# Preface

Pathophysiology describes mechanisms of disease and is thus at the interface between basic research and clinical medicine. The aim of this comprehensive encyclopedia is to supply the reader with concise information on molecular pathophysiology, a research area of breathtaking gain of knowledge. We trust that the book shall be a valuable companion for both basic scientists exploring the clinical hallmarks of the diseases they are interested in, and clinicians searching for insight into the molecular pathophysiology of their patients. The entries are structured to allow rapid retrieval of the desired information. For more detailed reading, each entry is followed by key references.

The editor is indebted to the section editors for their superb support in selecting the appropriate entries and choosing the leading experts in the respective areas of research. The editor further wishes to express his appreciation to the many brilliant authors who delivered outstanding state-of-the-art descriptions of pathophysiological mechanisms.

In addition, the book would not have come to reality without the dedicated, professional and creative support of my secretaries Tanya Loch and Jasmin Bühringer and by several staff members of the Springer Publishing house including Dr. Michaela Bilic, Jana Simniok, Hiltrud Wilbertz, Dr. Rolf Lange, and Dr. Thomas Mager.

Florian Lang, March 2008

## Editor-in-Chief

Prof. Dr. med. Florian Lang

## Abetalipoproteinemia

Hubert Scharnagl[1], Winfried März[2]
[1]Clinical Institute of Medical and Chemical Laboratory Diagnostics, Medical University Graz, Graz, Austria
[2]Synlab Center of Laboratory Diagnostics, Heidelberg, Germany

### Synonyms

Microsomal triglyceride transfer protein deficiency; Apo B deficiency; ABL; MTP deficiency

### Definition and Characteristics

Abetalipoproteinemia (ABL) is an autosomal recessive disorder characterized by the virtual absence of apolipoprotein B containing lipoproteins from plasma. Clinical manifestations are chronic fat malabsorption, deficiency of fat-soluble vitamins, retinopathy, acanthocytosis, steatorrhea and variable neurological manifestations.

### Prevalence

Rare.

### Genes

MTP gene localized on chromosome 4q22 coding for the microsomal triglyceride transfer protein [1,2].

### Molecular and Systemic Pathophysiology

The microsomal triglyceride transfer protein (MTP) is required for the assembly and secretion of apoB containing lipoproteins in the liver and intestine [3]. The role of MTP is to translocate apoB across the endoplasmic reticulum (ER) membrane and to catalyze the assembly of apoB with triglycerides, cholesteryl ester and phospholipids. MTP is a heterodimer consisting of protein disulfide isomerase and a 97-kDa M subunit essential for the lipid transfer activity. The MTP complex is found in the lumen of the endoplasmic reticulum of liver and intestinal cells.

Approximately 20 frameshift, missense and splice site mutations in the MTP gene have been reported. These mutations result in truncated or structurally modified proteins devoid of function [4]. In patients with ABL the intestinal fat absorption is defective, serum concentration of cholesterol and triglycerides are very low and apo B containing lipoproteins (chylomicrons, VLDL, IDL, and LDL) are virtually absent.

### Diagnostic Principles

Very low concentrations of serum total cholesterol and triglycerides and the absence of detectable apo B points to ABL. Detection of mutations in the MTP gene confirms the diagnosis.

### Therapeutic Principles

The intake of triglycerides containing long-chain fatty acids should be restricted. Long-chain fatty acids should be substituted by medium-chain fatty acids. Fat-soluble vitamins may be given to prevent neurological deficits.

## Acanthosis Nigricans

Markus Böhm, Thomas A. Luger
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Pseudoacanthosis nigricans; Acanthosis nigricans (AN) maligna

### Definition and Characteristics

A mostly symmetric eruption characterized by hyperpigmented, velvety cutaneous thickening typically involving the axillae, neck, groin, antecubital, popliteal and umbilical areas. Histologically, there is epidermal papillomatosis, acanthosis, occasionally with increased melanization of the epidermis and presence of melanophages in the upper corium.

### Prevalence

The prevalence is highly associated with obesity: Up to 66% of adolescents and up to 74% of adults with obesity have AN. AN maligna is exceedingly rare with only 2 out of 12,000 cancer patients [1].

### Genes

INSR (MIM#147670), PPAR-γ (MIM#601487), AGPAT2 (MIM#603100), BSCL (MIM#606158), LMNA (MIM#150330), ALMSI (MIM#606844), FGFR2 (MIM#176943), FGFR3 (MIM#134934) [2].

### Molecular and Systemic Pathophysiology

The molecular causes underlying AN are heterogenous and depend on the clinical subtype [1]. All pathogenetic events lead to increased epidermal proliferation and suppressed differentiation in the affected areas. Insulin resistance is most often implicated as the molecular cause of obesity-associated AN and of several forms of syndromic AN including type A syndrome (**h**yper**a**ndrogenemia, **i**nsulin **r**esistance, **a**canthosis **n**igricans, HAIR-AN syndrome), type B syndrome, Leprachaunism or Rabson-Mendenhall syndrome. In obesity-associated AN reduction in the number of insulin receptors and/or postreceptor alterations were suggested. In type A syndrome, Leprachaunism and Rabson-Mendenhall syndrome mutations involving the insulin receptor have been reported while in other conditions insulin receptor antibodies have been detected. The resulting hyperinsulinemia leads to interaction of insulin with insulin-like receptors such as

the insulin-like growth factor-1 receptor mediating enhanced epidermal prolilferation. In other rare syndromic AN subtypes, e.g. cutis gyrata syndrome, Crouzon syndrome, thanatophoric dysplasia and SADDAN syndrome, the development of AN is linked to mutations of fibroblast growth factor receptor 2 and 3, two receptor tyrosine kinases mediating also proliferative activities on epidermal cells. In addition, an epidermal nevus-like form of AN has been described [3]. In AN maligna elevated levels of distinct circulating growth factors such as α-melanocyte-stimulating hormone and transforming growth factor-α have been described. An altered expression of the epidermal growth factor receptor and increased activation of the extracellular signal-regulated kinase have been shown in lesional skin of patients with AN maligna [4].

### Diagnostic Principles

Benign and syndromic types of AN must be distinguished from AN maligna. Sudden onset and rapid spread are suggestive for AN maligna. Any underlying neoplasm (especially a gastrointestinal cancer) must be ruled out. In contrast, benign AN and AN associated with obesity are usually mild and easy to diagnose in light of a positive family history, or apparent obesity, respectively.

### Therapeutic Principles

Treatment depends on the underlying condition. In obesity-associated AN weight reduction reduces AN. In patients with AN maligna complete removal of the underlying tumor is curative while in syndromes with insulin resistance treatment of hyperinsulinemia will improve AN. Drugs known to induce AN (systemic corticosteroids, nicotinic acid, estrogens, oral contraceptives, methyltestosterone, and topical fucidinic acid) should be replaced or reduced in their dosage when possible. Symptomatic treatment has been described in anecdotal reports and includes topical keratolytics, podophyllin, retinoids, calcipotriol as well as systemic cyproheptadine and dietary fish oil supplement in some cases [1].

## Accelerated Idioventricular Rhythm

Federico Fracassi, Alessia Diana
Dipartimento Clinico Veterinario, Università degli Studi di Bologna, Bologna, Italy

### Synonyms

Slow ventricular tachycardia; AIVR

### Definition and Characteristics

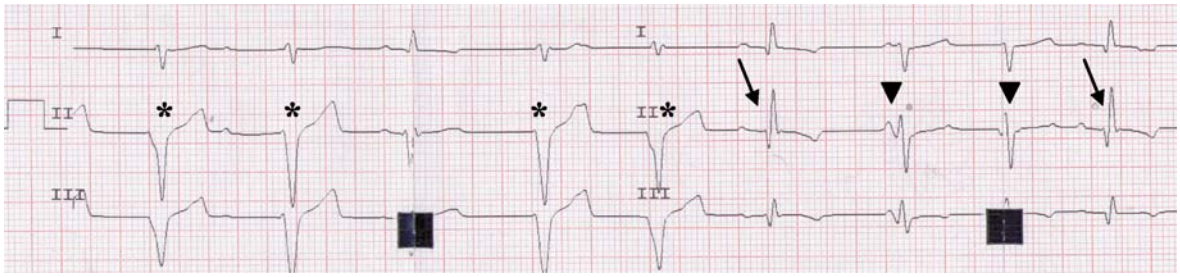
Accelerated idioventricular rhythm (AIVR) is an ectopic rhythm with three or more consecutive ventricular premature beats with a faster rate than the normal ventricular intrinsic escape rate (30–40 beats/min) but slower than ventricular tachycardia.

### Prevalence

Clinically, AIVR can occur in conjunction with any heart disorder (e.g., coronary artery disease, rheumatic heart disease, dilated cardiomyopathy, acute myocarditis, hypertensive heart disease and digitalis intoxication) or in absence of apparent heart disease both in adults and in children. No age and sex predilection have been described.

### Molecular and Systemic Pathophysiology

Accelerated idioventricular rhythm is generated by abnormalities in the ventricular myocardium that set up the mechanisms for generating an ectopic rhythm (reentry, abnormal automaticity and triggered activity) but abnormal automaticity is likely the electrophysiological mechanism behind the genesis of AIVR. In particular, enhanced phase-4 depolarization of the ventricular muscle fibers is the underlying mechanism in many cases. Several conditions, including myocardial ischemia (especially inferior wall ischemia or infarction), digoxin toxicity, electrolyte imbalance (e.g., hypokalemia) and hypoxemia may accentuate the phase-4 depolarization in the subordinate pacemaker tissues of the atrioventricular (AV) junction or His-Purkinje system, thus increasing the rate of impulse generation. Accelerated idioventricular rhythm occurs when the rate of an ectopic ventricular focus exceeds the sinus rate because of sinus slowing or when the ventricular focus accelerates sufficiently to overtake



**Accelerated Idioventricular Rhythm. Figure 1** Three leads (I, II, and III) ECG showing an accelerated idioventricular rhythm. The QRS complexes (asterisk) are wide and bizarre and have large negative amplitudes and an overall uniform appearance with T waves of opposite polarity. Note the capture complexes (arrows) and the fusion beats (head arrows) inserted into run of accelerated idioventricular rhythm. Paper speed = 50 mm/sec; 5 mm = 1 mV.

the sinus rate. Because the ventricular ectopic rate and the sinus rate are similar, both compete for the dominance of the cardiac rhythm.

## Diagnostic Principles

The electrocardiographic features of AIVR are following (Fig. 1)

- Three or more consecutive ventricular premature beats with a faster rate than the normal ventricular intrinsic escape rate (30–40 beats/min) but slower than ventricular tachycardia;
- Gradual onset when the rate of ectopic ventricular focus exceeds the sinus rate because of sinus slowing or when the ventricular focus accelerates sufficiently to overtake the sinus rate;
- Gradual termination when the sinus rhythm accelerates and/or the ectopic ventricular rhythm decelerates;
- Presence of fusion beats when the two pacemaker sites compete for the control of ventricular depolarization;
- Presence of capture beats because of the slow rate of the ectopic ventricular focus;
- Usually one regular ventricular focus, rarely multiform irregular ventricular foci.

## Therapeutic Principles

Accelerated idioventricular rhythm associated with an absence of a paroxysmal onset of the arrhythmia, a slow rate of the ventricular ectopic focus and intermittence of the ventricular runs is usually hemodynamically well tolerated with benign prognosis. Therefore, administration of specific antiarrhythmic drugs is not required but any underlying heart disorder must be cared.

