric acid. Hyperoxaluria leads to recurrent kidney stones and/or progressive nephrocalcinosis and concomitantly to kidney failure.

## Prevalence

Approximately 0.8–2.9:1,000,000, incidence approximately 0.1–0.2:1,000,000 (both regionally different) (Fig. 1).



**Hyperoxalurias, Primary. Figure 1** Presentation of primary hyperoxaluria with severe urolithiasis, nephrocalcinosis, systemic calcium oxalate deposition on skin and in bone marrow with birefringent crystals.

## Genes

Liver-specific peroxisomal AGT (AGXT gene on chromosome 2p37.3) in PH type I and lack of ubiquitous glyoxylate reductase (GR gene on chromosome 9p11) in PH type II.

## Molecular and Systemic Pathophysiology

The overproduction of oxalate increases plasma oxalate levels with subsequent hyperoxaluria and formation of kidney stones eventually leading to renal failure. Impaired renal function leads to further increase of plasma oxalate concentrations, which become extremely high in end stage renal failure (often >100 μmol/l, normal <7.4 μmol/l), thus leading to persistent oversaturation with respect to calcium oxalate in blood and hence to systemic calcium oxalate deposition (= systemic oxalosis). At least 90% of cases express their first symptom in infancy or early childhood with recurrent urolithiasis and/or progressive nephrocalcinosis. Other patients become evident due to hematuria, a suspected urinary tract infection, or only by abdominal pain and routine renal ultrasonography. Although all patients with such symptoms should be screened for urinary oxalate excretion, up to 35% of patients only receive their diagnosis in end stage renal failure! The clinical presentation of the hyperoxalurias is extremely heterogeneous with kidney failure due to severe nephrocalcinosis in early infancy to only a stone passage later in adult life with fully preserved kidney function. Even siblings with the same disease-specific genotype can express a completely different phenotype.

## Diagnostic Principles

For diagnostic purposes, determination of 24 h urinary oxalate, glycolate, and L-glyceric acid excretion is necessary. In newborns, infants, and young children, repeated spot urine examinations are possible. However, age-related normal values have to be considered. If the clinical symptoms and the urinary parameters suggest primary hyperoxaluria, either liver biopsy to show the underlying enzyme defect or mutation analysis with screening of the AGXT gene on chromosome 2p37.3 or

the GR gene on chromosome 9p11 is possible. Currently, liver biopsy is still considered state of the art, especially before transplantation is performed. More then 60 mutations of the AGXT gene are known, which are spread over all 11 exons. The c.508A>C, 33_34insC and 731T>C mutations account for ~50% of all mutations found in European PH I patients. For the GR gene, 14 mutations are currently known.

## Therapeutic Principles

All patients are recommended to increase their daily fluid intake to at least 1.5–2 l/m$^2$ body surface area. In addition, they should receive alkaline citrate or orthophosphate therapy to increase both urinary pH and citrate excretion that increases the solubility index of calcium oxalate. Around 35% of patients with PH type I express a normalization or at least a fair reduction of their endogenous oxalate production and hence of the urinary oxalate excretion under therapy with pyridoxine, a cofactor of the AGT. This effect is said to be genotype-specific. Future therapeutic interventions may include oral treatment with intestinal oxalate degrading bacteria (Oxalobacter formigenes) or chaperone therapy. Hepatocyte transplantation in PH I or gene therapy are still not available.

In those patients with end stage renal failure, hemodialysis with a structured regimen, e.g., five- to six times a week, has to be installed quickly and might even be supported by nightly peritoneal dialysis sessions. As no renal replacement therapy is capable of eliminating sufficient amounts of oxalate, early and preferably combined liver–kidney transplantation in PH type I and isolated kidney transplantation in PH type II is recommended. The longer the period of dialysis is before transplantation, the worse is the eventual outcome.

# Hyperparathyroidism, Primary

Geoffrey N. Hendy[1], David E. C. Cole[2]
[1]Calcium Research Laboratory, Royal Victoria Hospital, and Departments of Medicine, Physiology and Human Genetics, McGill University, Montreal, QC, Canada
[2]Departments of Laboratory Medicine and Pathobiology, Medicine and Pediatrics (Genetics), University of Toronto, Toronto, ON, Canada

## Definition and Characteristics

The important biochemical features of primary hyperparathyroidism are: elevated serum calcium, decreased fasting serum phosphate, increased serum parathyroid hormone (PTH), and hypercalciuria. Eighty-five percent of cases involve a single benign parathyroid adenoma, while hyperplasia (multiple hypercellular glands) is present in 15%. Parathyroid carcinoma is seen in less than 1% of cases, and ectopic secretion of PTH by nonparathyroid tumors is extremely rare.

Although primary hyperparathyroidism is most often detected by its biochemical features, nephrolithiasis due to hypercalciuria is a frequent clinical manifestation. Nephrolithiasis with kidney stones occurs in 20% of patients. Other organ systems can be involved, including skeleton, gastro-intestinal tract, and central nervous system. Formerly a classic feature, overt bone disease (osteitis fibrosa cystica, brown tumors, or pathological fractures) is now rare. Gastrointestinal manifestations (nausea, vomiting, or constipation) are common but nonspecific, while pancreatitis and peptic ulcer disease are now rare. Hypercalcemia and hypercalciuria lead to increased urinary frequency, and progressive nocturia is common. Even mild elevations of calcium can be associated with weakness and a feeling of lassitude. Major mood disturbances and psychotic behavior can be seen with more severe hypercalcemia.

## Prevalence

Primary hyperparathyroidism is one of the common causes of hypercalcemia in adults. With the advent of multichannel autoanalyzer screening, the population incidence was shown to be one in 1,000. Although the disorder can occur at any age, it is most frequent in the sixth decade. More women than men are affected, the ratio being about 3:1. When found in children, primary hyperparathyroidism is likely to be a component of a familial endocrinopathy and a sex bias is not observed.

## Genes

Molecular analyses have determined that most, if not all, parathyroid adenomas and carcinomas, are monoclonal

cell expansions. Alterations in two genes, cyclin D1 and the multiple endocrine neoplasia type 1 (MEN1) gene, have been implicated in the development of some sporadic parathyroid adenomas. Cytogenetic loss of 13q containing the retinoblastoma (RB) and other tumor suppressor genes has also been implicated in parathyroid carcinoma. Karyotopic abnormalities involving several other chromosomal regions have been observed in parathyroid adenomas, but the genes remain to be identified (see Table 1).

One in ten cases of primary hyperparathyroidism is hereditary, occurring as an isolated form or associated with other abnormalities. Genetic linkage studies have confirmed the hereditary nature of these syndromes and in some cases identified specific mutations responsible for parathyroid hyperfunction. These entities include familial hypocalciuric hypercalcemia (FHH)/neonatal severe hyperparathyroidism (NSHPT), MEN1 and multiple endocrine neoplasia type 2 (MEN2), the hyperparathyroidism-jaw tumor syndrome (HPT-JT), and familial isolated hyperparathyroidism (FIHP).

## Molecular and Systemic Pathophysiology

Hypercalcemia and elevated serum PTH levels are biochemical hallmarks of primary hyperparathyroidism. It is recommended that more than one measurement of these parameters be made, as values may be within the normal range early in the disease. Changes in serum proteins affect the ionized (biologically active) calcium fraction and total calcium values should be corrected for albumin concentration, or direct measurement of the ionized calcium made. Serum PTH should be assayed by a two-site immunoradiometric assay which detects the intact molecule. Elevated PTH levels occur in 90% of primary hyperparathyroid patients, but a high normal PTH level in the face of hypercalcemia indicates lack of suppression and is consistent with hyperparathyroidism. Serum phosphate is usually at the lower end of the normal range because of the phosphaturic action of PTH. Hypophosphatemia occurs in about 25% of patients. To be diagnostically useful, serum phosphate measurements should be made in the fasting state to avoid postprandial fluctuations. Serum bone-specific alkaline phosphatase is a practical measure of skeletal involvement. Mild hyperchloremic acidosis is common because of the effects of PTH on renal chloride and bicarbonate handling. Urinary calcium is frankly elevated in one-third of patients. The effect of PTH on the renal 25-hydroxyvitamin D-1α-hydroxylase enzyme is reflected in serum 1,25-dihydroxyvitamin D levels at the upper end of the normal range or frank elevations in a third of cases.

## Diagnostic Principles

With the frequent detection of hypercalcemia in biochemical screening programs, the differentiation of primary hyperparathyroidism from other conditions causing hypercalcemia has become increasingly important. Causes of non-parathyroid hypercalcemia include humoral hypercalcemia of malignancy, vitamin D or A intoxication, milk-alkali syndrome, granulomatous disorders (especially sarcoidosis), immobilization of patients with a pre-existing high bone turnover state such as adolescence, thyrotoxicosis, Paget's disease, and treatment with thiazide diuretics or lithium. Parathyroid hormone-related protein (PTHrP) is the major causative agent in the humoral hypercalcemia of malignancy, although many other circulating factors may contribute. New immunoassays for PTH and PTHrP have greatly facilitated the differential diagnosis of primary hyperparathyroidism from malignancy-associated hypercalcemia.

Study of the relatives of patients with hypercalcemia can contribute to establishing the diagnosis in the 10% of all cases of primary hyperparathyroidism that prove to be hereditary. The finding of another relative with hypercalcemia furnishes evidence of primary hyperparathyroidism, if FHH is not suggested by a relatively low urinary calcium-to-creatinine clearance ratio or definitively diagnosed by the identification of a mutation of the calcium-sensing receptor (CASR) gene. The finding of a hypercalcemic relative also requires

investigation of the patient for manifestations of the MEN or HPT-JT syndromes.

## Therapeutic Principles

Standard clinical treatments for symptomatic hypercalcemia and/or hypercalciuria should be considered, but only until definitive surgical therapy is carried out, or surgical therapy is contra-indicated. Long-term medical therapy (estrogens, progestins, bisphosphonates) is unsatisfactory at present and is reserved for patients unable to undergo surgery. For the future, calcimimetics that activate the parathyroid CASR, inhibiting PTH secretion and lowering the serum calcium level, hold the promise of becoming the first specific medical therapy for primary hyperparathyroidism.

Parathyroidectomy by an experienced surgeon is the treatment of choice. In cases of multiglandular disease, total parathyroidectomy is the definitive treatment and the patient is maintained on life-long calcium and vitamin D supplementation. Some centers perform either subtotal parathyroidectomy (removal of 3 ½ glands), or total parathyroidectomy with autotransplantation of parathyroid tissue into the non-dominant forearm. However, persistent or recurrent hypercalcemia may ensue if the transplanted tissue resumes its autonomous growth, necessitating further surgery.

Criteria for surgery in hyperparathyroidism have been established by a consensus conference of the National Institutes of Health. Candidates for surgery are those having one or more of the following: hypercalcemia >12 mg/dL; hypercalciuria >400 mg/day; kidney stones: reduced bone density; or age <50years). Asymptomatic patients who are managed conservatively with twice yearly serum calcium and urinary calcium excretion determinations and annual bone densitometry generally do well since the progression of the disease is usually quite slow.

# Hyperparathyroidism, Secondary in Chronic Kidney Disease

Charles R. Nolan
Department of Medicine & Surgery, University of Texas, Health Science Center, San Antonio, TX, USA

## Definition and Characteristics

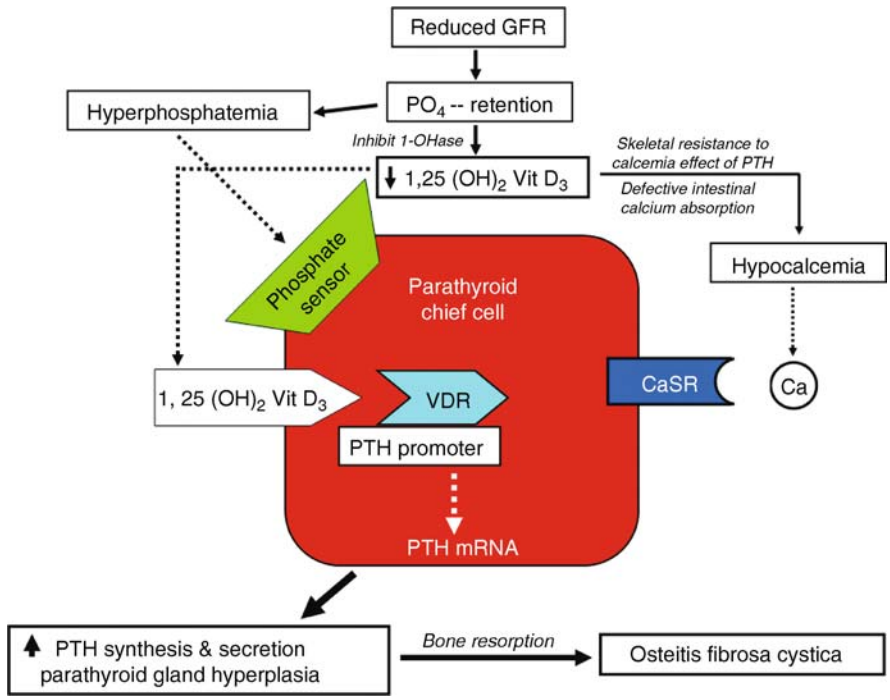
An acquired disorder in patients with chronic kidney disease manifest by hyperplasia of the parathyroid glands, over-production of parathyroid hormone (PTH) and a form of renal osteodystrophy known as osteitis fibrosis cystica [1]. Skeletal manifestations of the disease include pathologic fractures and shortening of the fingers due to resorption of the distal phalanges. Radiographic manifestations of hyperparathyroid bone disease include resorption of the distal phalanges and medial aspect of the middle phalanges of the fingers, resorption of the distal clavicles, alternating radiodensity and radiolucency of the vertebral bodies known as "rugger-jersey spine," patchy demineralization of the skull, loss of the lamina dura surrounding the teeth, and increased marrow fibrosis with punched out lesions on skeletal radiographs called "brown tumors." Abnormal phosphorus metabolism can also cause deposition of calcium – phosphate (hydroxyapatite) in the tissues leading to periarticular deposits (tumoral calcinosis) or vascular calcification.

## Prevalence

Varying degrees of secondary hyperparathyroidism occur in virtually all patients with advanced chronic kidney disease. The severity of the disease increases progressively as renal function declines and steadily worsens with increasing duration of chronic renal failure in patients on maintenance hemodialysis (Fig. 1).

## Molecular and Systemic Pathophysiology

In the setting of advancing CKD, secondary hyperparathyroidism develops as a consequence of phosphate retention as well as reduced renal production of active vitamin D, resulting in hyperphosphatemia, hypocalcemia, and elevated parathyroid hormone levels (Fig. 1). When the glomerular filtration rate falls below 70 ml/min, renal excretion of phosphate can no longer keep pace with gastrointestinal absorption and phosphorus retention occurs. The resulting hyperphosphatemia inhibits the renal 1-alpha hydroxylase so that production of active 1,25 $(OH)_2$ vitamin $D_3$ by the kidney is reduced. Vitamin D deficiency then leads to hypocalcemia as a consequence of defective gastrointestinal calcium absorption and skeletal resistance to the calcemic effect of PTH. The serum ionized calcium is the most important factor regulating PTH secretion. The effects of calcium on



**Hyperparathyroidism, Secondary in Chronic Kidney Disease. Figure 1** Factors regulating parathyroid hormone secretion and gland hyperplasia [3,4].

parathyroid cells are sensed and transduced by a membrane-bound G-protein coupled calcium-sensing receptor (CaSR) [2]. Low serum calcium leads to an increase in PTH secretion, an increase in PTH messenger RNA stability, and parathyroid cell proliferation. Calcimimetic agents such as cinacalcet increase the sensitivity of the CaSR to extracellular calcium thereby inhibiting the release of PTH and lowering PTH levels within a few hours of administration. Active 1,25 $(OH)_2$ vitamin D inhibits PTH production by the parathyroid gland by binding to the cytoplasmic vitamin D receptor (VDR). The 1,25 $(OH)_2$ vitamin $D_3$ – VDR complex binds to the PTH promoter region of the PTH genome and inhibits the transcription of PTH mRNA. Conversely, vitamin D deficiency leads to increased transcript levels of PTH. A chronic decrease in vitamin D levels also leads to parathyroid cell proliferation and gland hyperplasia. Treatment with vitamin D sterols decreases transcription of the PTH gene and reduces hormone synthesis and release over a period of hours to days. There also appears to be a direct effect of phosphate on PTH production by the parathyroid gland. Although the putative phosphate sensor has not yet been characterized, hyperphosphatemia has a direct effect of the parathyroid gland to increase PTH secretion, increase PTH messenger RNA stability, and cause parathyroid cell proliferation [3]. A long-term increase in PTH levels causes osteoclast activation, leading to bone resorption, increased bone turnover, and bone disease known as osteitis fibrosa cystica [1,2].

## Diagnostic Principles

The coincidence of chronic kidney disease with renal insufficiency in association with hyperphosphatemia, hypocalcemia and elevated intact parathyroid hormone levels suggests the diagnosis.

## Therapeutic Principles

The pathophysiology summarized in Fig. 1 that underlie the development of hyperphosphatemia and secondary hyperparathyroidism in chronic kidney disease provide the clinical rationale for treatment strategies in patients with end-stage renal disease on maintenance hemodialysis which include maintenance of normal serum phosphorus levels (dietary phosphorus restriction, adequate dialysis, and dietary phosphate binders such as calcium acetate, sevelamer hydrochloride or lanthanum carbonate), maintenance of normal serum calcium levels, treatment with oral or intravenous 1,25 $(OH)_2$ vitamin D analogues and the use of orally administered calcimimetic agents such as cinacalcet [2].

# Hyperphenylalaninemia

Haruo Shintaku[1], Hiroshi Ichinose[2]
[1]Department of Pediatrics, Osaka City University Graduate School of Medicine, Osaka, Japan
[2]Department of Life Science, Graduate School of Bioscience and Biotechnology, Tokyo Institute of Technology, Yokohama, Japan

## Synonyms

Phenylketonuria; PKU; Tetrahydrobiopterin; BH4 deficiency; Mild PKU; Mild hyperphenylalaninemia; Atypical PKU; Malignant hyperphenylalaninemia; Malignant PKU; BH4-responsive PAH deficiency; BH4-responsive HPA; BH4-responsive mild PKU; HPA

## Definition and Characteristics

Hyperphenylalaninemia (HPA) is defined as a plasma phenylalanine value of more than 120 μM (2 mg/dl) and an autosomal recessive trait (OMIM 261600) with disorders of phenylalanine hydroxylation, which results from a deficiency of the enzyme phenylalanine-4-hydroxylase (PAH) or its cofactor, tetrahydrobiopterin ($BH_4$) [1,2]. The former due to altered integrity of PAH should be subdivided into different forms, phenylketonuria (PKU) and mild PKU, based on plasma phenylalanine of more than 1,200 μM (20 mg/dl) and of less than 1,200 μM, respectively. The latter include a defect of several enzymes necessary for synthesis and recycling of BH4 (Fig. 1) [1,3,4].

Among patients with mild PKU, BH4-responsive PAH deficiency has shown a gradual decrease in serum phenylalanine concentrations over 1 day following BH4 administration. These patients showed no abnormalities in BH4 metabolism but had mutations in the PAH gene [5].

Prompt diagnosis of neonates with HPA discovered by newborn screening for HPA is necessary, because early treatment helps to prevent neurological injury.

Patients with HPA appear normal at birth and in the neonatal period. Phenylalanine accumulates within the first days of life, and tyrosine levels tend to be low. Clinical features in later infancy can include mental retardation (due to elevated phenylalanine levels and impaired brain myelination), and pale pigmentation of the hair and skin (due to low tyrosine levels and impaired melanine generation). However, more critical neurological symptoms such as convulsions and dystonia are characteristics of BH4 deficiency (due to impaired catecholamine and serotonin biosynthesis) [4].

## Prevalence

The incidence of HPA is on average 1 in 10,000 live births in Europeans; the prevalence of patients with BH4 deficiency is 1% of those with HPA (1 in 1,000,000 live births), and the prevalence of patients with BH4-responsive PAH deficiency is estimated to be more than half of those with mild PKU [1].

## Genes

Several causative genes have been identified. Known genetic causes are listed in Table 1 [2].
BH4-responsive PAH deficiency has at least one mild PKU mutation or missense mutation [5].

## Molecular and Systemic Pathophysiology

There are at least two molecular mechanisms that may explain how mutations in genes that cause HPA may affect pathogenesis of the most important phenotype (impaired cognitive development and neurophysiological functions): (i) impaired PAH and phenylalanine itself, at elevated concentrations, which are harmful molecules; (ii) decreased BH4 levels and three impaired aromatic amino acid hydroxylases (PAH, tyrosine-3-hydroxylase (TH), and tryptophan-5- hydroxylase (TPH)).

The latter, BH4 deficiencies, are disorders affecting phenylalanine homeostasis, and catecholamine and serotonin biosynthesis. The minimum requirements for normal reaction are the apoenzymes, (PAH, TH, or TPH), oxygen, the corresponding aromatic amino acids, (phenylalanine, tyrosine, or tryptophan), and BH4. The complete hydroxylating system consists of two additional BH4-regenerating enzymes, pterin-4a-carbinolamine dehydratase (PCD) and dihydropteridine reductase (DHPR). BH4 is synthesized from guanosine triphosphate (GTP) catalyzed sequentially by GTP cyclohydrolase I (GTPCH), 6-pyruvoyl-tetrahydropterin synthase (PTPS), and sepiapterin reductase (Fig. 1) [2,5]. The first two steps are clinically relevant.

A likely mechanism for BH4 responsiveness would involve the mutant PAH molecules with a high Michaelis-Menten constant (Km) for BH4, requiring a higher BH4 concentration. Furthermore, BH4 might stabilize these mutant PAH molecules, considering that some of the missense mutations rendered the PAH molecule

[b]AR autosomal recessive.

unstable, leading to a shorter half-life; this could account for the gradual nature of the effect. In either case, PAH activity should increase in response to exogenous BH4 [1,5].

## Diagnostic Principles

Infants with HPA are clinically normal at birth, and urinary phenylalanine metabolites (phenylpyruvic acid) may be negative in the first few days of life, so that the diagnosis depends on measuring blood phenylalanine levels. The diagnosis of HPA is ascertained by mass screening of newborn infants, which began with Guthrie's bacterial inhibition assay method and has progressed to the use of tandem mass spectrometry. All newborns with plasma phenylalanine levels higher than 120 mmol/l should be tested for BH4 defects. This requires the measurement of pterins (neopterin and biopterin) in plasma or urine, DHPR activity in blood from a Guthrie card, and, if indicated, neurotransmitter metabolites in CSF. One-week $BH_4$ administration at 20 mg/kg per day is the most sensitive test for the diagnosis of the BH4-responsive PAH deficiency, and this additional test should be performed in all PKU patients who show more than a 20% decrease in blood phenylalanine in a single-dose BH4 loading test [5].

## Therapeutic Principles

Patients with HPA need to maintain normal, physiological levels of phenylalanine and tyrosine for life. Studies have shown that periods of elevated phenylalanine affect brain development and function. Newborns diagnosed with HPA should begin dietary treatment as soon as possible, if their plasma phenylalanine levels are more than 240 μM (4 mg/dl). Several commercial PKU formulas and various phenylalanine-restricted foods are available. Phenylalanine (and tyrosine) should be measured on a regular basis to follow dietary control. Patients with BH4-responsive PAH deficiency may replace a phenylalanine-restricted diet with BH4 monotherapy, or may combine BH4 with a less-strict diet regimn [5].

The treatment of BH4 deficiency requires not only control of HPA, but also correction of neurotransmitter deficiencies. The administration of BH4 is effective for the former but, since BH4 passes poorly through the blood-brain barrier, administration of BH4 is relatively ineffective for the latter. The administration of L-dopa and 5-hydroxytryptophan (5-HTP) is a more effective strategy to combat the deficiency of neurotransmitters. In addition, some patients with DHPR deficiency require restoration of tetrahydrofolate homeostasis and supplements of folinic acid [1,3,4].

# Hyperphosphatasia, Idiopathic

Henry J. Mankin
Department of Orthopedic Surgery, Massachusetts General Hospital, Boston, MA, USA

## Synonyms

Juvenile Paget's disease; Bakwin-Eiger syndrome; Hyperostosis corticalis deformans juvenilis

## Definition and Characteristics

Idiopathic hyperphosphatasia, otherwise known as juvenile Paget's disease is a rare genetic autosomal recessive disorder first identified by Bakwin and Eiger in 1956. It becomes evident early in life, affects both sexes and has a characteristic pattern of cortical bone hyperplasia, enlargement of the skull, thickening and bowing of the long bones and additional clinical findings, which cause impairment and poor survival for affected children. The descriptive term hyperphosphatasia is related to the marked increase in the bone specific alkaline phosphatase [1].

## Prevalence

Hyperphosphatasia is a rare entity with less than a 5,000 cases present in the United States. It is much less common than adult Paget's disease which occurs in ~3% of the population.

## Genes

The original description by Bakwin and Eiger was of a child with fusiform swelling and bowing of the long bones, enlargement of the calvarium and elevation of the serum alkaline phosphatase. Because of the resemblance to Paget's disease the name "Juvenile Paget's Disease" was introduced, along with other names including chronic osteopathy-hyperphosphatasia, hyperostostosis corticalis deformans juvenilis, hyperphosphatasia-osteoectasia syndrome and familial osteoectasia.

Following the initial report a number of authors described cases. In 1996, Whyte et al identified the genetic error in TNFRS11B gene and Cundy in the same year was able to establish the relationship of the disease to an error in the synthesis of osteoprotegerin [2].

## Molecular and Systemic Pathophysiology

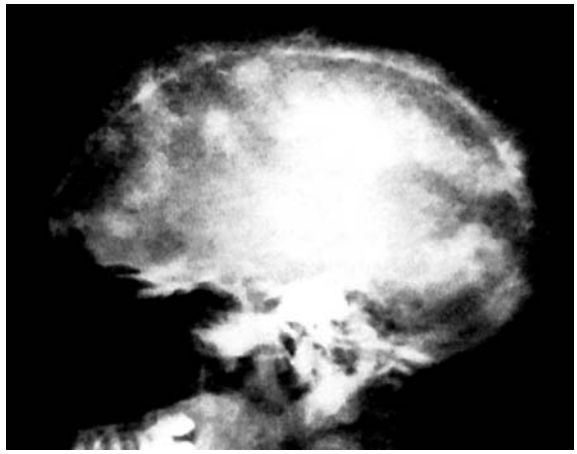
In terms of genesis, the disease appears to be caused by a truncating TNFRSF11B mutation on chromosome 8q24.2, which causes a deficiency of osteoprotegerin (OPG) [3]. OPG is closely tied to the system, which results in synthesis of osteoclasts, specifically RANK (receptor activator of nuclear factor kB) and RANK-ligand (RANKL). Under normal circumstances, OPG acts to suppress bone turnover by functioning as a decoy receptor for RANKL. The absence of OPG allows RANKL to activate RANK to markedly increase the synthesis of osteoclasts by activation of hematopoietic precursor cells. This alteration appears to increase the number of osteoblasts as well, which then results in alterations of the bones based on the coupling of osteoblastic synthesis and osteoclastic resorption and also allows the production of excessive amounts of bone-specific alkaline phosphatase [4,5].

## Diagnostic Principles

The disorder presents an array of findings in young children with very marked deformity of bones and disorders of the skull associated with increase in bone specific alkaline phosphatase. Clinically the children are generally of short stature and display muscular weakness but only rarely have mental retardation. The head is larger than normal and imaging studies show marked thickening of the calvarium with islands of increased density (Fig. 1).

Hearing loss, blue sclerae, retinal degradation and dental abnormalities are common. Bones generally show a modest osteopenia, expanded structure and frequent bowing deformities (Fig. 2).

Pelvic deformities may be present along with vertebral abnormalities and sometime collapsed spinal segments. Fractures are common and lead to increased skeletal deformity and sometimes, marked disability. Imaging studies are similar to those seen in some



**Hyperphosphatasia, Idiopathic. Figure 1** Radiograph of the calvarium from a child with hyperphosphatasia. Note the thickening of the cortices and the irregular distribution of the bone production.

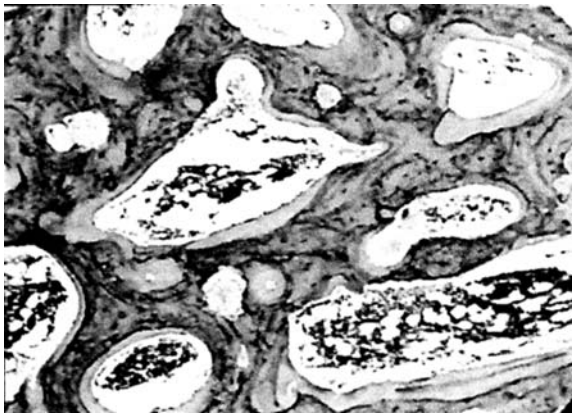
**Hyperphosphatasia, Idiopathic. Figure 2** Roentgenologic study of the bones of a child with hyperphosphatasia. Note that the bones are wide, and bowed but the structure shows less bone present than is seen in Paget's disease and there appears to be some osteolysis.

patients with early active Paget's disease and the bone scan is virtually always positive [1,2]. Laboratory data show increased bone specific serum alkaline phosphatase, acid phosphatase elevated phosphate levels, increased serum uric acid and periodic episodes of hypercalcemia. Histologic studies show changes similar to active adult Paget's disease with marked increase in the number of osteoclasts destroying bone, coupled with increased osteoblastic activity, resulting in a disorder in structure and alignment of the bones (Fig. 3).

Stress fractures are common and woven bone may be present rather than mature cortical structural bone.

## Therapeutic Principles

Until relatively recently there was no treatment available for patients with this syndrome. Fractures required fixation and repairs were often operative and the children were disabled, educationally impaired and psychiatrically damaged. Skeletal abnormalities, visual and hearing disturbances made it difficult for them to function in a school environment. A great contribution was the introduction of inhalation calcitonin, which markedly reduced the rate of bone destruction and for many patients resulted in fewer fractures and less deformity and disability. The bisphosphonates were also introduced and these agents markedly reduced



**Hyperphosphatasia, Idiopathic. Figure 3** Histologic picture of bone from a patient with hyperphosphatasia. Although the cortices are thickened, poorly calcified osteoid seams are present. Cellular elements suggest increase osteoclastic activity (Hematoxyhn and eosin X200).

bone destruction and the level of alkaline phosphatase. Most recently recombinant osteoprotegerin administered subcutaneously once weekly has been utilized and appears to be effective in increasing bone structural mass and reducing the biochemical findings in he serum [4,5].

\

# Hyperplastic Gastropathy

►Menetriere's Disease

# Hyperprolactinemia

Christian A. Koch, Gabriel I. Uwaifo
Division of Endocrinology, University of Mississippi Medical Center, Jackson, MS, USA

## Definition and Characteristics

Hyperprolactinemia can result from hypothalamic dopamine deficiency, defective transport mechanisms of dopamine to the lactorophs in the anterior pituitary gland, insensitivity of lactotrophs to dopamine, and stimulation of lactotrophs, for instance from increased TRH production in severe hypothyroidism. In a few patients with hyperprolactinemia, the cause cannot be identified. Most commonly, the cause is a prolactin-secreting pituitary tumor with prolactin levels exceeding 200 ng/ml. Such prolactin levels can also be seen in the third trimester of pregnancy. Various medications including neuroleptics, tricyclic antidepressants, opiates, cocaine, antihypertensives, protease inhibitors, and others raise prolactin levels, as can lactation, stress, renal disease and cirrhosis of the liver. In up to 20% of patients with hyperprolactinemia (usually without any symptoms), macroprolactin is found [1–3]. Women may become amenorrhoeic and develop galactorrhea, whereas men may develop impotence/sexual dysfunction (rarely galactorrhea).

## Prevalence

Up to 10% of subjects without evidence of an endocrine abnormality. At autopsy, at least 5% of pituitary glands reveal a prolactinoma which was not diagnosed during lifetime. Approximately 10% of individuals have a so-called pituitary incidentaloma which most of the time is a non-secreting adenoma. Approximately 100/million of children and adolescents have a prolactinoma. In patients with multiple endocrine neoplasia type 1, prolactinomas occur in approx. 30% of patients [4,5].

## Genes

*MEN1*: Tumor suppressor gene that encodes the protein menin, found to be abnormal in patients with multiple endocrine neoplasia type 1.

*Protein kinase A regulatory subunit 1alpha/PRKAR1A*: Gene found in patients with Carney complex, a disorder that can lead to growth-hormone (and prolactin co-secreting) pituitary tumors.

*GNAS1*: encoding the subunit of the G protein. Activating mutations in this gene encoding the Gs protein alpha subunit coupling 7-transmembrane-domain receptors to adenylate cyclase can lead to constitutive adenylate cyclase activation and cAMP overproduction as seen in patients with McCune-Albright syndrome, characterized by cafe-au-lait spots, precocious puberty and fibrous dysplasia.

## Molecular and Systemic Pathophysiology

Diminished synthesis or release of dopamine, for instance by tumors, inflammatory disorders such as sarcoidosis, arteriovenous malformations, drugs such as reserpine. Impaired transport of dopamine from the hypothalamus to the lactotrophs by pituitary stalk compression or injury. Diminishing sensitivity of dopamine receptors to dopamine, for instance by phenothiazines, benzamides (metoclopramide). Stimulation of lactotrophs by various mechanisms including TRH production (in severe hypothyroidism), estrogens, chest wall injury.

## Diagnostic Principles

Serum prolactin (in dilution in any patient with a large pituitary lesion, if an IRMA is used, cave: hook effect), macroprolactin by polyethylene glycol precipitation.

Checking clinical symptoms and signs such as amenorrhea, oligomenorrhea, galactorrhea, sexual dysfunction/impotence, bone density, gross visual fields.

Pituitary imaging with MRI (cave gadolinium in patients with renal impairment).

Ophthalmological evaluation with visual acuity and visual field measurements.

IGF-1 and oral glucose tolerance testing for patients with acromegaloid appearance, especially if Carney complex is known (co-secreting pituitary tumors).

## Therapeutic Principles

Assure euthyroidism/replacement with thyroxine in cases of severe hypothyroidism. In drug-related hyperprolactinemia, attempt withdrawal after consulting with prescribing physician (i.e. psychiatrist). In patients with prolactinoma, primarily medical therapy with dopamine agonists. In women with pregnancy, close observation with frequent ophthalmological evaluations and perhaps MRI scanning of the pituitary (cave: gadolinium), especially if macroprolactinoma. If severe impingement on optic chiasm/nerve, standby of neurosurgery for rapid intervention (transsphenoidal/surgical debulking). If CSF leak/rhinorrhea or medically refractory prolactinoma, consider surgical debulking and/or gammaknife radiosurgery.

## Synonyms

Hyperprolinemia type I (#239500) Proline oxidase deficiency; Hyperprolinemia type II (#239510) 1-pyrroline-5carboxylate dehydrogenase deficiency

## Definition and Characteristics

Hyperprolinemia is a rare disorder in proline metabolism resulting in an elevated proline serum level and elevated proline excretion in the urine. Clinically and biochemically two types of hyperprolinemia can be distinguished.

*Type I:* The phenotype is thought to be mostly benign but more severe cases with mental retardation and/or generalized epilepsy have been described [1]. A link between adult schizophrenia or schizoaffective disorders and hyperprolinemia type I has been discussed [2]. In some cases renal symptoms have been reported.

*Type II:* Patients mostly suffer from epilepsy often presenting with different types of seizures; the disorder is often associated with mild to moderate mental retardation [3].

Proline levels tend to be higher in type II than type I.

## Prevalence

Both types are extremely rare disorders.

*Type I:* Prevalence of the most common 22q11 microdeletion is 1/4000 births, but not all patients with a 22q11 microdeletion suffer from hyperprolinemia.

*Type II:* Prevalence cannot be established due to the rarity of the disorder.

## Genes

*Type I:* The PRODH gene on chromosome 22q11.2 codes for proline dehydrogenase (= oxidase). Various different mutations have been described including several missense mutations, deletion of the whole PRODH gene and inclusion of the PRODH gene in cases of 22q11 microdeletions (including DiGeorge syndrome chromosomal region or DGCR). Inheritance is autosomal recessive, however in some cases elevated proline levels have been found in heterozygous gene carriers.

*Type II:* The ALDH4A1 gene on chromosome 1p36 codes for delta-1-pyrrolin-5-carboxylate-dehydrogenase which catalyses the conversion of delta-1-pyrrolin-5-carboxylate to glutamate.

Two frameshift, two missense and one mutation generating a stop codon have so far been described. Inheritance is autosomal recessive.

## Molecular and Systemic Pathophysiology

*Type I:* The defective enzyme proline dehydrogenase catalyses the conversion of proline to pyrroline-5-carboxylate, proline accumulates in serum and urine whereas delta-1-pyrroline-5-carboxylate levels are normal to low. A residual activity of less than 30% results in the occurrence of the disorder. The enzyme is located in the mitochondrial membrane.

*Type II:* Delta-1-pyrroline-5-carboxylate dehydrogenase catalyses the conversion of delta-1–5-carboxylate to glutamate. A defective enzyme results in the accumulation of proline and delta-1-pyrroline-5-carboxylate in serum and urine. The enzyme is located in the mitochondrial membrane (Fig. 1).

The exact pathophysiology of the psychiatric and neurological symptoms of hyperprolinemia has not yet been detected. Delta-1-pyrroline-5-carboxylate is a precursor of the two neurotransmitters gamma-hydroxy-butyrate (GABA) and glutamate.

An animal model with PRODH deficient mice showed significant reductions of aspartate, glutamate and GABA in hippocampus and frontal cortex.

A toxic effect of high L-proline doses on hippocampal neurons in rat brains has been described; proline could be shown to induce potentiation of glutamate transmission in hippocampal rat brain cells [4] but also to induce an inhibition of glutamate release in hippocampal rat cells of the area CA1.

Seizures in hyperprolinemia type II might also be induced by a vitamine B6 deficiency as delta-1-pyrroline-5-carboxylate has been detected to deactivate endogenous pyridoxal phosphate [5].

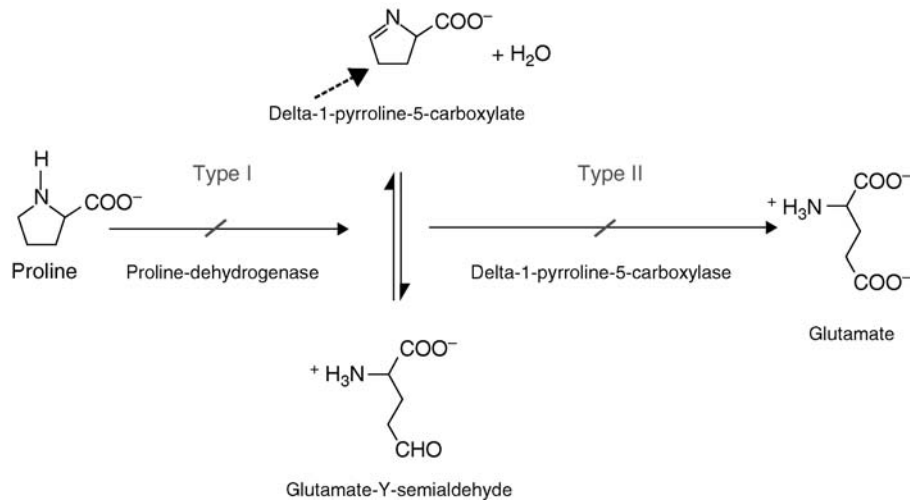
The phenotypical differences between Type I and II despite the common elevated proline levels and the possible lack of glutamate and GABA remain not fully understood.

## Diagnostic Principles

Determination of amino acids in the serum and excretion in the urine is the first step to diagnose hyperprolinemia.

In the case of an elevated proline level, the tool to differentiate between Hyperprolinemia Type I and II is the determination of delta-1-pyrrolin-5-carboxylate excretion in the urine. An elevated level confirms the diagnosis of hyperprolinemia type II.

For a first assessment proline levels tend to be higher in hyperprolinemia type II, whereas heterozygous gene carriers have mildly elevated proline levels in hyperprolinemia type I.



**Hyperprolinemia. Figure 1** Enzymatic defects in Hyperprolinemia type I and II. Type I is due to a deficient proline – dehydrogenase catalysing the conversion of proline into delta-1-pyrroline-5-carboxylate. Type II is due to a deficient delta-1-pyrroline-5-carboxylase catalysing the conversion of delta-1–5-carboxylate into glutamate. Delta-1-pyrroline-5-carboxylate is in equilibrium with glutamate-Y-semialdehyde.

Sequencing of the PRODH or ALDH4A1 genes can confirm the diagnosis on a molecular basis.

On the other hand, patients with a known 22q11 microdeletion and corresponding symptoms should be tested for hyperprolinemia.

## Therapeutic Principles

The defects of hyperprolinemia type I and II cannot be cured. As proline is not an essential amino acid and an important component of many proteins and precursor of the two important neurotransmitters glutamate and GABA, a low protein diet is ineffective.

Therapy of schizophrenia and seizures is symptomatic. However, epilepsy in patients with hyperprolinemia can be difficult to treat, often requiring several attempts with different anticonvulsants.

In hyperprolinemia Type II the additional administration of vitamin B6 can be tried, as delta-1-pyrroline-5-carboxylate has been found to de-activate endogenous pyridoxal phosphate as a possible pro-epileptic effect [5].

# Hyperreflectoric Rhinitis

Werner Heppt, Annette Cryer
Department of Otorhinolaryngology, Klinikum Karlsruhe gGmbH, Karlsruhe, Germany

## Synonyms

Idiopathic rhinitis; Vasomotor rhinitis

## Definition and Characteristics

Hyperreflectoric rhinitis is a chronic irritation of the nasal mucosa with an unspecific hyperreactivity towards various stimuli.

## Prevalence

Five to ten percent in the general population with higher prevalence in females [1]. In general initial onset of symptoms after the age of 20.

## Genes

No correlation known.

## Molecular and Systemic Pathophysiology

It is defined by the absence of allergy, microbial infection, structural lesions, systemic disease, or drug abuse. Various exogenous (physical, chemical, mechanic) or endogenous (hormonal, autonomic nervous system) stimuli lead to an irritation of the nasal mucosa with the symptoms of nasal obstruction, sneezing and increased secretion. Obviously a dysfunction of the autonomic nervous system plays a major role with preponderance of the parasympathetic tonus. A major modulatory role may be attributed to the mucosal innervation and neuropeptide-specific subpopulations of nerve fibers, such as C. fibers. Significant increases of neuropeptide-contents in mucosal nerves were found for substance P and VIP compared to the control group [2].

## Diagnostic Principles

History, nasal endoscopy, allergy testing, nasal cytology, anterior rhinomanometry, CT or MRI. The classic triad is sneezing, profuse nasal discharge and nasal obstruction due to defined stimuli. Even though the symptoms are similar to those of an allergic rhinitis, all diagnostic tests are negative (in vitro diagnosis, skin test, nasal and conjunctival challenge). But even in allergic rhinitis the phenomenon of nasal hyperreactivity may occur. Seasonal allergens lead to an unspecific irritation of the nasal mucosa with a peak at the end of the annual pollination (called “nasal priming”).

Rhinoscopy shows a normal or hyperplastic nasal mucosa and while stimulated an increase of clear mucus. CT or MRI of the paranasal sinuses excludes a chronic sinusitis. In contrast to eosinophilic rhinitis the nasal smear is quite normal with a moderate increase of goblet cells and mastcells in only some cases [3]. No valid or reproducible assessment of nasal hyperreactivity by the use of rhinomanometry or acoustic rhinometry.

## Therapeutic Principles

If avoidance of the irritants is not sufficient, the topical administration of corticosteroids, antihistamines or anticholinergic substances (ipratropiumbromid) might smooth the symptoms [4]. But local administration of Capsaicin may be more effective degenerating peptidergic neurons, although the overall neurogenic staining in the nasal mucosa after Capsaicin-treatment was unaffected [5]. Hyperplasia of the nasal mucosa may be treated by laser or conservative turbinoplasty.

# Hypersensitivity Pneumonitis

Rade Tomic, Jesse Roman
Division of Pulmonary, Allergy and Critical Care Medicine and VA Medical Center, Emory University, Atlanta, GA, USA

## Synonyms

Extrinsic allergic alveolitis; Farmer’s lung disease

## Definition and Characteristics

A group of pulmonary disorders characterized by lung infiltrations and respiratory symptoms caused by repeated exposure and sensitization to a variety of organic and inorganic antigens.

## Prevalence

The incidence and prevalence of hypersensitivity pneumonitis are unknown. Most studies are focused

on farmer's lung disease, a form of hypersensitivity pneumonitis caused by thermoactinomycetes. Estimates vary significantly by region, but the prevalence of farmer's lung is considered to be between 2.3 and 12%. The prevalence of hypersensitivity pneumonitis among bird hobbyists ranges from 0.5 to 21%. Among isocyanate workers, the prevalence of hypersensitivity pneumonitis is approximately 1%.

### Molecular and Systemic Pathophysiology

Hypersensitivity pneumonitis is caused by repeated antigen exposure leading to immunologic sensitization and subsequent immune-mediated lung inflammation. Cell-mediated immunity is primarily involved with activated T-helper memory cells with Th1 differentiation playing an important role [1]. Unique host factors influence individual responses to inhaled antigens. Recent work suggests that polymorphisms in the tumor necrosis factor-alpha gene promoter causing increased expression of this cytokine may be associated with disease susceptibility [2]. Also, some studies suggest a linkage between hypersensitivity pneumonitis and HLA haplotype (significant increase of alleles HLA-DRB1 1305 and HLA-DQB1 0501 and decrease of HLA-DRB1 0802) [3]. Elevations in several chemokines and cytokines have been detected in animal models, but their true role in the pathogenesis of this illness is unknown. Thus, it appears that both exposure-related factors and host immunity play important roles in the pathogenesis of hypersensitivity pneumonitis. The consequences include an aggressive inflammatory response of the lung characterized by granulomatous, interstitial, bronchiolar and alveolar filling pulmonary infiltrations [4].

### Diagnostic Principles

Hypersensitivity pneumonitis often presents as a subacute process characterized by dyspnea on exertion, recurrent febrile episodes, and inspiratory crackles on inspiration. Typically, chest radiography shows pulmonary infiltrations predominantly in the upper lobes. High resolution computer tomography might show ground-glass attenuation, centrilobular nodules, mosaic pattern, fibrosis, emphysema, or a combination of these changes [5]. Pulmonary function tests may show restriction. Because this is an interstitial inflammatory disorder affecting the distal gas exchanging units of the lung, decreased diffusion lung capacity of carbon monoxide may be found. Fiberoptic bronchoscopy shows lung inflammation with poorly defined non-necrotizing granulomas. Precipitating antibodies to causative agents may be found in serum but are not diagnostic.

### Therapeutic Principles

The cornerstone of therapy is avoidance of antigen exposure. Oral corticosteroids are frequently used to supplement antigen avoidance in severe or progressive disease; however, they are often not useful in chronic illness. Supplemental oxygen is used for hypoxemic patients, and inhaled steroids and β-agonists for patients with airflow limitation. In refractory cases, cytotoxic agents such as cyclophosphamide, azathioprine and cyclosporine have been used.

## Hypersensitivity Type I

►Allergy

## Hypersensitivity Vasculitis

►Leukocytoclastic Vasculitis

## Hypersomnia

Jan Rémi, Soheyl Noachtar
Section of Sleep, Department of Neurology, University of Munich, Munich, Germany

### Synonyms

Recurrent hypersomnia (Kleine-Levine syndrome); Posttraumatic hypersomnia; Idiopathic (central nervous system) hypersomnia

### Definition and Characteristics

Excessive daytime sleepiness with daytime sleep episodes of more than 1 hour is typical for all subtypes. The major sleep episode may also be prolonged. The subtypes differ in their course, accompanying symptoms and possible reasons [1].

In recurrent hypersomnia, the patients experience phases of hypersomnia with sleep episodes of up to 20 h per day, lasting several days to a few weeks. The episodes recur on average twice a year. In the most common subtype, the Kleine-Levine-syndrome, the episodes are accompanied by hyperphagia, hypersexuality and personality changes (aggression, depression, depersonalization experiences) [2].

Idiopathic hypersomnia shows a chronic and often progressing course, which can be often stabilized at the time of diagnosis. The hypersomnia can be accompanied by other symptoms like orthostatic hypotension and headaches. Differential diagnosis against depression may be difficult.

Posttraumatic hypersomnia presents after central nervous injury and usually resolves after weeks to months. Symptoms of sleepiness can reside in severe cases [1].

### Prevalence

The prevalences for recurrent hypersomnia and post traumatic hypersomnia are not known. Idiopathic hypersomnia is considered to account for 5–10% of patients reporting to a sleep clinic. The prevalence in the general population is unknown.

### Genes

Only in idiopathic hypersomnia, an increased incidence of HLA Cw2 can be observed. HLA allels that are typically associated with narcolepsy (HLA DR15 and DQ6) are normally distributed in hypersomnic patients.

### Molecular and Systemic Pathophysiology

The causes of hypersomnia are so far not well understood. It has been shown that the level of hypocretin, an excitatory neurotransmitter, is decreased in episodes of hypersomnia, but normal in times between episodes, implicating that the hypocretin system may play a role in the pathophysiology of these disorders [3].

### Diagnostic Principles

A detailed history is essential for all subtypes to distinguish the syndromes from their differential diagnoses (depression, chronic fatigue syndrome, sleep apnea). Polysomnography mostly reveals only unspecific changes like a lengthened sleep period and increased tendency to fall asleep in daytime sleep latency tests. To distinguish against narcolepsy, HLA testing may be helpful and polysomnography does not show atypical episodes of REM sleep or apneic episodes during sleep [1].

### Therapeutic Principles

Therapy is limited to symptomatic treatment. Stimulants can be helpful in episodes of sleepiness. Also behavioural adaptation (scheduled naps) can alleviate the sleepiness.

## Hypertension and Obesity

Miki Nagase, Toshiro Fujita
Department of Nephrology and Endocrinology, University of Tokyo Graduate School of Medicine, Tokyo, Japan

### Synonyms

Metabolic syndrome; Insulin-resistance syndrome; Multiple risk factor syndrome

## Definition and Characteristics

Obesity, especially visceral obesity, is closely related to hypertension. Blood pressure (BP) increases ~4.5 mmHg for every 10 lb (4.5 kg) weight gain. Both obesity and hypertension convey increased risk for cardiovascular disease. In addition, visceral obesity and hypertension often cluster with glucose intolerance and dyslipidemia. This risk factor clustering condition, called metabolic syndrome, is a highly predisposing condition for target organ injury. Furthermore, high salt intake increases BP and worsens cardiovascular outcome in obese subjects. Recent studies have underscored the importance of adipokines in obesity hypertension.

## Prevalence

The prevalence of hypertension in obese subjects is 42% in men and 38% in women (NHANES III). A Finland study shows that more than 85% of hypertension occurs in overweight or obese subjects.

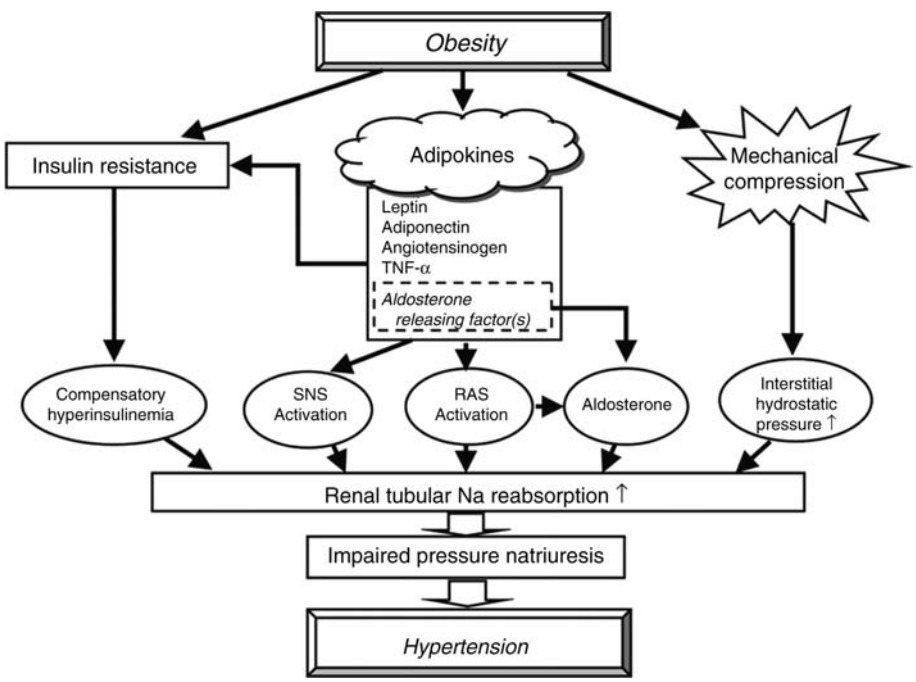
## Genes

Several candidate chromosomal loci or SNPs are postulated. For example, a whole-genome scan suggests a locus at 1p36 for obesity hypertension. An activated variant of the Sgk1 gene is associated with both higher BP and increased body mass index (BMI) [1]. Diseases of civilization, including obesity and hypertension, may result from the mismatch between contemporary environment and "energy-thrifty genotype" of genes, which helped our ancestors to survive occasional famines.

## Molecular and Systemic Pathophysiology

Obese subjects have increased cardiac output and plasma volume, and reduced peripheral vascular resistance (see [2]). Enhanced renal tubular sodium reabsorption plays a central role in the pathogenesis of obesity hypertension. Sodium retention impairs pressure natriuresis; higher pressure is necessary to maintain a sodium balance, resulting in hypertension. Multiple factors are postulated to contribute to the enhanced sodium reabsorption, as described below.

1. *Sympathetic Nervous System (SNS):* Renal sympathetic overactivity increases sodium reabsorption and vasoconstriction. Leptin, an adipokine secreted in proportion to adiposity, is thought to be an important mediator linking obesity, renal sympathetic activation, and hypertension. Leptin acts in the hypothalamus and regulates energy homeostasis by reducing appetite and increasing energy expenditure. It also modulates renal sympathetic outflow through the melanocortin system. Obesity may cause "selective leptin resistance,"



**Hypertension and Obesity. Figure 1** Mechanisms of obesity hypertension. Activation of sympathetic nervous system (SNS), renin-angiotensin system (RAS), aldosterone, hyperinsulinemia, mechanical compression of the kidney cause increased renal tubular sodium reabsorption and hypertension. Alipocyte-derived factors such as leptin, angiotensinogen, and aldosterone-releasing factors are supposed to play important roles.

whereby the SNS responses to leptin are maintained while its anorexic effect is blunted.

2. *Renin-Angiotensin System (RAS):* Despite marked sodium retention, obesity hypertension is associated with activation of the RAS. Angiotensinogen produced by adipose tissue may contribute to the high circulating angiotensinogen levels in obesity hypertension. Angiotensin II stimulates sodium reabsorption and shifts pressure natriuresis. Weight reduction lowers circulating RAS and BP in obese subjects.

3. *Aldosterone* [3,4]: Plasma aldosterone level and renal expression of aldosterone effector kinase Sgk1 are elevated in some obese hypertensives. Hyperaldosteronemia in obesity may be attributed to adipocyte-derived aldosterone releasing factors or oxidized products of fatty acids. Aldosterone promotes renal sodium reabsorption and augments renal sympathetic activity. Aldosterone blockers effectively reduce BP in obesity hypertension.

4. *Hyperinsulinemia* [5]: Similar to the case of leptin, insulin actions are blunted in the muscle and adipose tissues, whereas renal action is preserved and facilitated by hyperinsulinemia, resulting in enhanced sodium absorption. The former actions are mediated by insulin receptor substrates (IRS)-1, while the latter by IRS-2.

5. *Renal Mechanical Compression:* Visceral fat mass may compress the kidney and increase tubular reabsorption. Changes in the renal medullary histology may elevate interstitial hydrostatic pressure, compress the thin loops of Henle and vasa recta, and enhance tubular reabsorption.

## Diagnostic Principles

It is important to determine global risk factors and target organ damage, in addition to BP (>140/90 mmHg) and BMI (>30 kg/m$^2$). Too small cuff will result in an overestimate of BP. Obese hypertensives resistant to treatment may have sleep apnea.

## Therapeutic Principles

The goal of therapy is to retard the progression of target organ injury. Weight reduction is the most fundamental strategy. Although there is still no evidence for antihypertensive drugs in obesity hypertension, it is better to use drugs that do not worsen other metabolic risk factors.

1. *Lifestyle Modification:* Low-caloric, low-fat diet rich in fruits and vegetables, together with moderate aerobic exercise are recommended. Salt restriction (<6 g/day) is also effective.

2. *Antihypertensive Drugs:* ACE inhibitors and ARBs may be preferable as first-line therapy, because they are metabolically neutral or beneficial, they may retard the development of diabetes, and they may be effective in preventing target organ injury. Ca channel blockers may also be recommended, which are neutral to glucose and lipid metabolisms. The use of β-blockers is not suitable as routine first-line therapy, except for patients with coronary artery disease or a recent myocardial infarction, or for youths with increased sympathetic activity, because they increase the risk of diabetes, stroke, and weight gain. Low doses of thiazide diuretics may be effective, since they directly correct the volume-expanded state.

3. *Weight-Loss Agents:* Orlistat (an inhibitor of gastrointestinal lipases) showed mild hypotensive effect, whereas sibutramine (a reuptake inhibitor of serotonin and norepinephrine in the brain) failed to reduce BP. For rimonabant (a selective blocker of the cannabinoid receptor 1), the effects on BP are still controversial.

# Hypertension, Arterial

Angel Cogolludo
Department of Pharmacology, School of Medicine, University Complutense of Madrid, Madrid, Spain

## Definition and Characteristics

Hypertension is defined by repeated values of systolic/diastolic blood pressure (BP) of 140/90 mmHg or above. Arterial hypertension remains the most common risk

factor for cardiovascular (heart disease, stroke, congestive heart failure, and end-stage renal disease) morbidity and mortality [1]. This disorder has a multifactorial origin arising from an interaction between susceptibility genes and environmental factors and can be divided into primary (essential) or secondary.

## Prevalence

It is estimated that hypertension affects approximately one billion individuals worldwide. Hypertension occurs more often in black adults (32%) than in white (23%) or Mexican American (23%) adults, and morbidity and mortality are greater in blacks.

## Genes

The fact that single genes can impart large effects on BP is demonstrated by rare Mendelian forms of high and low blood pressure [2]. These include mutations affecting renal $Na^+$ handling, and therefore in volume homeostasis and BP regulation, such as mutations in the epithelial $Na^+$ channels α subunit causing pseudohypoaldosteronism type I, mutations in the transporters located in the loop of Henle causing Bartter's syndrome, and mutations in the sodium chloride cotransporter causing Gitelman's syndrome. Although the Mendelian traits have quantitatively large effects in affected individuals, because of their rarity, they likely account for a very small fraction of the variation in BP in the general population. A variant in the angiotensinogen gene (M235T) is associated with higher circulating angiotensinogen levels and hypertension in several but not all populations. Similarly, a common variant in the angiotensin converting enzyme (ACE) is strongly associated with variations in ACE levels. A variant in the β subunit of the epithelial $Na^+$ channel (T594M) has also been associated with hypertension. Elevated BP is also associated with a downregulation of the $\beta_1$ subunit of large conductance $Ca^{2+}$-activated $K^+$ channels, a main target for endogenous vasodilators as nitric oxide. A gain-of-function mutation in this subunit is associated with a low prevalence of diastolic hypertension [3]. A gain-of-function gene variant of the Serum and glucocorticoid-inducible kinase may result in enhanced insulin sensitivity of blood pressure [4].

## Molecular and Systemic Pathophysiology

Secondary hypertension caused by endocrine or renal disease represents about a 5% of all hypertensives. In the remainder, no clear identifiable cause is found and their condition is labeled as "essential hypertension," which is a very complex condition of unknown etiology [5]. Essential hypertension is a heterogeneous disease that is multifunctional on origin. Heredity is a predisposing factor, but the exact mechanism is unclear. Environmental factors such as stress, dietary $Na^+$, and obesity seem to act only in genetically susceptible persons. The pathogenic mechanisms must lead to increased total peripheral vascular resistance (PVR) by inducing vasoconstriction, to increased cardiac output (CO), or to both. An increase in CO plays an important role in young hypertensives whereas an increase in PVR is more commonly found in older patients.

Abnormalities of $Na^+$ transport across the cell wall due to a defect in or inhibition of the $Na^+$–$K^+$ pump or due to increased permeability to $Na^+$ has been described in some cases of hypertension. The net result is increased intracellular $Na^+$ that via the sodium calcium exchanger promotes an increase in cytosolic calcium and vasoconstriction. The neurogenic theory proposes that the early phase of hypertension is often characterized by increased α-adrenergic activity, leading to peripheral arteriolar vasoconstriction. Stimulation of the sympathetic nervous system raises BP, usually more in hypertensive or prehypertensive patients than in normotensive patients. The renin-angiotensin-aldosterone system (RAAS) plays a central role in BP control. Renin catalyzes the first and rate-limiting step of the RAAS, which is the conversion of the protein angiotensinogen to angiotensin I. This inactive product is rapidly converted by ACE to angiotensin II, which is a potent vasoconstrictor that also stimulates release of aldosterone, which results in a further rise in blood pressure related to sodium and water retention. Additionally, hypertension is associated with endothelial dysfunction. Hypothetically, either hypertension could cause endothelial dysfunction or the latter could promote hypertension. Endothelial cells produce potent vasodilators (nitric oxide, prostacyclin) and the most potent vasoconstrictor, endothelin. Reactive oxygen species may interact with nitric oxide activity promoting the formation of peroxynitrite. The main source of oxidative stress is the NADPH oxidase, whose activity is enhanced by shear stress and angiotensin II [5]. In addition, the RhoA/Rho kinase pathway, which is a main signal in vascular smooth muscle contraction, is upregulated in hypertensive patients [6].

## Diagnostic Principles

Diagnosis of primary hypertension depends on repeatedly demonstrating higher-than-normal systolic and/or diastolic BP and excluding secondary causes. Diagnosis of hypertension is generally on the basis of a persistently high blood pressure. At least two BP determinations should be taken on each of 3 days before a patient is diagnosed as hypertensive. Most national and international guidelines for diagnosing hypertension also include 24-h ambulatory blood pressure monitoring.

## Therapeutic Principles

Aggressive lifestyle modification is strongly encouraged for all patients. Major lifestyle modifications shown to lower BP include weight reduction among

the obese, dietary sodium reduction, maintenance of good physical condition, moderation of alcohol consumption, and avoidance of unnecessary stress. Drug therapy should be initiated with a diuretic or a β blocker, unless these drugs are contraindicated or another class of drugs is indicated. If these drugs are ineffective, alternative classes suitable for initial therapy include $Ca^{2+}$ blockers, ACE inhibitors, angiotensin II receptor antagonists, and $\alpha_1$-adrenergic blockers.

# Hypertension, Idiopathic and Familial Pulmonary Arterial

Jason X.-J. Yuan, Lewis J. Rubin
Division of Pulmonary and Critical Care Medicine, Department of Medicine, University of California at San Diego, La Jolla, CA, USA

## Synonyms

Primary pulmonary hypertension; PPH; Sporadic and familial PPH; Sclerosis of the pulmonary arteries

## Definition and Characteristics

Idiopathic pulmonary arterial hypertension (PAH), or when supported by genetic investigation, familial PAH, is defined hemodynamically as a mean pulmonary arterial pressure (PAP) ≥25 mmHg, with a pulmonary capillary wedge pressure ≤15 mmHg, both measured at rest by right-heart catheterization. PAH is a pulmonary arteriopathy characterized pathologically by severe vascular remodeling (e.g., obliteration of small arteries and arterioles, intimal lesions and fibrosis and the plexiform lesion) and sustained vasoconstriction (in some patients). Patients with PAH may die because of right heart failure.

## Prevalence

1–2:1,000,000 for idiopathic PAH in industrialized countries. The ratio of female to male is 1.7:1. Approximately 15% of PAH patients have a familial history.

## Genes

Mutations in BMPR2 (2q33) encoding bone morphogenetic protein (BMP) receptor type II (BMP-RII) in 50% familial PAH patients and 15–25% idiopathic PAH patients [1].

Point mutation in the promoter region of TRPC6 (11q21–q22) encoding transient receptor potential channel canonical isoform 6, a membrane protein that forms receptor-operated cation channels [2].

L-allele polymorphism in SLC6A4 (17q11.1–q12) encoding 5-hydroxytryptamine (5-HT) transporter [3].

## Molecular and Systemic Pathophysiology

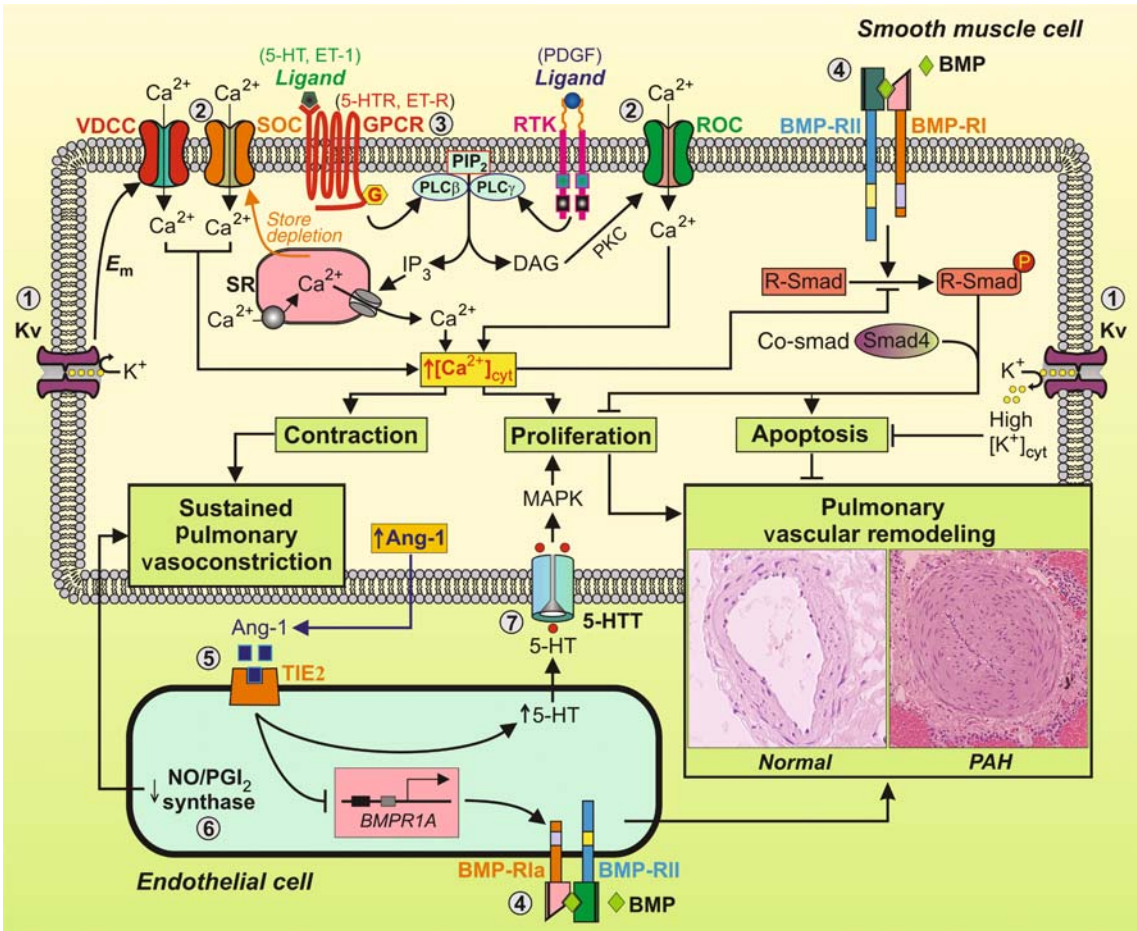
Elevated PAP is caused by increased pulmonary vascular resistance (PVR) in PAH patients. Excessive vascular remodeling is a major contributor to the elevated PVR, while sustained vasoconstriction contributes to the elevated PVR in 15–20% PAH patients. The pathogenic mechanisms involve multiple abnormalities in pulmonary arterial smooth muscle (PASMC) and endothelial (PAEC) cells [4].

In some patients with PAH, sustained pulmonary vasoconstriction is caused by injury of vascular endothelium, which inhibits nitric oxide (NO) and prostacyclin ($PGI_2$) production in PAEC, and by dysfunction of voltage-gated $K^+$(Kv) channels, which causes membrane depolarization, $Ca^{2+}$ influx through voltage-dependent $Ca^{2+}$ channels (VDCC), and a rise in cytosolic $Ca^{2+}$($[Ca^{2+}]_{cyt}$) in PASMC.