## Achalasia

Thomas Frieling
Medical Clinic II, Helios Klinikum Krefeld, Krefeld, Germany

### Synonyms

Cardiospasm; Aperistalsis; Megaesophagus; Esophageal dystonia; Dolichoesophagus

### Definition and Characteristics

The defining characteristics of achalasia are failure of the esophago-gastric-junction (EGJ) high-pressure zone to relax adequately with swallowing and aperistalsis in the smooth muscle esophagus as measured by manometry. The lower esophageal resting pressure (LES) is elevated in 60% [1]. The functional significance is of poor bolus transit as evident by fluoroscopy, scintigraphy or impedance measurement. Dysphagia is a fundamental symptom of achalasia and is perceived as a relative obstruction to the passage of food or liquid from the oral cavity to the stomach. However, other symptoms such as regurgitation, chest pain, heart burn, and weight lost may predominate. Achalasia has been divided into classic and vigorous forms, the latter defining a subset of patients with higher mean simultaneous esophageal contraction amplitudes. However, the cutoff values for higher esophageal contractions has been arbitrarily (>50–70 mmHg) and much overlap with classic achalasia (esophageal dilation, tortuosity, tertiary contractions, chest pain, response to pneumatic dilation) may be detected. Achalasia may be primary (idiopathic) or secondary. Secondary achalasia can be caused by infiltration of the LES (carcinoma, lymphoma, amyloidosis), as a result of a paraneoplastic syndrome (pseudoachalasia), by protozoal infection with Trypanosoma cruzi (Chaga disease) or surgery (fundoplication, gastric banding, vagal injury).

### Prevalence

Achalasia is a relatively rare condition. Prevalence appears to be less than 10/100,000. Incidence ranges from 0.03 to 1 case per 100,000 people per year. The incidence increases with age and peaks in the seventh decade. Additionally, a small incidence peak occurs in the 20–40 years age group. Hereditary components are not proven yet and there is only one single twin study. However, familial occurrence of achalasia may be detected [2]. Allgrove's, or 4 À' syndrome may be a rare cause of achalasia.

### Molecular and Systemic Pathophysiology

Achalasia is the most recognized motor disorder of the esophagus and the only primary motility disorder with an established pathology. The complex physiology of esophageal motility provides several potential pathological defects that may lead to achalasia. Potential targets include extrinsic and intrinsic inervation, interstitial cells of Cajal (ICC), and smooth muscle. Among the most consistent described abnormalities is the loss of myenteric nerve fibres in the LES and esophageal body. Substantial decrease or complete lack of NOS positive innervation in the myenteric plexus of the LES as well as possibly also in the gastric fundus have been reported in human. The neuronal loss is not selective for nitrergic nerves and eventually also affects other neurons including cholinergic neurons. Immunohistochemical techniques have demonstrated the presence of a lymphocytic infiltrate and collagen deposition within the myenteric plexus. There is little evidence to suggest a defect in smooth muscle, but together with loss of myenteric neurons, secondary loss of ICC may occur. It has been suggested that an immune mediated process accounts for the loss of myenteric neurons and that loss of nitrergic neurons may be early in the development of achalasia (e.g. vigorous achalasia) with generalized neuronal loss later in the disease process. The findings of circulating antineuronal nuclear autoantibody type 1 (anti-Hu) in secondary achalasia caused by paraneoplastic syndromes and antineuronal antibodies in serum of primary achalasia patients labeling myenteric and submucosal neurons suggest an autoimmune etiology. The concept that circulating mediators may contribute to the development of

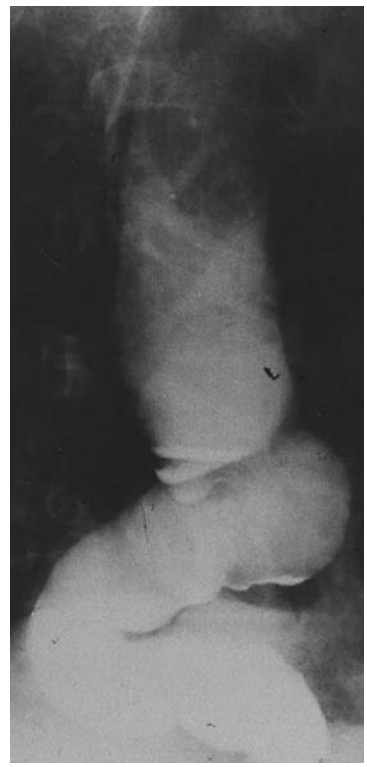
achalasia is also supported by the finding that serum from achalasia patients alters neurochemical coding in the myenteric plexus and NO-mediated motor response in normal human fundus [3].

## Diagnostic Principles

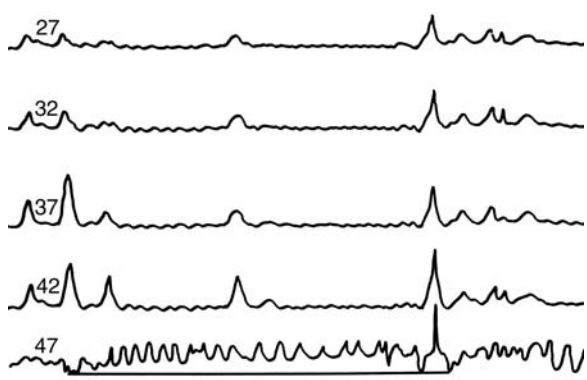
The diagnosis of achalasia should be suspected in anyone with dysphagia for solids and liquids with regurgitation of food and saliva. Patients usually learn to live with their dysphagia by using various manoeuvres, including lifting the neck or drinking carbonated beverages to help empty the esophagus. Regurgitation becomes a problem with progression of the disease, especially when the esophagus begins to dilate. Heartburn is a frequent complaint and chest pain occurs in some patients. Most patients with achalasia have some slight degree of weight loss. Patients with achalasia often develop dysphagia for solids and fluids simultaneously, whereas patients with esophageal peptic or tumor stenosis complain about dysphagia only for solids at the beginning and develop dysphagia for fluids later on disease progress with increasing stenosis. However, in any case, esophageal cancer has to be ruled out by upper GI endoscopy. In achalasia, the endoscope can be easily pushed through the LES into the stomach whereas rigidity is always suspicious of malignoma. Endoscopy together with endoscopic ultrasonography and computed tomography may also be helpful to make the diagnosis of pseudoachalasia. In addition, it has been suggested that patients with achalasia more likely develop esophageal carcinoma. When achalasia is suspected, a barium swallow with fluoroscopy should be obtained. Early in the disease, the esophagus is normal in diameter, but with a loss of normal peristalsis replaced by to-and-fro movement in the supine position. As the disease progresses, the esophagus becomes more dilated and tortuous, does not empty, and retained food and saliva produce a heterogeneous air-fluid level at the to of the barium collum. The distal esophagus is characterized by by a smooth tapering leading to the closed LES, resembling bird's beak (Fig. 1).

Esophageal manometry is the gold standard by which to establish the diagnosis of achalasia. However, it does not rule out pseudoachalasia. Characteristic is aperistasis of the smooth muscle part of the tubular esophagus, meaning that all wet or dry swallows are followed by simuataneous contractions that are identical to each other (isobaric or mirror images) (Fig. 2).

In addition, abnormal LES function is seen in all patients with achalasia, incomplete or absent LES relaxation in 70–80% and shortened and functionally inadequate LES relaxation (<6 sec) in 20–30% of patients. The sphincter pressure is usually raised, but can be normal in 20–40% of patients.



**Achalasia. Figure 1** Achalasia of the esophagus showing elongated and tortuated esophagus following barium swallow.



**Achalasia. Figure 2** Esophageal manometry illustrates characteristic aperistalsis of the tubular esophagus (manometry ports at 27, 32, and 37 cm inc.) with simultaneous contractions of low amplitude. The LES (47 cm inc.) fails to relax upon swallowing.

## Therapeutic Principles

Esophageal aperistalsis and impaired LES relaxation is usually not reversed by any mode of therapy. Therefore, every treatment option for achalasia is limited to

reducing the pressure gradient across the LES, thus facilitating esophageal emptying by gravity and preventing development of megaesophagus [4,5]. This can be achieved most effectively by pneumatic dilation, surgical myotomy, or, less effectively by pharmacological agents injected endoscopically into the LES (e.g. botulinum toxin) or taken orally (e.g. calcium-channel blockers or nitrates). Dilation and myotomy both provide definitive therapy for the majority of patients, whereas smooth-muscle relaxants provide only minor relief with decreasing effectiveness with time. Therefore, pneumatic dilation of the LES is usually the first treatment choice. The clinical response upon dilation improves proportionally with increasing balloon diameter. About 30–40% of patients might require subsequent dilations. This can be performed several times, however, the success rate may decrease with subsequent dilations. The main adverse event with pneumatic dilation is esophageal perforation, which occurs at a cumulative rate of 2%. For unknown reasons, dilation is less effective in children. Surgical myotomy for achalasia involves carrying out an anterior myotomy across the LES (Heller's myotomy). Myotomies are usually done laparocopically through the abdomen and may be combined with an antireflux procedure (loose Nissen fundoplication, incomplete Toupet, Dor fundoplication). Endoscopic injection of botulinum toxin type A into the LES inhibits the release of acetylcholine from nerve terminals, thereby countering the effect of the selective loss of inhibitory neurotransmitters. It is initially effective in 80–90% of patients, however, symptoms may recur in more than 50% of these patients within 6 months, possibly because of regeneration of the affected receptors. It has been suggested that older patients (>60 years) and those with vigorous achalasia are more likely to have a sustained responses to botulinum toxin. However, injection of botulinum toxin should be reserved to those patients who are not candidates for pneumatic dilation or surgical myotomy.

# Achondrodoplasia

Susanna Mac, Dan Donoghue
Department of Chemistry and Biochemistry, University of California-San Diego, La Jolla, CA, USA

## Synonyms

Dwarfism for achondroplasia group; Ach

## Definition and Characteristics

For Ach group, autosomal dominant FGFR3 mutations with complete penetrance leading to dwarfism and other defects, some of which are neonatal lethal. FGFR2 mutations are associated with craniosynostosis and syndactyly. SHOX haploinsufficiency, including in Turner's syndrome, is associated with short stature and other skeletal defects.

## Prevalence

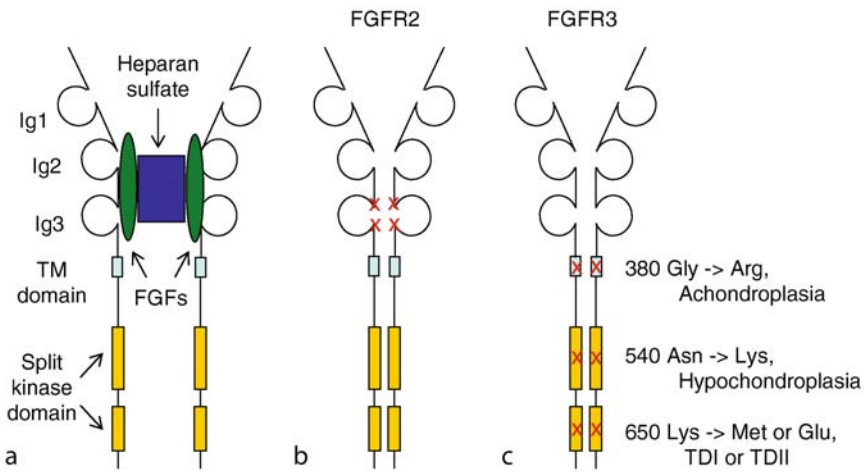
For Ach group, prevalence varies from 1/10,000 to 1/40,000, with 7/8 of mutations being sporadic. SHOX is mutated in 2% of children with short stature.

## Genes

FGFR3 on chromosome 4p16.3, FGFR2 on chromosome 10q25.3–q26. SHOX is on chromosome Xpter-p22.32, in pseudoautosomal region 1 (so not inactivated with X inactivation).

## Molecular and Systemic Pathophysiology

Fibroblast growth factor receptors (FGFRs) are receptor tyrosine kinases with an extracellular ligand binding domain consisting of three Ig domains, a transmembrane domain, and a cytoplasmic kinase domain (Fig. 1). These receptors are activated by fibroblast growth factors (FGFs) in conjunction with heparan sulfate. After activation, the receptors dimerize and autophosphorylate, leading to signal transduction through various pathways. The FGFR mutations are gain-of-function, activating through stabilizing dimers or leading to constitutively active kinases. As FGFR3 is important for growth regulation of long bones, activating mutations result in short-limbed dwarfism and mid-face hypoplasia. Disease severity varies with the degree of FGFR3 activation, such that the more benign forms of hypochondroplasia, exhibiting mild short stature, and achondroplasia (Ach),



**Achondrodoplasia. Figure 1** (a) Depicted is a general schematic of fibroblast growth factor receptors (FGFRs), which exist as dimers when activated. In the monomer, the extracellular ligand binding domain is made up of three Ig domains (Ig1, Ig2, Ig3) which bind fibroblast growth factors (FGFs) in conjunction with heparan sulfate. Shown is one possible configuration of two FGF molecules, heparan sulfate and an FGFR dimer. FGFRs also have a single pass transmembrane (TM) domain and a split kinase domain. (b) In Apert, Crouzon and Pfeiffer syndromes, FGFR2 is activated by mutations (depicted by x) which disrupt the intrachain disulfide bonds of Ig3, allowing unpaired cysteines to form interchain disulfide bonds, resulting in dimerization. (c) Activating FGFR3 mutations (depicted by x) result in various dwarfism syndromes, ranging from achondroplasia (380 Gly → Arg) and hypochondroplasia (540 Asn → Lys) to the more severe neonatal lethal thanatophoric dysplasias, TDI (650 Lys → Met) and TDII (650 Lys → Glu).

exhibiting short limbed dwarfism, are associated with mildly activating mutations, 540 Asn → Lys and 380 Gly → Arg respectively. Mutations in the kinase loop which result in greater activation, such as 650 Lys → Met and 650 Lys → Glu are associated with the neonatal lethal thanatophoric dysplasia (TD) syndromes TDI and TDII respectively. As FGFR2 is important for skull bone fusion, FGFR2 mutant syndromes Apert and Crouzon and Pfeiffer exhibit craniosynostosis and syndactyly. FGFR2 mutations disrupt the intrachain disulfide bonds that form the Ig domains of the extracellular domain. The unpaired cysteines can then form interchain disulfide bonds, resulting in dimerization and activation of the mutant FGFR2.

SHOX (short stature HOmeoboX containing gene), also known as PHOG (pseudoautosomal homeobox containing osteogenic gene), haploinsufficiency is associated with idiopathic short stature, as well as short stature in various syndromes, such as Turner's (XO), Leri-Weill dyschondrosteosis (LWD), and Langer. As loss of SHOX is associated with premature growth plate fusion, SHOX appears to repress growth plate fusion and skeletal maturation in distal limbs. Loss of SHOX appears to account for some of the skeletal defects associated with Turner's syndrome (in which one copy of the SHOX gene is deleted), including the Madelung deformity (which is bilateral shortening and bowing of the radius with a dorsal subluxation of the distal ulna), short fourth metacarpals, cubitus valgus, and sensorineural deafness.

## Diagnostic Principles

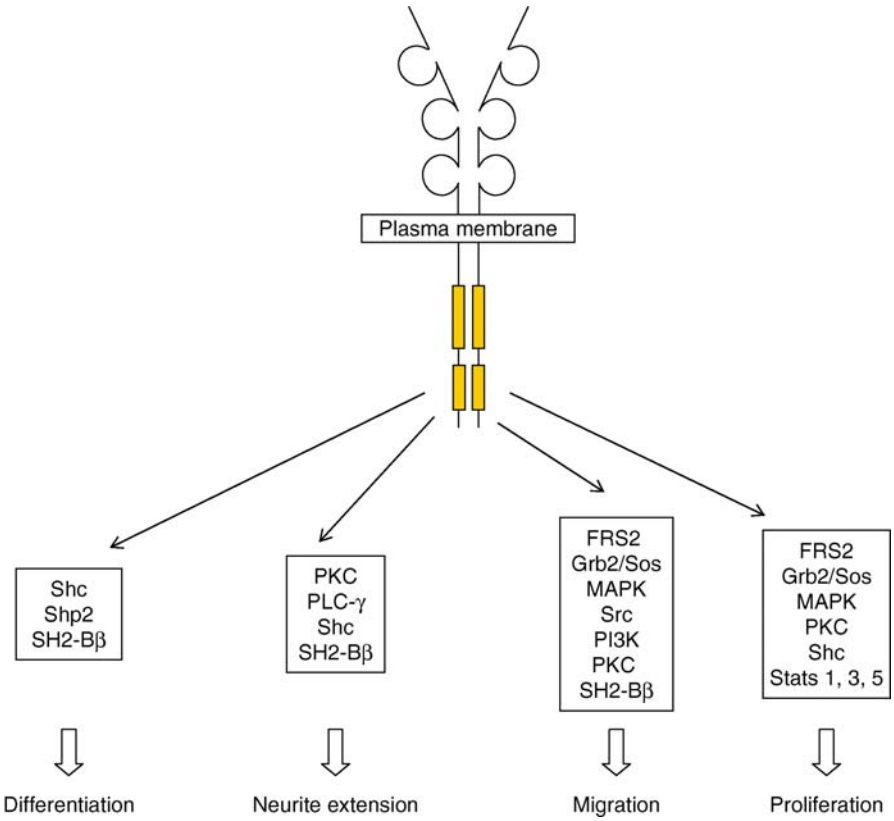
The neonatal lethal syndromes TDI and TDII can be diagnosed before birth, by ultrasound, or at birth, by presentation of very short limbs and large heads with midfacial hypoplasia. TDII patients have long straight femurs, while TDI patients have short curved femurs. Patients with Ach present with short limb dwarfism and large heads with midfacial hypoplasia. Diagnosis is confirmed by X-rays, as achondroplasia patients exhibit large calvarial and small facial bones, as well as other abnormalities.

SHOX haploinsufficiency should be considered in children with otherwise unexplained short stature, and especially in patients with any X chromosome abnormalities, such as those with Turner's syndrome.

## Therapeutic Principles

Growth hormone, GnRH analog or antiestrogen for SHOX haploinsufficiency. Ach-surgery for stenotic spinal cords and tibial bowing.

►Physeal Dysplasia



**Achondrodoplasia. Figure 2** Once activated by ligand or mutation, fibroblast growth factor receptors (FGFRs) dimerize and autophosphorylate, leading to signal transduction through various pathways. These pathways, some of which are depicted here, activate different cellular processes, such as differentiation, neurite extension, migration and proliferation.

# Achromatopsia

Susanne Kohl
Molecular Genetics Laboratory, Institute for Ophthalmic Research, Center for Ophthalmology, University of Tuebingen, Tuebingen, Germany

## Synonyms

Rod monochromatism; Rod monochromacy; Total colorblindness; Pingelapese blindness

## Definition and Characteristics

Achromatopsia is a rare autosomal recessively inherited disorder of the retina, characterized by nonprogressive low vision from early infancy, pendular nystagmus, photophobia, loss of color discrimination, absent photopic, but normal scotopic electroretinographic (ERG) responses.

Most individuals have complete achromatopsia with total lack of function of all three types of cone photoreceptors. Rarely, individuals have incomplete achromatopsia, in which symptoms are less severe.

## Prevalence

Estimated prevalence is less than 1:30,000 [1]. On the island of Pingelap in Micronesia, the prevalence of achromatopsia or 'Pingelapese blindness' is between 1:25 and 1:100 [2], secondary to gene drift and the founder mutation S435F in the CNGB3 gene.

## Genes

CNGA3 (ACHM2 locus; OMIM *600053, #216900) on Chr. 2q11.2 encodes the alpha-subunit of the cyclic nucleotide-gated channel 3 and consists of 8 exons distributed over 53 kb of genomic sequence. The 3.8 kb mRNA transcript generates a 749 amino acid polypeptide. In the retina it is cone-specific.

Mutations in CNGA3 account for 20–25% of all patients and have been described in autosomal recessive complete and incomplete achromatopsia, and also cone dystrophy [3]. Most CNGA3 mutant alleles are missense mutations that spread over the whole gene and protein.

CNGB3 (ACHM3 locus; OMIM *605080, #262300) on Chr. 8q21–q22 consists of 18 exons encompassing over 200 kb of genomic sequence and encodes the 809 amino acid long beta-subunit of the cyclic nucleotide-gated channel 3. Northern blot analysis revealed a major transcript of 4.4 kb, specifically expressed in cones.

The vast majority of CNGB3 mutations give rise to truncated polypeptides and several recurrent mutations have been found: the most common mutation c.1148delC accounts for 75% of all CNGB3 mutant alleles. CNGB3 mutations are found in 45–50% of all achromats, rendering the ACHM3 locus the major locus for autosomal recessive achromatopsia [4].

GNAT2 (ACHM4 locus, OMIM + 139340) on Chr. 1p13 encodes the guanine nucleotide-binding protein, alpha-transducing activity polypeptide 2 (syn.: cone transducin). Eight exons form a transcriptional unit of 9967 bp and code for a 354 amino acid polypeptide. Northern blot analysis revealed a cone-specific major transcript of 1.7 kb.

Mutations in GNAT2 play only a minor role in autosomal recessive achromatopsia, accounting for less than 2% of all patients with complete and incomplete achromatopsia, and also a very mild phenotype of oligo-cone trichromacy [5].

## Molecular and Systemic Pathophysiology

CNGA3 and CNGB3 encode the alpha- and beta-subunit of the cone photoreceptor cGMP-gated channel (CNG channel), while GNAT2 encodes the cone-specific alpha-subunit of transducin, the G-protein that couples to the cone visual pigment (Fig. 1). Transducin thus mediates one of the first steps of the phototransduction cascade, while the CNG channels represent the final component.

An animal model may help to clarify the underlying pathogenic mechanisms. The analysis of the CNGA3 knockout mouse model shows complete absence of physiologically measurable cone function, a decrease in the number of cones in the retina, and morphologic abnormalities of the remaining cones. CNGA3(–/–) cones fail to transport opsin into the outer segment and down-regulate various proteins of the phototransduction cascade. Apoptotic cell death is induced.

Autosomal recessive canine cone degeneration (cd) in the Alaskan malamute and the German shorthaired pointer breeds is due to mutations in the canine CNGB3 gene. Cd pups develop dayblindness and photophobia, but remain ophthalmoscopically normal throughout life. Cone function is detectable in electroretinograms in very young cd-pups, but begins to fail at a few weeks of age and is undetectable in mature cd-affected dogs. Adult cd-retinae lack all cones.

In addition, heterologous *in vitro* expression of mutant CNG channels have shown that the mutations observed in human achromats can disrupt channel function, including defects in protein production, trafficking and processing, and altered single channel properties.