Pulmonary vascular remodeling, or arterial wall thickening and obliteration of small arteries and arterioles, is caused by overgrowth and accelerated migration of PASMC and PAEC. Augmented production of mitogenic, angiogenic and contractile factors (endothelin-1, PDGF, VEGF, 5-HT, angiopoietin-1, tenascin C) as well as upregulated membrane receptors, transporters, and $Ca^{2+}$ channels (5-HT receptors and transporters, $ET_A$/$ET_B$, TRP channels) are involved in causing PASMC overgrowth. Furthermore, inhibited PASMC apoptosis due to dysfunctional BMP signaling and abnormal $K^+$ channel function also contribute to vascular medial hypertrophy. Breakdown of extracellular matrix by elastases and metalloproteinases releases matrix-bound proliferative and antiapoptotic factors into vascular media, stimulates PASMC proliferation and inhibits PASMC apoptosis. Dysfunctional BMP signaling, as a result of BMPR2 mutation or BMP receptor down-regulation, attenuates BMP-mediated apoptosis in PASMC and thus contributes to the medial hypertrophy. Furthermore, dysfunctional BMP receptors also stimulate

other signaling cascades related to cell growth and enhance mitogen-mediated PASMC proliferation. A gain-function mutation in the promoter regions of TRPC6 and SLC6A4 results respectively in the upregulation of TRPC6 channels and 5-HT transporters, which then enhances PASMC proliferation by increasing $[Ca^{2+}]_{cyt}$ and by activating the MAPK pathway (Fig. 1).

Excessive pulmonary vascular remodeling and sustained vasoconstriction in PAH patients are believed to stem from a combination of multiple genetic defects



**Hypertension, Idiopathic and Familial Pulmonary Arterial. Figure 1** Proposed cellular mechanisms in the development of PAH. A rise in $[Ca^{2+}]_{cyt}$ in PASMC due to (i) decreased Kv channel (Kv) activity (1) and membrane depolarization which opens voltage-dependent $Ca^{2+}$ channels (VDCC), (ii) upregulated TRPC channels that form receptor- (ROC) and store- (SOC) operated $Ca^{2+}$ channels (2), and (iii) upregulated membrane receptors (e.g., serotonin and endothelin receptors) (3) causes pulmonary vasoconstriction, stimulates PASMC proliferation, and inhibits the BMP-mediated antiproliferative and proapoptotic effects on PASMC. Dysfunction of BMP signaling due to *BMPR2* mutation and BMP-RII/BMP-RI downregulation (4), and inhibition of Kv channel function and expression (1), attenuate PASMC apoptosis and promote PASMC proliferation. Increased angiopoietin-1 (Ang-1) production (5) from PASMC enhances 5-HT production and downregulates BMP-RIa in PAEC, which further enhance PASMC contraction and proliferation. Inhibited NO and prostacyclin ($PGI_2$) synthesis (6) in PAEC attenuates the endothelium-derived relaxing effect on pulmonary arteries and promotes sustained vasoconstriction and PASMC proliferation. Increased activity and expression of the 5-HT transporter (5-HTT) (7), encoded by SLC6A4, serve as an additional pathway to stimulate PASMC growth via the MAP kinase pathway. In addition, extracellular metalloproteinases and serine elastases, growth factors (e.g., PDGF), and viral infection-mediated inflammatory response all contribute to mediating the phenotypical transition of normal cells to "misguided" contractive or hypertrophied cells, and maintaining the progression of PAH. $E_m$, membrane potential; GPCR, G protein coupled receptor; RTK, receptor tyrosine kinase; PDGF, platelet-derived growth factor; ET-1, endothelin-1; SR, sarcoplasmic reticulum; $IP_3$, inositol 1,4,5-trisphosphate; DAG, diacylglycerol; PLC, phospholipase C; PKC, protein kinase C.

and multiple signal transduction abnormalities in PASMC and PAEC.

### Diagnostic Principles

Common symptoms of PAH include dyspnea, fatigue, chest pain, leg swelling, abdominal distension, anorexia, plethora, cyanosis and palpitations. The risk factors for PAH include use of anorexigens (aminorex, fenfluramine, dexfenfluramine), drug abuse (amphetamines, cocaine) and HIV infection. Non-invasive approaches like echocardiography, CT scan and angioscopy are used for diagnosis. Direct measurement of PAP and PVR by right-heart catheterization is an ultimate diagnostic approach for the patients.

### Therapeutic Principles

Elevated PVR and PAP are the major hemodynamic abnormalities in PAH patients, which may lead to right heart failure. Vasodilatation, restoration of dysfunctional endothelium, and regression of hypertrophied arteries by inhibiting PASMC/PAEC proliferation and migration are the major therapeutic strategies. Combined use of vasodilators and antiproliferative agents has proven to be more effective. The current medication includes $Ca^{2+}$ channel blockers (nifedipine, diltiazem), anticoagulants (warfarin), prostacyclin and its analogs (epoprostenol, treprostinil, iloprost), guanylyl cyclase activator (NO) and phosphodiesterase inhibitor (sildenafil), and endothelin-1 receptor blockers (bosentan, ambrisentan, sitaxsentan) [5]. Surgical treatment includes double-or single-lung transplantation. New treatment undergoing clinical trials includes statins and tyrosine kinase antagonists as well as gene therapy and stem cell therapy.

## Hypertension, Portal

►Portal Hypertension

## Hypertension, Renal

Manning R. Davis
Department of Physiology and Biophysics, University of Mississippi Medical Center, Jackson, MS, USA

### Definition and Characteristics

The classical definition of renal hypertension is diseases of the kidney leading to hypertension, and this accounts for 5% of hypertension. However, in all forms of hypertension studied to date, there is an altered renal-pressure natriuresis which is the inability of the kidney to excrete a sodium load except at elevated arterial pressures [1]. Therefore, renal hypertension should include both primary and secondary forms of hypertension and can be caused by (i) intrarenal disturbances that increase tubular reabsorption or decrease renal blood flow or GFR and (ii) extrarenal disturbances, such as increased antinatriuretic substances or increased sympathetic nervous system activity.

### Prevalence

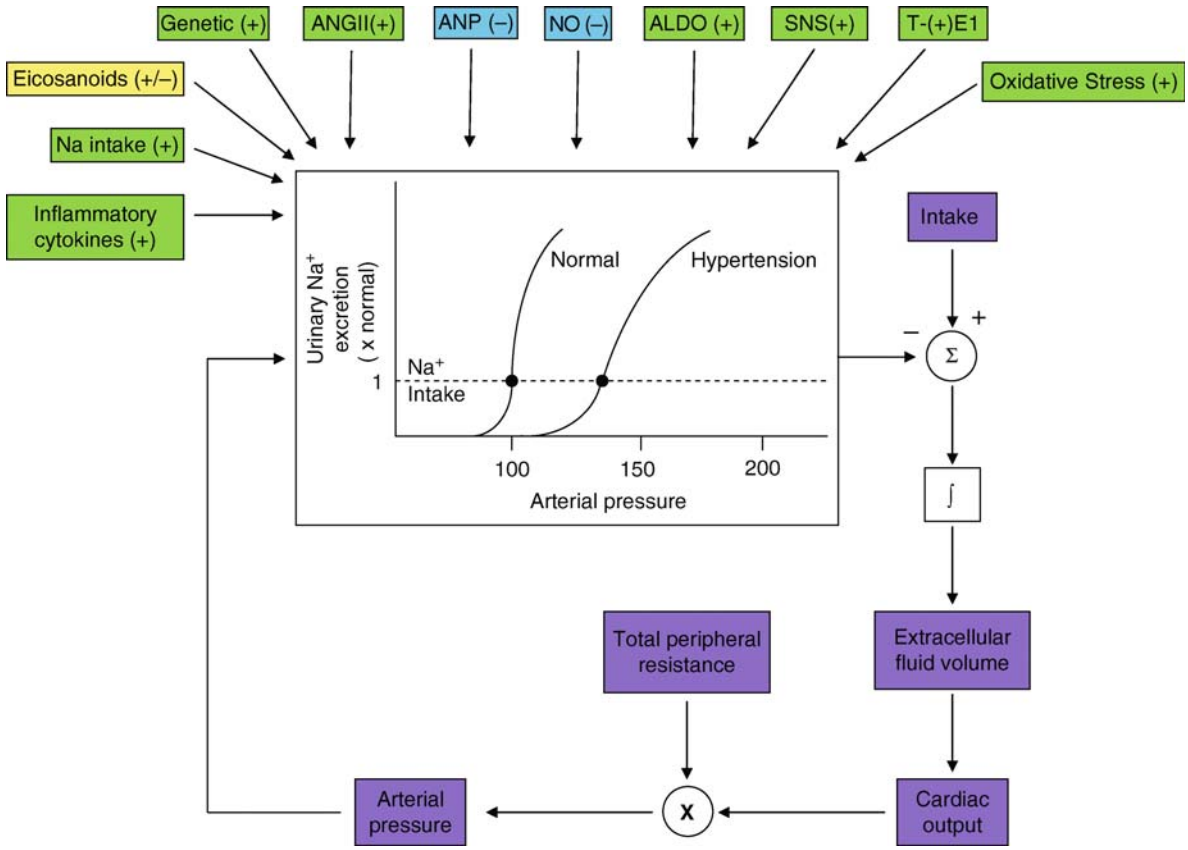
Nearly 1 billion people have hypertension worldwide as defined as a blood pressure greater than 140/90. The highest percentage of hypertensives in any country is in Germany in which 55.3% have hypertension.

### Genes

Several genetic defects have been identified in humans causing severe hypertension due to enhanced renal salt retention. Those monogenetic hypertensive disorders are, however, rare. On the other hand, a wide variety genetic polymorphisms have been identified, which do not necessarily cause but predispose to hypertension, Most if not all of those polymorphisms are effective through alteration of renal salt excretion. Some of them are more frequent in Africans than Caucasians. Accordingly, 30% of African-Americans have hypertension compared to only 20% of Caucasians.

### Molecular and Systemic Pathophysiology

As shown in Fig. 1, several factors contribute to the renal ability to excrete sodium and water, and each of these has long-term effects on arterial pressure. Angiotensin II affects blood pressure by renal vasoconstriction and increased renal tubular reabsorption both of which will increase arterial pressure. Aldosterone, a powerful sodium retaining hormone, primarily acts in the distal parts of the nephron. Aldosteronism can occur independent or dependent on angiotensin II. Stimulation of the sympathetic nervous system, such as occurs in obesity, can directly cause increased renal sodium



**Hypertension, Renal. Figure 1** Basic renal-pressure natriuresis-body fluid feedback mechanism for the long-term regulation of arterial pressure and body fluids. Factors in green, yellow and blue boxes affect the renal-pressure natriuresis mechanism, which thus changes renal excretion of sodium and water in a positive (+) or negative (–) direction and ultimately affect arterial pressure. *ANG II* angiotensin II, *ANP* atrial natriuretic peptide; *NO* nitric oxide; *ALDO* aldosterone; *SNS* sympathetic nervous system; *ET-I* endothelin-1.

retention thus increasing blood pressure. Elevation of oxidative stress with release of reactive oxygen species has been shown to contribute to decreases in renal hemodynamics and decreased pressure natriuresis [2,3]. Reduction of oxidative stress with antioxidants reduces renal vasoconstriction and lowers arterial pressure [3]. Inflammatory cytokines such as tumor necrosis factor alpha and interleukin-6 have been found in renal tissues in experimental hypertension, and renal lymphocytes and macrophages are elevated. In human studies the acute phase reactant, C-reactive protein is used as a marker of inflammation, and elevations in this agent have been reported in hypertensive patients and are used as a predictor of hypertension. Antiinflammatory agents, such as mycophenolate mofetil, reduce renal macrophage invasion and renal cytokines, and arterial pressure is lowered markedly [4]. Reactive oxygen species have been shown to directly stimulate renal inflammation primarily through stimulation of nuclear factor kappa B, which is an important transcription factor that causes elevations in cytokines. In experimental hypertension, antioxidant therapy causes large decreases in nuclear factor kappa B, decreased renal cytokines, and decreased arterial pressure. Endothelin does not appear to have a major influence on blood pressure and renal function in normotensive individuals but may contribute to renal sodium reabsorption after hypertension is established. Eicosanoids contribute the vascular tone, sodium reabsorption and renin release, and some of these substances act as vasodilators and others as vasoconstrictors. Two factors are shown in Fig. 1 which act as natriuretic agents. Atrial natriuretic peptide, which is stimulated by atrial stretch, causes increases in renal sodium excretion. Nitric oxide, which is generated by three major isoforms of NO synthases, acts as a vasodilator and enhances renal sodium excretion. Some forms of experi mental hypertension, such as in Dahl salt-sensitive hypertension, have lowered amounts of renal nitric oxide. Experiments in Dahl rats in which excess arginine, the substrate of nitric oxide, was given, caused increased nitric oxide levels, enhanced pressure-natriuresis, and decreased arterial pressure. In other experiments nitric oxide was blocked, and arterial pressure increased markedly, and in some experiments

severe renal damage occurred. Nitric oxide has proven to be an important antihypertensive agent.

### Diagnostic Principles

Hypertension is classified as normal blood pressure: less than 120/80 mmHg; prehypertension: 120–139/80–89 mmHg: and hypertension: greater than 140/90 mmHg.

1. Patients should not smoke or ingest caffeine for 30 min prior to blood pressure measurement.
2. Patients should sit down and remain quiet for at least 5 min before blood pressure is measured.
3. Patients should sit with their arms supported at the level of the heart during the measurement.
4. The bladder (inflatable part) of the blood pressure cuff should encircle at least 80% of the arm. A large cuff should be used for patients with thick arms.
5. Two or more readings should be taken at least 2 min apart.

### Therapeutic Principles

Prevention and treatment of high blood pressure consists of lifestyle changes and medications. Important lifestyle changes include (i) losing weight for overweight individuals, (ii) stop smoking, (iii) eating a healthy diet such as the DASH diet (fruits, vegetables, low fat dairy products, and food with low saturated and total fat), (iv) reduction of dietary sodium, (v) regular aerobic exercise, and (vi) limiting alcohol intake. Medications to treat hypertension include diuretics, angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, beta blockers, and calcium channel blockers. Diuretics are usually the first line of therapy, and if necessary other antihypertensive agents listed above can be added to or as a substitute for diuretics.

## Hyperthermia of Anesthesia

►Malignant Hyperthermia

## Hyperthermia

T. Balakrishna Poduval, Saurabh Chatterjee
Immunology and Hyperthermia Section, Radiation Biology and Health Sciences Division, Bhabha Atomic Research Centre, Mumbai, India

### Synonyms

Hyperpyrexia; Heat stroke

### Definition and Characteristics

Hyperthermia (HT) is the general name given to a variety of heat-related illness (HRI). HT is an acute condition that occurs when the body produces or absorbs more heat than it can dissipate, leading to a rise in body temperature above the hypothalamic set point, caused by excessive heat, exercise, disease, or drug, either alone or in combination. Heat stroke (HS) is a hyperthermic condition, which is the most severe form of a continuum of HRI that is associated with systemic inflammatory response syndrome (SIRS), multiorgan dysfunction syndrome (MODS) in which encephalopathy predominates, and death [1]. Maternal hyperthermia in early pregnancy is associated with increased risk for neural tube defects and may be a human teratogen. Malignant hyperthermia (MHT), a pharmacogenetic disorder, is a potentially life-threatening event triggered by the administration of certain anesthetics, neuromuscular blocking agents, fever, and extreme exercise, particularly in hot weather. The clinical features of MHT include contracture, rigidity, and heat production from skeletal muscle resulting in severe hyperthermia.

### Prevalence

The incidence data on HRI are imprecise. Ambient temperature, exercise, duration of heat exposure, relative humidity, wind velocity, acclimatization, hydration status of the host, inherent susceptibility of the host to HT, disease, all contribute to the development of HS. HRI can exacerbate existing medical condition and cause death. The heat waves in 2003 killed more than 35,000 people in Europe and more than 1,600 people in India [2]. Data from the Centers for Disease Control and Prevention, USA show that average annual HT-related death during 1999–2003 is 688.

### Genes

In over 50% of the families with MHT, a linkage is found between the phenotype as measured by the contracture test and a mutation in the gene RyR-1 at chromosome 19q13.2, encoding the skeletal muscle ryanodine receptor (RYR-1). Over 20 mutations in a region of the gene that

encodes the cytoplasmic face of the receptor have been described [3]. Studies of mice carrying a homozygous hsf-1$^{(-/-)}$ null mutation (hsf-1 knockouts) illustrate the importance of this transcription system to thermotolerance, survival and stress adaptation.

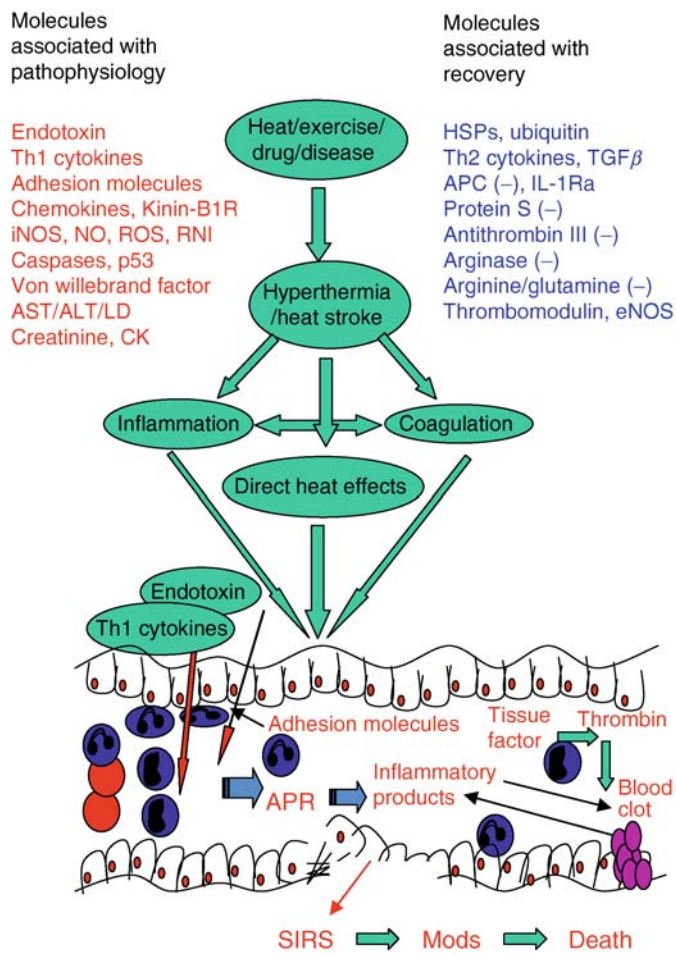
## Molecular and Systemic Pathophysiology

The severity of the heat injury depends on the thermal load of the host. Severe HT puts strain on the physiology of all the systems in the body, leading to homeostatic failure. Heat-induced tissue damage is likely to occur at core temperature ($T_c$) > 42°C, where proteins begin to denature. The current knowledge suggests that HS is triggered by a thermoregulatory and circulatory collapse during HT and driven by endotoxemia, initiated by HT-induced intestinal barrier dysfunction [1]. The acute-phase response (APR), inflammatory response, coagulation response of the host to HT and the direct cytotoxic effects of heat result in the generation of inflammatory molecules, reactive oxygen species (ROS), and reactive nitrogen intermediates (RNI) that lead to cell injury and overwhelm the natural defense systems leading to SIRS, MODS, and death (Fig. 1).

HT triggers an APR involving several signaling pathways; some of them facilitate death and some survival. The molecular mechanisms that take a host from a hyperthermic insult through MODS and death are not completely understood. Global genome profiles of human lymphocytes from patients with exertional heat injury indicated a twofold or greater increased expression of 361 transcripts and a twofold or greater decreased expression of 331 transcripts [4].

## Diagnostic Principles

HS: diagnosis is based on the medical history including visible symptoms and physical examination. The blood



**Hyperthermia. Figure 1** Possible molecular pathways involved in the pathogenesis of HT. The movement of endotoxin and Th1 cytokines into the systemic circulation initiates an uncontrolled cascade of inflammation and coagulation. This coupled with the direct cytotoxic effects of heat; fuel the progression of HT to HS. The molecules contributing to the injury are upregulated. A minus sign in the bracket indicates the deficiency of the molecule in the hyperthermic host.

and urine chemistry is used as a supplementary test. The clinical presentation of HS patients suggest dry and hot skin, a $T_c > 40^{\circ}C$, with systemic inflammation, CNS dysfunction, disseminated vascular coagulation, and MODS; and cardiovascular deterioration may be observed at times. MHT: determination of susceptibility is made with an in vitro contracture test on a fresh biopsy of skeletal muscle, to an anesthetic stimuli and genetic test for the RyR-1 gene for confirming the diagnosis.

## Therapeutic Principles

HS is a preventable disease. There is no therapeutic molecule that is useful in managing the HS. Potential therapeutic protocols should aim at reducing the heat load, inflammatory response, and coagulatory response. Antibodies to interleukin-1 (IL-1), endotoxin (ET), IL-1 receptor antagonist (IL-1Ra) have offered beneficial effect in experimental HS. Activated protein C (APC), which modulates both the inflammatory and the coagulation cascade, has been used in experimental HS [5]. Correction of reduced antithrombin III levels contributed to the recovery of HS patient. Arginine and glutamine, which downregulate the inflammatory response, coagulatory response, and increase the expression of heat shock proteins (HSPs), have shown therapeutic benefit in experimental HS. A decrease in the ratio of $Th_1$ and $Th_2$ (Th1/Th2) cytokines correlate with a decrease in the severity of experimental HS. A shift in the arginine metabolism toward arginase with a concomitant decrease in the expression of inducible nitric oxide synthase (iNOS) expression, without compromising the endothelial NOS (eNOS) expression, favors recovery from HS.

H

## Synonyms

Autonomously functioning thyroid nodules; AFTNs; Hot nodule; Toxic thyroid adenoma

## Definition and Characteristics

Hot nodules are characterized by their capacity to grow and produce and secrete thyroid hormones independent from serum levels of thyroid hormones and TSH. Autonomy can present in different histologic forms, such as adenoma or adenomatous nodule or as microscopic hot areas in euthyroid goiters and only very rarely as a malignant thyroid epithelial tumor with hyperthyroidism. Thyroid autonomy occurs mostly in toxic multinodular goiters (TMNGs). Structural and functional heterogeneity are the most characteristic hallmarks of TMNG. It is encountered in a wide spectrum ranging from a single hyperfunctioning nodule in an otherwise normal thyroid gland to an enlarged thyroid gland that has additional nonfunctioning nodules and also multiple hyperfunctioning nodules. A hot nodule is a benign thyroid neoplasm characterized by a circumscribed increased tracer uptake with suppression (decreased uptake) of the surrounding normal thyroid tissue on scintigraphy. The clinical features of thyroid autonomy can be attributed to the symptoms of thyrotoxicosis with or without goiter [1].

## Prevalence

In iodine-deficient regions, hot nodules account for 50–60% of cases with thyrotoxicosis. In contrast, in iodine-replete regions, only 3–10% of the cases with hyperthyroidism are due to hot nodules. Hot nodules are more frequent in women (4 to 10 times higher than men), smokers, and older age groups [1,2].

## Genes

Hot nodules are caused by activating mutations in either the TSH receptor (TSHR) or the Gs alpha protein gene (GNAS) [1,2]. The TSHR is a member of the

rhodopsin/β-adrenergic receptor family, a subfamily of G-protein-coupled receptors. This gene is encoded by ten exons that spread over 60 kb on chromosome 14q31. The polypeptide backbone is 764 amino acids in length (84.5 kDa) (OMIM 603372) [3]. GNAS (Guanine nucleotide binding protein, alpha stimulating, Gsα) is a member of a large family of GTP binding proteins. This gene is localized on 20q13.2. It is composed of 13 exons that encode 394 amino acids (45 and 52 kDa) (OMIM 139320) [3]. Many somatic gain of function mutations are located in the third extracellular loop and sixth transmembrane segment of the TSHR and in exons 8 and 9 of the GNAS gene [1–3] (TSH Receptor Mutation Database II, http://www.uni-leipzig.de/innere/_forschung/index.html).

If exons 9 and 10 of the TSHR are screened with sufficiently sensitive methods like denaturing gradient gel electrophoresis, somatic TSHR mutations can be detected in 57–70.2% and somatic GNAS mutations in 1.3–3% of the hot nodules [4,5].

## Molecular and Systemic Pathophysiology

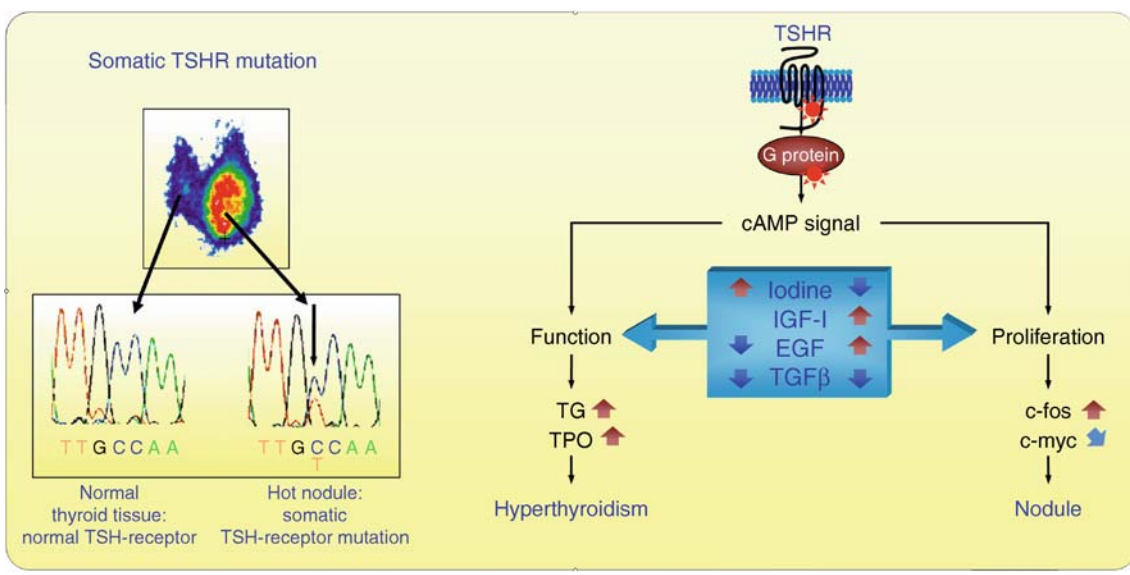
In normal physiologic conditions, TSH binds and stimulates the TSHR. After activation, the TSHR couples to the heterotrimeric G protein, inducing the exchange of GDP with GTP. Thus the G protein is separated into its α and βγ subunits. Gsα stimulates the adenylate cyclase pathway, which leads to the formation of cAMP and subsequently to the activation of protein kinase A (PKA). PKA consists of two regulatory and two catalytic subunits. When two cAMP molecules bind to the R subunit, active C subunits are released and enter the nucleus where they phosphorylate CREB, which is involved in the transcription regulation process [1–5].

Somatic mutations in the signal transduction pathway (TSHR or GNAS) constitutively activate the cAMP cascade and result in growth and hyperfunction of the thyroid follicular cells and ultimately thyroid autonomy. Iodine deficiency results in impaired thyroid hormone synthesis that is further compensated by thyroid hyperplasia. The increase in mitotic activity and proliferation of thyroid follicular cells increases the number of cell divisions and DNA replications leading to increased chances for mutagenesis of the TSHR. Autocrine factors might further cause expansion of hot thyroid nodules. In TSHR and GNAS mutation negative hot nodules, mutation in other candidate genes of the cAMP signal transduction pathway (e.g., other G-protein subunits, adenylate cyclase, phosphodiesterase) or overexpression of signaling proteins might cause hot nodules [1–5] (Fig. 1).

## Diagnostic Principles

The diagnosis of thyroid autonomy is based on clinic, laboratory, and radionuclide uptake characteristics of thyrotoxic patients [1,2].

1. Whereas younger patients may show the full range of symptoms of hyperthyroidism older patients are frequently oligo- or even asymptomatic.



**Hyperthyroidism due to Thyroid Autonomy. Figure 1** Technetium scintiscan of a toxic thyroid adenoma. Molecular analysis of genomic DNA extracted from the adenoma tissue shows a heterozygous TSH receptor (TSHR) point mutation. In the surrounding thyroid tissue, the wild-type TSHR sequence is detected. The TSHR is coupled to G proteins and mainly stimulates the adenylate cyclase pathway. The cAMP cascade positively regulates thyroid hormone production and thyroid epithelial cell proliferation. It mediates both the formation of hyperthyroidism and thyroid nodule growth via growth factors like IGF I, EGF, TGFβ, and FGF (modified according to [3]).

2. Typically laboratory evaluation identifies overt thyrotoxicosis with low serum TSH and high fT4 and fT3 levels. Moreover, a hot nodule may occur with subclinical hyperthyroidism, and may even be present in euthyroid individuals.
3. The hot nodules show increased radionuclide uptake ($^{131}$I or $^{99m}$Tc) typically concomitant with a decreased uptake in the rest of the thyroid tissue.

## Therapeutic Principles

The first line treatment is antithyroid drugs. Propylthiouracil or methimazole should be started with a dose of 300 or 30 mg/day, respectively. Alternatively or additionally beta blocking drugs (Propranolol 80 mg/day) can be used to inhibit $T_4$ to $T_3$ conversion and to decrease tachycardia. Spontaneous resolution of thyroid autonomy by apoplexia of the hot nodule is rare. Therefore, definite ablative treatment by either surgery or radioiodine therapy is necessary after induction of euthyroidism.

Surgery is mostly used in the patients who have a large goiter or concomitant cold nodules. Hemithyroidectomy is usually adequate for single hot nodules without further thyroid nodules. Otherwise a subtotal, near-total, or total thyroidectomy is the treatment of choice for toxic multinodular goiter.

Radioiodine treatment with $^{131}$I is highly effective for single hot nodules. It is not the treatment of choice for large goiters or in case of suspicion of malignancy. The required doses range from 10 to 200 mCi [1,2]. The success rates range between 85 and 100% for single hot nodules and up to 90% for TMNGs [1,2].

# Hyperthyroidism, Non-autoimmune Autosomal Dominant

Hulya Iliksu Gozu[1], Julia Lüblinghoff[2], Rifat Bircan[3], Ralf Paschke[2]

[1]Section of Endocrinology and Metabolism, Dr. Lutfi Kirdar Kartal Education and Research Hospital, Istanbul, Turkey

[2]Department of Internal Medicine III, University of Leipzig, Leipzig, Germany

[3]Department of Medical Biology, Marmara University Medical School, Istanbul, Turkey

H

## Synonyms

Hereditary nonautoimmune autosomal dominant toxic thyroid hyperplasia

## Definition and Characteristics

Nonautoimmune autosomal dominant hyperthyroidism is caused by germline mutations in the TSH receptor (TSHR).

This disorder is characterized by the following (Table 1) (TSH receptor Mutation Database II, http://www.uni-leipzig.de/~innere) (OMIM 609152) [1–5]:

1. A positive family history for nonautoimmune hyperthyroidism [1–4].
2. Absence of clinical (ophthalmopathy, pretibial myxoedema or dermopathy) or other (anti-TSHR antibodies, TPO antibodies or lymphocytic infiltration of the thyroid gland) stigmata of autoimmunity [1–4].
3. The goiters are generally diffuse in children and tend to become multinodular later in life as described for several families (Tonacchera et al., 1996; Schwab et al., 1997; Fuhrer et al., 1997; Arturi et al., 2002; Vaidya et al., 2004; Claus et al., 2005; and Karges et al., 2005, all described in http://www.uni-leipzig.de/~innere and [2–4].
4. The age of manifestation of hyperthyroidism is highly variable and ranges between the neonatal period (Schwab et al., 1997) and 60 years (Karges et al., 2005). It is also highly variable within the same family; 10–36 years in the Nancy family, 18 months to 53 years in the Reims family, 2–21 years in the Cardiff family, and 4–60 years in the family reported by Karges et al., all described in http://www.uni-leipzig.de/~innere and [4].
5. Hyperthyroidism may vary from mild (Lee et al., 2002) or subclinical (two members in the Nancy family and one member in the family by Vaidya et al.) to severe, all described in http://www.uni-leipzig.de/~innere and [2].

6. Recurrences after antithyroid drug therapy, nonablative radioiodine treatment or partial thyroidectomy are frequent [1–4].

## Prevalence

Neonatal thyrotoxicosis is rare and it is nearly always associated with maternal Graves' disease. In addition to this form of thyrotoxicosis, a rarer form of neonatal thyrotoxicosis, nonautoimmune autosomal dominant hyperthyroidism due to TSHR germline mutations has also been described [1]. To date, 17 families with nonautoimmune autosomal dominant hyperthyroidism have been published. Women were affected more frequently (Table 1) (see TSH receptor Mutation Database II, http://www.uni-leipzig.de/~innere) (OMIM 609152) [1–5].

## Genes

Nonautoimmune autosomal dominant hyperthyroidism is caused by germline TSHR activating mutations. The TSHR belongs to a large family of receptors coupled to heterotrimeric GTP-binding proteins (GPCRs). This gene is encoded by ten exons that spread over 60 kb on chromosome 14q31. The polypeptide backbone is 764 amino acids in length (84.5 kDa) (OMIM 603372) [1]. The phenotype of a family with nonautoimmune autosomal dominant hyperthyroidism was first described by Thomas et al. in 1982. In this family, thyrotoxicosis without evidence for Graves' disease was observed in 16 of 48 examined family members. Later, a V509A germline mutation that displays a higher constitutive activation of the adenylyl cyclase than the wild-type TSHR was identified in this pedigree from Nancy (Table 1). Hereditary TSHR germline mutations are mostly located at the transmembrane (TM) segments of the receptor (G431S in 1.TM, M463V in 2.TM, S505N, S505R and V509A in 3.TM, V597F in 5.TM, A623V, L629F and P639S in 6.TM, C672Y in 7.TM) except R310C that is located in the extracellular (EC) domain, I568V located in the 2.EC loop, and N650Y located in the 3.EC loop (Table 1) (TSH receptor Mutation Database II, http://www.uni-leipzig.de/~innere) (OMIM 609152) [1–5].

## Molecular and Systemic Pathophysiology

Upon binding to its receptor, TSH exerts its action via both the cAMP and inositol phosphate pathways. The main signal transduction pathway involves the activation of adenylate cyclase through G-protein coupling and the intracellular production of cAMP. The cAMP pathway has been shown to stimulate thyroid hormone secretion and growth of thyrocytes. Constitutive activation of the cAMP pathway results in alterations of both function and proliferation of the thyroid cells. Since a TSHR somatic mutation leads to the development of a toxic thyroid nodule, it is expected that activating germline mutations will be associated with hereditary disease characterized by diffuse hyperplasia and hyperthyroidism [1].