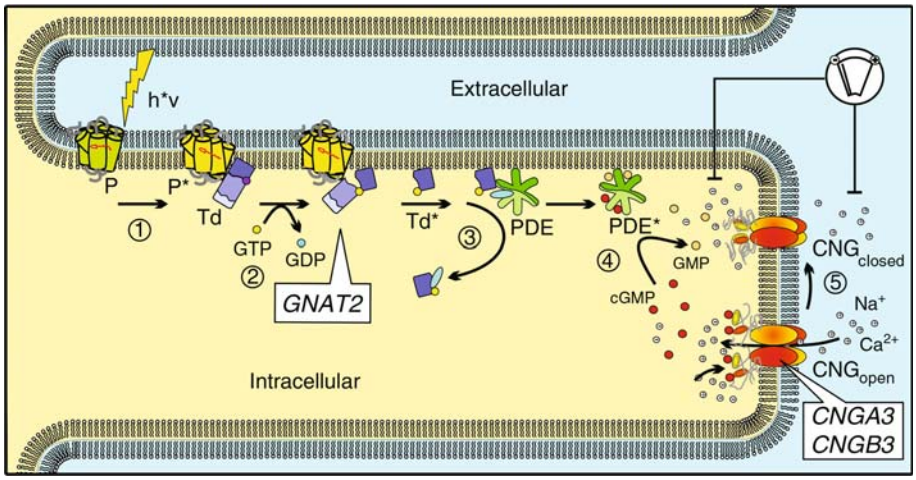
Cpfl3 (cone photoreceptor function loss) mice are a model for GNAT2 associated achromatopsia and have poor cone-mediated responses on electroretinograms at 3 weeks of age that become undetectable by 9 months. Rod function is initially normal, but declines with age. Microscopy of retinae reveal progressive vacuolization of photoreceptor outer segments. Immunocytochemistry with cone-specific markers show progressive loss of labelling for alpha-transducin, but cone outer segments remain intact throughout life.

## Diagnostic Principles

Diagnosis of achromatopsia is based on color vision tests (Farnsworth Munsell 100-Hue test; saturated/desaturated Panel D-15 test, Rayleigh anomaloscope equation), electrophysiology (single-flash/30-Hz flicker electroretinogram), fundus appearance, and visual fields.

## Therapeutic Principles

In the absence of causal therapy, the treatment of achromatopsia includes dark or special filter glasses, red-tinted contact lenses to reduce photophobia and improve visual acuity, low vision aids, and occupational aids. Surveillance includes regular ophthalmologic examination. To avoid additional light damage to the



**Achromatopsia. Figure 1** Schematic drawing of the phototransduction cascade in the cone outer segment. Components known to be associated with autosomal recessive achromatopsia are highlighted. The visual pigment (P) of the photoreceptor cell consists of the transmembrane-spanning protein opsin and the chromophore 11-*cis*-retinal. Following the absorption of a photon (hv) [1], the light-activated P* repeatedly contacts the G-protein transducin Td catalyzing the exchange of GDP for GTP at the guanosine binding site of the transducin alpha-subunit (GNAT2) and its subsequent release from the inhibitory beta/gamma-subunits [2]. The activated GTP•transducin Td* then binds the inhibitory gamma-subunit of the phosphodiesterase (PDE) thereby activating the catalytic alpha'-subunits of the membrane-associated PDE [3]. The heterotetrameric cGMP-gated cation channels (CNG), consisting of two alpha- (CNGA3) and two beta-subunits (CNGB3), are directly gated by cGMP and control the influx of cations across the photoreceptor plasma membrane in the dark. The hydrolysis of cGMP by the activated PDE* [4] results in a decrease of the intracellular cGMP level and in channel closure [5]. This decreases the conductance of the plasma membrane to the cation influx, and results in the hyperpolarization of the plasma membrane, inhibition of neurotransmitter release at the synaptic ends, and signalling of the light stimulus to adjacent neurons.

retina, appropriate protective (dark) glasses in bright light are recommended.

### Synonyms

Acidemia

### Definition and Characteristics

*Acidemia* is defined by a reduced blood pH, which reflects increased hydrogen ion concentration [$H^+$], whereas *acidosis* is used to describe the processes leading to acidemia either of metabolic or respiratory origin. Normally, blood [$H^+$] is ≈40 nmols/L, corresponding to an arterial blood pH of 7.35–7.45. Blood arterial $pCO_2$ is maintained between 36 and 40 mmHg and blood [$HCO_3^-$] between 24 and 26 mEq/L.

*Metabolic acidosis* (MA) is an acid/base disorder caused by a primary decrease in plasma [$HCO_3^-$]. Both types of acidosis lead to acidemia despite compensatory responses which attenuate it. Compensatory responses for MA include: (i) extracellular and intracellular buffering, (ii) increased ventilation (blood $pCO_2$ decreases by ≈1.2 mmHg per each 1.0 mEq decrease in plasma [$HCO_3^-$] to a nadir of 12–15 mmHg in 12–24 h), and (iii) increased renal acid excretion [1].

### Prevalence

It is very common, particularly among acutely unwell/critical care patients. There are no reliable figures for its overall incidence or prevalence in the population at large.

### Genes

The renal response to metabolic acidosis is mediated, in part, by increased expression of the genes encoding key enzymes of glutamine catabolism and various ion transporters that contribute to the increased synthesis and excretion of ammonium ions and the net production and release of bicarbonate ions (Table 1). Changes in the intracellular pH may affect protein folding in the ER of the renal proximal convoluted tubule and initiate an ER-stress response. This stress response leads to an increased expression of specific genes and cytosolic stress granules. This response generally leads to selective stabilization of the mRNAs that encode the responsive proteins such as ζ-crystallin (ζ-cryst), AU-factor 1 (AUF1), and HuR [2].

### Molecular and Systemic Pathophysiology

During normal acid-base balance, the kidneys extract and metabolize very little of the plasma glutamine. During chronic acidosis, plasma glutamine increases and, moreover, >33% of plasma glutamine is extracted in a single pass through the nephron, exceeding its filtered fraction, and suggesting tubular contribution to the glutamine uptake. Within the mitochondria, glutamine is deaminated by a phosphate-activated glutaminase (GA) and then oxidatively deaminated by glutamate dehydrogenase (GDH) to yield two ammonium ions and α-ketoglutarate. This pathway generates two $H^+$ and two $HCO_3^-$ ions per mole of α-ketoglutarate. During chronic metabolic acidosis

ammonium excretion increases three to ten fold. The adaptation occurs throughout the nephron particularly in the proximal tubule and the collecting tubule [3].

Chronic MA results in alterations in nitrogen balance, protein synthesis, and muscle proteolysis. In the kidney, MA increases sodium and potassium excretion. Mineral balance effects of MA are hypercalciuria as a result of (i) enhanced bone resorption, (ii) reduced tubular calcium reabsorption and (iii) parathyroid hormone (PTH) resistance. Citrate excretion is reduced. MA may alter [1,25$(OH)_2$D]s and PTH levels. In children, reversible growth failure is a dramatic consequence of chronic MA. Cardiovascular effects include negative inotropism, reduced fibrillation threshold, peripheral vasodilatation, and central vasoconstriction.

MA is caused by three general mechanisms (i) organic acid overproduction (e.g. lactic acidosis) or overdosing with toxins (e.g. methanol) that accumulate $H^+$ and consume bicarbonate; (ii) inability of the kidneys to excrete acid as in chronic kidney insufficiency; and (iii) gastrointestinal or renal bicarbonate loss. It is convenient to divide the causes of MA on the basis of plasma anion gap:

1. High AG acidosis:
   Lactic acidosis, ketoacidosis (diabetic, starvation, alcohol, inborn errors of metabolism), toxins (salicylates, methanol, ethylene-glycol) and renal failure.
2. Normal AG acidosis:
   Bicarbonate loss (diarrhea, ureteral-gastrointestinal diversions), renal tubular acidosis, chronic kidney disease, drugs (triamterene, amiloride, spironolactone), acid loads (ammonium chloride, parenteral nutrition) [4].

## Diagnostic Principles

*Plasma anion gap (AG):* The plasma AG helps differentiate hyperchloremic metabolic acidosis (normal AG) from high AG metabolic acidosis. In the former there is an increase in plasma chloride equivalent to the fall in plasma bicarbonate whereas in the latter the fall in plasma bicarbonate is matched by an increase in an unmeasured anion such as lactate. The concept of the plasma AG is based on the principle of electro neutrality: The sum of all anions must equal all the cations: [$Na^+ + K^+$ + unmeasured cations (calcium, magnesium, others)] = [$Cl^- + HCO_3^-$ + unmeasured anions (albumin, phosphate, sulfate and organic acids)]. Potassium can be omitted because of its small magnitude.

$AG = Na^+ - [Cl^- + HCO_3^-]$ = normally 10–12 mEq/L

To account for hypoalbuminemia, the following correction should be made:

Albumin-corrected AG = AG + 2.5*(4.4 − albumin in g/dl) [5].

## Therapeutic Principles

Treatment is based on removing the underlying cause. When MA is acute the focus should be the correction of the blood pH. If acidosis is severe, blood pH less than 7.20, then the administration of bicarbonate is usually required. Blood $pCO_2$ should be appropriately low either by spontaneous compensation or by ventilatory support. The treatment of chronic MA should focus on the correction of the bicarbonate deficit to prevent the cumulative long term complications of acidosis mainly on bone disease, growth and skeletal muscle.

## Synonyms

Renal acidosis; Hyperchloremic metabolic acidosis; RTA

## Definition and Characteristics

Renal tubular acidosis (RTA) is a syndrome characterized by hyperchloremic metabolic acidosis secondary to defective renal acidification caused by either impaired tubular reabsorption of filtered bicarbonate, defective renal $H^+$ excretion or both, in the absence of markedly decreased glomerular filtration rate. The resulting decrease in the rate of net acid excretion is insufficient to maintain the normal acid load generated from diet and a metabolic acidosis ensues [1].

RTA was initially separated into three types: distal RTA (DRTA) (type 1), from a direct inhability to secrete acid in distal nephron, proximal RTA (type 2) caused by defective proximal bicarbonate reabsorption, and a combined proximal and distal RTA (or type 3), which represents a transient phenomenon consequence of proximal immaturity in infants with DRTA or due to carbonic anhydrase (CA) deficiency. Type 1 and type 2 are usually associated with hypokalemia. Type 4 RTA designates a hyperkalemic form associated with aldosterone deficiency. An additional type of hyperkalemic distal RTA referred to as voltage dependent DRTA was later described where there is secretory failure for both hydrogen ions and potassium possibly related to impaired sodium reabsorption in the distal nephron. It was first described in patients with chronic obstructive uropathy, and resembles the distal RTA caused by the administration of amiloride and other epithelial sodium channel (ENaC) antagonists such as triamterene and pentamidine. Incomplete DRTA is defined as impaired ability to maximally decrease urinary pH after acid loading but absence of spontaneous metabolic acidosis (Table 1).

## Prevalence

The acquired forms of distal RTA are common in patients with chronic interstitial nephropathies such as obstructive uropathy, but the precise prevalence is unknown. Isolated hereditary proximal RTA is an extremely rare disorder, but proximal RTA as part of the Fanconi syndrome is more common. Similarly, hereditary DRTA is relatively rare.

## Genes

Inactivating mutations in SLC4A4, the gene coding for the $Na^+/HCO_3^-$ symporter (OMIM 604278), cause permanent isolated proximal RTA with various ocular abnormalities such as band keratopathy, glaucoma, and cataracts, as it is abundantly expressed in ocular tissues. Recessive mixed proximal-distal RTA accompanied by osteopetrosis and mental retardation is caused by inactivating mutations in the cytoplasmic carbonic anhydrase II gene (OMIM 259730) [1].

Hereditary DRTA is a genetically heterogeneous disorder with mutations identified in the genes encoding the anion exchanger (AE1), cytosolic carbonic anhydrase enzyme (CA II), and $H^+$ -ATPase (B1 and A4 subunits) (Table 2) [1–3]. AE1 gene mutations are often responsible for the autosomal-dominant type of DRTA (OMIM 179800) or autosomal-recessive (OMIM 109270). ATP6V1B1 mutations are associated with autosomal-recessive DRTA and severe deafness in childhood (OMIM 267300), whereas ATP6V0A4 mutations (OMIM 602722) are associated with mild hearing loss that develops later, in early adulthood. Deficiency of CA II is also the primary defect underlying the autosomal-recessive syndromes of osteopetrosis, renal tubular acidosis, and cerebral calcification [1].

## Molecular and Systemic Pathophysiology

An average western diet generates ~60–80 mEq of acid per day (~1 mEq/Kg body weight). The kidney eliminates 1/3 of acid excess as phosphate and other weak acids collectively referred to as titratable acidity (TA), and about 2/3 as ammonium ($NH_4^+$). Freely filtered bicarbonate (~4,320 mEq daily) is largely reabsorbed at the proximal tubule (PT). The process involves luminal secretion of $H^+$ by a specific $Na^+/H^+$ exchanger (NHE-3), and basolateral absorption of $HCO3^-$ via a specific $1Na^+/3HCO_3^-$ co-transporter (NBC-1). Simultaneously, the actively secreted $H^+$

reacts with $HCO_3^-$ to form $H_2O$ and $CO_2$ by CA type IV at the luminal membrane. The net result is the removal of a filtered $HCO_3^-$ and a transfer of one $HCO_3^-$ to the blood compartment (Fig. 1).

In the α-type intercalated cell of the cortical collecting duct (CCD), $H^+$ secretion is tightly regulated by $H^+$ pumps on the apical surface that actively secrete acid to the lumen. The net urinary elimination of $H^+$ depends on its buffering and excretion as TA and $NH_4^+$. Availability of phosphate as a buffer depends on the amount filtered, whereas $NH_4^+$ is stimulated by acidosis via increased production of $NH_3$ in the proximal tubule followed by a complex process of $NH_4^+$ transport in the thick ascending limb and final transfer to the collecting tubule as $NH_3$, which reacts with secreted $H^+$. $NH_4^+$ excretion leads to the new addition of $HCO_3^-$ to the blood via $Cl^-/HCO_3^-$ exchange, through an anion exchanger (AEI), at the basolateral cellular surface. Cytoplasmic CA type II is also involved in this process (Fig. 2).

Urinary Anion Gap (UAG) can be used as a tool to roughly estimate urinary ammonium. The major anions in the urine include $Cl^-$, $HCO_3^-$, sulfate, phosphate, and organic anions. The main cations are $Na^+$, $K^+$, $NH_4^+$,

$Ca^{++}$, and $Mg^{++}$. Since only urinary $Cl^-$, $Na^+$, and $K^+$ are routinely measured, it follows that $Cl^- + UA = Na^+ + K^+ + UC$. $UAG = UA - UC = (Na^+ + K^+) - Cl^-$. $NH^+$ is an abundant cation in the urine particularly when acidosis is present and thus changes in its concentration will affect the UAG [4]. Therefore, UAG is most helpful in differentiating patients with distal RTA in whom the UAG is increased (i.e. positive), from other causes of hyperchloremic acidosis such as diarrhea with an enhanced $NH_4^+$ excretion resulting in a decreased UAG (i.e. negative). Urinary sodium availability affects the ability to lower pH, and in salt-retaining states distal $H^+$ secretion may be impaired.

## Diagnostic Principles

The clinical phenotype of patients with RTA, particularly in the hereditary forms, often suggests the diagnosis in the context of a non-anion gap metabolic acidosis. Primary proximal RTA is characterized by vomiting and growth retardation early in infancy, eventually with psychomotor delay and sometimes ocular abnormalities. In secondary forms, patients' symptoms are those of Fanconi syndrome and underlying disorders. Prominent clinical features in patients with primary DRTA include growth retardation, polyuria, hypercalciuria, and nephrocalcinosis-lithiasis. Hypokalemia is a feature of both proximal and distal RTA. In

some cases of hereditary DRTA, severe hypokalemia causing muscle paralysis is the form of presentation [5]. Neurosensory deafness is a clue to the presence of DRTA caused by ATP6V1B1 mutations. In secondary forms, the primary disease may be responsible for the main symptoms. The hyperkalemic forms are usually asymptomatic and diagnosed based on hyperkalemic metabolic acidosis.

During acidosis, patients with proximal RTA can lower the urine pH <5.5. Ammonium excretion is only slightly reduced or even normal. During correction of the acidosis, with alkali loading, urine pH is high and fractional bicarbonate excretion is higher than normal (5–15%).

Type I DRTA is characterized by low plasma potassium and reduced net acid excretion. Ammonium excretion is low and this can be inferred by the finding of a positive UAG. The urine pH is >5.5 regardless of the degree of the acidosis. $K^+$ and $Ca^{++}$ are wasted in urine whereas citrate excretion is very low. After an alkali loading, fractional bicarbonate excretion remains <5%, and the urine-blood $pCO_2$ gradient is less than 20 mmHg, reflecting impaired distal $H^+$ secretion.

## Therapeutic Principles

Proximal RTA is treated with high doses of oral bicarbonate or citrate (10–20 mEq/Kg/d), sometimes combined with thiazides to enhance proximal reabosorption of bicarbonate, and the specific treatment of the underlying disease. Primary DRTA requires treatment often throughout life with oral supplements of mixed sodium and potassium bicarbonate, or potassium bicarbonate alone. Infants require as much as 5–8 mEq per Kg of citrate or $HCO_3^-$ per Kg body weight, whereas adults require only about 0.5–1 mEq per Kg body weight. Citrate salts partially correct the hypocitraturia, and prevent nephrolithiasis. Correction of the metabolic acidosis allows normal growth if initiated early in life. In type 4 RTA fludrocortisone combined with loop diuretics and sometimes bicarbonate may be useful.

## Synonyms

Hypercapnia

## Definition and Characteristics

Respiratory acidosis (RA) is an acid-base disorder characterized by a primary elevation of arterial carbon dioxide tension ($PaCO_2$). Compensation for RA involves an increase in plasma $HCO_3^-$ that occurs in two phases: (i) a rapid response from titration of non-bicarbonate buffers which has a modest effect, and (ii) a slower kidney response that leads to suppression of net acid excretion and reduced bicarbonate reabsorption. As a result of these compensations [$HCO_3^-$] rises by about 0.4 mEq/L per each 1.0 mm/Hg increase in blood $pCO_2$ elevation.

## Prevalence

The prevalence of RA is not precisely known, but it is recognized as a common acid-base disorder. According to the National Institutes of Health, ►chronic obstructive pulmonary disease (COPD) kills over 120,000 people in the United States each year and is the fourth leading cause of death and of the top leading causes of death in the U.S., it is the only one that is rising. RA is frequently seen in hospitalized patients particularly those with respiratory failure. Patients with COPD develop chronic RA and exacerbations leading to superimposed acute RA.

## Genes

Specific genes in humans and mice regulate the breathing pattern at baseline and breathing control during chemical stimulation. Most mammalian cells maintain tight control of intracellular pH using a group of transmembrane proteins that specialize in acid-base transport. Exposure to chronic hypercapnia induces changes in expression of acid-base transporters in alveolar and renal epithelial cells [1]. In response to hypercapnia, several transcription

factors such as c-Jun, kinase Fos and small Maf proteins are involved in the brain adaptation to hypercapnia. At the genomic level, hypercapnic acidosis attenuates the activation of nuclear factor-kappaB, a key regulator of the expression of multiple genes involved in the inflammatory response. Hypercapnic stimulation also activates c-Jun $NH_2$-terminal (JNK) cascade via influx of extracellular $Ca^{2+}$ through voltage-gated $Ca^{2+}$ channels. In addition, several transmembrane proteins including Rhombex-29 (rhombencephalic expression protein-29 kDa) and Past-A (proton-associated sugar transporter-A) have been implicated in the regulation of $H^+$ sensitivity and brain acidosis-mediated energy metabolism, respectively (Table 1).

## Molecular and Systemic Pathophysiology

Carbon dioxide ($CO_2$), also known as the "green gas," is a by-product of cellular energy utilization and its elimination is effected by alveolar epithelial cells. The effects of the "green gas" on human health are not completely understood. In patients with acute respiratory failure, gas exchange is impaired due to the accumulation of fluid in the lung airspaces. Non-excitable, alveolar epithelial cells sense and respond to high levels of $CO_2$. Increased levels of $CO_2$ inhibit alveolar fluid reabsorption independently of pH. High $CO_2$, inhibits Na, K-ATPase function, via activation of protein kinase C ζ (PKC), which phosphorylates the Na,K-ATPase, causing it to endocytose from the plasma membrane into intracellular pools [2]. Within a few seconds of high $CO_2$ there is calcium mobilization and activation of AMP-dependent kinase. Once activated, AMPK up-regulates energy-generating pathways while inhibiting energy-consuming events, thereby promoting cellular adaptation to stressful conditions like high $CO_2$ concentrations and activating a signaling cascade leading to the inhibition of alveolar function [3]. Renal epithelial cells also respond to changes in $CO_2$ concentrations via yet unidentified mechanisms, which seem independent of intracellular pH suggesting the existence of a $CO_2$ sensor. RA has been reported to impair cellular functions such as host inflammatory response and other deleterious effects including intracranial bleeding, decreased colonic $Na^+$ transport and changes in pulmonary vascular resistance leading to ventilation/perfusion mismatch.

RA can be *acute* or *chronic*. Acute causes of RA include acute lung injury, aspiration, angioedema, bronchospasm, pulmonary embolism, pneumothorax, severe obstructive sleep-apnea. The most common causes of chronic RA are bronchitis and emphysema leading to chronic obstructive pulmonary disease. Other common causes of chronic RA include central sleep apnea, obesity hypoventilation syndrome, hypothyroidism and severe chronic interstitial lung disease [4].

Most of the important clinical manifestations of hypercapnia result from its effects on the central nervous system (CNS). CNS effects of acute RA include an excitable state, severe breathlessness, disorientation, confusion and coma. Motor effects, which include myoclonic jerks and seizures, occur in both acute and chronic hypercapnia. RA also produces cerebral vasodilation and intracranial hypertension. Cardiovascular effects include depressed myocardial contractility, sympathetic system stimulation, arrhythmias and vascular vasodilatation. In the kidneys, acute RA stimulates antidiuretic hormone release and reduces renal sodium and water excretion. Salt and water retention commonly follow sustained hypercapnia.

## Diagnostic Principles

Arterial blood gases are required to assess RA. Differentiating between acute and chronic RA is made on clinical grounds. Acute RA is associated with normal plasma bicarbonate whereas chronic hypercapnia is associated with increased plasma $HCO_3^-$ owing to renal compensation. Patient's medical history, physical and radiological exams are useful.