Twelve years after the initial description of nonautoimmune autosomal dominant hyperthyroidism in the Nancy family in 1982, the V509A germline -mutation that displayed a threefold basal cAMP increment over the wild-type TSHR was identified in this family. The other germline TSHR mutations described in the literature also showed increased basal cAMP compared with the wild-type TSHR ranging from 1.5 to 5 (Table 1) (TSH receptor Mutation Database II, http://www.uni-leipzig.de/~innere) [1–5]. In order to be transmitted over generations, germline mutations are likely to be milder. The members of the same family harboring the same TSHR germline mutation show large differences in disease onset. Therefore, besides the constitutive activation of the cAMP pathway, most likely additional factors, for example, genetic background, and/or iodine intake modify the phenotypic expression [1].

## Diagnostic Principles

Diagnosis of nonautoimmune autosomal dominant hyperthyroidism should be considered in the presence of [1–4]:

1. A history of familial nonautoimmune thyrotoxicosis
2. Moderate diffuse goiter in children or multinodular goiter in adulthood
3. Absence of evidence of autoimmunity (no ophthalmopathy or pretibial myxoedema, absence of anti-TSHR antibodies and TPO antibodies)
4. Hyperthyroidism confirmed by high serum level of free T4 (FT4) and low serum level of TSH
5. Recurrence after medical treatment, or nonablative surgical or radioiodine treatment

## Therapeutic Principles

In case of the presence of the above signs and symptoms, all family members together with the index case should be analyzed for the presence/absence of a TSHR germline mutation to confirm the diagnosis and to detect potential discrepancies between mutation status and clinical phenotypes. In case of discrepancies, the additional search for further somatic constitutively activating mutations in hyperthyroid family members is necessary to explain possible discrepancies [3,5]. Antithyroid drugs should only be used to prepare the patients for surgery. The patients should be treated with either propylthiouracile or carbimazole. In order to control symptoms caused by adrenergic stimulation, beta blocking drugs (Propranolol) may be used. If the disease relapses, a complete ablation of the thyroid

## Synonyms

Congenital nonautoimmune hyperthyroidism

## Definition and Characteristics

Persistent sporadic nonautoimmune hyperthyroidism with an onset of disease during the neonatal period or even later has been found to be caused by sporadic (de novo) germline mutations in the TSH receptor (TSHR) gene. Twelve case reports have been published until January 2007 (Table 1 and see TSH Receptor Mutation Database II, http://www.uni-leipzig.de/innere/forschung/index.html) (OMIM 609152) [1–5]. It is characterized by:

1. An earlier (neonatal period – 11 months) and more severe onset than hereditary autosomal dominant nonautoimmune hyperthyroidism.
2. Goiter was reported in all except the one reported by Gruters et al. The goiters are mostly diffuse at the onset and become progressively nodular with increasing duration of the disease.
3. No TSHR or TPO antibodies; absence of lymphocytic infiltration in the thyroid gland.
4. Negative family history for nonautoimmune congenital hyperthyroidism.
5. Hyperthyroidism commonly relapses following withdrawal of antithyroid drugs and also after subtotal thyroidectomy.
6. Radioiodine in addition to surgery was necessary to induce euthyroidism in many cases [1,3,5].
7. In addition various consequences of prolonged neonatal hyperthyroidism have been reported (Table 1 and see TSH Receptor Mutation Database II, http://www.uni-leipzig.de/innere/forschung/index.html) (OMIM 609152) [1–5].

## Prevalence

Neonatal thyrotoxicosis is rare and has been reported in 1% of the babies born to mothers with Graves' disease due to transplacental passage of maternal TSAb. This form of neonatal hyperthyroidism is usually transient. Persistent neonatal hyperthyroidism is caused by germline mutations in the TSHR. These mutations may be inherited in autosomal dominant nonautoimmune hyperthyroidism or occur sporadically as de novo mutations. Constitutively activating de novo mutations of the TSHR (sporadic nonautoimmune hyperthyroidism) have been reported in 12 children with sporadic nonautoimmune hyperthyroidism up to date (Table 1) [1–3,5].

## Genes

Sporadic nonautoimmune hyperthyroidism is caused by sporadic (de novo) germline mutations in the TSHR gene, which is more than 60 kb long and has been localized on the long arm of chromosome 14 (14q31). It consists of ten exons. The large part of the extracellular domain is encoded by nine exons. The carboxyterminal part of the extracellular (EC) domain, the seven transmembrane domains (TMDs), and the intracellular loops (ICL) are encoded by exon 10. The TSHR is a 764-aa protein, which comprises a signal peptide of 21 aa; a large, glycosylated ectodomain of 394 residues; and

349 residues that constitute the 7 TMDs and cytoplasmic tail [5]. Sporadic nonautoimmune hyperthyroidism due to a sporadic mutation of the TSHR (Leu631Phe) with thyroid hyperplasia was first described by Kopp et al. (1995). Sporadic TSHR mutations have been mostly located at the transmembrane segments of the TSHR (A428V in 1.TMD; M453T in 2.TMD; S505N and L512Q in 3.TMD; V597L in 5.TMD; L631F, T632I and D633Y in 6.TMD except S281N germline mutation, which is located in exon 9 and the I568T germline mutation, which is located in the 2.EC loop (see TSH Receptor Mutation Database II, http://www.uni-leipzig.de/innere/forschung/index.htm) [1–3].

## Molecular and Systemic Pathophysiology

The TSHR has a high-affinity for TSH binding. The activation of the TSHR preferentially leads to stimulation of the adenylyl cyclase via the $G_s\alpha$ protein. Thus TSH stimulates the growth and function of the thyroid follicular cells and regulates the synthesis and secretion of the thyroid hormones. Chronic in vivo stimulation of the cAMP cascade also stimulates epithelial cell proliferation in vivo. Germline TSHR mutations may give rise to autosomal dominant nonautoimmune hyperthyroidism or to sporadic nonautoimmune congenital hyperthyroidism in the case of de novo mutations [5].

Sporadic nonautoimmune hyperthyroidism due to a sporadic mutation of the TSHR (Leu631Phe) with thyroid hyperplasia was first described by Kopp et al. (1995). The basal cAMP accumulation of this mutation was five- to sixfold increased compared with the wt TSHR. Functional analysis of the further de novo germline TSHR mutations indicated that basal cAMP accumulation of these mutations ranged from 2.4 to 7 fold increase of basal cAMP compared with the wt TSHR (Table 1) (see TSH Receptor Mutation Database II, http://www.uni-leipzig.de/innere/forschung/index.htm) [1–4].

## Diagnostic Principles

Diagnosis of sporadic nonautoimmune hyperthyroidism should be considered in the presence of [1–3,5]:

1. Persistent neonatal hyperthyroidism
2. Recurrence of neonatal hyperthyroidism after antithyroid drug withdrawal, subtotal thyroidectomy or radioiodine treatment
3. Negative family history for hyperthyroidism
4. Diffuse goiter in neonatal period or nodular goiter later on
5. Absence of TSHR or TPO antibodies

The diagnostic principles of sporadic nonautoimmune hyperthyroidism resemble those of autosomal dominant nonautoimmune hyperthyroidism. However, the clinical severity of hyperthyroidism is often more pronounced in sporadic than in autosomal dominant nonautoimmune hyperthyroidism and a family history of thyrotoxycosis is absent in sporadic nonautoimmune hyperthyroidism.

## Therapeutic Principles

Although this form of hyperthyroidism is rare, the specific diagnosis will lead to an earlier and more persistent antithyroid drug treatment and an earlier thyroid ablation with fewer consequences of persistent or relapsing hyperthyroidism. Immediate treatment of overt neonatal hyperthyroidism is essential for a good prognosis and for the prevention of advanced bone age or mental retardation. Propylthiouracile or Methimazole should be administered in order to achieve euthyroidism. Long-term treatment with antithyroid drugs could control hyperthyroidism in some cases with good compliance with antithyroid drug treatment, but antithyroid drug treatment can not prevent thyroid enlargement. A close follow up is necessary since mild side effects have been documented in 20–30% and agranulocytosis and hepatitis in 0.4% of children with Graves' disease [3].

After controlling thyroid function with antithyroid drugs, a near-total thyroidectomy should be recommended. In addition, early radioiodine treatment may be necessary to avoid relapses. Radioiodine treatment is recommended in children over 5 years [3]. Furthermore, genetic counseling of the patients is very important [1,3,5].

# Hypertriglyceridemia

Shui-Ping Zhao, Hui-Jun Ye
Department of Cardiology, Second Xiangya Hospital, Central South University, Changsha, Hunan, People's Republic of China

## Synonyms

High triglycerides; High blood triglycerides

## Definition and Characteristics

Hypertriglyceridemia is defined as an elevated concentration of triglyceride (TG) in the blood. According to the National Cholesterol Education Program Adult Treatment Panel III (NCEP ATP III) guidelines, a normal triglyceride level is <150 mg/dl (Table 1). ATP III adopts the following classification of serum triglycerides [1]:

Recent meta-analyses of prospective studies indicate that elevated triglycerides are also an independent risk factor for coronary heart disease (CHD). In clinical practice, elevated serum triglycerides are most often observed in persons with the metabolic syndrome, although secondary or genetic factors can heighten triglyceride levels. Most cases of hypertriglyceridemia are discovered after performing a routine lipid profile. However, severe hypertriglyceridemia (>500 mg/dl) may cause pancreatitis, eruptive xanthomas, or lipemia retinalis. In some cases, extremely high levels of chylomicrons can cause chylomicronemia syndrome. Eruptive xanthomas are 1- to 3-mm yellow papules that can erupt anywhere but are usually seen on the back, chest, and proximal extremities. Palmar xanthomas, yellow creases on the palm, may be seen in patients with type III hyperlipidemia. Lipemia retinalis is the visualization of lipemic blood in the retinal blood vessels.

## Prevalence

The prevalence of hypertriglyceridemia may differ in different areas. In the US, for example, the prevalence of hypertriglyceridemia defined as a triglyceride level >150 mg/dl is ~30%. The prevalence of hypertriglyceridemia in China is 11.9%, and the prevalence of hypertriglyceridemia in Turkey is 35.54%.

**Hypertriglyceridemia. Table 1** Classification of triglyceride levels

| | |
|---|---|
| Normal triglycerides | <150 mg/dl |
| Borderline-high triglycerides | 150–199 mg/dl |
| High triglycerides | 200–499 mg/dl |
| Very high triglycerides | 500 mg/dl |

## Genes

Patterns of dyslipidemia have been found to cluster in some families, suggesting a strong genetic component. Three conditions with elevated triglycerides have been identified, i.e., familial combined hyperlipidemia, familial hypertriglyceridemia, and familial dysbetalipoproteinemia.

Familial combined hyperlipidemia is an autosomal dominant disorder characterized by patients and their first-degree relatives who may have either isolated TG or low-density lipoprotein cholesterol (LDL-C) elevations or both. This disease is genetic and inherited, although, whether the underlying defect is monogenic or polygenic is not known. Many patients exhibit high levels of apo B-100 (hyperapobetalipoproteinemia). Diagnosis of the disorder in a particular patient requires a family history of premature CHD in one or more first-degree relatives and a family history for elevated TGs with or without elevated LDL-C levels.

Familial elevation of triglycerides without increased serum cholesterol levels characterizes familial hypertriglyceridemia, which also is an autosomal dominant trait. Familial hypertriglyceridemia occurs in about 1 in 500 individuals in the US. Many patients with familial hypertriglyceridemia also manifest obesity, but in some, triglycerides are elevated without obesity or any other evidence for metabolic syndrome. These patients may have a defect in the catabolism of triglyceride-rich lipoproteins (TGRLP) (e.g., an abnormality in lipoprotein lipase activity).

A third category of familial disorders with elevated triglycerides includes increased remnant lipoproteins (familial dysbetalipoproteinemia). This condition also has been named type 3 hyperlipoproteinemia. The defining defect in this disorder is an isoform variation in apolipoprotein E. Affected patients usually are homozygous for apo E-2($Arg_{158}$→Cys). Since apo E mediates binding of VLDL remnants and chylomicron remnants to their hepatic receptors, these remnants accumulate in plasma when the dysfunctional apo E-2 is present.

Apolipoprotein A5(apo A5) is part of the regulatory gene cluster on chromosome 11, which has been recognized for many years and contains the genes for apo A1, apo C3, and apo A4. Polymorphisms in this cluster have been linked to both CHD and hypertriglyceridemia. In apo A5-knockout mice, triglycerides increased fourfold, and expression of the human A5 genetic sequence in transgenic mice decreased serum triglyceride concentrations by 50–70% [2].

## Molecular and Systemic Pathophysiology

Dietary triglycerides are absorbed by the small intestine, secreted into the lymph system, and enter the systemic circulation as chylomicrons via the thoracic

duct. The liver also produces and secretes triglycerides, and packages them into lipoproteins. Chylomicrons are synthesized in the intestine, and VLDLs are synthesized in the liver. These lipoproteins transport triglycerides and cholesterol throughout the circulation. Triglycerides comprise ~50 and 85% of the dry weight of VLDLs and chylomicrons, respectively, and are present in LDL and high-density lipoprotein (HDL) in much smaller quantities.

Chylomicrons and VLDLs normally undergo rapid metabolism via the action of LPL, hepatic lipase, and cholesterol ester transfer protein. The normal half-life of chylomicrons and VLDLs is about 10 min and 9 h, respectively. During catabolism, triglycerides are hydrolyzed, free fatty acids are released to the plasma, and cholesterol is transferred from HDL to VLDL.

Any disturbance that causes increased synthesis of chylomicrons and/or VLDLs or decreased metabolic breakdown will cause elevations in triglyceride levels. That disturbance may be common such as dietary indiscretion or rare such as a genetic mutation of an enzyme in the lipid metabolism pathway.

## Diagnostic Principles

The NCEP recommends obtaining a fasting lipid panel (total cholesterol, LDL-C, HDL-C, and triglycerides) on patients beginning at age 20 and repeated every 5 years. In healthy asymptomatic patients without risk factors, it is acceptable to obtain a nonfasting total cholesterol and HDL cholesterol level every 5 years. However, for patients with CHD, CHD risk equivalents, familial dyslipidemia, or risk factors for CHD, a fasting lipid panel should be obtained yearly. If the triglyceride level is discovered to be >150 mg/dl, it should be rechecked again after a 12- to 16-h fast for confirmation. If the triglyceride level is >1,000 mg/dl, beta-quantification by ultra centrifugation and electrophoresis can be performed to determine the exact dyslipidemia [3].

## Therapeutic Principles

The treatment strategy for elevated triglycerides depends on the causes of the elevation and its severity. For all persons with elevated triglycerides, the primary aim of therapy is to achieve the target goal for LDL cholesterol. When triglycerides are borderline high (150–199 mg/dl), emphasis should be placed on weight reduction and increased physical activity. For high triglycerides (200–499 mg/dl), non-HDL cholesterol becomes a secondary target of therapy. Aside from weight reduction and increased physical activity, drug therapy can be considered in high-risk patients to achieve the non-HDL cholesterol goal. There are two approaches to drug therapy. First, the non-HDL cholesterol goal can be achieved by intensifying therapy with an LDL-lowering drug; or second, nicotinic acid or fibrate can be added, if used with appropriate caution, to achieve the non-HDL cholesterol goal by further lowering of VLDL cholesterol. In rare cases, in which triglycerides are very high (≥500 mg/dl), the initial aim of therapy is to prevent acute pancreatitis through triglyceride lowering. This approach requires very low fat diets (≤15% of calorie intake), weight reduction, increased physical activity, and usually a triglyceride-lowering drug (fibrate or nicotinic acid). Only after triglyceride levels have been lowered to <500 mg/dl should attention turn to LDL lowering to reduce risk for CHD.

# Hypertrophic Cardiomyopathy

Jens Mogensen
Department of Cardiology, Aarhus University Hospital, Skejby, Denmark

## Synonyms

HCM; Heart hypertrophy

## Definition and Characteristics

Hypertrophic cardiomyopathy (HCM) is the most common hereditary cardiac condition and transmitted by autosomal dominant inheritance. It is characterized by unexplained thickening of the myocardium and is a frequent cause of sudden cardiac death in young individuals. However, the disease expression is very heterogeneous even among related individuals and penetrance is incomplete. Disease presentation may occur at any age. In general, no specific genotype-phenotype correlation is apparent [1,2].

## Prevalence

The prevalence of HCM is about 0.2% and similar among different racial groups based on large population studies comprising more than 16,000 subjects [3].

**Hypertrophic Cardiomyopathy. Table 1** Disease genes in HCM

| Titin | *TTN* |

## Genes

HCM is primarily a disease of the cardiac sarcomere. Eight disease genes have been identified and mutation analyses of these genes in large cohorts of HCM patients have revealed a mutation in 50–60% of cases [4]. Recently mutations in genes encoding Z-disk proteins have been identified accounting for approximately 4% of HCM cases (Table 1).

More than 300 different mutations have been identified with missense mutations being most frequent. Furthermore, the majority of affected families tends to have their own "private" mutation implying that founder mutations as well as "hot-spot" mutations are rare.

## Molecular and Systemic Pathophysiology

The sarcomere is the contractile unit of the myocyte and organized in thick and thin filaments. Myosin heavy chain, myosin binding protein C, the regulatory and essential myosin light chains are localized in the thick filament and associated with the giant protein titin while the thin filament is composed of cardiac actin, tropomyosin, and the troponin complex. Contraction occurs by sliding of the thick and thin filaments. Regulation of muscle contraction is primarily dependent on the intracellular concentration of $Ca^{2+}$. The major sensor of the intracellular $Ca^{2+}$ level is the troponin complex which is composed of three subunits, Troponin C, I, and T. Their primary function is to control the interaction between the thick and thin filament during muscle contraction and relaxation. Troponin I can bind to actin-tropomyosin and prevent muscle contraction by inhibition of actin-tropomyosin-activated myosin (actomyosin) ATPase activity. The inhibitory effect of Troponin I is reversed by Troponin C binding of $Ca^{2+}$ which, subsequently introduces conformational changes in the entire Troponin complex leading to muscle contraction.

Due to the complex composition and function of the sarcomere there are several mechanisms by which mutations may lead to development of HCM. Several mutations have successfully been expressed in animals developing an HCM like phenotype. Much has been learnt about mechanisms involved in disease development in relation to changes in $Ca^{++}$- sensitivity, energy metabolism, impact on protein-protein interaction and consequences for force generation within the sarcomere. Most expression studies of specific sarcomeric mutations in transgenic animals have reported development of a homogeneous phenotype and a uniform effect on various muscle parameters investigated. Similarly, studies of specific mutations in myotube test systems have lead to unambiguous results. However, these results do not readily explain the extreme heterogeneous clinical disease expression observed in humans indicating that the human phenotype is a product of more than one single amino acid substitution in a sarcomeric gene. Environmental factors may influence the phenotype significantly as indicated in a recent study of transgenic HCM mice fed on various diets [5].

## Diagnostic Principles

HCM is diagnosed by demonstration of unexplained myocardial hypertrophy by use of echocardiography. Most commonly the interventricular septum is affected and about 25% of patients have a dynamic obstruction of the left ventricle outflow tract. About 2% develop heart failure indistinguishable from dilated cardiomyopathy. ECG abnormalities are present in most patients and may be the sole manifestation of the condition. Arrhythmias are common and include supra- as well as ventricular- rhythm disturbances. Abnormal blood pressure response to upright exercise occurs in up to 25% of patients with a flat blood pressure response or direct fall in systolic blood pressure.

The histopathology of HCM is characterized by disarray of myocytes, myocyte hypertrophy, and interstitial fibrosis.

## Therapeutic Principles

The major clinical problems in HCM are reduced exercise capacity, risk of cardiac arrhythmia and thromboembolic events. Furthermore sudden death may occur as the first manifestation of the disease. Symptoms include shortness of breath, palpitations and chest pain. Several studies have proposed specific risk factors for sudden death and it is generally accepted that the presence of

more than one risk factor should lead to considerations about prophylactic treatment.

- Previous cardiac arrest
- Sustained ventricular tachycardia
- Family history of sudden death
- Unexplained syncope
- LV thickness greater ≥30mm
- Abnormal exercise blood pressure
- Non-sustained ventricular tachycardia

From ACC/ESC expert consensus document [1].

This could either be implantation of a cardiac defibrillator, (ICD), and/or treatment with anti-arrhythmic drugs such as amiodarone. Treatment of low-risk patients aims at alleviating symptoms and beta-blockers as well as calcium antagonists are the primary drugs used. Recent studies have indicated that aggressive therapy is warranted in symptomatic patients with significant obstruction in the left ventricle outflow tract. Several treatment modalities are available and include medical therapy, (beta-blockers, disopyramide), surgical myectomi and alcohol septal ablation which has been developed as a percutaneous alternative to surgery. Atrial fibrillation is common in HCM and patients with severe diastolic impairment are at risk of circulatory collapse emphasizing the importance of well controlled cardiac rhythm. To avoid thrombo-embolic events a low threshold for anticoagulation is generally recommended.

## Synonyms

Hypertrophic pulmonary osteoarthropathy; Pierre-Marie-Bamberger disease; HOA

## Definition and Characteristics

Hypertrophic osteoarthropathy (HOA) is a syndrome characterized by clubbing of the fingers and toes, periosteal new bone formation of the tubular bones, and polyarthritis [1,2]. Although, intrathoracic neoplasms, especially nonsmall cell lung cancer (NSCLC), are one of the major causes of HOA in adults, HOA is rarely associated with intrathoracic malignancies in children.

HOA was first described by Bamberger in 1898 and Marie in 1890 in association with intrathoracic inflammatory lesions. HOA syndrome can be either primary or secondary [1]. Primary HOA and secondary HOA are two distinct clinical entities as manifested by clinical and radiological findings and also in treatment. Primary familial HOA is extremely rare, and is not associated with an underlying disease. It has been associated with myeloid metaplasia and skin changes. Secondary HOA has been associated with various underlying pulmonary and nonpulmonary causes, including intrathoracic tumors, primarily NSCLC, cystic fibrosis, cyanotic congenital heart disease, liver disease, biliary atresia, inflammatory bowel disease, Graves' disease, and chronic lung diseases [1]. Secondary HOA is also called hypertrophic pulmonary osteoarthropathy when there is an underlying pulmonary cause.

From 1890 to 2006, only 37 children under age of 18 years with malignancy and associated HOA have been reported [3]. Twelve patients were diagnosed with nasopharyngeal carcinoma, 8 with osteosarcoma, 8 with Hodgkin lymphoma, 5 with thymus carcinoma, 1 with a periosteal sarcoma, 1 with a pleural mesothelioma, 1 with rhabdomyosarcoma, and 1 with Langerhans cell histiocytosis.

In adults, intrathoracic neoplasms, especially NSCLC, are one of the major causes of HOA. Interestingly, it is not common in small cell lung carcinoma. Beside NSCLC, HOA can occasionally be seen in other

malignancies of adults, such as melanoma, breast cancer, leiomyosarcoma, gastrointestinal stromal tumor, and in Poems syndrome [1].

Radiologic findings of HOA are usually characteristic. Periosteal new bone formation is seen as a thin opaque line of new bone formation separated from the bony cortex by a narrow translucent band. Later, the two layers of bone gradually fuse and lamellar patterns of periosteal new bone may be seen [1]. Radiological findings may not always be evident.

HOA may precede the neoplastic pulmonary symptoms by 1–18 months. The presence of HOA has been thought to be a poor prognostic sign in patients with malignancy.

### Prevalence

HPO is reported to be seen in 29% of NSCLC patients. Neoplastic disorders account for 92% of the HOA cases in adults, whereas only 12% of HOA in childhood has been associated with neoplasia.

### Genes

Primary HOA is generally heterogenous, with evidence for both autosomal dominant and autosomal recessive inheritance. In primary cranio-HOA, which has a decreased neurocranium ossification as an additional feature, autosomal recessive inheritance is suggested [4].

### Molecular and Systemic Pathophysiology

Although the pathogenesis of HOA is not precisely known, some studies have revealed some responsible causes: unfragmented megakaryocytes, high circulating von Willebrand factor, increased prostaglandin F2-alpha and E levels, increased VEGF level and overexpressed VEGF receptors in stromal fibroblasts [5]. Prolonged prostaglandin E therapy has led to HOA in severe liver disease patients, and HOA was reported to have regressed after cessation of prostaglandin E therapy.

It has been suggested that afferent impulses traveling through the vagal or intercostal nerves from the pulmonary lesion to the central nervous system may be responsible for the symptoms of HOA; this has been clinically supported by the patients' relief of symptoms after vagotomy or after transection of the intercostal nerves, but vagotomy does not yield clubbing regression.

### Diagnostic Principles

HOA is a syndrome characterized by clubbing of the fingers and toes, periosteal new bone formation of the tubular bones, and polyarthritis. Radiologic findings of HOA are periosteal new bone formation that is seen as a thin opaque line of new bone formation separated from the bony cortex by a narrow translucent band. Radionuclide bone scanning and FDG PET/CT could detect periosteal involvement.

### Therapeutic Principles

The prognosis of primary HOA is good and the changes may resolve spontaneously. Symptoms associated with secondary HOA may be reversible after successful treatment of the lung abnormality [1–3]. Chemotherapy does not yield regression in HOA in NSCLC. Bisphosphonates may be used for pain palliation in adults with cancer.

# Hyperuricaciduria

►Hyperuricosuria

# Hyperuricemia

Michael A. Becker
University of Chicago Medical Center, Chicago, IL, USA

## Definition and Characteristics

Hyperuricemia is a common biochemical aberration in which serum (or plasma) uric acid concentration exceeds the limit of solubility for urate (~6.8 mg/dL or 405 μM in serum). For practical purposes, serum urate values exceeding 7.0 mg/dL or 415 μM by clinical laboratory analysis qualify as hyperuricemia. Primary hyperuricemia is defined as hyperuricemia developing in the absence of an identifiable causal disease, abnormal physiological state or drug or toxin exposure. When any of an extensive list of such influences on serum urate levels [1] account for urate supersaturation, the hyperuricemia is referred to as secondary hyperuricemia. Hyperuricemia in industrialized nations is frequently secondary, as, for example, during the administration of uric acid-retaining drugs. In the steady state, serum urate concentration reflects extracellular fluid urate concentration and persistent hyperuricemia indicates extracellular fluid urate supersaturation and an increased risk of the urate crystal deposition disease, gout. Although the risk for urate crystal deposition increases with increasing degree and duration of hyperuricemia, the clinical features of gout are relatively uncommon among hyperuricemic individuals (80–90% of these persons have decades of asymptomatic hyperuricemia). Thus, hyperuricemia is a necessary pathogenetic factor in the development of gout but is insufficient to define gout and does not usually warrant treatment in the asymptomatic state. Although hyperuricemia (independent of crystal deposition) is also a risk factor for hypertension, chronic kidney disease, cardiovascular disease and the components that together define metabolic syndrome X (1–3), it is uncertain whether hyperuricemia (or even high "normal" levels of serum urate) plays a causal role in these disorders [1–3]. The current standard of practice therefore, does not include treatment for most persons with asymptomatic hyperuricemia [2].

## Prevalence

Common among adult men and post-menopausal women in the US and Europe, prevalence is estimated at 5–8% or more; among Asian-Pacific and Native Americans, prevalence exceeding 20% has been reported. Hyperuricemia is rare in children.

## Genes

Genes directly implicated in hyperuricemia have largely been those relating to disorders in which hyperuricemia (and gout) have been secondary to uncommon inherited metabolic or renal diseases [1]. Despite historic recognition of familial gout, little is known about genes involved in "primary metabolic gout" or in the association between hyperuricemia and highly prevalent metabolic and cardiovascular disorders (see below). Recent identification of uric acid renal tubular exchangers/transporters and their genes [4] may clarify the impairment in uric acid renal clearance demonstrable in more than 80% of persons with primary gout [1].

## Molecular and Systemic Pathophysiology

Hyperuricemia results from either excessive uric acid production or relative impairment of uric acid renal clearance [1]. For several decades, the focus has been on urate crystal deposition as the major pathophysiological consequence of hyperuricemia. Controversy has, however, existed regarding whether or not the high prevalence of hyperuricemia in persons with hypertension, chronic renal insufficiency, hypertriglyceridemia, obesity, atherosclerotic heart disease and metabolic syndrome X denotes pathophysiological, crystal-unrelated roles for urate in the pathogenesis of these disorders [1–3]. Interest in this possibility and the mechanisms involved has recently increased [2,3].

## Therapeutic Principles

Asymptomatic hyperuricemia rarely warrants treatment to normalize urate levels. In exceptional circumstances, treatment follows that for gout.

## Hyperuricemic Nephropathy

►Nephropathy, Familial Juvenile Hyperuricemic

## Hyperuricosuria

John R. Asplin
Department of Medicine, Section Nephrology, University of Chicago, Chicago, IL, USA

### Synonyms

Hyperuricuria; Hyperuricaciduria

### Definition and Characteristics

Excessive urinary uric acid excretion secondary to either iatrogenic overproduction or increased renal clearance. Excretion rates of over 800 mg (4.8 mmol) per day in men and 750 mg (4.5 mmol) per day in women are considered abnormal.

### Prevalence

Using the above definition, 7–12% of adults in the United States have hyperuricosuria. Amongst kidney stone formers, 20–30% have hyperuricosuria.

### Molecular and Systemic Pathophysiology

Uric acid is produced in the liver and intestinal mucosa as the end product of purine nucleotide degradation. Both endogenous and dietary purines contribute significantly to daily uric acid production. Approximately one third of the uric acid load is secreted into the gastrointestinal tract and degraded by bacteria. The kidneys account for the remainder of uric acid excretion. Uric acid is freely filtered at the glomerulus and then both secreted and reabsorbed in the proximal tubule. The fractional excretion of uric acid is 7–10% in normal adult subjects. The most common cause of hyperuricosuria is dietary overingestion of purines, mainly found in meats and legumes. In a minority of patients, endogenous overproduction can be documented, often associated with hyperuricemia and gout and sometimes the result of inherited aberrations of purine synthetic enzymes, such as hypoxanthine-guanine phosphoribosyltransferase or PRPP synthetase. High renal clearance of uric acid may also be inherited as an isolated defect. (These inherited conditions are discussed elsewhere.) Renal hypouricemia may also be acquired in association with malignancies such as Hodgkin's lymphoma or be induced by uricosuric drugs such as probenecid and losartan.

The major clinical consequence of chronic hyperuricosuria is kidney stone formation.

Urate solubility is highly pH dependent. Uric acid has one proton that can dissociate in the physiological pH range of urine. The estimated pK of this proton in urine is 5.35. Uric acid is prone to precipitate in urine due to water extraction and proton secretion in the collecting duct. The solubility of protonated uric acid in urine is approximately 100 mg/l (0.6 mmol/l). Hyperuricosuria can lead to uric acid stone formation by increasing the urine concentration of uric acid. However, urine pH is the most critical factor in determining the concentration of protonated uric acid and most patients with uric acid stones have an overly acidic urine as the major cause of stone formation. Hyperuricosuria is also related to calcium oxalate stone formation. Uric acid appears to "salt out" calcium oxalate from solution, promoting stone formation [1].

Hyperuricosuria can be associated with massive precipitation of uric acid in the renal tubules, leading to acute urate nephropathy, as seen in tumor lysis syndrome or rhabdomyolysis, when intracellular purines are released and converted to uric acid. Acute urate nephropathy has also been found in the setting of extreme exercise in patients with renal hypouricemia [2]. ATP breakdown during exercise leads to excess uric acid production, which is rapidly cleared by the kidney, but may precipitate in the setting of a concentrated acidic urine.

### Diagnostic Principles

Diagnosis of hyperuricosuria requires a 24-h urine collection. In patients with recurrent nephrolithiasis, excretion rates of greater than 800 mg/day (4.8 mmol/24 h) in men and 750 mg/day (4.5 mmol/24 h) in women on an unrestricted diet are diagnostic. In the setting of acute renal failure, a uric acid to creatinine ratio of >1 (both expressed in mg/dl) suggests acute uric nephropathy.

### Therapeutic Principles

Patients with uric acid stones are treated with high fluid intake and alkali to increase urine pH to above 6.0. Allopurinol is rarely needed. Patients with calcium oxalate stones and hyperuricosuria should be placed on a low purine diet; if hyperuricosuria does not improve allopurinol should be added. In a prospective placebo controlled trial, allopurinol has been shown to reduce calcium oxalate stone recurrence in hyperuricosuric patients [3].

In patients at risk for acute uric acid nephropathy, such as patients with leukemia receiving chemotherapy, a high urine flow rate should be maintained and alkali given to

bring the urine pH into the range of 6.0–6.5. Raising the urine pH above 6.5 does not significantly improve uric acid solubility but does increase the risk of renal calcium phosphate precipitation in tumor lysis syndrome. Allopurinol should be administered prior to chemotherapy, at doses up to 600 mg per day. Alternatively, rasburicase, a recombinant form of uric acid oxidase, which converts uric acid to allantoin, has established efficacy in preventing and treating tumor lysis syndrome [4] and established acute uric acid nephropathy. Rasburicase lowers serum uric acid levels more rapidly than allopurinol but requires intravenous administration, costs significantly more and can cause anaphylaxis.

## Hyperuricuria

►Hyperuricosuria

## Hypervalinemia

Keiya Tada, Yoichi Matsubara
Department of Pediatrics and Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan

### Synonyms

Valinemia; Valine aminotransferase deficiency

### Definition and Characteristics

Probably autosomal recessive disorder of valine metabolism. The patient started to vomit shortly after birth and showed horizontal nystagmus, hyperkinesia of the extremities, and developmental delay. Her plasma level of valine was ten times higher than normal without abnormality of other aminoacids. Keto acid was absent in the urine [1,2]. Mental and physical development was found to be definitely delayed at the age of 24 months.

### Prevalence

Unknown, very rare. Two family cases have been reported [1,3].

### Genes

Unconfirmed.

### Molecular and Systemic Pathophysiology

A defect in valine transamination was demonstrated in peripheral leukocytes from the patient [4].

### Diagnostic Principles

Aminoacid analysis shows the increase of valine in plasma and urine, but no increase in leucine and isoleucine. The activity of valine transaminase in leukocytes is low, but the transaminase activities of leucine and isoleucine are normal. Prenatal diagnosis might be possible by determining the activity of valine transaminase, because the enzyme is demonstrable in placenta [4].

### Therapeutic Principles

A dietary treatment using the milk low in valine was temporally tried to the patient with hypervalinemia at the age of 9 months, resulting in decrease of valine in urine and plasma [4]. Therefore, early treatment following birth may be effective.