**Acidosis, Respiratory. Table 1** Hypercapnia and changes in the expression of acid-base transporters

| | |
|---|---|
| Na, K-ATPase (Sodium Potassium ATPase) | High $CO_2$ level results in decreased activity in a concentration dependent manner by activating protein kinase C ζ (PKC) in alveolar epithelial cells |
| Erythroid chloride-bicarbonate exchanger (band 3 protein) | Chronic RA increases basolateral $Cl^-/HCO_3^-$ exchanger mRNA in type α intercalated cells of distal nephron |
| NHE1 (Sodium hydrogen exchanger 1) | Chronic exposure to $CO_2$ increases expression of NHE1 protein in cerebral cortex, heart and kidney of neonatal mouse |
| NBCn1 (Sodium bicarbonate cotransporter) | Chronic exposure to $CO_2$ increases expression of NBCn1 protein in cerebral cortex, heart and kidney of neonatal mouse |
| AE3 (Anion exchanger 3) | Hypercapnia decreases expression of AE3 protein in brain of mouse, but increases expression of AE3 in heart of neonatal mouse |
| Past A (Proton-associated sugar transporter-A; Mammalian sugar transporter) | Hypercapnia increases expression of Past-A in neurons of the ventral medullary surface (VMS) |

### Therapeutic Principles

Hypoxemia secondary to carbon dioxide retention is a crucial factor determining morbidity and mortality of patients with acute or chronic RA. Therefore an emphasis should be placed on adequate oxygenation and lowering of $CO_2$ levels. In addition to oxygen and $CO_2$ elimination, other goals in treatment should include removal of the underlying cause and airway preservation. When RA is severe, ventilatory support in the form of either noninvasive positive pressure ventilation or mechanical ventilation may be required. The large tidal volumes with excessively high airway pressure associated with mechanical ventilation in patients with acute respiratory failure and in patients with acute exacerbations of COPD often lead to alveolar distension and barotrauma. Therefore, an alternate approach that uses lung-protective ventilation [5] strategy and allows $PaCO_2$ to rise is called "permissive hypercapnia" (or controlled mechanical hypoventilation). In this form of induced RA, lower tidal volumes (5–7 ml/kg) and peak inspiratory pressures can be used. The degree of permissive hypercapnia is severe, typically between 70 and 80 mmHg, and a bicarbonate drip needs to be used to prevent the development of acidemia. Permissive hypercapnia is sometimes used in the management of acute lung injury, acute respiratory distress syndrome, status asthmaticus, and neonatal respiratory failure but it may have deleterious effects on alveolar epithelial cell function that outweigh its potential benefits.

## Acne Rosacea

►Rosacea

## Acne Vulgaris

Christos C. Zouboulis
Departments of Dermatology, Venereology, Allergology and Immunology, Dessau Medical Center, Dessau, Germany

### Definition and Characteristics

Exclusively human disorder of the pilosebaceous unit, mostly affecting the so called "sebaceous follicles" located on the face, chest, shoulders and back (seborrheic areas).

### Prevalence

Initiating with the adrenarche and mostly with puberty it exhibits a peak incidence at 15–18 years of age. Neonatal and infantile acne can occur but are rare. Adolescents are reported to experience acne lesions in 70–87%, whereas acne is clinically relevant in 30%. There is a spontaneous regression after puberty, but acne persists over the age of 25 years in 10% and can last up to the fourth decade of life, and even up to the sixth decade of life in some cases. Two to 7% of the patients with acne experience a severe course associated with considerable scarring. Acne occurs in all races with a more severe course in Caucasians than in pigmented races. Japanese usually present a milder course of acne than other populations.

### Genes

Identical sebum excretion rates but varying distribution and severity of acne were described in homozygotic twins [1]. Among heterozygous twins acne was present in both twins in 54% sets only. An association of frequency and severity of acne in a family with a heavy course in the descendants was described. Nodulocystic infantile acne is often observed in relatives of patients with extensive steatocystoma, adolescent and postadolescent acne [2]. A correlation has been suggested between neonatal acne and familial hyperandrogenism. 50% of postadolescent acne patients have at least one first-degree relative with the condition. Several chromosomal abnormalities, including 46XYY genotype, 46XY+ (4p+; 14q–), and partial trisomy 13

**Acne Vulgaris. Table 1** Gene mutations reported in patients with acne or acneiform disorders [2,4,5]

| Gene | Locus | Type of mutation | Clinical picture |
|---|---|---|---|
| FGFR2 | 10q26 | Somatic mutation | Apert syndrome with acne, acneiform naevus [4] |
| GCCR | 5q31 | Point mutations, microdeletion | Acne in females with familial glucocorticoid resistance |
| CYP21A2 | 6p21.3 | Several mutations | Acne in heterogenous or homogenous females with nonclassic congenital adrenal hyperplasia |
| HSD11B1 | Chr. 1 | | Hypercortisolism with acne |
| CYP1A1 | 15q22–q24 | Mutation in exon 7 (m1) | Acne vulgaris [5] |
| MUC1 | 1q21 | Higher frequency of longer repeat length of tandem repeats | Severe acne |
| PSTPIP1 | 15q24–q26.1 | Missense mutations | PAPA syndrome |
| RBP4 | 10q24 | | Retinol-binding protein deficiency with acne |

FGFR2, fibroblast growth factor receptor 2; GCCR, glucocorticoid receptor; CYP, cytochrome P450; HSD, hydroxysteroid dehydrogenase; MUC, polymorphous epithelial mucin; PAPA, pyogenic arthritis, pyoderma gangrenosum, severe cystic acne; RBP, retinol-binding protein

have been reported associated with nodulocystic acne. Recent investigations provided first evidence for a possible association of gene mutations and the development of acne (Table 1).

## Molecular and Systemic Pathophysiology

Several factors contribute to the pathogenesis of acne, among them increased sebaceous gland activity with hyperseborrhea, abnormal follicular differentiation and increased cornification, bacterial hypercolonization as well as inflammation and immunological host reaction are considered to be the major ones [3].

Several clinical observations point to the importance of androgens in acne. Androgens play an essential role in stimulating sebum production; androgen-insensitive subjects who lack functional androgen receptors do not produce sebum and do not develop acne. Moreover, systemic administration of testosterone and dehydroepiandrosterone increases the size and secretion of sebaceous glands. Irregularities of the menstrual cycle, pregnancy etc. have some influence on the acne course in females. Further, nutritional factors, weather, including ultraviolet light, and other environmental factors are accused to modify acne in some patients. Psychological factors and stress have still no proven influence on the pathogenesis of acne but are often involved in its course. Several drugs can induce acne or acneiform lesions.

## Diagnostic Principles

The diagnosis is made from the clinical appearance of the patient (see above).

## Therapeutic Principles

The exact classification of acne is a fundamental requirement for the decision of the therapeutic regimen (Table 2).

Formation of scars requires the administration of systemic treatment. Bacterial hypercolonization is not involved at the onset of acne but it plays a role in the maintenance of the disease. In comedonic acne abnormal keratinization of the infundibulum and the distal part of the sebaceous duct leading to formation of comedones can be directly influenced through cical retinoids and in mild forms through cical azelaic acid or salicylic acid. In papulopustular acne, benzoyl peroxide and topical and systemic antibiotics primarily exhibit antimicrobial but also anti-inflammatory activities. Inflammation leading to formation of papules, pustules, cysts and nodules has been considered as secondary to bacterial hypercolonization till recently and, consequently, it has neither been carefully investigated nor became direct target of treatment. Current research indicates that acne could be an inflammatory disorder, therefore, treatment with anti-inflammatory compounds may be introduced in the future. Nodulocystic (conglobate) acne requires systemic administration of anti-androgens and/or isotretinoin, these compounds classically induce sebosuppression. Special acne forms, such as infantile and prepubertal acne, androgenization signs in female patients with acne tarda, patients with acne fulminans, or those with acneiform diseases, such as acne inversa (hidradenitis suppurativa), may necessitate an alternative treatment. Targeting the androgen receptor or androgen-metabolizing enzymes may become an interesting approach for cical gene therapy in the future.

**Acne Vulgaris. Table 2** Simplified acne classification for the therapeutic decision

| Acne form | Comedones | Inflammation | Papules/ pustules | Small nodules, cysts, fistules | Nodules | Scar formation |
|---|---|---|---|---|---|---|
| Comedonic | Few | None | None or few | None | None | None |
| Mild papulopustular | Numerous | Marked | Few to many | None or few | None | None |
| Severe papulopustular | Numerous | Strong | Very numerous | Many | None or few | Present |
| *Nodulocystic (conglobate)* | Fistule-comedones | Very strong | Very numerous | Many | Few to many, deeply located | Present |

# Acosta's Disease

►Mountain Sickness, Acute

# Acoustic Neurinoma

Markus Pfister
Department of Otolaryngology, University of Tuebingen, Tuebingen, Germany

## Definition and Characteristics

Acoustic neurinomas (AN) are Schwann cell tumors originating from the vestibular portion of the eighth cranial nerve.

## Prevalence

AN are the most common lesion of the cerebellopontine angle and constitute about 6% of all intracranial tumors. The incidence in the United States is 1 in 100,000 with 2,500 new cases diagnosed each year (US) [1].

## Molecular and Systemic Pathophysiology

An AN is a slowly growing lesion which arises from Schwann cells surrounding the vestibular portion of the eighth cranial nerve. There are two forms known, sporadic and familiar cases (neurofibromatosis 2). The sporadic form constitutes over 90% and is not hereditary. NF2 is the only gene known to be associated with neurofibromatosis 2.

Unilateral hearing loss is the most common presenting symptom. Other possible symptoms are tinnitus, disequilibrium, vertigo, headache and aural fullness. In a later stage, facial numbness, facial weakness, diplopia, neuropathies of cranial nerves III, IV, VI, IX, X and XI and cerebellar and brainstem compression can occur.

## Diagnostic Principles

The gold standard is gadolinium enhanced magnetic resonance imaging.

## Therapeutic Principles

Therapy depends on size and clinic. Asymptomatic lesions can be followed. Symptomatic or extending lesions beyond the inner auditory canal (IAC) should be removed by surgery [2]. The alternative therapy is stereotactic radiation or gamma knife with the drawback of certain complications, including hydrocephalus and cranial nerve neuropathies as well as a lack of elimination of the tumor [3].

### Synonyms

AIDS

### Definition and Characteristics

Acquired immunodeficiency syndrome is a result of progressive immune dysfunction due to infection with the human immunodeficiency virus (HIV). The incubation period may be shorter for children who have perinatally acquired HIV infection than for children infected through blood or blood products, and it is usually shorter than for HIV-infected adults. Early clinical signs and symptoms of HIV infection are nonspecific such as failure to thrive and developmental delay. Pulmonary diseases are common and include Pneumocysti carinii pneumonia and lymphoid interstitial pneumonitis. Microcephaly, developmental delay, spasticity, gait abnormalities and abnormal reflexes may be present. Hepatomegaly is also commonly seen. HIV cardiomyopathy is not uncommon and may cause congestive cardiac failure. Proteinuria may be caused by HIV nephropathy and may progress to nephrotic syndrome. Chronic diarrhea may result from infections with opportunistic pathogens. Recurrent herpes simplex and varicella-zoster virus infections, severe molluscum contagiosum, chronic fungal infections, atopic dermatitis, and drug-induced eruptions, particularly with cotrimoxazole treatment, are common skin manifestations. Children with AIDS are frequently stunted and severe wasting may be seen in advanced disease.

## Prevalence

In 2006, approximately 10,000 children less than 13 years of age were living with AIDS in the US [1]. The prevalence is higher in developing countries.

## Molecular and Systemic Pathophysiology

Perinatal transmission of HIV in untreated women ranges from 13 to 30% [2]. However, with administration of zidovudine to women during pregnancy and labor and to infants for the first 6 weeks of life has been shown to reduce perinatal HIV transmission by two-thirds [3]. The risk of HIV infection from blood or blood products is very small and is estimated to be 1 in 2 million from a single unit of blood [4]. HIV transmission through sexual contact occurs in children who are sexually abused or in sexually active adolescents. The primary target for HIV is $CD4^+$ T lymphocyte. HIV also requires a chemokine coreceptor to enter cells and polymorphisms in these receptors are associated with resistance to HIV infection and different rates of disease progression. Infection with HIV leads to a progressive decrease in $CD4^+$ T lymphocyte number as well as function. Therefore, in addition to T cell dysfunction, humoral immunity can also be significantly impaired in children with AIDS.