## Hyperventilation

Robert W. Gotshall
Health and Exercise Science, Colorado State University, Fort Collins, CO, USA

### Synonyms

Over-breathing; Hyperventilation syndrome; Idiopathic hyperventilation

## Definition and Characteristics

The physiological definition of hyperventilation is: "alveolar ventilation that is inappropriately greater than the metabolic production of carbon dioxide, resulting in reduction of arterial $PCO_2$ below the normal range (hypocapnia), and respiratory alkalosis." The combination of reduced arterial $PCO_2$ and alkalosis can lead to selective vasoconstriction of vascular beds and to neuronal hyper-excitability that produces symptoms involving many organ systems. Common symptoms include numbness or tingling in the hands, feet and lips (paraesthesia and tetany); lightheadedness, dizziness, and headache (cerebral vasoconstriction and hypoxia); chest pain; slurred speech; and sometimes fainting. Chronic hyperventilation is distinguished from acute hyperventilation in that the depletion of carbon dioxide stores is complete and the respiratory alkalosis is largely, if not fully, compensated by a reduction in bicarbonate concentration.

Clinically, hyperventilation has avoided a precise definition beyond that of the physiological definition. In part, this is due to the question as to whether hyperventilation is a condition or syndrome in and of itself, or is primarily a clinical finding for which a cause should be sought. In the context of hyperventilation as a syndrome *per se*, the terms "hyperventilation syndrome" and "idiopathic hyperventilation" have been applied. However, some would argue against the use of this terminology as this practice may preclude the seeking of the root cause of the hyperventilation [1].

## Prevalence

The prevalence of hyperventilation in the general population is unknown (estimated at 6%), but hyperventilation is a common cause of emergency department visits. Hyperventilation is commonly associated with asthma. In one study, 80% of patients presenting with acute hyperventilation to an inner-city emergency department had previously undiagnosed asthma [2]. In a survey of the prevalence of hyperventilation in a general population in the United Kingdom, 8% of non-asthmatics and 29% of asthmatics were scored as positive for hyperventilation. In the United States, up to 10% of patients in an internal medicine practice were reported to have had hyperventilation as the primary diagnosis. In general, there is a preponderance of female cases of hyperventilation than male.

## Genes

There is no known genetic basis for hyperventilation per se.

## Molecular and Systemic Pathophysiology

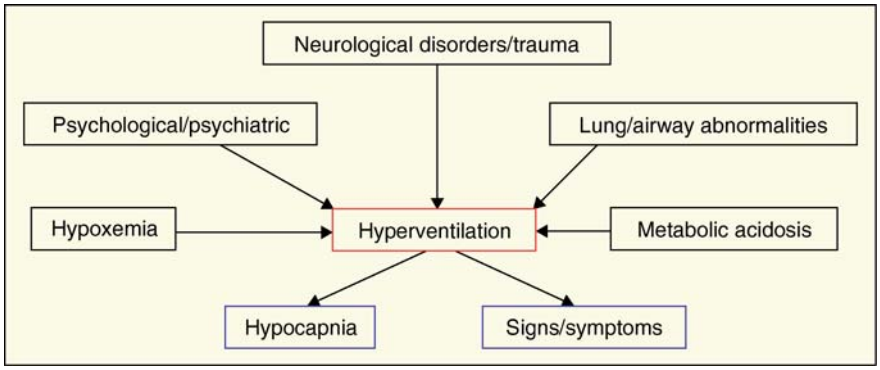
Hypoxemia is a common cause of hyperventilation, for example: occurring in congenital heart disease with right-to-left shunting and in pulmonary pathology, including pulmonary embolism. Metabolic acidosis produces compensatory hyperventilation and air hunger, as with diabetic ketosis [3]. Mechanical abnormalities of the lung drive ventilation through the vagus in conditions such as pulmonary fibrosis, pulmonary edema and asthma. Neurological disorders may result in hyperventilation in conditions caused by head injury or sub-arachnoid hemorrhage. Hyperventilation is often associated with psychological/psychiatric disorders such as anxiety and panic disorder [4].

## Diagnostic Principles

Because respiratory distress and/or chest pain may have potentially serious causes, diagnosis should never be made in the field. The methodology for diagnosing hyperventilation is controversial, although strict adherence to the physiological definition requiring documentation of hypocapnia is helpful, where the technology exits to determine hypocapnia. Thus, the diagnostic criteria become: (i) the patient should hyperventilate and have low $P_aCO_2$, and (ii) the patient should have a number of signs/symptoms which are, or have been, related to the hypocapnia. Thus, the main approach to diagnosis is the detection of signs of (possible) dysregulation of breathing leading to hypocapnia. Chronic hyperventilation may or may not present with hypocapnia depending on cause; however bicarbonate may be lower due to renal compensation or due to metabolic acidosis. The diagnosis of hyperventilation should not exclude the determination of the ultimate cause of the hyperventilation, such as hypoxemia, metabolic acidosis, mechanical abnormalities of the lung, neurological disorder, or psychological/psychiatric disorder. A differential diagnosis eliminating carbon monoxide poisoning may be necessary by measuring carboxyhemoglobin, as carbon monoxide poisoning symptoms may closely resemble those of hyperventilation.

## Therapeutic Principles

Treatment is ultimately directed to the organic cause of the hyperventilation. Acutely, once serious causes of hyperventilation have been ruled out, and a diagnosis of hyperventilation per se is made, treatment can be directed at restoring normal ventilation. Rebreathing techniques are not recommended because significant hypoxia and death have been reported. Provoking symptoms with voluntary hyperventilation is not considered either diagnostic or useful in treatment. Breathing therapy is no longer considered effective treatment for hyperventilation. While hyperventilation may be related to anxiety or panic, these are not necessarily synonymous. However, if reassurance of the patient is not effective, use of benzodiazepines for stress relief and for



**Hyperventilation. Figure 1** Overview of the general causes of hyperventilation.

resetting the trigger for hyperventilation is often effective [5]. Prolonged use of sedation is not recommended. Chronic therapy is best provided by the appropriate medial specialist, be it a psychiatric, chest, cardiovascular, endocrinologist, family, or other physician.

An overview of hyperventilation and the main general causes is presented in Fig. 1.

# Hyperventilation Syndrome

►Hyperventilation

# Hypervitaminosis E

►Vitamin E Excess

# Hypoaldosteronism

Christian A. Koch
Division of Endocrinology, Diabetes and Metabolism, University of Mississippi Medical Center, Jackson, MS, USA

## Definition and Characteristics

Decreased plasma aldosterone levels and elevated plasma renin (activity) levels, leading to a salt-wasting syndrome in the first weeks of life in children with congenital hypoaldosteronism. In secondary and tertiary adrenal insufficiency, plasma renin activity levels may be normal or low, as opposed to primary adrenal insufficiency with low or undetectable aldosterone and high plasma renin activity levels [1,2].

## Prevalence

Unknown but presumably higher frequency of aldosterone synthase deficiency typ II than of type I; the estimated incidence of 21-hydroxylase deficiency is about one in 14,200 live births; congenital adrenal hypoplasia occurs in about one of 12,500 births; adrenoleukodystrophy affects about 1 in 20,000 males.

## Genes

Autosomal recessively inherited defects in CYP11B or CYP21A2; X-linked recessive inheritance with gene location on Xq28 in adrenoleukodystrophy; in the X-linked forms of congenital adrenal hypoplasia the gene is located on Xp21 encoding DAX1; in autoimmune polyglandular deficiency type 1, the

responsible AIRE gene is located on chromosome 21q22.3 [2,3].

## Molecular and Systemic Pathophysiology

Deficient aldosterone synthase in the zona glomerulosa leads to inefficient conversion of 11-deoxycorticosterone to aldosterone with subsequent sodium wasting. Biosynthesis of cortisol and 17-OH-progesterone are otherwise unaffected as opposed to 21-hydroxylase deficiency. Aldosterone synthase deficiency type I leads to decreased plasma levels of 18-OH-corticosterone, whereas type II is associated with elevated levels of 18-OH-corticosterone. In autoimmune polyglandular deficiency type 1, an autoimmune adrenalitis destroys the adrenal cortex. In infectious disorders affecting the adrenal cortex (e.g., tuberculosis, histoplasmosis, CMV), more than 90% of the adrenal cortex have to be destroyed before symptoms of adrenal insufficiency including hypoaldosteronism develop. In adrenoleukodystrophy, defective fatty acid beta oxidation in peroxisomes leads to accumulation of very long chain saturated fatty acids, their esters and gangliosides, in the membranes of cells in the adrenal cortex and other organs. In acquired secondary hyporeninemic hypoaldosteronism, half of the patients have diabetes mellitus. Other associated conditions include POEMS syndrome, sickle cell anemia, renal amyloidosis, systemic lupus erythematosus, multiple myeloma, and the use of nonsteroidal antiinflammatory drugs, cyclosporin A, mitomycin C, and others. Heparin therapy suppresses aldosterone biosynthesis and can lead to acquired primary hypoaldosteronism with a compensatory rise in plasma renin activity.

*Etiology:* Congenital adrenal hypoplasia, 21-hydroxylase deficiency (a small group of patients have only aldosterone deficiency and no disturbances in cortisol and androgen biosynthesis), aldosterone synthase deficiency type 1 and type 2, adrenal insufficiency (primary, but also secondary and tertiary, if long-standing with subsequent adrenal cortex atrophy) caused by autoimmune disease, hemorrhage, adrenoleukodystrophy, infection, drugs, and others. Hyporeninemic hypoaldosteronism (acquired secondary aldosterone deficiency), acquired primary aldosterone deficiency [4,5].

## Diagnostic Principles

Any patient with unexplained chronic hyperkalemia should be considered for hypoaldosteronism. Usually, a low plasma renin activity and low plasma or urinary aldosterone level are detected under conditions that should activate the renin-angiotensin-aldosterone system such as upright posture for 3 h and admininistration of furosemide. In aldosterone synthase deficiency, inadequately low/undetectable plasma aldosterone levels in the face of low sodium levels, and elevated steroid levels prior the aldosterone synthase block (corticosterone, 11-deoxycorticosterone, 18-OH-corticosterone (in type II) are found. In all neonates/infants presenting with salt-wasting, 21-hydroxylase deficiency should be excluded by measuring 17-OH-progesterone. In addition, basal aldosterone, cortisol, and plasma renin activity should be determined. It is important to determine plasma steroids with highly specific methods (RIA after extraction and chromatography) especially in newborns (possible interference with steroids from the fetoplacental unit). Family history and mutation screening of the respective gene including AIRE, CYP11B2 and CYP21A2. Basal and ACTH-stimulated aldosterone and renin levels. Patients with acquired secondary hyporeninemic hypoaldosteronism have renal tubular acidosis type IV as a consequence of decreased renal ammoniagenesis (consequence of hyperkalemia).

## Therapeutic Principles

With increasing age, compensatory extraadrenal salt-conserving mechanisms mature and may make continuous mineralocorticoid replacement therapy unnecessary in patients with aldosterone synthase deficiency. Until then, 9 alpha–fluorocortisol (100–250 mcg/$m^2$/d should be admininistered. Patients with 21-hydroxylase deficiency should be treated according to standard protocols (10–25 mg/$m^2$/d of hydrocortisone plus 70 µg/$m^2$/d of fludrocortisone), depending whether cortisol production is also affected in addition to aldosterone deficiency. Neither gene therapy nor other treatments are available.

# Hypobetalipoproteinemia, Familial

Hubert Scharnagl[1], Winfried März[2]
[1]Clinical Institute of Medical and Chemical Laboratory Diagnostics, Medical University of Graz, Graz, Austria
[2]Synlab Center of Laboratory Diagnostics, Heidelberg, Germany

## Synonyms

FHBL

## Definition and Characteristics

FHBL is an autosomal co-dominant disorder of lipoprotein metabolism defined as less than 5th percentile of plasma concentrations of apolipoprotein (apo) B and LDL cholesterol.

The majority of subjects with heterozygous FHBL are asymptomatic. Non-alcoholic fatty liver is common among subjects heterozygous for truncated forms of apoB, but absent in FHBL linked to chromosome 3p21 [1]. The long-term consequences of fatty liver in these patients are unknown. Homozygous or compound heterozygous patients are clinically indistinguashable from patients with abetalipoproteinemia (ABL) and may suffer from acanthocytosis, neuromuscular disability, and fat malabsorption.

## Prevalence

The prevalence is estimated to vary from 0.1 to 1.9% in the general population.

## Genes

The genetic bases are unknown in most cases. There are three genetic forms: linkage to the APOB gene (chromosome 2), linkage to a locus on chromosome 3p21, and linkage neither to APOB gene nor to chromosome 3p21 [2,3].

## Molecular and Systemic Pathophysiology

The best-characerized cases are those linked to missense or frame-shift mutations of the ABOB gene resulting in the production of truncated apoB proteins. The full-length apoB synthesized in the liver consists of 4,536 amino acid residues and is designated as apoB-100. ApoB-100 is secreted from the liver as a constituent of VLDL particles. A physiological truncated variant, apoB-48, is produced in the intestine and is associated with chylomicrons. Approximately 50 different forms of truncated apoB (from 2 to 89% of the mature protein) have been reported. VLDL particles bearing truncated apoB transport a lower number of triglyceride molecules than apoB-100 particles. The plasma concentration of truncated apoB is low due to both, a more rapid clearance from plasma and a lower production rate compared to apoB-100. This reduced capacity of triglyceride secretion from liver caused by apoB defects results in an accumulation of lipids in the liver [4,5].

## Diagnostic Principles

Determination of plasma concentration of LDL cholesterol (<70 mg/dl) and apoB (<50 mg/dl).

Secondary causes of HBL (vegetarian or vegan diet, malnutrition, intestinal fat malabsorption, chronic pancreatitis, severe liver disease, hyperthyroidism) have to be ruled out.

## Therapeutic Principles

Fat malabsorption is treated by reduced intake of dietary fat. Fat-soluble vitamins, in particular vitamin E, may be given to prevent neurological deficits.

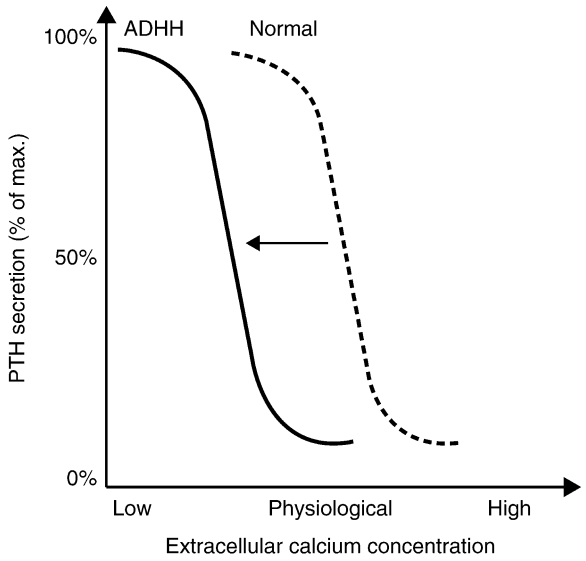
# Hypocalcemia with Hypercalciuria, Autosomal Dominant

John A. Sayer, Simon H. Pearce
Institute of Human Genetics, International Centre for Life, University of Newcastle upon Tyne, Newcastle upon Tyne, UK

## Synonyms

Familial hypercalciuric hypocalcemia; ADHH



**Hypocalcemia with Hypercalciuria, Autosomal Dominant. Figure 1** CaSR gene mutations causing ADHH produce a left-shift in Calcium-responsive PTH secretion compared to wild type.

## Definition and Characteristics

Autosomal dominant disorder associated with activating mutations in the calcium-sensing receptor (CaSR) leading to hypocalcemia and hypomagnesemia together with a urinary calcium excretion which is inappropriately high-normal or elevated [1,2]. A low serum calcium concentration is perceived by the parathyroid gland as normal, leading to a downward resetting of the PTH–calcium relationship (Fig. 1).

## Prevalence

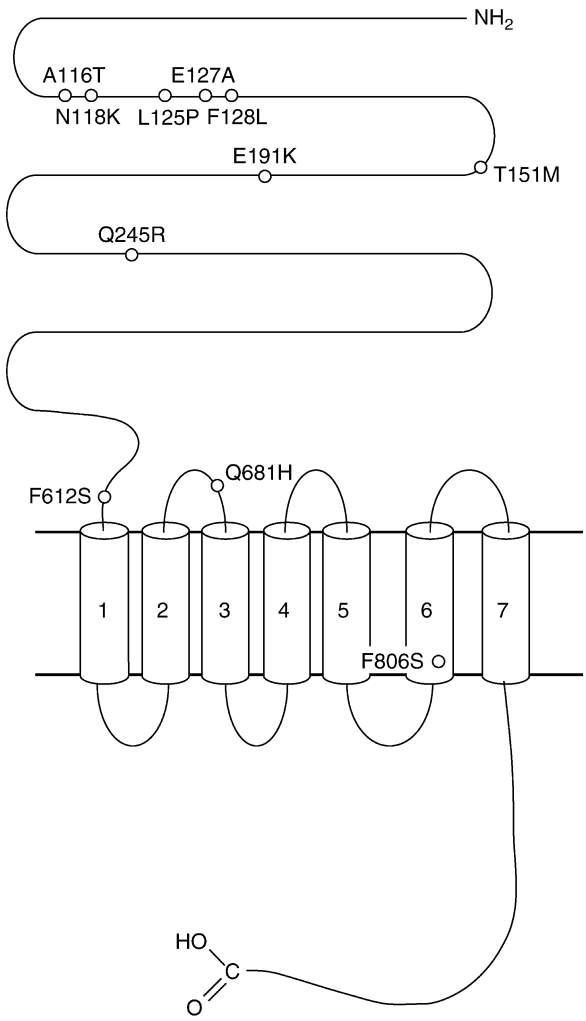
Less than 1:70,000.

## Genes

The disease is caused by mutations of CaSR. Known CaSR mutations (Fig. 2) may be found on the CaSR database: http://www.casrdb.mcgill.ca/ and the Human Gene Mutation Database: http://www.hgmd.cf.ac.uk/ac/gene.php?gene = CaSR.

## Molecular and Systemic Pathophysiology

Activating mutations in the calcium-sensing receptor (CaSR) shift the set-point of calcium-responsive parathyroid hormone release, allowing a low serum calcium to be perceived by the parathyroid gland as normal (Fig. 1). This shift in the set-point of the CaSR also allows hypercalciuria, due to activated CaSR in the loop of Henle. Extreme activation mutations of CaSR have been shown to cause a Bartter's like syndrome [3]. CaSR activation inhibits the apical potassium channel ROMK in the thick ascending limb of the loop of Henle,



**Hypocalcemia with Hypercalciuria, Autosomal Dominant. Figure 2** Examples of CaSR activating mutations leading to ADHH and their location within the CaSR protein.

disrupting potassium recycling and leads to renal potassium wasting, resulting in hypokalaemia and a metabolic alkalosis [4].

## Diagnostic Principles

The diagnosis of autosomal dominant hypocalcemia should be suspected in hypocalcemic patients with normal serum PTH concentrations whom are relatively asymptomatic despite low serum calcium level. Hypomagnesemia is also typically present. A high or high-normal urinary calcium excretion could be found together with a family history of hypocalcemia or recurrent renal stones. There will be no previous normal serum calcium values and treatment with vitamin D analogs characteristically makes little change in the serum calcium but dramatically increases the urine calcium excretion (and suppresses PTH release). Patients may present

throughout life, most commonly through incidental biochemical screening, but some manifest childhood seizures, abdominal pains or parathesias.

## Therapeutic Principles

Attempts to raise the serum calcium (using calcium and vitamin D analogs) should only be made in those patients who are symptomatic. The aim of treatment should be to reduce symptoms, not to normalize serum calcium. Caution must be used as attempts to normalize serum calcium may lead to nephrocalcinosis, nephrolithisis and renal impairment [5]. Patients with ADHH who are treated may complain of thirst and polyuria when their serum calcium is in the normal range; a resetting of the normal mechanism that gives nephrogenic diabetes insipidus in hypercalcemic individuals. Basal ganglian calcification may also occur. Thiazide diuretics may be used adjunctively to limit hypercalciuria and raise serum calcium levels.

# Hypocalcemia

James J. Paparello[1], Philip J. Klemmer[2], Abhijit V. Kshirsagar[2]

[1]Division of Nephrology and Hypertension, Northwestern University Medical School, Chicago, IL, USA

[2]Division of Nephrology and Hypertension, University of North Carolina School of Medicine, Chapel Hill, NC, USA

## Definition and Characteristics

Hypocalcemia is defined as a low serum calcium concentration. Since most laboratories measure total serum calcium, the level at which a patient is hypocalcemic is approximately 9 mg/dL (less than 2.25 mmol/L). Three different fractions comprise the measured serum calcium: ionized (accounting for 50% of total serum calcium), protein-bound (40%), and complexed to anions (10%). Ionized calcium is the biologically active form and is the critical fraction when evaluating hypocalcemia. Levels of ionized calcium below 4.5 mg/dL (1mmol/L) are considered hypocalcemia.

## Prevalence

Hypocalcemia, defined by low levels of ionized calcium, is a rare condition. Prevalence data on hypocalcemia is not available in the general population. It occurs under certain pathophysiological conditions discussed in the following sections.

## Genes

The human calcium-sensing receptor (CSR), encoded by six exons of the CSR gene located on chromosome 3q13.3-21, is a 1,070-amino acid glycoprotein. It has a predicted topology of a large extracellular domain, an intramembranous region that crosses the cell membrane seven times, and an intracellular tail.

## Molecular and Systemic Pathophysiology

The maintenance of normal calcemia (calcium set-point) is a classic physiologic negative-feedback system involving parathyroid hormone (PTH) and exchangeable calcium from the skeleton, with lesser effects contributed by the kidney and gastrointestinal tract. In essence, PTH regulates ionic calcium and ionic calcium regulates PTH.

Most of the body's calcium (>99%) is located in bone, and less than 0.1% is located in the ECF. Even smaller amounts are located within cells. Calcium entry into cells is highly regulated since it is a messenger for diverse cellular functions. The serum ionic calcium concentration is tightly regulated in order to maintain normal neuromuscular function, which explains why the symptoms of hypocalcemia are generally neuromuscular in nature (muscle weakness and numbness). While the *set-point* represents the normal concentration of ionic calcium in ECF, *calcium balance* is the difference between intestinal absorption and the sum of urinary and fecal calcium excretion. The serum calcium concentration cannot be used as a surrogate for calcium balance since it represents an internal homeostatic set-point. The principle regulator of ionic calcium concentration in ECF is the action of parathyroid hormone (PTH) on the skeleton, specifically the bone envelope that contains readily available calcium with a bidirectional flux of almost

4,000 mg/day. Due to the large calcium stores in bone, and the primacy of PTH as the calcium regulatory hormone 1,25 dihydroxy vitamin D has little to do with the maintenance of normocalcemia over short time frames. Hypocalcemia can occur with profound vitamin D deficiency of many months duration causing bone resistance to PTH due to osteomalacia or rickets (in children). The ionic serum calcium detected by the calcium-sensing receptor (CSR) on the cell membrane of the parathyroid cell provides the afferent signal for control of calcium set-point. In hypocalcemia, the calcium-sensing receptor causes an increase in PTH secretion and synthesis by the parathyroid cell, which causes an increase in outward calcium flux from the skeleton. The increase in calcium corrects the hypocalcemia, and activates the calcium-sensing receptor, returning PTH secretion to basal level.

Hypocalcemia usually results from either deficiency of PTH or resistance to the effects of PTH at the level of the skeleton. PTH deficiency occurs in hereditary diseases (DiGeorge syndrome), post-surgical parathyroidectomy, calcimimetic therapy (which alters the calcium set-point with the CSR), hyper- or hypomagnesemia, which decrease PTH secretion, and states of bone resistance to PTH effect, including hyperphosphatemia, osteomalacia, and rickets in children.

The vitamin D system acts primarily on the small intestine to regulate adaptation to different levels of dietary calcium intake. When dietary calcium is low (below 500 mg/day), synthesis of 1,25 dihydroxy vitamin D3 increases, which results in an increase in absorptive fraction of enteric calcium. Reciprocally, when dietary calcium intake is high (greater than 1,500 mg/day) synthesis of 1,25 dihydroxy vitamin D3 decreases, which results in a decrease in absorptive fraction of enteric calcium. Failure to synthesize sufficient 1,25 dihydroxy vitamin D (nutritional deficiency, malabsorption syndrome, chronic renal failure) may cause enteric calcium malabsorption, hypocalcemia, and osteomalacia in adults or rickets in children. Certain drugs such as dilantin and phenobarbital can stimulate the hepatic P450 microsomal system to increase the clearance and excretion of vitamin D derivatives thus leading to hypovitaminosis D and hypocalcemia.

In the presence of hyperphosphatemia associated with chronic renal failure or due to muscle breakdown or tumor lysis, hyperphosphatemia can lead to calcium phosphate deposition in soft tissues, resulting in profound hypocalcemia. Acute pancreatitis can also lead to hypocalcemia due to the digestion of fat by pancreatic lipase and deposition of calcium in soft tissue. Administration of sodium citrate as an anticoagulant may cause ionic hypocalcemia by increasing complexed calcium citrate.

## Diagnostic Principles

Serum calcium may cause a false impression of hypocalcemia when the total (albumin-bound and ionic) calcium is measured. To correct the total serum calcium for hypoalbuminemia, the total serum calcium increases by 0.8 mg/dL for each 1 mg/dL decrease in serum albumin concentration below 4 gm/dL. Symptoms of hypocalcemia include acral and/or perioral paresthesias, seizures, laryngeal spasm, muscle weakness, pathologic bone fractures, growth retardation or skeletal deformity in infants and children, or prolonged QT interval on electrocardiogram. Neuromuscular signs of hypocalcemia can be elicited at the bedside by gently tapping on a facial nerve at the front of the ear and noting facial twitching (Chvostek's sign) or noting carpal spasm after inflating a blood pressure cuff to a pressure midway between systolic and diastolic blood pressure on the upper extremity for at least 2 min. (Trousseau's sign).

## Therapeutic Principles

Clinical symptoms of hypocalcemia usually dictate the decision to treat. In cases of severe symptomatic hypocalcemia (for example, seizures), calcium should be administered intravenously and frequently monitored with blood calcium measurement. When hypocalcemia occurs following parathyroidectomy, intravenous and then oral calcium supplementation can be given between meals along with a high dose (1–2 μg/day) of 1,25 dihydroxy vitamin $D_3$. In the hypoparathyroid state, restoration of normocalcemia depends totally on enteric calcium, since bone is akinetic in the absence of PTH. When relative hypoparathyroidism occurs due to the use of a calcimimetic drug, the dose of the calcimimetic simply needs to be lowered, which will restore normocalcemia. Supplemental active vitamin D and/or calcium are not required in this setting. When hypocalcemia is present with severe hyperphosphatemia, emphasis should be on lowering the level of the serum phosphorus, which will cause a reciprocal rise in the serum calcium concentration. Such patients do not usually demonstrate hypocalcemic neuromuscular symptoms. Acute renal failure due to rhabdomyolysis is frequently associated with profound hyperphosphatemia and hypocalcemia. During the recovery phase of acute renal failure, rebound hypercalcemia may occur associated with massive phosphaturia.

Replacement of inactive vitamin D precursors (ergocalciferol from plants or cholecalciferol from sunlight or animal sources) will correct the hypocalcemia of nutritional vitamin D deficiency. In chronic renal failure, active vitamin D metabolites must be administered since the diseased kidney is no longer capable of activating 25-hydroxy cholecalciferol to the hormonally active metabolite, 1,25 dihydroxy vitamin D.

# Hypocalciuric Hypercalcemia, Familial

►Hypercalcemia, Familial Hypocalciuric

# Hypocholesterolemia

Patrick T. S. Ma[1], Lucia K. Ma[2], Alexander K. C. Leung[3]

[1]Heart Health Institute and Department of Cardiac Science, The University of Calgary, Calgary, AB, Canada

[2]Royal College of Surgeons, Dublin, Ireland

[3]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Hypocholesterolemia (HC) is either primary or secondary. Secondary and nonfamilial causes of HC include a high catabolic state (malignancy, chronic liver disease, anorexia, hyperthyroidism, etc), malabsorption, intense dieting, lipid lowering medications and a primitive hunter-gatherer lifestyle. Primary hypocholesterolemia (PHC) includes primary hypobetalipoproteinemia (PHBL), which is a heterogeneous group of inherited disorders characterized by very low plasma level (<5th percentile of the distribution in the population) of low density lipoprotein–cholesterol (LDL-C) and apolipoprotein B (ApoB). PHBL has three subgroups: abetalipoproteinemia (ABL), familial hypobetalipoproteinemia (FHBL), and chylomicron retention disease (CRD). Tangier disease (TGD) is also a cause of PHC with a mean plasma total cholesterol (TC) of $1.75 \pm 0.35$ mmol/L. Patients with TGD have very low apolipoprotein AI (apo AI) and high density lipoprotein–cholesterol (HDL-C), with HDL-C levels below 0.13 mmol/L. The phenotypic expression of both homozygous ABL and FHBL are similar and characterized by early presentation in infancy, failure to thrive, fat malabsorption, steatorrhea, low plasma level of fat soluble vitamins, acanthocytosis, atypical retinitis pigmentosa, fatty liver, enterocyte lipid accumulation, spinocerebellar ataxia, peripheral neuropathies. FHBL heterozygotes are usually asymptomatic and have reduced LDL-C and ApoB levels, mild fat malabsorption, fatty liver, and possibly reduced risk of atherosclerosis. The clinical manifestation of CRD includes growth retardation starting in infancy, fat and fat soluble vitamins malabsorption, vitamin malnutrition, steatorrhea, fatty enterocytes, low ApoB and LDL-C, absence of postprandial chylomicron (CM) and Apo B48. ABL and CRD are both autosomal recessive, whereas FHB and TGD are autosomal co-dominant.

## Prevalence

The prevalence of both homozygous ABL and FHB is estimated to be 1:1,000,000, whereas that of heterozygous FHBL is 1:500–1:1,000. CRD and TGD are exceedingly rare.

## Genes

All cases of ABL are due to mutations in the microsomal triglyceride transfer protein (MTP) gene [1]. FHBL may be linked to the APOB gene. Most mutations in the APOB gene cause the formation of truncated forms of ApoB, which may or may not be secreted into the plasma [2]. Approximately 50% of FHBL subjects are carriers of pathogenic mutations in the APOB gene. The FHBL plasma lipid phenotype can also be caused by mutations of the PCSK9 gene [3]. CRD is caused by mutations in the SARA2 gene which encodes a small GTPase (SAR 1b) involved in the intracellular trafficking of large CM [4]. TGD is caused by mutation in the gene encoding adenosine triphosphate binding cassette A1 (ABCA1).

## Molecular and Systemic Pathophysiology

In ABL, mutations in the MTP gene result in truncated and non-functional MTP. MTP is an 894 amino acid protein involved in the early stages of lipidation of ApoB in liver and intestine. MTP plays an important role in the assembly of ApoB – containing triglyceride rich lipoproteins by transporting lipid from its site of synthesis in the endoplasmic reticulum (ER) membrane to nascent lipoproteins within the ER lumen. In FHBL secondary to APOB gene mutations, the malformed ApoBs interfere with their own lipidation and the intracellular assembly of ApoB containing lipoprotein. Hence, both ABL and FHBL have low levels of chylomicrons (CM), very low density lipoprotein (VLDL), LDL, Apo B48 and Apo B100. The MTP and APOB mutation also lead to fat accumulation in hepatocytes and enterocytes, and malabsorption of fat and fat soluble vitamins (ADEK), leading to

**Hypocholesterolemia. Table 1** Features of primary hypercholesterolemia (PHC)

| PHC | Inheritence | Gene | Lipids | Clinical characteristics |
|---|---|---|---|---|
| ABL | Hom AR | MTP | TC: very low; CM, VLDL, LDL, Apo B: absent | Fat malabsorption, fatty hepatocytes and enterocytes, and fat soluble vitamins, steatorrhea, spinocerebellar degeneration, acantocytosis, retinitis pigmentosa, failure to thrive from infancy |
| FHBL | Hom AC | APOB | TC: very low (similar to ABL) | (similar to ABL) |
| FHBL | Heter AC | APOB | TC, LDL, Apo B: low | Asymptomatic, mild fat malabsorption, fatty liver, allstones, loose stool |
| FHBL | Hom AC | PCSK9 | TC, LDL, Apo B: low | Asymptomatic, much reduced risk of atherosclerosis |
| CRD | Hom AR | SARA 2 | TC, LDL: low Apo B 48, CM: absent | (similar to ABL) |
| TGD | Hom AC | ABCA1 | TC, LDL: low, HDL, Apo A1: very low | Hepatosplenomegaly, enlarged tonsils, peripheral neuropathy, premature atherosclerosis |

*ABL* abetalipoproteinemia; *FHBL* familial hypobetalipoproteinemia; *CRD* chylomicron retention disease; *TGD* Tangier disease; *Hom AR* homozygous autosomal recessive; *Hom AC*, homozygous autosomal codominant; *Heter AC*, heterozygous autosomal codominant. See text for other abbreviations.

steatorrhea, acanthocytosis, retinitis pigmentosa and neurological defects such as spinocerebellar degeneration and peripheral neuropathy. The PCSK9 gene encodes a cholesterol regulated proprotein convertase, which is a member of the subtilisin/kexin type 9 serine protease subfamily of proprotein convertases. Loss of function mutations of the PCSK9 gene would increase the number of liver LDL- receptors, leading to a 30–40% reduction of plasma LDL-C [5], and many result in a marked reduction of coronary heart disease. In CRD, the absence of Apo B48 would lead to fat malabsorption, steatorrhea, and growth retardation. In TGD, the low HDL is caused by a nonfunctional ABCA1 protein that normally facilitates efflux of unesterified cholesterol and phospholipids from cells to apo A-1. ABCA1 stabilizes the mature HDL. The absence of ABCA1 would lead to rapid clearance of HDL from the circulation and the accumulation of lipids in the reticuloendothelial system resulting in hepatosplenomagealy, tonsil enlargement, peripheral neuropathy, and premature atherosclerotic disease.

## Diagnostic Principles

The clinical diagnosis of the various forms of hypocholesteremia can be derived from the lipid profile, clinical characteristic and modalities of inheritance as summarized in the Table 1. The diagnosis of ABL, FHBL, and CRD may be histologically established by the fat – laiden enterocytes in small intestine biopsy. ABL can be confirmed by low or absent MTP in the intestinal biopsy. Specific mutations can be identified with DNA analysis in specialized research laboratories.

## Therapeutic Principles

The treatment of secondary HC is that of the underlying conditions. There is no specific treatment in PHBL other than high dose fat-soluble vitamin supplementation, particularly high-dose vitamin E. Symptomatic medications for diarrhea and malabsorption may be needed. A low fat diet, especially replacing long-chain (C16–C24) with medium chain (C8–C14) fatty acids (MCFA) and polyunsaturated fatty acids is helpful, as MCFA do not require CM formation for transport.

# Hypochondrogenesis

Marco Castori
Medical Genetics, Experimental Medicine Department, University La Sapienza, S. Camillo-Forlanini Hospital, Rome, Italy

## Synonyms

Achondrogenesis type II (some examples); Achondrogenesis type IV [1]; HCG

## Definition and Characteristics

HCG is a lethal osteochondrodysplasia of the "short limbs" type. At birth (or after therapeutic abortion), its clinical presentation includes short limbs with relative macrocephaly, flat face, widely spaced and slanted eyes, micrognathia, cleft palate, small chest, pear-shaped abdomen, and nuchal or generalized oedema. On X-rays examination, the skeletal hallmarks of HCG are shortened tubular bones, mild methaphyseal flaring often with blunt ends and lateral spurs, thin ribs, bell-shaped thorax, underdeveloped ilia with horizontal acetabular roofs, unossified pubic bones, small, round and vertical ischia, widening of the synchondrosis between the exoccipital and supraoccipital portions of the occiput, defective ossification of the cervical and sacral metameres, and vertebral coronal clefts (Fig. 1).

The hands and membranous bones (e.g., cranial vault and the lateral portion of the clavicles) are relatively spared. Death occurs due to cardiorespiratory failure within hours or days. Despite this archetypal description, HCG indeed represents, together with the more severe achondrogenesis type II (ACG2) and the milder spondyloepyphyseal dysplasia congenita (SEDC), a continuous clinical spectrum with several bridging phenotypes [2].

## Prevalence

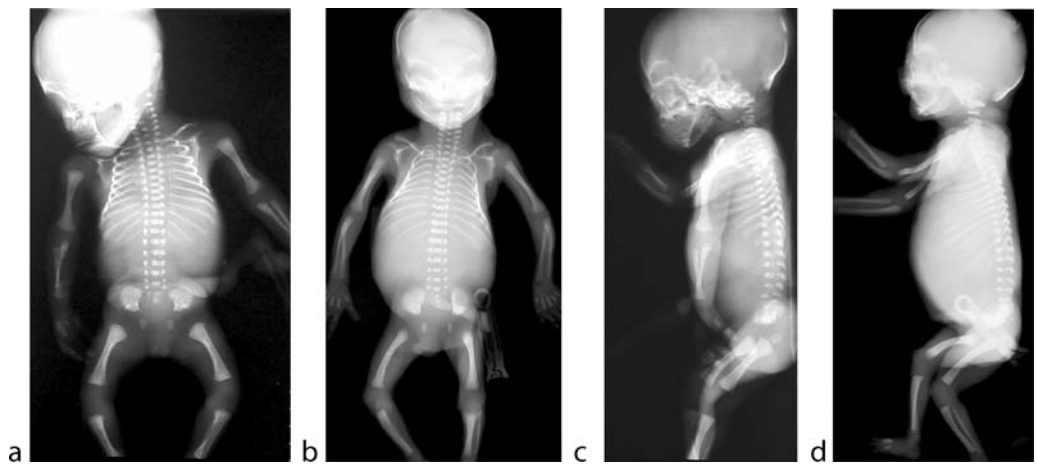
The real frequency of HCG is still unknown. The only available data are those related to the entire achondrogenesis group, that also include achodrogenesis type 1A, 1B and ACG2. The overall prevalence of "achondrogenesis disorders" is about 1:350,000 births [1].

## Genes

HCG is caused by heterozygous mutations in the gene encoding the collagen type 2 (COL2A1), which maps to 12q13.11-q13.2 [3]. All reported cases arise from fresh mutations. COL2A1 is also responsible for the phenotypically overlapping conditions ACG2 and SEDC, thus confirming at the molecular level the hypothesis of a single family of bone dysplasias encompassing these three disorders. At the moment, the identified pathogenic variations associated with HCG are the following: p.G313S, p.G517V, p.G571A, p.G574C, p.G604D, p.G694E, p.G805S, p.G853V, p.G910C, p.G913C, p.G943C, p.T1191N. Most of these mutations involve the glycine residue of the Gly-X-Y invariant structural motif of the collagen molecule. This evidence has a strict relationship with the disease pathogenesis (see below). Interestingly, several other bone dysplasias are associated with COL2A1 mutations and comprise, among others, Kniest syndrome, Stickler syndrome type I, some cases of otospondylomegaepiphyseal dysplasia, spondyloperipheral dysplasia, spondyloepimetaphyseal dysplasia Strudwick type, and platyspondylic skeletal dysplasia Torrace type. Taken together, these data demonstrate that COL2A1 is one of the most commonly mutated gene in human osteocondrodysplasias and suggest that the spectrum of associated phenotypes very probably will expand in the future.

## Molecular and Systemic Pathophysiology

Chondrogenesis is the process during which cartilage templates are produced as temporary models for the



**Hypochodrogenesis. Figure 1** Babygram of a 24-week-old fetus with HCG (a, c) compared to an age-matched control showing normal skeletal development (b, d). Note the generalized endochondral ossification defect consisting in shortened tubular bones, broad metaphyses, short ribs, hypoplastic ilia, horizontal acetabular roof with lateral spurs, short and broad ischia, mild platyspondyly, unspecific coronal clefts of the lumbar region, and ossification deficit of the occiput, cervical and sacral metameres. Normal control presents mild femoral bowing.

vertebrate skeleton. This process is crucial for the development and linear growth of those bones which are generated by endochondral ossification. For proper embryonic bone formation, differentiated chondrocytes must produce a highly ordered extracellular matrix. It is composed by a collagen network, fibrils, which consist of heteropolymers of collagen II, IX and XI that are covalently cross-linked in the molar ratio of 8:1:1, and other matrix constituents, such as proteoglycans. Therefore, correct synthesis and maturation of type II collagen, which is, in turn, a homotrimer of pro-alpha-1 chains, is critical for an adequate ossification process. Mutations in the glycine residue of the Gly-X-Y invariant motif of the procollagen type II aminoacid sequence (as observed in HCG) directly cause triple helix misfolding, increased post-translational hydroxylation of lysine and helix instabilility. It has been calculated that in presence of a COL2A1 heterozygous mutation nearly seven-eights of the procollagen type II homotrimers contain at least one mutated molecule. Probably, only homotrimers containing a single mutant collagen chain are capable to be secreted and, than, are slowly and abnormally processed, while those with two or three abnormal molecules never fold and are retained and degraded within the cell. This event influences both chondrocyte metabolism and extracellular matrix composition. Intracellular procollagen retention manifests with multiple dilated rough endoplasmic reticulum profiles containing type II collagen [4]. Columnization at the growth plate is completely disorganized with irregular chondrocyte columns and calcified chondrocytes extending into the metaphyseal trabeculae. Cartilage matrix production is decreased with relative predominance of collagen type I and III and proteoglycans, and the sparse matrix is crossed by numerous vascular canals (i.e., hypervascularity of the resting cartilage) [5]. The degree of these histological and ultrastructural changes seems to be directly related to the severity of the phenotype. In fact, extracellular matrix collagen type II is completely absent in the more severe ACG2, reduced in HCG and mostly secreted but structurally abnormal in the milder SEDC.

## Diagnostic Principles

HCG is a sporadic disorder, therefore the diagnosis often follows an occasional abnormal prenatal ultrasound scan (US). In case of HCG, the suspect of fetal osteochondrodysplasia is usually formulated around the 19th gestational week or afterwards. The pattern of standard US abnormalities includes short limbs, small chest with short ribs, poorly ossified sacrum, cystic hygroma and/or hydrops (more common in ACG2), and polydramnios. Three-dimensional US eases the identification of additional craniofacial anomalies, such as micrognathia. Fetal magnetic resonance imaging has been demonstrated capable to reveal defective ossification of the cervical vertebrae and pubic bones during the 3rd trimester of pregnancy. Definite diagnosis is reached by performing postnatal complete X-ray survey (i.e., babygram). Molecular investigation may confirm the diagnosis, but its application in monitoring future pregnancies is limited due to the extreme rarity of gonadal mosaicism.

## Therapeutic Principles

HCG is an invariably lethal condition caused by early perturbation of the normal chondrogenesis with devastating consequences on skeletal development. Thus, at the moment a specific therapy for HCG is not available.

# Hypocitraturia

Roswitha Siener, Albrecht Hesse
Department of Urology, University of Bonn, Bonn, Germany

## Definition and Characteristics

Hypocitraturia is an important risk factor for calcium urolithiasis. Urinary citrate inhibits calcium stone formation by forming a soluble complex with calcium and by effects on nucleation, agglomeration, and crystal growth. Hypocitraturia, defined as urinary citrate excretion below 2.5 mmol/24 h, is commonly encountered in patients with urolithiasis [1]. However, hypocitraturia is only rarely the single cause of calcium stone formation. Oral citrate is absorbed in the intestine and nearly completely metabolized to bicarbonate,

providing an alkali load which in turn increases urinary citrate excretion. The majority of urinary citrate is derived from endogenous production in the tricarboxylic acid cycle (Krebs cycle).

Citrate is freely filtered in the renal glomeruli. Some 65–90% of filtered load are reabsorbed in the renal proximal tubule [2]. Hypocitraturia results from increased tubular citrate reabsorption. Changes in acid-base homeostasis are the major physiologic determinants of reabsorption and urinary excretion of citrate. A low intracellular and/or luminal pH increases citrate reabsorption by modifying the citrate$^{2-}$ to citrate$^{3-}$ ratio, by increasing the number of NaDC-1 cotransporters in the apical membrane, by rising cytoplasmic ATP citrate lyase activity, and by increasing mitochondrial uptake and metabolism of citrate by the proximal tubule cell [3]. All of these mechanisms probably contribute to a decrease in urinary citrate excretion with acid loads.

## Prevalence

The prevalence of hypocitraturia is estimated to occur in up to 60% of patients with calcium oxalate stone disease [4].

## Genes

Genetic influence on citrate excretion is possible but has not been defined [5].

## Molecular and Systemic Pathophysiology

The major causes of hypocitraturia involve states of acidosis or oral acid load. Consequently, a low citrate excretion mainly results from pathological conditions characterized by acidosis, e.g. distal renal tubular acidosis (dRTA), chronic diarrheal and/or malabsorption syndrome, starvation and potassium depletion, or from high intake of protein (Table 1) However, in many patients with stone disease, the causes and underlying mechanisms for hypocitraturia are presently unknown ("idiopathic").

**Hypocitraturia. Table 1** Factors inducing hypocitraturia

| |
|---|
| Kidney diseases |
| Distal renal tubular acidosis (complete or incomplete dRTA) |
| Chronic renal insufficiency |
| Gastrointestinal diseases |
| Chronic diarrheal states or malabsorption |
| Inflammatory bowel disease |
| Ileal resection |
| Diet |
| High protein intake |
| Low potassium intake |
| Starvation |
| Drugs |
| Thiazide diuretics |
| ACE inhibitors |
| Acetazolamide |
| Ethacrynic acid |
| Ammonium chloride |
| Others |
| Hypokalemia and potassium deficiency |
| Intensive physical exercise |
| Idiopathic |

## Diagnostic Principles

- Analysis of 24-h urinary citrate excretion and pH value [1]
- Urinary pH profile (minimum pH determination: four times a day) [1]
- Ammonium chloride loading test (differentiation between complete and incomplete dRTA) [1]

## Therapeutic Principles

Pharmacological therapy includes potassium citrate or sodium bicarbonate in patients with a history of hyperkalemia or renal insufficiency (dosage for adults: 9–12 g/day) [1]. Dietary therapy includes alkalizing beverages (mineral water rich in bicarbonate; citrate-rich beverages, e.g. citrus juices), fruits and vegetables (650 g/day), as well as restriction of dietary protein intake to 0.8 g/kg body weight per day. Other treatments include reduction of overweight without extreme fasting.

# Hypodysfibrinogenemia

►Fibrinogen: Qualitative Disorders

# Hypogammaglobulinemia of Childhood, Transient

Pirmin Habermehl, Markus Knuf
Pediatric University Hospital, Johannes Gutenberg University, Mainz, Germany

## Synonyms

Transient hypogammaglobulinemia of infancy; THI

## Definition and Characteristics

Mature newborns have usually the immunoglobulin levels of their mothers. During the first months of life, the immunoglobulin levels decrease and reach the lowest levels at 4–6 months. The levels then increase physiologically. In some children, the IgG-levels (and mostly the IgA levels too) stay below 2 SD (standard deviation) of the mean of age-matched children. In transient hypogammaglobulinemia, the immunoglobulin levels are normalizing during infancy or early childhood. Some of the children may develop a selective IgA deficiency [1,2].

## Prevalence

Since there are no epidemiological data, the exact prevalence is not known. It is probably less than 1/1,000.

## Molecular and Systemic Pathophysiology

The pathophysiologic mechanisms that lead to the transient hypogammaglobulinemia are not known. Some authors state that it might be a delay of the physiologic hypogammaglobulinemia. Recent data state that the increase of immunoglobulins is faster in boys compared with girls. In a recent publication, a diminished proportion of CD40 positive monocytes were found, which might lead to lack of interaction between monocytes and $CD4^+$ T-cells [3].

## Diagnostic Principles

The infants or young children usually have a history of recurrent otitis media or wheezing bronchitis. One or more immunoglobulin classes are below the 2 SD of the mean, specific antibody titers to tetanus and diphtheria are detectable (in vaccinated children). B- and T-cell-subsets and T-cell function are normal. The immunoglobulin levels are increasing over time and usually reach age-matched normal levels at 3–5 years of age.

Therefore, THI can be diagnosed only retrospectively.

## Therapeutic Principles

The treatment of bacterial infections with antibiotics is usually adequate. Intravenous immunoglobulins are in most cases not necessary.

# Hypoglycemia

Christoph Michalski, Jörg Kleeff
Department of General Surgery, University of Heidelberg, Heidelberg, Germany

## Definition and Characteristics

Plasma glucose levels below 70 mg/dl (3.9 mmol/l); counterregulatory symptoms (caused by e.g., glucagon and/or adrenaline), i.e., tremor, tachycardia, anxiety, hunger; neuroglycopenic symptoms (low brain sugar levels), i.e., abnormal mentation/neurology, fatigue, confusion, ataxia, coma [1].

## Prevalence

Among diabetics, prevalence of hypoglycemia episodes is between 10% and 30% and is mainly dependent on the amount of exogenously administered insulin [2,3]. Rarely, familial hyperinsulinemic hypoglycemia (1 in 50,000 live births).

## Genes

Familial hyperinsulinemic hypoglycemia [4] (also referred to as congenital hyperinsulinism, nesidioblastosis, or persistent hyperinsulinemic hypoglycemia of infancy (PPHI); gene map locus: chromosome 11p15.1) is a cause of congenital hypoglycemia (generally extremely rare). The disorder results from mutations in the gene encoding SUR1 (subunit of the pancreatic beta cell inwardly rectifying potassium channel) or the Kir6.2 subunit of the pancreatic beta cell potassium channel, the glucokinase gene, the HADH gene, the insulin receptor gene, or the GLUT1 gene. In addition, FOXA2 has been suggested as a candidate gene for familial hyperinsulinism (further information: Online Mendelian Inheritance in Man™ at www.ncbi.nlm.nih.gov).

## Molecular and Systemic Pathophysiology

Brain metabolism depends on continuous supply of glucose since the limited amount of glucose from astrocytic glycogen stores is exhausted within minutes. Hypoglycemia occurs as (i) reactive, (ii) tumor induced,

(iii) metabolic, (iv) hormone induced, (v) congenital. Reactive hypoglycemia can be due to inherited disorders such as fructose intolerance, leucine sensitivity, and galactosemia, or it may be iatrogenic after gastrointestinal surgery (dumping syndrome). Hypoglycemia is induced by beta-cell tumors (adenoma or carcinoma) leading to elevated insulin levels or by insulin-like growth factor-producing tumors mimicking natural insulin secretion. Metabolic causes for hypoglycemia are rare and can occur because of malfunctioning of several enzymes of gluconeogensis and/or fatty acid oxidization (i.e., deficiency of glucose-6-phosphatase, fructose-1.6-diphosphatase, or glycogen synthetase). Furthermore, hormonal deficiencies may lead to hypoglycemia mainly under fasting conditions such as hypoadrenalism, hypopituitarism, or glucagon deficiency. Sulfonyl urea abuse in diabetics may also cause hypoglycemia.

In rare cases, hypoglycemia is the result of genetic defects (see above).

## Diagnostic Principles

The Whipple's Triad is commonly used for diagnosis of hypoglycemia, incorporating the following: (i) symptoms of hypoglycemia (as mentioned above), (ii) plasma glucose below 70 mg/dl, (iii) increase of plasma glucose leads to symptom relief. Subsequently, a 72-h fast is performed with measurements of plasma glucose and insulin every 6 h [5].

## Therapeutic Principles

Apart from treating the underlying disease, acute hypoglycemia is managed by administration of glucose, other carbohydrates, and occasionally glucagon [1]. Moreover, diazoxide (inhibitor of insulin secretion) may be used especially for glucose level management in patients with insulinomas. In the long term, patients with episodes of hypoglycemia should consume a protein-rich diet, slowly digested/absorbed carbohydrates and frequent meals. Glutamine may increase gluconeogenesis-mediated glucose production.

# Hypoglycemia, Non-islet Cell

►Non-islet Cell Hypoglycemia

# Hypogonadotropic Hypogonadism

Annette Richter-Unruh
Endokrinologikum Ruhr, Bochum, Germany

## Synonyms

Gonadotropin deficiency

## Definition and Characteristics

Isolated idiopathic hypogonadotropic hypogonadism (HH) is characterized by selective deficiency of gonadotropins owing a defect at the level of the hypothalamus involving the GnRH pulse generator or the gonadotropins, or both without anatomic lesions. As a consequence, children display absent or arrested puberty. In boys, micropenis and/or undescended testes may evidence fetal LH deficiency. Clinically, HH can be arranged in HH associated with an/hypoosmia, called Kallmann syndrome (KS), and isolated HH. In patients with KS, associated defects are inconsistently present: cleft lip, cleft palate, imperfect facial fusion, seizure disorders, short metacarpals, neurosensory hearing loss, cerebellar ataxia and ocular motor abnormalities and, limited to the X-linked form, unilateral or rarely bilateral renal aplasia or dysplasia and mirror movements of the upper extremities.

## Prevalence

HH has a prevalence of approximately 1 in 8,000 newborns with a 4:1 male: female ratio. Several genes are involved, and despite this genetic heterogeneity, only 10–20% of all patients with HH have their genetic basis elucidated.

## Genes

Although the neuroendocrine mechanism regulating the timing of puberty is still largely unknown, some genes involved in migration of GnRH neurons and in regulation of GnRH secretion have been identified. The discovery of the Kallman syndrome 1 (KAL-1) gene on Xp22.3 has led to pathophysiological model correlating GnRH deficiency with abnormal olfactory bulb development in x-linked KS [1]. Mutations in the fibroblast growth factor receptor 1 (FGFR-1) gene

cause an autosomal dominant form of KS [2]. The KAL-1 gene product, anosmin-1, is a protein localized in the olfactory bulb. It might be involved in signal transduction of FGFR-1. Mutations of KAL-1 and FGFR-1 (KAL-2) genes result in the same phenotype suggesting an interaction between the two factors. Several mutations of the KAL-1 and KAL-2 (FGFR-1) genes have been reported. Prokineticin receptor 2 (PKR-2) represents an experimental candidate gene for the autosomal recessive form of KS (KAL-3?) [3].

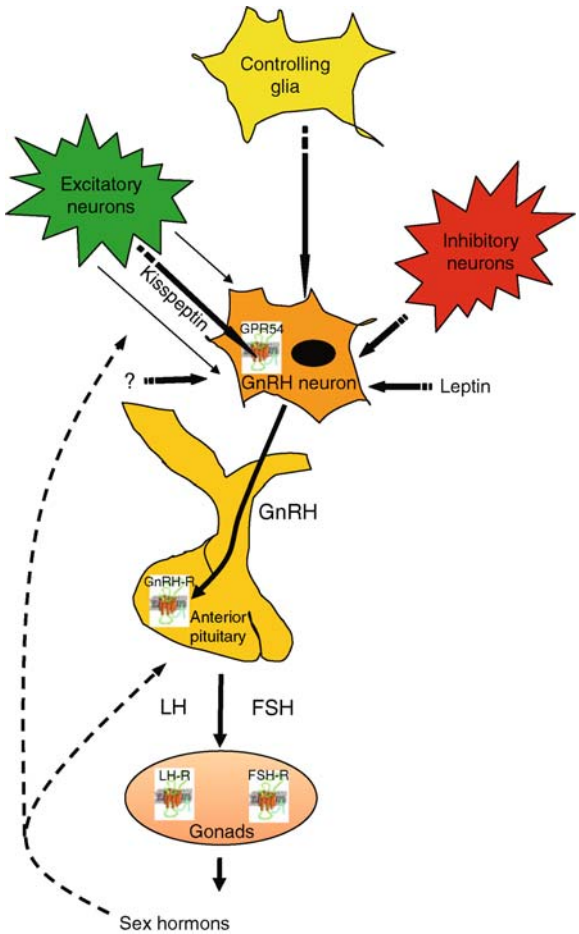
Inactivating mutations in the gonadotropin release hormone receptor (GnRH-R) represent a cause of autosomal recessive HH with normal olfaction. So far, more than 16 mutations in the GnRH-R have been described [4]. The discovery of loss-of-functions mutations in the G protein-coupled receptor 54 (GPR54) as an important factor regulating GnRH production has shed new light on neuroendocrine control of gonadotropin secretion [5]. More than seven mutations are identified. Kisspeptin (also called metastin) is the product of the metastasis suppressor (KISS-1) gene, which encodes a GPR54 ligand. A short duplication of the coding sequence of the KISS-1 gene was found in one case of HH. Two new candidate genes with potential influence on migration of GnRH neurons are the nasal embryonic LH releasing hormone factor (NELF) and EBF-2.

## Molecular and Systemic Pathophysiology

KS is a clinically and genetically heterogeneous disorder consisting of idiopathic HH and anosmia/hypoosmia. The anatomical explanation for KS stems from incomplete or total failure of the GnRH secreting neurons to migrate from the olfactory epithelium to their final destination in the mediobasal hypothalamus. The KAL-1 gene product, anosmin-1, may be also involved in signal transduction of FGFR-1 and in morphogenesis of the olfactory bulb. It was shown that olfactory bulb formation is hampered in mutant mice in which fgfr1 expression in the elencephalon was conditionally knocked out. Homozygous loss-of-function mutations of the FGFR-1 gene are incompatible with life.

GnRH binds to the G-protein-coupled GnRH-R on gonadotrope cells at the anterior pituitary. It activates phospholipase C and mobilizes intracellular calcium via G proteins that are needed for production of LH and FSH.

Kisspeptins, products of the KISS-1 gene, were originally identified as metastasis suppressor peptides with the ability to bind GPR54. This is a G-protein-coupled receptor expressed mainly in the brain, pituitary, and placenta. Kisspeptins and their putative receptor, GPR54, are indispensable factors for pubertal development, with a key role as gatekeepers of GnRH neurons (Fig. 1).



**Hypogonadotropic Hypogonadism.**
**Figure 1** Hypothalamus (neuroendocrine control) – pituitary (gonadotropin secretion) – gonadal (sex steroid secretion) – axis. Hypothalamic kisspeptin stimulates GnRH neurons via its receptor GPR54 that is located at the surface of GnRH neurons. Further gonadotropin secretion is under the control of glia cells, inhibitory neurons, and exhibitory neurons. Other factors, hormones, steroids, or other signals may also influence GnRH neurons. GnRH binds to its receptor at the surface of gonadotrope cells of the anterior pituitary and stimulates production of LH and FSH. Gonadotropins activate sex steroid secretion via their receptors in the gonads. Sex steroids will give feedback to hypothalamus and pituitary.

## Diagnostic Principles

The majority of cases of HH are sporadic. Genetic screening should be performed in patients with consangious parents and familial forms. In patients with KS in 10% of familial cases mutations in the KAL-1 are found and also about 10% are identified in the FGFR1 (KAL-2). In HH with normal olfaction in more than 50% of familial cases mutation are found (40% GnRH-R, 10–15% GPR54). In sporadic cases only in 5%

H

the underlying disease can be diagnosed. In all patients with HH a MRT of the hypothalamus–pituitary regions should be performed to exclude organic lesions or tumors.

## Therapeutic Principles

When diagnosis is established, normal adolescent development is approximated. During puberty, a replacement therapy is performed in boys with testosterone and in girls with estrons/gestagens. To induce fertility at appropriate time a pulsatile GnRH pump, FSH or an hCG therapy can be used.

# Hypohidrotic Ectodermal Dysplasias

Denis J. Headon[1], Paul A. Overbeek[2], Alanna F. Bree[3]

[1]Faculty of Life Sciences, University of Manchester, Manchester, UK

[2]Department of Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX, USA

[3]Texas Children's Hospital, Houston, TX, USA

## Synonyms

Hypohidrotic ectodermal dysplasia; HED; Anhidrotic ectodermal dysplasia; EDA1; Christ-Siemens-Touraine syndrome; X-linked HED XEDA; XHED; XLEDA; XLHED; Hypohidrotic ectodermal dysplasia with immune deficiency; HED-ID; Anhidrotic ectodermal dysplasia with immunodeficiency, osteopetrosis and lymphedema; OL-EDA-ID

## Definition and Characteristics

Ectodermal appendages are structures other than the epidermis that develop from the embryonic surface ectoderm. These appendages include the teeth, nails, hair, and glandular structures, including eccrine, mammary, Meibomian, salivary and lacrimal glands. The ectodermal dysplasias are a heterogenous group of over 150 distinct disorders characterized by hypoplasia or absence of two or more ectodermal appendage types. Hypohidrotic ectodermal dysplasia (HED) is defined by a combination of characteristic features: variable inability to sweat that can lead to life-threatening hyperthermia, typical facies, hair and nail changes, and dental abnormalities. HED is typically present in isolation, but can be part of a broader syndrome including immune deficiency, osteopetrosis and lymphedema.

## Prevalence

*X-linked HED*: 1:5,000–10,000.
*Autosomal recessive HED* (*EDAR*, *EDARADD*, *IKBA* mutations): Very rare.
*Autosomal dominant HED*: Very rare.
*HED-ID*: Extremely rare.
*OL-EDA-ID*: Extremely rare.

## Genes

*X-linked HED*: Caused by loss of function mutations in *EDA* (Ectodysplasin; Xq12-q13.1) that impair binding to EDAR; sometimes caused by loss of furin-mediated cleavage of the transmembrane EDA protein.
*Autosomal dominant or recessive HED*: Caused by mutations in *EDAR* (EDA receptor; 2q11-q13) or *EDARADD* (EDAR associated death domain; 1q42.2-q43).
*HED-ID (autosomal dominant)*: Caused by a gain of function missense mutation altering serine 32 of *IKB* (14q13), encoding IκBα. Produces a hypermorphic IκBα protein that is not phosphorylated by the IKK complex.
*HED-ID (X-linked recessive)*: Caused by point mutations in *IKBKG* (encoding NEMO; Xq28) that produce a hypomorphic NEMO protein that retains some signaling function.
*OL-EDA-ID (X-linked recessive)*: Caused by a point mutation in the *IKBKG* stop codon resulting in a C-terminal extension of the protein and a hypomorphic NEMO protein that retains limited signaling function.

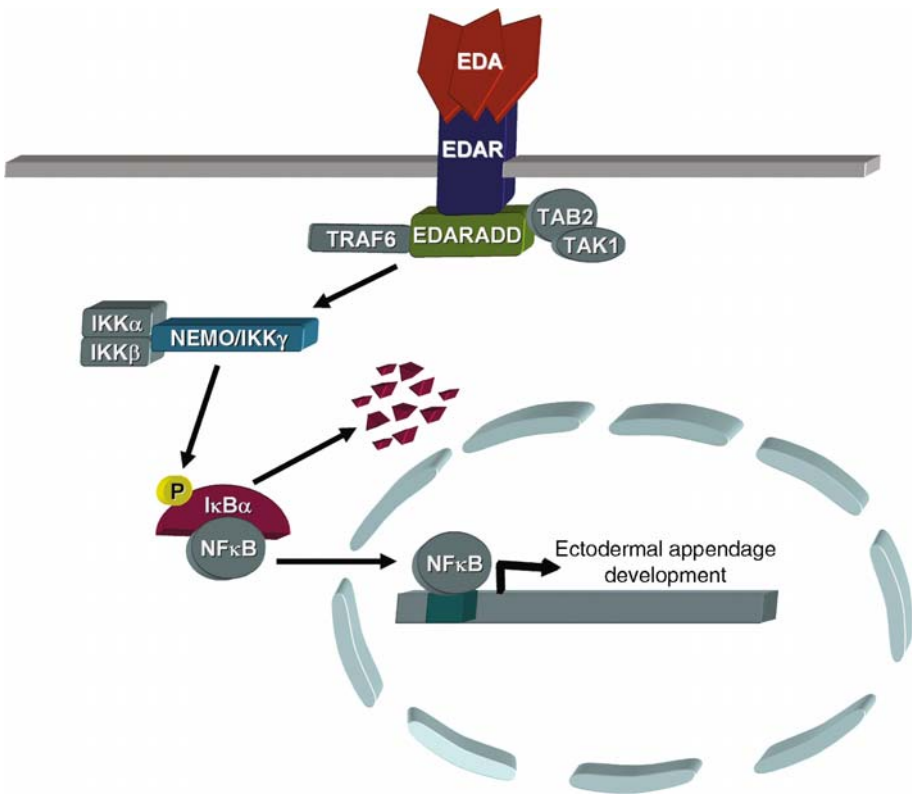
## Molecular and Systemic Pathophysiology

Hypohidrotic ectodermal dysplasias are caused by mutations in genes encoding components of the EDA signaling pathway (Fig. 1), which is required in the embryonic period to promote the formation of ectodermal appendages.

EDA is a TNF-like ligand initially synthesized as a type II transmembrane protein, the C-terminus of which is released from the cell membrane by furin-mediated cleavage. The EDA-A1 protein binds to EDAR, a TNFR-related transmembrane receptor, which then recruits EDARADD (via association between their respective death domains). Mutations in any of these three genes cause HED in isolation. Downstream cytoplasmic signal transducing proteins are used by EDAR/EDARADD and other members of the TNFR superfamily. EDARADD has been found to signal through TRAF6, TAB2 and TAK1, though to date these proteins have not been implicated in human disease. Signals are transduced to the IκB kinase (IKK) complex, consisting of IKKα, IKKβ and NEMO/IKKγ, resulting in phosphorylation and subsequent proteasomal degradation of IκB. The transcription factor NF-κB is thereby released from its cytoplasmic anchor, becomes translocated to the nucleus and alters gene expression to initiate ectodermal appendage development. As NEMO and IκBα are employed in many signaling pathways, their mutations result in broader syndromes that include immunodeficiency, osteopetrosis and lymphedema, in addition to HED.

## Diagnostic Principles

Patients with HED typically present in infancy with unexplained fevers. Classic facial features, including frontal bossing, periorbital hyperpigmentation, saddle nose and thick, everted lips, can be a clue to diagnosis in infancy. Often diagnosis is delayed until the eruption of conical or peg-shaped teeth with evidence of hypodontia on radiographs. Hair remains sparse and grows slowly; nails are often abnormal; and skin becomes dry with an increased frequency of atopic dermatitis. Sweating is reduced or absent in most patients. Impaired sweating can be evidenced on palmar starch iodine testing with a positive predictive value



**Hypohidrotic Ectodermal Dysplasias. Figure 1** The EDA signaling pathway. Direct protein-protein interactions are indicated by proteins touching, functional interactions by arrows. Colored proteins cause HED when mutated. Proteins that are involved in EDA signal transduction but which have not been implicated in ectodermal dysplasias are shown in gray. Engagement of EDAR by multimeric EDA initiates signaling via EDARADD, ultimately leading to phosphorylation and degradation of IκB. This releases NF-κB, allowing its nuclear translocation and DNA binding, ultimately altering gene expression to promote ectodermal appendage development.

(PPV) of 92% if little or no sweating is identified. In one small study, lack of eccrine structures on a scalp biopsy was found to be a valuable diagnostic tool with a specificity and PPV of 100%. Abnormal glands in the eyes, mouth, ears, nose, respiratory and gastrointestinal tracts can lead to reduced or thickened secretions.

HED is most commonly inherited in an X-linked recessive manner. Carrier females often have more subtle clinical features with dental defects, hair abnormalities and reduced sweating.

HED with immune deficiency (HED-ID) is very rare. Consistent clinical features include hypohidrosis and dental abnormalities. There is variability in hair and cutaneous changes. Multiple infections frequently develop with both gram-positive and gram-negative bacteria. These include otitis media, pulmonary infections with bronchiectasis, skin and soft tissue abscesses and cellulitis, osteomyelitis, meningitis, sepsis and gastrointestinal infections leading to intractable diarrhea and failure to thrive. Immunologic abnormalities identified include poor antibody response to polysaccharide antigens (isohemagglutinin, and antipneumococcal antibodies), dysgammaglobulinemia, decreased lipopolysaccharide response and defective natural killer cell function. Life expectancy is reduced due to infectious complications.

Even rarer is EDA with immunodeficiency, osteopetrosis and lymphedema (OL-EDA-ID). This has been reported in two unrelated male children with mothers having mild features of incontinentia pigmenti. Clinical features in these boys included mild facial dysmorphism, sparse hair, hypodontia and lack of sweating, along with lymphedema of the lower extremities confirmed with lymphoscintigraphy, and osteopetrosis demonstrated on skeletal radiographs of the long bones and iliac wings further confirmed with bone biopsy. After multiple infections with various bacteria, mycobacteria and fungi, both boys died before 3 years of age. Both had impaired cellular responses to proinflammatory cytokines and impaired recognition of pathogenic microorganisms.

## Therapeutic Principles

Management involves cooling techniques to prevent hyperthermia, including cooling vests, dampened clothing, water bottles, and air conditioning. Activities do not need to be avoided but precautions should be taken and accommodations made as necessary. Dental treatment is very important and should be pursued from a very early age. Bonding and dentures are preferred for young children, while orthodontia and dental implants are options for older individuals. For patients with associated immunodeficiency, appropriate antimicrobials and IVIG are recommended. Allogenic hemopoietic stem cell transplantation and umbilical cord blood transplantation have been successful in correcting the immune deficiency in HED-ID, while one patient with OL-EDA-ID died after stem cell transplant due to complications.

For X-linked EDA caused by mutations in *EDA*, experimental work using animal models suggests that in utero or early postnatal recombinant EDA protein administration may permanently rescue development of some appendages, depending on the timing of administration relative to developmental events.