## Diagnostic Principles

Detecting HIV DNA or RNA by PCR is the preferred method for diagnosing HIV infection in infants. Almost all of them have a positive HIV PCR by 1 month of age [5]. HIV-exposed infants should be tested by 48 h of age and if negative, repeat PCR testing should be performed at 14 days of age. Infants negative for HIV by PCR at 48 h and at 14 days should be retested at 1–2 months of age, and if negative, again at 3–6 months of age. HIV infection is diagnosed by two positive HIV PCR tests performed on separate blood samples. Similarly, two negative PCR results, one performed at 1–2 months and the other at 4–6 months of age, make the diagnosis of HIV infection extremely unlikely. The HIV antibody test is the appropriate screening test for children older than 18 months of age. Positive ELISA reactions for HIV are confirmed by Western blot analysis. CD4 cell count should be monitored carefully in children with AIDS.

## Therapeutic Principles

Proper care of HIV-infected children requires a multidisciplinary team. The primary care practitioner should rely on HIV care providers for the management of antiretroviral drugs.

Immunizations generally are safe for HIV-infected children, although the immune response may be poor. In children with AIDS, live viral vaccines may result in infections and diseases resulting from vaccine viruses, although the risk is quite small. It is recommended to withhold measles and varicella vaccines from children with AIDS who have severe immunosuppression, defined as $CD4^+$ T lymphocytes less than 15%. Pneumocysti carinii pneumonia prophylaxis should be administered to HIV-exposed infants beginning at 6 weeks of age, even if HIV infection is not confirmed and to children with AIDS. The recommended regimen is cotrimoxazole taken orally 3 days a week. Alternative regimens include dapsone or pentamidine. Children with AIDS who have recurrent oral candidiasis may benefit from antifungal prophylaxis with oral nystatin, clotrimazole, or fluconazole. Weekly azithromycin or daily rifabutin is suggested as prophylaxis against Mycobacterium avium-intracellulare infection in children who have $CD4^+$ T lymphocyte cell counts less than 100 cells per mm. The treatment of HIV infection with antiretroviral drugs is complex and should be supervised by a specialist who has knowledge of the mechanisms of action of antiretroviral agents, their toxicities, drug interactions, and cross-resistance patterns. The choice of antiretroviral regimen for children is based on factors such as the availability of pediatric formulations, drug interactions, and the frequency of drug dosing. Combination antiretroviral therapy consists of a protease inhibitor or nonnucleoside reverse transcriptase inhibitor in combination with two or more nucleoside reverse transcriptase inhibitors. Adherence to complex drug regimens can be difficult and poor compliance to medications is the result of a large number or volume of medications, poor palatability, varied dosing schedules, and different effects of food on drug bioavailability.

Thomas Schwarz[1], Jorge Frank[2]
[1]Department of Dermatology and Allergology, University Hospital of Schleswig-Holstein, Campus Kiel, Kiel, Germany
[2]MUCMD, University Medical Center Maastricht, Maastricht, The Netherlands

### Definition and Characteristics

Acrodermatitis enteropathica (AE; OMIM 201100) is an autosomal recessive disease that manifests with acral dermatitis and low serum zinc levels.

Erythematous scaly plaques and eczematous or vesiculobullous lesions are mostly located in the groins, in the perioral and periorbital areas and on the acres. Nail changes such as onychodystrophy, onycholysis, and paronychia, and oral and ocular manifestations such as stomatitis, perlèche, blepharitis, conjunctivitis, and photophobia may occur. Other manifestations include loss of appetite, apathy, diarrhea, stomatitis, glossitis, growth retardation, hair loss, hypogonadism, testicular atrophy and neuropsychiatric features. Severe AE can be complicated by an immunodeficiency status with secondary infections mostly due to candida albicans.

### Prevalence

Very rare.

### Molecular and Systemic Pathophysiology

Autosomal recessive disease with chromosomal location at 8q24.3. Mutations in the SLC39A4 gene (SLC, solute carrier family 39, member 4) are the reason for AE. The SLC39A4 gene encodes hZIP4, one member of a human zinc/iron-regulated transporter-like protein (hZIP). In the murine system ZIP4 recently has been identified as a tissue-specific, zinc-regulated zinc transporter and thus shares functional similarities with the three other members of the ZIP family (ZIP1, ZIP2, ZIP3). Acquired zinc deficiency is caused by a too low supplementation of oral zinc. Causes for acquired zinc deficiency include intestinal malabsorption syndromes, Crohn's disease, pancreatic insufficiency, deficient diets, and parerenteral nutrition.

### Diagnostic Principles

The eczematous lesions located in the typical areas lead to the diagnosis which is confirmed by the determination of the plasma zinc level. Low levels of alkaline phosphatase, a zinc-dependent metalloenzyme, may indicate zinc deficiency as well.

### Therapeutic Principles

Zinc supplementation is very effective and causes a rapid resolution of the skin manifestations.

►Zinc Deficiency and Excess

# Acromegaly

Sven Schinner[1], Stefan R. Bornstein[2]
[1]Department of Endocrinology, Diabetes and Rheumatology, University Hospital Duesseldorf, Duesseldorf, Germany
[2]Medical Clinic III, University Hospital Dresden, Dresden, Germany

## Synonyms

Occurence of GH-producing adenomas prior to epiphyseal closure leads to gigantism

## Definition and Characteristics

Somatotroph adenomas of the anterior pituitary gland leading to elevated levels of growth hormone (GH) and insulin-like growth-factor-1 (IGF-1, somatomedin-C) with thickening of skin and bones and enlargement of most viscera.

## Prevalence

Fifty cases per million. 10–15% of all pituitary adenomas are GH-producing.

By far, the most common cause for acromegaly is pituitary adenomas (>98%). GH-producing pituitary carcinomas are rare. Other rare causes are paraneoplastic GH-producing tumors (breast cancer, lung cancer, pancreatic cancer), hypothalamic and ectopic (lung cancer, pancreatic cancer, carcinoids) GH-RH producing tumors.

## Genes

About 40% of somatotroph tumors exhibit a mutation in the alpha subunit of a stimulatory G-protein (Gs), which is located on chromosome 20.

Acromegaly can be associated with the MEN-I syndrome and the McCune-Albright syndrome.

## Molecular and Systemic Pathophysiology

Pituitary tumors appear to be intrinsic, i.e., they arise from the gland itself and are not the result of a constant hypothalamic stimulation. Pituitary tumors are of monoclonal origin. In about 40% of patients with acromegaly, a mutation in the Gs alpha protein is found. This mutant Gs alpha oncogene is named Gsp (G stimulatory protein). The encoded protein has lost its GTPase-activity, which normally disrupts cAMP stimulation. Thus Gsp leads to continuous cAMP stimulation and excessive GH secretion as well as somatotroph proliferation without GH-RH stimulation.

As a consequence, the mutation correlates with constitutively increased cAMP response element-binding protein (CREB) phosphorylation and activity leading to enhanced GH synthesis.

Human growth hormone is produced by somatotroph cells in the anterior pituitary gland. Secretion of GH is stimulated by growth hormone-releasing hormone (GH-RH) and inhibited by somatostatin.

Binding of GH to its receptors on target tissues causes a dimerization and activation of the two adjacent receptors. Most of the GH effects are mediated by IGF-1, which is predominantly expressed in the liver. However, local IGF-1 appears to be the main cause of growth stimulation in the respective organs.

GH-producing pituitary tumors can cause three groups of symptoms:

1. Symptoms due to local tumor growth within the sella turcica, including decreased vision (e.g., hemianopsia) and headache
2. Symptoms due to loss of function or impaired normal pituitary function
3. Symptoms due to GH excess

Occurence of GH-producing adenomas prior to epiphyseal closure leads to gigantism. After epiphyseal closure, GH excess causes a variety of symptoms, which are mainly mediated by IGF-1: coarsening facial features are as typical as enlarging hands and feet. Enlargement of viscera, especially cardiomegaly is a severe problem, as it can cause congestive heart failure.

Patients with acromegaly can also present with hypertension, sleep apnea, and impaired glucose tolerance. Furthermore, GH-producing tumors can exhibit a cosecretion of prolactin.

Acromegaly is associated with an increased risk to develop colon cancer.

## Diagnostic Principles

Firstly, one should consider the typical clinical features. Confirmation of the diagnosis is made by elevated serum levels of glucose-supressed GH concentrations and IGF-1 concentrations followed by radiologic investigations.

Furthermore, screening for MEN-1 should be done once the diagnosis of acromegaly is confirmed.

## Therapeutic Principles

Treatment options include surgery, radiation, or pharmacological suppression of GH release (bromocriptine, long-acting somartostatin analogs).

### Synonyms

Solar keratosis; Senile keratosis; On the lip: Actinic cheilitis

### Definition and Characteristics

Actinic keratosis (AK) is a common sun-induced precancerous neoplasm of epidermal keratinocytes confined to the epidermis. The AK is the initial manifestation of a continuum of clinical and histologic abnormalities that progresses from AK or Bowen's disease to invasive squamous cell carcinoma (SCC) in 5–10% of the cases.

AK present on sun-exposed regions as skin colored to reddish brown or yellowish black, thin or raised papules or plaques with discrete keratosis (appearing like dry adherent scale), sometimes also with marked or even horn-like keratosis.

### Prevalence

It affects over 50% of elderly fair-skinned people who have been frequently exposed to the sun. The incidence of AK differs in various regions depending on the degree of sun exposure. Together with squamous cell carcinoma (SCC) it is the second most common type of skin cancer (after basal cell carcinoma) and the number of patients with AK and SCC is increasing dramatically (in the Netherlands approx. by 80% until 2015) [1].

### Genes

Inactivating mutations in the p53 tumor suppressor gene are frequent.

### Molecular and Systemic Pathophysiology

The major carcinogenic agent in skin carcinogenesis is cumulative life time exposure to ultraviolet (UV) radiation. Other risk factors include race, age, gender, and DNA repair capacity. Chronic UV radiation causes (i) mutations in cellular DNA, and (ii) relative immunosuppression in the cutaneous immune system (e.g., dendritic cells), thus impairing immunological tumor rejection. The combination of immunosuppressive drugs

with UV radiation (e.g., in patients after organ transplantation) increases the risk for SCC 65- to 250-fold. The UV-A spectrum may also be involved by generating oxidative stress which may participate in chromosomal changes, thus inducing genomic instability, a characteristic finding when AK have developed into SSC [2]. UV-B is absorbed in DNA with the formation of UV-specific dipyrimidine photoproducts, which, if insufficiently repaired and erroneously replicated, lead to characteristic mutations in dipyrimidine sequences (C→T and CC→TT transition mutations).

In AK these mutations are often found in the p53 tumor suppressor gene and may present the initial event in skin carcinogenesis. Upon stress p53 alters expression of genes, leading to cell cycle arrest for repair of DNA damage. Mutations in the p53 gene prevent UVB-induced apoptosis and deletion of DNA-damaged cells, resulting in clonal expansion of mutated cells which become targets to further mutations (for review, see [3]).

Another gene likely to be mutated in SSC by UV-radiation (10–20%) is the ras oncogene [4]. Its exact role in the carcinogenic cascade is not clear yet, but it appears to be important in SSC, especially in xeroderma pigmentosum.

For complete tumorigenic conversion from AK into SSC functional loss of p53, mutations of ras and other genes and certain chromosomal aberrations need to be completed by additional chromosomal aberrations [3]. They can be provoked by an oxidative damage response (induced e.g., by UV-A [2]).