# Hypokalemia

Hendrica Belge, Eva Riveira-Munoz, Olivier Devuyst
Division of Nephrology, UCL Medical School, Brussels, Belgium

## Definition and Characteristics

Hypokalemia is defined as a reduction in serum $K^+$ concentration below 3.5 mmol/l. Mild hypokalemia (serum $K^+$ between 3.0 and 3.5 mmol/l) is often asymptomatic, but generalized weakness, lassitude, and constipation can occur. Severe cardiovascular (arrythmias) and neuromuscular (ileus, ascending paralysis, impairment of respiratory function, rhabdomyolysis) complications can develop in case of profound hypokalemia (serum $K^+$ <2.5 mmol/l). Hypokalemia is also associated with metabolic manifestations (glucose intolerance, metabolic alkalosis) and, in some chronic cases, with structural changes in the kidney and resistance to vasopressin (nephrogenic diabetes insipidus). Pseudohypokalemia (uptake of $K^+$ by metabolically active cells) can be observed in samples with very high white blood cell count left at room temperature for several hours.

## Prevalence

Hypokalemia might be the most common electrolyte disorder encountered in clinical practice, observed in

up to 20% of hospitalized patients. The prevalence of hypokalemia in outpatients is unknown, but it is observed in up to 40% of patients treated with thiazide diuretics [1].

## Molecular and Systemic Pathophysiology

Potassium is the most abundant cation in the human body, with total body $K^+$ stores amounting 50 mmol/kg in adults. In contrast to $Na^+$, less than 2% of $K^+$ is located in extracellular fluid. The compartmentalization of $K^+$ inside cells is critical for maintaining cell volume, DNA and protein synthesis, and cell growth. Since the resting membrane potential primarily depends on the transmembrane $K^+$ gradient, variations in the extracellular $K^+$ concentration influence the excitability of neuromuscular tissue including the heart, nervous system, and skeletal and smooth muscles [2].

Short-term $K^+$ homeostasis occurs via transcellular $K^+$ shifts, regulated by insulin and β-adrenergic catecholamines (β2 receptors) which increase the cellular $K^+$ uptake by stimulating the $Na^+/K^+$-ATPase. Metabolic alkalosis also stimulates cellular $K^+$ uptake. Normal individuals ingesting 80–100 mmol of $K^+$ daily remain in balance by excreting 90% of the ingested $K^+$ in the urine and the remaining 10% in stool. The kidney is thus the major regulator of long term $K^+$ homeostasis and serum $K^+$ [3]. The filtered $K^+$ is largely reabsorbed in the proximal nephron and subsequently in the thick ascending limb of the Henle's loop, whereas the distal nephron segments regulate $K^+$ excretion under the influence of aldosterone. The $K^+$ secretion occurs through the selective $K^+$ channel ROMK1 located in the apical plasma membrane of the principal cells of the collecting ducts. It is coupled to $Na^+$ reabsorption via the amiloride-sensitive sodium channel ENaC. Both ENaC and ROMK1 are stimulated by aldosterone, which acts through its cytosolic mineralocorticoid receptor (MR) to stimulate the activity of the basolateral $Na^+$-$K^+$-ATPase, resulting in $Na^+$ reabsorption and $K^+$ excretion in the urine [4].

Hypertensive renal $K^+$ wasting syndromes are associated with high levels of renin, aldosterone, cortisol, or deoxycorticosterone; congenital/acquired defects of 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which transforms cortisol into cortisone (syndrome of apparent mineralocorticoid excess); congenital adrenal hyperplasia, resulting from deficiency in the enzymes of cortisol biosynthesis (17α-hydroxylase, 11β-hydroxylase); activating mutations of ENaC (Liddle syndrome); gain-of-function mutations of MR; or chimeric gene duplication bringing aldosterone under the control of ACTH rather than renin (glucocorticoid-remediable hyperaldosteronism).

Normotensive (or hypotensive) renal $K^+$ wasting is associated with all conditions that increase the distal delivery of $Na^+$, and secondary hyperaldosteronism due to volume depletion: thiazide and loop diuretics, inherited tubulopathies of the TAL (Bartter's syndromes) and DCT (Gitelman's syndrome); but also with distal (type 1) renal tubular acidosis; diabetic ketoacidosis; and vomiting (loss of $K^+$ with $HCO_3^-$ in the urine).

Extra-renal losses include any cause of diarrhea, cathartic abuse, potassium binding (clay or kayexalate).

Hypokalemias due to transcellular $K^+$ shifts include hypokalemic periodic paralysis, in a rare association with hyperthyroidism (particularly in people of Asian origin) or dominantly inherited (Familial hypokalemic periodic paralysis, due to mutations in the L-type calcium channel or the voltage-gated $Na^+$ channel of the skeletal muscle); correction of vitamin $B_{12}$ deficiency; and ingestion of barium or cesium salts [1–4].

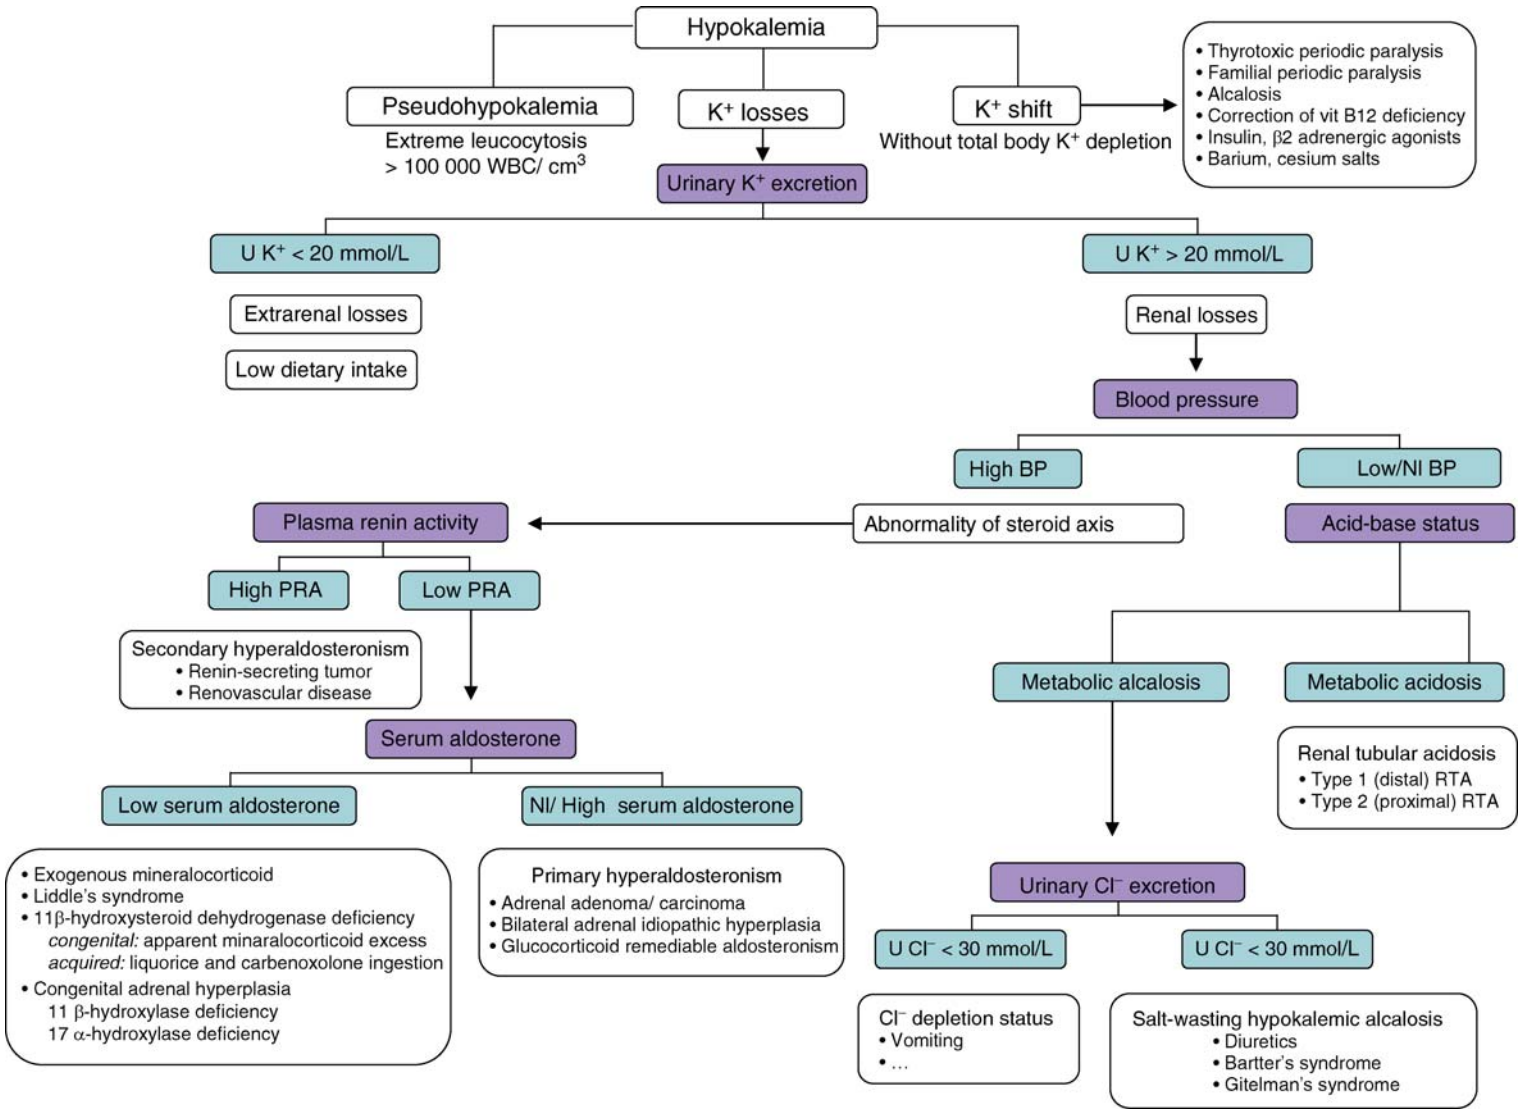
## Diagnostic Principles

The diagnosis of hypokalemia is often fortuitous, made by measurement of serum $K^+$. Severe cardiac and neuromuscular manifestations, which may be life-threatening, must be treated first. Once pseudohypokalemia has been excluded, the most frequent causes of hypokalemia are excessive renal or gastrointestinal $K^+$ losses, followed by inadequate dietary $K^+$ intake and, more rarely, acute transcellular $K^+$ shifts into cells. A careful review of the medications which can be associated with either excessive $K^+$ losses or transcellular $K^+$ shifts, is critical in patients with hypokalemia [1]. The classical diagnostic approach, based on the assessment of urinary $K^+$, blood pressure, plasma renin activity and serum aldosterone, acid-base status, and urinary chloride, is depicted in Fig. 1.

Measurement of urinary $K^+$ helps to distinguish the renal (inappropriate kaliuresis, >20 mmol/l) or extrarenal origin of $K^+$ losses. In case of renal origin, blood pressure should be measured. The association of hypokalemia and hypertension points to an excess of mineralocorticoids (apparent or real), whereas a normal/low blood pressure rather evokes a diuretic intake or an inherited/acquired tubulopathy. In the former case, the measurement of plasma renin activity and aldosterone helps to distinguish primary vs. secondary hyperaldosteronism, or an apparent mineralocorticoid excess. In the latter case, the assessment of acid-base status helps to distinguish renal tubular acidosis from other tubulopathies. Finally, the measurement of urinary $Cl^-$ is helpful to exclude a $Cl^-$ depletion state when metabolic alkalosis accompanies hypokalemia (such as in vomiting).

## Therapeutic Principles

Potassium replacement is indicated to prevent cardiac and muscular complications, and replenish total body



**Hypokalemia. Figure 1** Sequential diagnostic approach in the patient with hypokalemia. BP, blood pressure; PRA, plasma renin activity; RTA, renal tubular acidosis; WBC, white blood cell count.

$K^+$ stores. Transcellular $K^+$ shifts may complicate the treatment, since body stores are normal in patients with periodic paralysis, and underestimated in patients with metabolic acidosis. Oral administration of $K^+$ is preferable, and factors such as the rapidity of the fall in serum $K^+$ and the presence or absence of symptoms dictate the aggressiveness of replacement therapy. The cause of $K^+$ loss must be addressed first, and any causative drug considered. In patients with arrhythmia, paralysis, or severe weakness, intravenous KCl replacement is indicated, with precautions in the access, rate of perfusion (maximum of 10–20 mmol/h), and monitoring the ECG and serum $K^+$. In asymptomatic patients, oral supplements can be administered with citrate or bicarbonate (metabolic acidosis due to RTA or diarrhea), or NaCl (metabolic alcalosis, normal blood pressure), in addition to an adequate dietary $K^+$ intake. Patients with hypokalemia and hypertension will benefit from $K^+$-sparing diuretics (spironolactone, amiloride), with the usual precautions in case of renal failure. Magnesium depletion, which reduces the intracellular $K^+$ concentration and causes renal $K^+$ wasting and often coexists with $K^+$ depletion, should also be corrected.

## Hypomagnesemia

Joel Michels Topf[1], Patrick Murray[2]
[1]Chronic Kidney Disease Clinic, Detroit, MI, USA
[2]University of Chicago, Chicago, IL, USA

### Synonyms

Isolated dominant hypomagnesemia; Familial hypomagnesemia; Intestinal hypomagnesemia; Hypomagnesemia with secondary hypocalcemia; Isolated renal magnesium loss

### Definition and Characteristics

Hypomagnesemia is a condition caused by primarily environmental conditions (diabetes, alcoholism, diuretic use) but also may be due to one of a handful of genetic conditions. Hypomagnesemia is a low serum magnesium level (<0.7 mmol/l). The low magnesium results in protean physiologic abnormalities. Neuromuscular irritability causing involuntary muscle contraction (tetany) and seizures. Hypocalcemia is often concurrently found with hypomagnesemia, and may result from either calcium wasting due to the primary defect or secondary to hypomagnesemia-induced PTH suppression.

### Prevalence

Hypomagnesemia has been repeatedly found in approximately 10% of nursing home and hospital admissions. The prevalence of genetic causes of hypomagnesemia is unmeasurably low, although it is likely that there is under-reporting of asymptomatic or minimally symptomatic cases.

**Hypomagnesemia. Table 1** Fully characterized genetic causes of hypomagnesemia

| Disease | Gene | Locus | Protein |
|---|---|---|---|
| Isolated dominant hypomagnesemia | FXYD2 | 11q23 | Gamma subunit of the Na-K-ATPase |
| Familial hypomagnesemia with hypercalciuria | CLDN16 | 3q27–29 | Paracellin-1 tight junction |
| Hypomagnesemia with secondary hypocalcemia (intestinal hypomagnesemia) | TRPM6 | 9q22 | TRMP6, a cation channel |

## Genes

Multiple genes have been found that result in hypomagnesemia. (See Table 1).

Other genetic causes of hypomagnesemia have been described but have not yet been fully genetically characterized. Still other genetic causes of hypomagnesemia are dominated by other phenotypes and will be covered in other entries in this book: ►Gitelman syndrome, ►autosomal dominant hypoparathyroidism, ►familial hypocalciuric hypercalcemia, and ►neonatal severe hyperparathyroidism [1].

## Molecular and Systemic Pathophysiology

Isolated dominant hypomagnesemia is due to decreased magnesium reabsorption in the distal convoluted tubule. The defect in the gamma subunit of the $Na^+$ -$K^+$ -ATPase results in decreased pump activity. By an unclear mechanism decreased $Na^+$ -$K^+$ -ATPase secondarily decreases magnesium reabsorption [2].

Familial hypomagnesemia with hypercalciuria results from a defect in the tight junctions between the cells of the thick ascending limb of the loop of Henle. These tight junctions contain a protein, Paracellin-1, that provides ion specificity to paracellular reabsorption. Lack of reabsorption increases urinary loss of both calcium and magnesium [3]. Familial hypomagnesemia is autosomal recessive. Heterozygotes may have hypercalciuria and be predisposed to kidney stones [4].

Hypomagnesemia with secondary hypocalcemia is due to defective intestinal magnesium absorption. TRMP6 has been localized throughout the entire length of small and large bowel and is responsible for magnesium absorption. TRMP6 has also been found in the distal convoluted tubule and participates in renal magnesium transport that only becomes clinically significant during treatment [5].

## Diagnostic Principles

The finding of hypomagnesemia in the absence of diabetes or diuretics should prompt the evaluation of disorders of magnesium regulation. A 24-h urine magnesium level greater than 24 mg indicates abnormal magnesium wasting (isolated dominant hypomagnesemia). Twenty-four hour urine magnesium less than 12 mg indicates decreased dietary magnesium absorption (familial hypomagnesemia). Family history may reveal genetic origin. Specialized genetic testing for specific diseases is not generally available and available for research purposes.

## Therapeutic Principles

Replacing magnesium can blunt symptoms from all of the hypomagnesemic diseases. Often these patients will have concurrent abnormalities of potassium and calcium that need to be corrected concurrently. These associated abnormalities are resistant to treatment prior to adequate magnesium replacement. The use of oral magnesium can usually correct familial hypomagnesemia despite defective intestinal absorption. A paracellular magnesium absorption pathway becomes the primary absorption pathway with increasing gut magnesium levels [5].

# Hypomagnesemia with Secondary Hypocalcemia

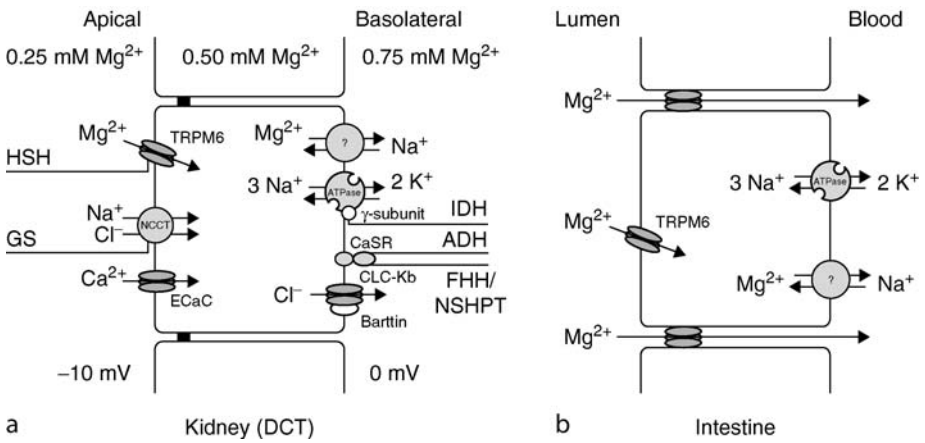
Stefanie Weber
Laboratory for Molecular Genetics, Department for Pediatric Nephrology, Children's University Hospital, Heidelberg, Germany

## Synonyms

Primary intestinal hypomagnesemia; HSH

## Definition and Characteristics

Autosomal recessive intestinal and renal magnesium transport defect leading to severe hypomagnesemia



**Hypomagnesemia with Secondary Hypocalcemia. Figure 1** Apical localization of the TRPM6 cation channel in the DCT of the kidney and the intestinal epithelium, involved in active transcellular magnesium ion uptake.

H

and secondary hypocalcemia that is only resolved after magnesium substitution.
First description by Paunier et al in 1968 [1].

## Prevalence

The prevalence of this very rare disorder in the general population is so far unknown.

## Genes

TRPM6, coding for TRPM6, a member of the transient receptor potential family of cation channels, localized on chromosome 9q22 [2,3].

## Molecular and Systemic Pathophysiology

Before the identification of the causative gene, the pathophysiology of HSH has largely been unknown, but physiologic studies pointed to a defect in saturable intestinal magnesium transport and to an additional renal leak of magnesium, probably caused by altered magnesium entry into epithelial cells of the distal convoluted tubule (DCT) [4, 5]. TRPM6 is expressed in both intestine and DCT (Fig. 1a, b) and seems to represent the major molecular component of active transcellular magnesium uptake in intestine and kidney.

## Diagnostic Principles

Severe hypomagnesemia (per definition <0.7 mmol/L, however, sometimes even <0.1 mmol/L) associated with low levels of serum calcium that only resolve after magnesium substitution point to HSH as underlying disease. The vast majority of patients presents within the first 3 months of life with generalized seizures, tetany and muscle spasms. Family history may reveal a genetic origin. Detection of mutations in the *TRPM6* gene confirms the diagnosis of this rare disease.

## Therapeutic Principles

Untreated the disorder may result in permanent neurologic damage or may be fatal. Hypocalcemia is secondary to parathyroid failure and peripheral parathyroid hormone resistance as a result of magnesium deficiency. Generally, the hypocalcemia is resistant to calcium or vitamin D therapy. Normal serum calcium levels and relief of clinical symptoms can be attained by high oral doses of magnesium, up to 20 times the normal intake, due to enhanced paracellular intestinal absorption. Alternatively, parenteral magnesium administration can be considered. Continuous nocturnal nasogastric magnesium infusions have been proven to efficiently reduce gastrointestinal side effects in some patients.

# Hyponatremia

Michael L. Moritz[1], Juan Carlos Ayus[2]
[1]Division of Nephrology, Children's Hospital of Pittsburgh, Pittsburgh, PA, USA
[2]Renal Consultants of Houston, Houston, TX, USA

## Synonyms

Hypoosmolality; Hypotonicity

## Definition and Characteristics

Serum sodium less than 135 mEq/l with a plasma osmolality less than 280 mOsm/kg/$H_2O$.

## Prevalence

Moderate hyponatremia (sodium <130 mEq/l) has a prevalence of 1–3% in hospitalized patients.

## Genes

No specific genes; gain of function mutations to the vasopressin two receptor gene (AVPR2) has been reported to cause a nephrogenic syndrome of inappropriate antidiuresis.

## Molecular and Systemic Pathophysiology

Under normal circumstances the human body is able to maintain the plasma osmolality within the normal range (135–145 mEq/l) despite wide fluctuations in fluid intake. The body's primary defense against developing hyponatremia is the kidney's ability to generate a dilute urine and excrete free water. Renal water handling is primarily under the control of arginine vasopressin (AVP) which is produced in the hypothalamus and released from the posterior pituitary. AVP release impairs water diuresis by increasing the permeability to water in the collecting tubule. Hyponatremia rarely develops from excessive water ingestion alone or from sodium losses in the absence of free water ingestion. Hyponatremia primarily develops from excess free water intake in conjunction with an underlying condition that causes increased AVP production and impairs renal free water excretion, such as: effective circulating volume depletion, the syndrome of inappropriate antidiuretic hormone production (SIADH) and the post-operative state [1].

The major consequence of hyponatremia is the influx of water into the intracranial space resulting in cellular swelling, which can lead to cerebral edema and encephalopathy (Table 1). The brain's adaptation to hyponatremia initially involves a loss of blood and cerebrospinal fluid, followed by a volume regulatory decrease from the extrusion of sodium, potassium, and organic osmolytes to decrease the brain osmolality. The major factors that can interfere with successful brain adaptation and predispose to hyponatremic encephalopathy are: (i) age less than 16 years, due to a relatively large brain to intracranial ratio, (ii) female gender, due to the inhibitory effect of sex steroids on cerebral circulation, and (iii) hypoxia [3]. Symptoms of hyponatremic encephalopathy are variable with the only consistent symptoms being headache, nausea, vomiting, emesis, and weakness. Signs of cerebral herniation include seizures, respiratory arrest, neurogenic pulmonary edema, dilated pupils, and decorticate posturing.

**Hyponatremia. Table 1** Anatomic changes and clinical symptoms of hyponatremic encephalopathy

| Anatomic changes | Clinical symptoms |
|---|---|
| Brains swelling | Headache, nausea, vomiting |
| Pressure on rigid skull | Seizures |
| Tentorial herniation | Respiratory arrest |

## Diagnostic Principles

Once hypo-osmolar hyponatremia has been confirmed, urine osmolality should be measured to determine if there is an impaired ability to excrete free water (urine osmolality >100 mOsm/kg/$H_2O$). An investigation should then be made to determine the source of excess free water intake, if there is hemodynamic or non-hemodynamic stimulus for AVP production, and if there are renal or extrarenal causes of electrolyte losses. SIADH is a diagnosis of exclusion; if renal, adrenal, and thyroid functions are normal, its hallmarks are mild volume expansion with low to normal plasma concentration of urea, creatinine and uric acid with an elevated urine sodium (>20 mEq/l, FeNa > 1%). SIADH is primarily associated with disorders of central nervous system and lung, with malignancies and with medications.

## Therapeutic Principles

The treatment of hyponatremia largely depends on the etiology and the presence or absence of neurological symptoms. If there are no neurological symptoms, therapy usually consists of treatment of the underlying condition and fluid restriction. Symptomatic hyponatremia, on the other hand, is a medical emergency requiring treatment with 3% sodium chloride (513 mEq/l) in a monitored setting. An acute elevation in serum sodium of 5–8 mEq/l is usually sufficient to reverse neurological symptoms. Three percent sodium chloride should be discontinued when neurologic symptoms abate. The magnitude of sodium correction should not exceed 20 mEq/l in the first 48 h, due to the potential for developing neurological complications from cerebral demyelination [4].

The most important measure that can be taken to prevent the development of hyponatremia in hospitalized patients is to avoid the administration of hypotonic parenteral fluids in patients with a potential stimulus of AVP production and to administer 0.9% sodium chloride when parenteral fluids are indicated [2].

# Hypoosmolality

►Hyponatremia

# Hypoparathyroidism, Familial

John A. Sayer, Simon H. S. Pearce
Institute of Human Genetics, International Centre for Life, University of Newcastle upon Tyne, Newcastle upon Tyne, UK

## Synonyms

Familial hypocalcemia

## Definition and Characteristics

Familial hypoparathyroidism includes inherited disorders of parathyroid hormone (PTH) deficiency and tissue resistance to the effects of PTH, as well as several conditions of complex genetic and mitochondrial DNA abnormalities.

## Prevalence

Unknown but rare.

## Genes

*Isolated hypoparathyroidism*: PTH, SOX3, GCM2 (alias GCMB)
*Syndromic hypoparathyroidism*:
GNAS1 (alias Gs-alpha) – pseudohypoparathyroidism
TBX1 and DGCR DiGeorge chromosomal region DiGeorge syndrome
GATA3 – HDR syndrome
Mitochondrial DNA deletion – Kearns-Sayre syndrome

## Molecular and Systemic Pathophysiology

PTH gene defects have been found in patients of several families, with patterns of inheritance consistent with either autosomal dominant or autosomal recessive. The autosomal dominant PTH gene mutation disrupted the signal peptide and led to disordered processing of the PTH protein through the parathyroid cell secretory pathway [1]. The autosomal recessive PTH gene abnormalities were described in consanguineous families where a single G-to-C transversion at the first nucleotide of intron 2 of the PTH gene led to exon skipping and loss of the start codon.

Isolated hypoparathyroidism has been reported to occur as an X-linked recessive disorder in two kindred from the USA. Only males were affected and they suffered from infantile onset of epilepsy and hypocalcemia. The molecular abnormality appears to be a 340 kb insertion at Xq27 disrupting the regulatory sequences of the SOX3 gene and leading to a failure of parathyroid gland development [2].

GCM2 (Glial Cells Missing 2) gene deletions were found in the proband of a large kindred with familial isolated hypoparathyroidism. The non-consanguineous, asymptomatic parents were heterozygous for the deletion [3]. In a consanguineous family from Pakistan with familial isolated hyperparathyroidism, a homozygous missense mutation in the GCM2 gene has been detected in affected members. GCM2 encodes a parathyroid-specific transcription factor.

Patients with the DiGeorge syndrome (DGS) suffer from neonatal hypoparathyroidism, T-cell immunodeficiency, congenital heart defects, and cleft lip and/or palate. The disorder arises from a congenital failure in the development of the derivatives of the third and fourth pharyngeal pouches with resulting absence or hypoplasia of the parathyroid glands and thymus. A frequent presentation is neonatal hypocalcemia, which may present as tetany or seizures. Genes implicated in the common deleted region include TBX1, RNEX40, NEX2.2-NEX3, and UDFIL [4]. TBX1 gene mutation or deletion may be responsible for five major phenotypes that are components of the DGS including parathyroid dysfunction with hypocalcemia. Mouse models have also revealed that Tbx1 is important in the development of the

pharyngeal arches and pouches, consistent with its mutation leading to the major DGS phenotypes.

Hypoparathyroidism, deafness and renal dysplasia syndrome (HDR) is an autosomal dominant condition characterized by hypocalcemia (often asymptomatic) with paradoxically normal PTH levels and normal responses to infused PTH (resulting in a rise in plasma cAMP levels) [5]. Bilateral sensorineural deafness is the most penetrant feature of the phenotype, and is present from birth. Renal anomalies are less frequent and include dysplasia and cystic kidney disease. HDR patients are haplo-insufficient for the zinc finger transcription factor GATA3. GATA3 is essential in the embryonic development of the parathyroids, auditory system, and kidneys.

Hypoparathyroidism may occur as a component of three disorders that are caused by defects in the mitochondrial genome. These are the Kearns-Sayre syndrome (KSS), the MELAS syndrome, and a mitochondrial trifunctional protein deficiency syndrome (MTPOS). Each of these conditions is associated with a specific neuromuscular phenotype and hypoparathyroidism is a rare feature of each. The molecular mechanism involved is obscure.

►Pseudohypoparathyroidism is a term applied to a heterogeneous group of disorders whose common feature is resistance to the tissue actions of parathyroid hormone. It is generally classified as types Ia, Ib, Ic, and II according to different phenotypes and pathogenesis. Patients with pseudohypoparathyroidism are characterized by hypocalcemia and hyperphosphatemia due to PTH resistance rather than PTH deficiency. Circulating PTH levels generally being substantially elevated or occasionally in the high-normal range. Pseudohypoparathyroidism type Ia (PHP Ia) is caused by defects in the GNAS1 gene and is often associated with Albright hereditary osteodystrophy (AHO). This syndrome is maternally transmitted and characterized by distinct physical features, including short stature, obesity, round facies, subcutaneous ossifications, brachydactyly, and other skeletal anomalies. Intelligence can be normal, but patients frequently exhibit learning or behavioral difficulties. Resistance to the action of TSH is often found leading to hypothyroidism. Pseudohypoparathyroidism type Ib (PHP Ib) is also caused by mutations in regulatory regions of the GNAS1 gene inherited from the mother that are predicted to interfere with the parent-specific methylation of this gene.

## Diagnostic Principles

Hypoparathyroidism is a clinical disorder characterized by hypocalcemia and hyperphosphatemia. Insufficient parathyroid hormone secreted from the parathyroid glands is unable to maintain normal extracellular fluid calcium concentrations. Less commonly, pseudohypoparathyroidism is when the key target tissues, namely bone and kidney are resistant to the actions of PTH, despite adequate (often elevated) circulating levels.

In DiGeorge/TBX1 mutations hypocalcemia secondary to hypoparathyroidism is the key biochemical feature and may be sufficiently severe to be symptomatic. Resolution in early childhood is typical, although the deficient function of the parathyroids may be exposed in adulthood by infusion of disodium edetate (EDTA).

Patients with PHP type Ia exhibit PTH resistance and features include hypocalcemia, hyperphosphatemia, elevated serum PTH and have an abnormally low urinary excretion of cyclic AMP and phosphate in response to PTH administration. They also have features of Albright's hereditary osteodystrophy (AHO) including brachydactyly. Patients with PHP type Ib exhibit PTH resistance only and do not have the somatic features of AHO. Patients with PHP type II have hypocalcemia, hyperphosphatemia, and increased serum PTH. Patients with Pseudohypoparathyroidism type II have a normal urinary cyclic AMP response to PTH but the phosphaturic response is deficient. Vitamin D deficiency, which mimics this disorder, should be excluded.

## Therapeutic Principles

Inherited forms of hypoparathyroidism may present in the neonatal or infantile periods with hypocalcemic fits and require life-long treatment with active vitamin D compounds such as calcitriol or 1-alpha calcidol. In the absence of PTH, renal 1-alpha hydroxylation of calciferol is defective and vitamin D analogues that are not hydroxylated in the 1-alpha position are ineffective in correcting hypocalcemia. Oral calcium (carbonate or lactate) supplements are generally recommended in the treatment of hypoparathyroidism as they may allow a lower overall dose of vitamin D analogue to be used, lessening the long-term risks of nephrocalcinosis or nephrolithiasis from such treatment. The aim of treatment should be to control symptoms which is often achieved with a serum calcium at the lower end of the normal range (2.0–2.2 mmol/l).

# Hypophosphatasia

Michael P. Whyte
Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children and Department of Medicine, Washington University School of Medicine, St. Louis, MO, USA

## Synonyms

HPP

## Definition and Characteristics

Hypophosphatasia (HPP) is a heritable rickets featuring deficient activity of the tissue-nonspecific isoenzyme of alkaline phosphatase (TNSALP) [1]. Expressivity is remarkably wide-ranging. Four types denote patient age when skeletal problems are discovered: perinatal, infantile, childhood, and adult HPP. Odonto-HPP refers to dental complications without skeletal disease [1].

*Perinatal HPP* manifests in utero. Extreme skeletal hypomineralization causes a soft skull and deformed limbs and chest. Survival is brief due to respiratory compromise and sometimes periodic bradycardia and vitamin $B_6$-dependent seizures [1].

*Infantile HPP* presents before age 6 months [2]. Development seems normal until poor feeding, hypotonia, and rachitic deformities. Widely "open" fontanels are hypomineralized calvarium and functional craniosynostosis can raise intracranial pressure. Hypercalcemia can cause vomiting, nephrocalcinosis, and renal compromise. Skeletal demineralization with fractures heralds a lethal outcome. A flail chest predisposes to pneumonia. Some babies die during infancy; others show considerable spontaneous improvement [1].

*Childhood HPP* severity is wide-ranging. Premature loss of deciduous teeth (<age 5) is typical. Rickets often includes a waddling gait from static myopathy. Spontaneous improvement can occur after puberty, but recurrence of complications is likely during adult life [1].

*Adult HPP* presents during middle age with poorly healing metatarsal stress fractures and femoral pseudofractures [3]. Past rickets and premature loss of deciduous teeth is sometimes recalled. Calcium pyrophosphate dihydrate crystal deposition troubles some patients [1].

*Odonto-HPP* typically sheds lower incisors first, but additional anterior teeth may be lost. Exfoliation occurs without root resorption. Radiographs show enlarged pulp chambers and root canals. Permanent dentition fares better [1].

## Prevalence

HPP occurs in all races. The severe forms affect ~1 per 100,000 births. Mild forms are more common, but there are no prevalence figures.

## Genes

Perinatal and infantile HPP are autosomal recessive traits. The milder forms can be autosomal dominant or recessive traits. More than 200 loss-of-function mutations in TNSALP have been identified [4]. Most are missense.

## Molecular and Systemic Pathophysiology

Although some TNSALP occurs in all tissues, HPP affects the skeleton and teeth directly. The defective mineralization is distinctive because extracellular levels of calcium and inorganic phosphate (Pi) are not low. In fact, hypercalcemia occurs frequently in perinatal and infantile HPP, apparently from defective skeletal growth, though there can also be skeletal demineralization. Serum Pi levels are above reference range means, and many patients are hyperphosphatemic. Enhanced renal reclamation of Pi partly explains this finding. Vitamin D and parathyroid hormone (PTH) levels are normal unless there is hypercalcemia. The lower the serum ALP activity the more severe the clinical manifestations.

Three phosphocompound substrates accumulate: phosphoethanolamine (PEA), inorganic pyrophosphate (PPi), and pyridoxal 5′-phosphate (PLP). Phosphoethanolaminuria supports the diagnosis, but is not specific. If vitamin $B_6$ supplements are avoided, elevated plasma PLP seems to be a sensitive and specific marker.

Vitamin $B_6$ metabolism in HPP shows that TNSALP regulates extracellular levels of these phosphocompounds [1]. Accumulation of PPi, an inhibitor of hydroxyapatite crystal growth, explains the impaired skeletal mineralization [1,5]. TNSALP knockout mice recapitulate infantile HPP [5].

## Diagnostic Principles

HPP can be diagnosed from a consistent clinical history and physical findings, characteristic radiographic changes, and low serum ALP activity recognizing that reference ranges vary by age and several disorders cause hypophosphatasemia (Table 1).

High plasma levels of PLP, a TNSALP substrate, support the diagnosis.

Perinatal HPP features pathognomonic x-ray changes. The skeleton may be nearly unmineralized, or the skull ossified only centrally in individual bones suggesting sutures are widely patent. Marked hypomineralization accompanies severe rachitic changes including fractures. Infantile HPP causes less severe findings. Childhood HPP often features "tongues" of radiolucency projecting from rachitic growth plates into metaphyses. Premature fusion of cranial sutures can cause a "beaten-copper" appearance. Adult HPP causes osteopenia, metatarsal fractures, and proximal femoral pseudofractures.

Nondecalcified bone histology reveals defective mineralization (except in odonto-HPP). Dental histopathology shows aplasia of cementum.

Perinatal HPP can be detected in utero with ultrasonography. Childhood HPP can manifest limb bowing in utero [1].

All patients studied to date have had one or two defective TNSALP alleles [4]. First trimester diagnosis is based on TNSALP mutation analysis.

## Therapeutic Principles

There is no established medical therapy [1]. Traditional treatments for rickets (e.g., vitamin D, mineral supplements) are avoided unless there is a specific deficiency because excesses could unmask hypercalcemia or hypercalciuria. Hypercalcemia may respond to dietary calcium restriction and to calcitonin and/or glucocorticoids.

**Hypophosphatasia. Table 1** Causes of hypophosphatasemia

| | |
|---|---|
| Hypophosphatasia | Clofibrate therapy |
| Familial benign? | Starvation |
| Pernicious or profound anemia | $Zn^{2+}$ or $Mg^{2+}$ deficiency |
| Hypothyroidism | Cushing's syndrome |
| Vitamin C deficiency | Celiac disease |
| Osteogenesis imperfecta (type II)[a] | Massive transfusion |
| | Cleidocranial dysplasia |
| Wilson's disease | Cardiac Bypass Surgery |
| Vitamin D intoxication | Improperly collected blood (e.g., EDTA, oxalate) |
| Inappropriate reference range | |
| Multiple myeloma | Radioactive heavy metals |

[a]Unpublished personal observation.

Fractures usually mend slowly. Placement of load-sharing intramedullary rods seems best for fractures or pseudofractures in adults [1]. Dietary Pi restriction could reduce competitive inhibition of TNSALP by Pi, but requires study [3]. Marrow cell transplantation seemed to rescue and improve two girls with infantile HPP [2]. Teriparatide (recombinant PTH fragment 1–34) can stimulate TNSALP synthesis by osteoblasts and may heal HPP fractures in select patients [3]. TNSALP targeted to bone has prevented HPP in knockout mice.

# Hypophosphatemia

Masafumi Fukagawa[1], Motoko Tanaka[2]
[1]Division of Nephrology & Kidney Center, Kobe University School of Medicine, Kobe, Japan
[2]Department of Nephrology, Akebono Clinic, Kumamoto, Japan

## Definition and Characteristics

Assay for serum phosphate measures inorganic phosphates, mainly $H_2PO_4^-$ and $HPO_4^{2-}$ (85%). Hypophosphatemia is defined as the fasting serum level less than 2.5 mg/dl (0.80 mmol/l). Less than 1.0 mg/dl (0.32 mmol/l) is considered to be severe hypophosphatemia that requires rapid correction.

Acute, severe hypophosphatemia may result in dysfunction of the cells, such as hemolysis, impaired chemotaxis of leukocytes, platelet dysfunction,

rhabdomyolysis, encephalopathy, and heart failure. Chronic hypophosphatemia may be manifested by anorexia, muscle pain, and rickets/osteomalacia [1].

## Prevalence

Hypophosphatemia is encountered as low as 0.43% of hospitalized patients. Higher prevalence has been reported in patients with alcoholism (0.9%), sepsis (2.4%), malnutrition (10.4%), and diabetic ketoacidosis (14.6%).

## Genes

Gene mutations have been identified in various diseases with hypophosphatemia, including X-linked hypophosphatemic rickets: XLH (PHEX gene mutation), autosomal dominant hypophosphatemic rickets: ADH (FGF23 mutation, human chromosome12p13), and in patients with nephrolithiasis and osteoporosis associated with hypophosphatemia (NaPi-IIa gene mutation, human chromosome 5q35).

## Molecular and Systemic Pathophysiology

Systemic phosphate balance is principally maintained by the kidney, which excretes the net amount of phosphate absorbed from the intestine (700 mg/day). Thus, most cases of hypophosphatemia develop as the result of negative balance of phosphate due to increased urinary excretion and/or decreased net intake.

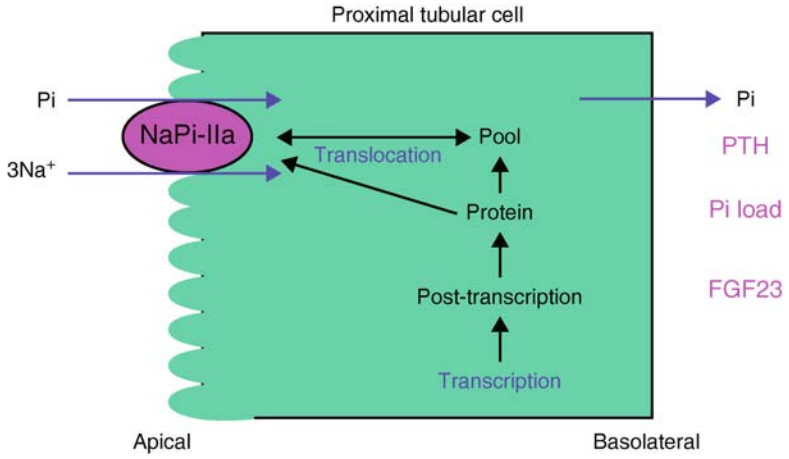
Urinary excretion of phosphate is determined by the reabsorption through the apical brush border membrane of the proximal tubular cells. This process is mediated by sodium-phosphate cotransporters (NaPi), mainly NaPi-IIa, mutation of which gene results in hypophosphatemia. NaPi activity is determined by translocation of protein as well as by the changes of mRNA abundance (Fig. 1) [2].

Decrease of phosphate reabsorption in the proximal tubular cells is achieved by the retrieval of NaPi-IIa from the apical membrane in the acute phase (translocation), followed by the chronic downregulation of mRNA level.

Increased activity of phosphaturic hormones, which decrease NaPi activity, is a major cause of enhanced urinary phosphate excretion, which include PTH, PTHrP, and more recently, so-called "phosphatonins" [3]. It has recently revealed that increased activity of fibroblast growth factor 23 (FGF23) by several mechanisms is responsible for hypophosphatemia in several diseases such as XLH, ADH, and tumor-induced osteomalacia [4,5]. Enhanced urinary phosphate excretion also develops as a part of Fanconi syndrome due to various etiology including heavy metals and medications.

Part of intestinal phosphorus absorption is mediated by NaPi-II2b, which is mainly regulated by dietary phosphorus content and active vitamin D (1,25D). Thus, starvation, use of antacids, malabsorption, and vitamin D deficiency may lead to hypophosphatemia. FGF23 contributes to the development of hypophosphatemia, not only by enhancing urinary phosphate excretion, but also in part by suppressing 1,25D production in the kidney.

Shift of phosphate into cells plays another critical role in hypophosphatemia caused by respiratory alkalosis, refeeding, leukemia with rapidly proliferating cells, and hungry bone syndrome after parathyroidectomy. In respiratory alkalosis, increased intracellular pH stimulates phospho-fructokinase, recruiting the entry of extracellular phosphate. Intracellular shift of phosphate by insulin release plays a major role in refeeding hypophosphatemia in malnourished patients.



**Hypophosphatemia. Figure 1** Control of sodium-phosphate cotransporter type IIa (NaPi-IIa) in the proximal tubular cells by phosphaturic hormones and dietary phosphorus load.

### Diagnostic Principles

After history taking, physical examination, and routine serum tests, evaluation of urinary phosphate excretion is a useful clue to the diagnosis of hypophosphatemia. In selected cases, measurement of serum levels of PTH, PTHrP, 25(OH)D, 1,25$(OH)_2$D, and FGF23 may provide additional information.

A spot urine with higher than 20 mg/dl of phosphate suggests renal phosphate loss. More precisely, decrease of renal phosphate threshold normalized for the glomerular filtration rate (TmP/GFR) can be used for the estimation of the activity phosphaturic hormones. TmP/GFR can be calculated either by a monograph or by the formula

$$\mathrm{TmP/GFR} = \mathrm{Serum\,P}\{1 - (\mathrm{Upi} \times \mathrm{Pcr})/(\mathrm{Ppi} \times \mathrm{Ucr})\}$$
$$(\mathrm{normal}\ 2.5{-}4.5\ \mathrm{mg/dl}).$$

### Therapeutic Principles

Treatment of responsible disorders, such as primary hyperparathyroidism and tumors, is warranted. Mild to moderate hypophosphatemia should be managed by oral replacement; however, more severe hypophosphatemia should be treated by intravenous replacement. In selected disorders with vitamin D deficiency, active vitamin D sterols need to be administered.

## Hypophosphatemia with Renal Phosphate Loss

►Mutations in the Type 2a Sodium-Phosphate Transporter

## Hypophosphatemia, X-linked

Harriet S. Tenenhouse
Montreal Children's Hospital Research Institute, McGill University, Montreal, QB, Canada

### Synonyms

Vitamin D resistant rickets; XLH

### Definition and Characteristics

X-linked hypophosphatemia (XLH) (OMIM 307800) is characterized by growth retardation, rickets and osteomalacia, dental abscesses and specific renal defects in the reabsorption of filtered phosphate and the metabolism of vitamin D [1].

### Prevalence

The prevalence of XLH is approximately one in 20,000. Although the disease is completely penetrant, disease severity can vary even among members of the same family. There is a minimal gene dose effect, i.e. disease severity is similar in males and females.

### Molecular and Systemic Pathophysiology

The gene responsible for XLH was identified by positional cloning and designated PHEX (formerly PEX) to signify a phosphate regulating gene with homology to endopeptidases on the X chromosome [2]. The PHEX gene encodes a protein that exhibits significant homology to the M13 family of zinc metallopeptidases, type II integral membrane glycoproteins known to activate or inactivate biologically active peptides [3]. Although PHEX can function as an endopeptidase, the nature of its endogenous substrate(s) is not yet known. PHEX is expressed predominantly in bone (osteoblasts and osteocytes) and teeth (odontoblasts), but not in kidney, consistent with the demonstration of a primary mineralization defect and a renal Pi leak that is dependent on a circulating factor in the murine Hyp homologue of XLH [4].The Hyp mouse harbors a large 3' deletion of the Phex gene and serves a model to study the pathophysiology of the human disease [4]. The 171 mutations in the PHEX gene that have been identified to date are catalogued in a locus-specific mutation database (www.phexdb.mcgill.ca) and are consistent with loss of PHEX function. Based on our current state of knowledge, it has been suggested that PHEX may activate or degrade peptide factors involved in the autocrine or paracrine regulation of osteoblast differentiation and/or mineralization. In addition, the PHEX gene product in bone, or at other sites, may activate or inactivate circulating factors that

influence renal phosphate reabsorption and vitamin D metabolism. One such candidate is FGF-23, a secreted peptide which is produced by tumors from patients with oncogenic hypophosphatemic osteomalacia (also known as tumor induced osteomalacia), an acquired disorder with the phenotypic features of XLH. The serum concentration of FGF-23 is markedly elevated in patients harboring these tumors as well as in patients with XLH [5]. The administration of FGF-23 to mice elicits renal Pi wasting, hypophosphatemia, dysregulated renal vitamin D metabolism and a mineralization defect [5]. Moreover, mutations in the FGF23 gene, which prevent FGF-23 processing, are responsible for autosomal dominant hypophosphatemic rickets (OMIM 193100), a rare Mendelian disorder with the features of XLH [5].

### Diagnostic Principles

All patients exhibit hypophosphatemia and isolated renal phosphate wasting, which is evaluated by measuring TMP/GFR using the nomogram of Bijvoet and Walton. Serum alkaline phosphatase is elevated and serum calcitriol concentrations are inappropriately normal for the degree of hypophosphatemia. Serum PTH is in the normal to high range. Radiological features of rickets are present in the majority of affected children. Skeletal abnormalities may be apparent in adults, depending on the severity of the disease. Detection of mutations in the PHEX gene will confirm the diagnosis. Absence of a family history is indicative of a sporadic mutation.

### Therapeutic Principles

Therapy consists of oral phosphate supplements, in four to five divided doses per day, and calcitriol [1]. Compliance is difficult and careful monitoring is essential to avoid potential complications [1]. Too much phosphate leads to the development of hyperparathyroidism and an excess of calcitriol to hypercalcemia, hypercalciuria, and nephrocalcinosis. Thus, novel therapeutic options, based on knowledge of the mechanism of PHEX action, are clearly required.

## Hypophosphatemic Rickets

►Osteomalacia

## Hypophysitis, Autoimmune

Angelika Gutenberg[1], Patrizio Caturegli[2]
[1]Department for Neurosurgery,
Georg-August-University, Goettingen, Germany
[2]Department for Pathology and Immunology,
The Johns Hopkins University, Baltimore, MD, USA

H

### Synonyms

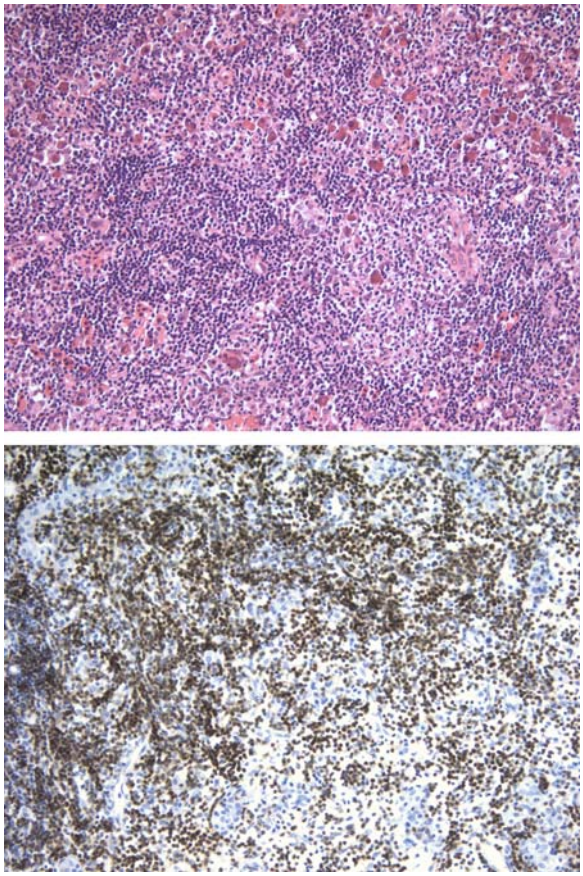
Lymphocytic hypophysitis; Primary hypophysitis

### Definition and Characteristics

Autoimmune hypophysitis (AH) is a rare but increasingly recognized entity in the differential diagnosis of pituitary masses [1]. AH encompasses three histological types: lymphocytic, the most common, granulomatous, and xanthomatous [2] (see Fig. 1). It is unclear whether these types are truly distinct entities or rather different expressions of the same disease. It affects more commonly women (female:male ratio 7:1), and often occurs during late pregnancy or the early post-partum period [1]. An autoimmune basis, the association with pregnancy, and the female predominance, however, is only seen in the lymphocytic form [3]. One-third of lymphocytic AH patients suffer from additional autoimmune diseases, such as Hashimoto's thyroiditis, Graves' disease, adrenalitis, and Sjögren's syndrome. Women tend to present at younger ages than men (35 ± 13 years and 45 ± 14 years, respectively) [1]. AH symptoms originate from hypopituitarism as well as from compression of the structures surrounding the pituitary gland. Mass effect symptoms include headache, visual field defects or anopsia and diplopia. Endocrine deficiencies most often comprise adrenal insufficiency, hypothyroidism, hypogonadism, and diabetes insipidus. Hyperprolactinemia due to compression of the pituitary stalk can be found in about a fifth of the cases.

### Prevalence

Data on the basic epidemiologic features of AH are limited, although undoubtedly it is a rare disease [1]. In consecutive surgical specimens of the pituitary gland,



**Hypophysitis, Autoimmune. Figure 1** Lymphocytic hypophysitis. Top: hematoxylin and eosin staining shows the marked disruption of the pituitary architecture caused by the diffuse lymphocytic infiltrate. Only a few eosinophilic endocrine cells remain in the background. Bottom: immunohistochemical staining for CD3, a pan T cell antigen, shows that the majority of infiltrating lymphocytes are indeed T-cells (original magnification × 20).

AH has prevalence between 0.5 and 1%. In the general population, the estimated incidence is one case in 9 million per year.

## Molecular and Systemic Pathophysiology

The precise pathogenetic mechanisms of AH are not yet known. AH is considered an autoimmune disease because of the characteristic lymphocytic infiltration of the pituitary, the responsiveness to immunosuppressive drugs, the association with other better characterized autoimmune diseases, and the presence of autoantibodies recognizing pituitary antigens in the patient's serum. The nature of such pituitary autoantigen(s), however, awaits identification. Several candidates have been proposed in recent years, but none has been confirmed in adequate case-control studies nor has been capable of reproducing the human disease when injected into animal models [3]. Candidate proteins for AH antigens have been growth hormone, enolase, pituitary gland specific factors 1 and 2, type 2 deiodinase, and secretogranin. T lymphocytes (CD4 more than CD8) are the most abundant infiltrating cells, and are considered the key mediators of tissue damage. The striking temporal association between AH and pregnancy remains unexplained as well.

## Diagnostic Principles

AH is difficult to diagnose because it clinically and radiologically resembles the more common non-secreting pituitary adenoma [1]. AH diagnosis and management require the teamwork of endocrinologists, radiologists, neurosurgeons and neuropathologists. Clinical suspicion should be raised if symptoms appear in relationship to pregnancy or postpartum, and if pituitary failure is disproportional to a relatively small size of the lesion. Evaluation of the anterior pituitary function in AH shows impairment of the adrenal (57%), gonadal (52%) and thyroidal (49%) axes. Growth hormone (39%) and prolactin deficiencies (23%) are infrequent [4]. The most evidentiary clinical sign of AH is diabetes insipidus (in about 50% of AH patients), as it is absent in pituitary adenomas. MRI is the best procedure for evaluation of pituitary pathologies. It can image soft tissue without interference from the bony surroundings of the sella and it can produce images in any plane. The MRI features of AH, however, are not specific enough to distinguish it with certainty from other sellar tumors. Radiological hints that, in the proper clinical context, favor AH diagnosis are: symmetry (dumbbell-shape) of the sellar mass, lack of erosive changes of the bony sellar floor, thickening of the pituitary stalk, loss of posterior pituitary signal in non-enhanced T1-weihgted images, presence of a meningeal enhancement ("dural tail"), and a very bright gadolinium-uptake of the entire gland, sometimes extending tongue-like shaped to the basal hypothalamus [5]. Either, only the anterior lobe, the posterior lobe and infundibulum, or the entire gland can be affected. Unfortunately, specific autoantibodies to diagnose and monitor AH are not characterized yet, so that a definite diagnosis can only be achieved through a transphenoidal pituitary biopsy. AH masses either appear liquid pus-like or hard, fibrotic and cartilagineous, features that are distinct from the fleshy consistence of pituitary adenomas. The histological hallmark of AH is the lymphocytic infiltration of the pituitary gland, ultimately resulting in the loss of endocrine cells and fibrosis.

## Therapeutic Principles

AH treatment at the moment is only symptomatic. It aims to replace the deficient hormones and to reduce the size of the pituitary mass. High-dose glucocorticoids

(60 mg of prednisolone daily, tapering the dose every 5 days) are generally recommended as first-line treatment in cases suspected for AH where vision is not endangered by the pituitary mass. Improvement under glucocorticoids, however, is sometimes incomplete, transient, or even lacking, especially in cases with the granulomatous or xanthomatous form [4]. If symptoms persist or worsen, transphenoidal surgery has to be performed. Given the diffuse nature of the pituitary lesion in AH, neurosurgical decompression should not be radical. Follow-up intervals should be short and include endocrinological and radiological updates [5].

# Hypopituitarism

Christy T. Oswalt, Christian A. Koch
Division of Endocrinology, University of Mississippi Medical Center, Jackson, MS, USA

## Synonyms

Combined pituitary hormone deficiency; Multiple anterior pituitary hormone deficiency; MPHD; Familial anterior hypopituitarism; Isolated pituitary hormone deficiency

## Definition and Characteristics

Hypopituitarism describes impairment of the pituitary to secrete one or more hormones. The main causes include heritable defects in pituitary development and acquired diseases disrupting the pituitary, hypothalamus, or pituitary stalk (Table 1) The presentation of patients with hypopituitarism is dependent on the cell types affected, the degree of impairment, and the age and rapidity of onset.

*KAL-1 Mutation (Kallman's Syndrome)*: Isolated gonadotropin deficiency with hyposmia can be sporadic or inherited as an autosomal or X-linked disorder. Patients with the X-linked disorder present with delayed puberty, hyposmia, eunuchoid proportions, small testes, short penis, and may have unilateral renal agenesis and synkinesis. Autosomal and sporadic disorders may cause midline facial defects, ocular coboma, choanal atresia, short metacarpals, and gut malrotation.

*DAX-1 Gene Mutation*: X-linked disorder presenting with hypogonadotrophic hypogonadism in males in conjunction with congenital adrenal hypoplasia.

*PIT-1 (POU1F1) Mutation*: Autosomal dominant or recessive disorder presenting with growth hormone (GH), prolactin (PRL), and variable thyroid stimulating hormone (TSH) deficiencies with a normal or hypoplastic pituitary.

*PROP1 Mutation*: Autosomal recessive disorder presenting with early onset GH, TSH, PRL, luteinizing hormone (LH), follicile stimulating hormone (FSH), and variable, progressive adrenocorticotropin hormone (ACTH) deficiencies with a normal, hypoplastic, or hyperplastic pituitary.

*HESX1 Gene Mutation*: Autosomal recessive disorder presenting with GH deficiency and variable TSH, PRL, LH, FSH, ACTH, and posterior pituitary deficiencies with a hypoplastic or hyperplastic anterior pituitary and normal or ectopic posterior pituitary; it may be associated with septo-optic dysplasia.

*LHX3 Gene Mutation:* Presents with GH, TSH, LH, FSH, and PRL deficiencies and a rigid cervical spine with a hypoplastic or hyperplastic anterior pituitary.

## Prevalence

Unclear and underestimated. Most common cause adult-onset hypopituitarism: pituitary adenomas and, craniopharyngiomas.

PROP1 mutations are more common than PIT-1 mutations.

*Kallman's Syndrome*: X-linked in 1/10,000–1/60,000 live births.

## Genes

*DAX-1*: Encodes a nuclear hormone receptor in a DNA-binding domain involved in the development of the hypothalamus, pituitary gland, adrenal gland, and gonads.

*PIT-1*: Encoding a 290-amino-acid protein; mutations lead to loss of DNA-binding or interfere transcriptional activation. Autosomal recessive mutations include complete deletion, Phe135Cys, Arg143Gln, Ala158Pro, Arg172Ter, Glu174Gly, Pro239Ser,

Glu250Ter, Trp 261Cys. Dominant mutations include Pro14Leu, Pro24Leu, Lys216Glu, and Arg271Trp.

*PROP1*: Encodes a 223-amino-acid protein. The most common mutation is 296delGA producing a nonfunctional protein due to a frameshift truncating in the DNA-binding domain due to a premature stop codon at codon 109. Autosomal recessive mutations include 150delA, 149–150delGA, Arg73Cys, Ser83Pro, Arg99Ter, 296delGA, A⇒ T nt 343–2, Phe117Ile, and Arg120Cys.

*HESX1*: Encodes a 185-amino-acid. A homozygous missense mutation Arg53Cys produces a non-functioning mutant protein unable to bind DNA.

*LHX3*: Encodes three protein isoforms, LHX3a, LHX3b, and M2-LHX3 which activate the genes encoding the alpha subunit, PRL, FSH beta, TSH beta, GnRH receptor, and PIT-1 transcription factor. A missense mutation involving an A to G transition producing a Y111C substitution in a LIM domain of LHX3a and a 23 base-pair deletion in exon 3 producing a truncated protein produce non-functional protein. A mutation in exon 2,g.159delT, causes a frameshift leading to the production of a truncated protein lacking the LIM domains and DNA-binding domain.

## Molecular and Systemic Pathophysiology

*KAL-1*: The KAL protein is necessary for migration of gonadotropin-releasing hormone (GnRH) neurons from the medial olfactory placode to the hypothalamus during embryonic development.

*PIT-1*: Pituitary specific transcription factor in somatotrophs, lactotrophs, and thyrotrophs that binds to the GH gene promoter sequence. PIT-1 is present beginning in early fetal development and persists throughout life; mutations prevent differentiation due to impaired GH and PRL gene activation and TSH beta promoter regulation.

*PROP1*: Pituitary specific transcription factor in somatotrophs, lactotrophs, and thyrotrophs needed for subsequent PIT-1 activation and extinction of HESX1 expression; mutations prevent differentiation of anterior pituitary progenitor cells.

*HESX1*: Protein found in all precursor pituitary cell types before PROP1 and is extinguished before PIT1 appears involved in development of the pituitary and the optic nerves.

*LHX3*: Transcription factor involved in development of the pituitary and nervous system; synergistic with PIT1 in activating transcription from promoters of PRL, TSH, and PIT1.

### Diagnostic Principles

Basal serum GH, Insulin-like growth factor-1, IGFBP-3 in children, TSH, LH, FSH, ACTH, PRL, Estradiol, Testosterone (0900), Cortisol (0900), Free thyroxine levels.
Stimulation tests for presumed hypofunction or suppression tests for hyperfunction of individual hormones.
Pituitary imaging with MRI.

### Therapeutic Principles

Treatment is dependent on etiology and includes replacement of deficient hormones (with glucocorticoids before thyroid hormone).

## Hypoplast

►Hypoplastic Left Heart Syndrome

## Hypoplastic Left Heart Syndrome

Pirooz Eghtesady
Division of Cardiothoracic Surgery, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA

### Synonyms

HLHS; Hypoplast

### Definition and Characteristics

HLHS is a congenital heart defect whose primary feature is a left ventricle (LV) that is too small or "hypoplastic" to support circulation after birth [1]. It is called a syndrome because it can have a variable presentation regarding degree of damage and underdevelopment of the left side of the heart, including the aorta, aortic valve, LV and mitral valve. The aortic or mitral valves may be quite small and obstructive to blood flow ("stenosis" or "stenotic") or completely closed ("atresia" or "atretic"). Some defects are classified as HLHS "variants" (e.g., double outlet right ventricle or transposition of great arteries, etc.), wherein a predominant pathology of LV hypoplasia occurs. These lesions, however, defer substantially from classic HLHS where normal anatomic relationships of the heart (atrioventricular concordance and ventriculo-arterial concordance along with an intact ventricular septum) are maintained. These variants represent a group of defect(s) that may have different embryological origins from classical HLHS.

### Prevalence

HLHS has the highest mortality rate of heart defects for infants <1 year of age and accounts for nearly 25% of neonatal deaths attributed to congenital heart disease. HLHS affects from 1.7 to 6.7 newborns per 10.000 live births or ~2000 babies/year in the United States. The ratio of affected males to females is 1.6:1. The reason for this gender predilection is unknown.

### Molecular and Systemic Pathophysiology

The etiology of HLHS and related pathologies remains unknown, although a variety of causative factors including genetics, abnormal intrauterine blood flow patterns, intrauterine infection and myocarditis or immunologic injury has been implicated. A genetic etiology has been strongly favored in part because HLHS and related defects can present with syndromic or chromosomal anomalies such as Turner's syndrome, Jacobson syndrome, chromosome 22 or chromosome 11 deletions, and trisomy 9. Although mutations in the cardiac

transcription factor NKX2.5 occur in a few patients with HLHS no specific disrupted gene(s) or single chromosomal anomaly has been consistently associated with these heart defects. Based on a few reports of familial occurrence, investigators have suggested autosomal recessive, dominant, oligogenic, or even polygenic patterns of inheritance. Our group has recently hypothesized that HLHS may be a manifestation of rheumatic heart disease in the fetus via an immune mechanism called "molecular mimicry" [2].

## Diagnostic Principles

The principal method for diagnosis of HLHS is fetal echocardiography and is the most commonly (and most easily) detected cardiac defect in screening obstetrical ultrasounds, as early as 12–14 weeks gestation. Cardiac catheterization, almost never needed for newborns with HLHS as part of the initial evaluation, is used in the evaluation of cardiopulmonary function and anatomy after the immediate newborn period and in older children with HLHS who have been treated with surgical palliation. If untreated, HLHS is usually fatal within the first days or months of life. If not detected prenataly, a baby with HLHS comes to medical attention within a few days of birth as the patent ductus arteriosus closes.

HLHS can also be associated with a restrictive or intact atrial septum (5–10% of all HLHS). These babies become extremely sick and unstable after birth with severe cyanosis and evidence of moribund acidosis. In the absence of rapid intervention to open up the atrial septum (create an atrial septal defect or ASD), the affected babies do not survive. Even then, the outcome is substantially worse than for neonates with an unrestrictive ASD, prompting increasing interest in fetal interventions for these babies.

## Therapeutic Principles

Prostaglandin E administration (to maintain patent ductus arteriosus or PDA) remains the first and most important measure to maintain perfusion to the newborn's vital organs. Previously many affected families chose termination of pregnancy or "comfort-care" measures (no treatment). With improvements in outcomes, increasingly alternative options are available [3,4]. The most common treatment for HLHS is staged reconstruction involving a series of three operations. The first operation, performed in the first week or so of life, is the Norwood procedure involving reconstruction of the aorta and pulmonary arteries so that blood flow from the right ventricle is directed primarily to the remodeled and augmented aorta. Blood flow to the lungs and body occur in parallel (parallel circulation) and the child remains blue after the Norwood. The second surgery is the bi-directional Glenn or HemiFontan procedure performed at 3 to 6 months of age and the third operation is the Fontan procedure performed in children older than 2 to 3 years old. After the Glenn/HemiFontan procedures (SVC blood flow directly redirected to the lungs) and the Fontan completion (IVC blood flow directly redirected to the lungs), the child finally ends up with a circulation in series and becomes acyanotic. Despite modifications to the Norwood operation, mortality associated with this procedure remains ~20–30%. Alternative "hybrid" approaches (surgery combined with catheter-based intervention) have been developed, wherein the PDA is kept open with a "stent" and the pulmonary blood flow is regulated with bilateral bands placed around the branch pulmonary arteries until a hybrid 2nd stage (Norwood and Glenn). In contrast to past practice, due to a limited donor pool and mortality while waiting for an available organ (~1015%), transplant is generally an option of last resort (e.g., after failed reconstructive surgery) or one that is used selectively.

►Periodic Paralysis, Familial

# Hypospadias

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Hypospadias is characterized by a urethral meatus located on the ventral aspect of the penis and proximal to the normal site [1]. The meatal position can be classified as

anterior or distal (glandular, coronal, subcoronal), middle (midpenile), or posterior or proximal (posterior penile, penoscrotal, scrotal, perineal) [1]. Characteristically, the foreskin on the ventral surface is thin or absent while the foreskin on the dorsal surface is abundant and has the appearance of a dorsal hood (Fig. 1).

Chordee is more commonly associated with proximal hypospadias. The clinical presentation varies with severity of the disorder. Children with hypospadias and a narrow meatus may have a weak urinary stream that is deflected downwards and splayed. Some affected children might not be able to void while standing. Uncorrected, erections might be painful in those children with chordee, and sexual intercourse might not be possible in severe cases. Cryptorchidism and inguinal hernia are the most common associated anomalies. Urinary tract anomalies occur in 1% and 5% of cases with isolated anterior and posterior hypospadias, respectively.

## Prevalence

The incidence of hypospadias has been estimated to be 0.4–8.2 per live male births [2]. The condition is more common in Caucasians, least common in Hispanics, and intermediate among African-Americans.

## Genes

The etiology is multifactorial. In the majority of cases the hypospadias develops as a sporadic problem and without an obvious underlying cause. In general, the more severe the hypospadias, the more likely an underlying cause can be identified. A high familial incidence of hypospadias is observed and a polygenic predisposition is likely. An autosomal dominant mode and an autosomal recessive mode of inheritance might be responsible for a small number of cases of hypospadias [3]. Hypospadias has also been found in various chromosomal aberrations, such as $4p^-$, $18q^-$, paracentric inversion of chromosome 14, and Klinefelter syndromes. Hypospadias can be associated with genetic syndromes such as Smith-Lemli-Opitz, hypertelorism, hand-foot-genital, Reifenstein, Wolf-Hirschhorn, Denys-Drash, Silver-Russell, and G [1].

**Hypospadias. Figure 1** A 4-year-old child with distal hypospadias. Note the foreskin on the ventral surface is absent while the foreskin on the dorsal surface is abundant.

## Molecular and Systemic Pathophysiology

Defects in testosterone production by the testes and adrenal glands, failure of conversion of testosterone to dihydrotestosterone, deficient numbers of androgen receptors in the penis, or reduced binding of dihydrotestosterone to the androgen receptors could all result in hypospadias [1,4].

## Diagnostic Principles