### Diagnostic Principles

Like SCCs, the vast majority of AKs and Bowen's disease lesions are asymptomatic. The diagnosis is usually made clinically, according to the clinical criteria described above. The lesions vary from pinhead size to several centimeters and are often better recognized by palpation than by visualization.

They are usually surrounded by sun-damaged skin (solar elastosis).

Erythema, induration, erosion and increase in size or thickness are indicative of evolution into SCC.

### Therapeutic Principles

AK and suspicious lesions should be treated before they progress to invasive SCC. Surgical excision with histological control are mandatory when clinical diagnosis is not clear or when there is suspicion of invasive SSC (induration, ulcer, or increase in size or thickness). In most cases, however, destructive modalities, such as cryosurgery using liquid nitrogen, electrodesiccation, curettage, laser therapy or photodynamic therapy or topical drugs such as 5-fluorouracil, imiquimod or diclofenac are the mainstays of therapy. An integrated program of skin cancer awareness, sun protection, and prophylactic approaches is critical.

## Actinic Keratosis and Squamous Cell Carcinoma

Thomas Schwarz[1], Mark Berneburg[2]
[1]Department of Dermatology, University Hospital of Schleswig-Holstein, Campus Kiel, Kiel, Germany
[2]Department of Dermatology, Eberhard-Karls-University, Tuebingen, Germany

### Synonyms

SCC

### Definition and Characteristics

SCC is a malignant tumor arising from the keratinocytes which show various degrees of maturation towards keratin formation. Actinic keratosis (AK) is the prestage of SCC, representing a carcinoma in situ. In contrast to SCC, spontaneous regression of AK in the early stage can be observed. The clinical appearance may vary, usually multiple or single standing nodules with hyperkeratotic surface, sometimes ulcerating. Most AK and SCC are located on the chronically UV-exposed skin areas (face, scalp, neck, arms, hands) of elderly people.

### Prevalence

160:100,000 in Australia. Non-melanoma skin cancer is the cancer with the most dramatically increasing frequency of all cancer types in the Western world [1].

## Molecular and Systemic Pathophysiology

Ultraviolet radiation, in particular the UVB range (290–320 nm), is the most important factor inducing AK and SCC. UVB radiation primarily hits the keratinocytes by inducing damage in DNA, including some in the tumor suppressor gene p53. Most of the photolesions are repaired by the nucleotide excision repair (see Xeroderma pigmentosum). If not, upon replication the DNA with the photoproduct is left mostly with a C→T mutation in the p53 gene ("UV signature"). Upon further UV exposure p53 is induced which, if the DNA damage is too severe, induces apoptosis of the keratinocyte (sunburn cell) [2,3]. For cells carrying a p53 mutation a 50% likelihood exists not to undergo apoptosis, but to survive and to divide later. Thereby a small clone of "apoptosis-defective" cells will arise. In the absence of further UV exposure this clone may undergo spontaneous regression via mechanisms not yet understood. Each additional UV exposure, however, will exert a selection pressure supporting the clonal expansion of the cells carrying mutated p53. Subsequent UV exposure will probably mutate the other p53 allele or other oncogenes in some cells of the clone, thereby inducing malignant transformation. At the early stage (actinic keratosis), (pre) malignant cells can be recognized and eliminated by the immune system which, however, is also impaired by UV radiation. Besides UV being by far the most important inducer of AK and SCC other factors include ionizing radiation, human papillomaviruses and chemical carcinogens (e.g. arsenic).

## Diagnostic Principles

The typical clinical features lead to the diagnosis, which is finally confirmed by histopathologic examination.

## Therapeutic Principles

Systemic retinoids and interferons may reduce the frequency of lesions in patients suffering from multiple tumors. Other than that, surgical removal, cautery, kryotherapy, photodynamic therapy, chemical peeling and topical immunomodulators are frequently used therapeutic strategies. UV protection is recommended as a preventive step.

## Synonyms

Subtype of nemaline myopathies or NEM3 [1]

## Definition and Characteristics

Congenital myopathy marked by clinical floppiness and large aggregates of actin filaments within muscle fibers [2], which may or may not be associated with nemaline bodies or rods [2]. To date, all observed cases of actin myopathy (accumulation of thin myofilaments) where ACTAI mutation have been identified have dominant mutations [2,3].

## Prevalence

Approximately 70% of patients whose histopathology shows accumulation of thin myofilaments have mutations in the ACTA1 gene. ACTA1 mutations cause approximately 20% of cases of nemaline myopathy.

## Genes

ACTA1 gene, located on chromosome 1q42.1, coding for α-skeletal actin, the skeletal muscle fiber-specific thin myofilament actin [4].

## Molecular and Systemic Pathophysiology

Actin or thin myofilaments are essential components of I-bands of sarcomeres anchoring bilaterally at the Z disk, extending between the myosin filaments in the A band and essential for contraction upon nerve stimulus. The overwhelming majority of missense mutations, encountered so far, appear as de novo mutations when parental ACTA1 genes had been analyzed [4]. While a complete genotype–morphophenotype correlative spectrum has not yet been established, i.e., correlation of missense mutations in the ACTA1 gene and the presence of large aggregates of actin filaments within muscle fibers, these two components have been identified in several patients with rods/nemaline bodies [2,4,5] and, hence, nemaline myopathy. In addition to

sarcomeric actin, demonstrated by immunohistochemistry and immunoelectron microscopy, only α-actinin, a major protein of Z bands, rods/nemaline bodies, and α-B crystallin, the molecular heat-shock or chaperone - protein, had been demonstrated within islands of actin filaments, quite unlike other protein aggregates within muscle fibers such as desmin-related aggregates in desmin-related myopathies or myofibrillar myopathies and tubulofilamentous aggregates in hereditary inclusion body myositis/myopathies. This lack of diverse proteins may indicate a defect in synthesis or assembly of intrasarcomeric thin filaments or incorporation of mutant actin filaments in regular sarcomeres which, however, are also seen in myofibrils with aggregates of actin filaments. Mutations in the ACTA1 gene have also been seen with aggregates of actin filaments, but without rods or nemaline myopathy and have been seen with rods/nemaline bodies in intranuclear location only. Failure to identify aggregates of actin filaments within biopsied muscle specimens, in spite of mutations in the ACTA1 gene in respective patients, may represent missampling or absence of actin filament aggregation. The mutations in ACTA1 that cause actinopathy are largely clustered at or near the nucleotide binding cleft in the actin monomer [3]. This has led to the hypothesis that the mutations in ACTA1 that cause actinopathy probably interfere with nucleotide binding and then in turn with actin polymerization [3].

### Diagnostic Principles

Clinical symptoms of a floppy infant, occasionally rapidly progressing to death or, in mild cases, of a slowly or nonprogressive myopathy, and a muscle biopsy specimen marked by patches of actin filaments identified by immunohistochemistry and/or electron microscopy, with or without nemaline bodies/rods or intranuclear rod bodies require molecular analysis of the ACTA1 gene for confirmation or alternative interpretation.

### Therapeutic Principles

As the pathogenesis of actin filament aggregation is as unclear, as is the morphogenesis of rods in nemaline myopathies, causative treatment concerning prevention or elimination of actin filament aggregates and restoration of normal muscle fibers is not available, but only supportive therapy concerning sequelae of muscle weakness, i.e., prevention of contractures and assistance in respiration is possible.

# Acylcarnitine Translocase Deficiency

Du Toit Loots
School of Physical and Chemical Sciences, Division of Biochemistry and School of Physiology, Nutrition and Consumers Science, Department of Nutrition, North-West University, Potchefstroom, South Africa

### Synonyms

Carnitine-acylcarnitine translocase (CACT or CAT) deficiency; Carnitine-acylcarnitine carrier (CAC) deficiency

### Definition and Characteristics

An autosomal recessive defect in the CACT protein [1], situated on the inner mitochondrial membrane, responsible for transporting long-chain acylcarnitines into the mitochondria for energy utilization, especially during fasting periods [2–4].

### Prevalence

Extremely rare with approximately 30 reported cases.

### Genes

The gene for CACT, the solute carrier family 25 member 20 (SLC25A20), is assigned to chromosome 3p21.31 [1,2,4].

### Molecular and Systemic Pathophysiology

A defective CACT protein in the brain, heart, skeletal muscle and liver, causes insufficient fatty acid oxidation in these tissues, consequently resulting in neurological disorders, heart beat disorders, skeletal muscle damage and liver dysfunction [4]. A failure to transport long-chain acylcarnitines formed by carnitine palmitoyltransferase I (CPT I), leads to an accumulation of these in addition to long-chain acyl-CoA intermediates and free long-chain fatty acids outside the mitochondrion of cells [3]. This abnormal fatty acid transport and disrupted β-oxidation results in hypoketosis. The surplus fatty acids are oxidised by microsomal ω-oxidation yielding dicarboxylic acids [4]. Additionally, short chain acylcarnitines (propionyl-carnitine, butyryl-/isobutyryl-carnitine and isovaleryl-/2-methylbutyryl-carnitine) are excreted in the urine and are present in the plasma of these patients. These are produced in the mitochondrial matrix from branched chain amino acid pathways [3]. Elevated propionyl-CoA and reduced acetyl-CoA, results in a lowered N-acetylglutamate, which in turn causes secondary urea cycle dysfunction and hyperammonaemia [4].

### Diagnostic Principles

Clinically two forms occur: a severe form with a high incidence of sudden childhood death, and a milder form [1–3]. Clinical symptoms or markers include coma, lethargy, cardiomyopathy, liver dysfunction, hypotonia, seizures, microcephaly and sudden death. Routine laboratory analyses show normal to low blood glucose (due to hepatic glycogen depletion and impaired gluconeogenesis), low blood ketones, acidosis, as well as increased lactate, ammonia, liver enzymes, creatine kinase (due to liver and muscle damage) and uric acid. Special laboratory analyses show slightly elevated dicarboxylic acids, normal acylglycines, lowered free carnitine and increased $C_{16}$–$C_{18}$ acylcarnitines [2,4].

### Therapeutic Principles

Treatment of these patients during acute episodes entails glucose infusion in order to normalize blood sugar levels [2,5]. Carnitine supplementation is guided by plasma levels [2–3]. Patients should avoid periods of fasting by eating regularly [5]. Long-chain fatty acids should be restricted and be replaced by medium chain triglycerides [3–4].

# Adenine Phosphoribosyltransferase Deficiency

Amrik Sahota[1], Jay A. Tischfield[1], H. Anne Simmonds[2]
[1]Nelson Laboratory, Department of Genetics, Rutgers University, Piscataway, NJ, USA
[2]Purine Research Unit, Guy's Hospital, King's College, London, UK

## Synonyms

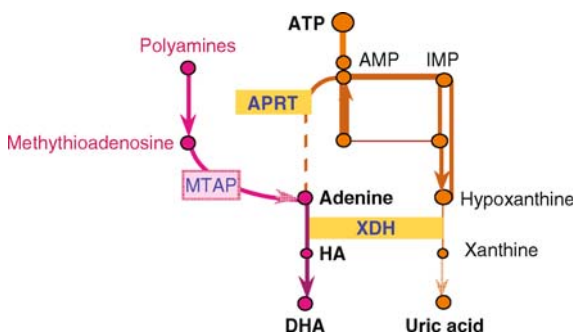
2,8-Dihydroxyadenine urolithiasis; APRT deficiency

## Definition and Characteristics

Autosomal recessive disorder involving adenine phosphoribosyltransferase (APRT), the enzyme that normally metabolizes adenine (a by-product of polyamine synthesis). In APRT deficiency (Fig. 1), adenine is metabolized via xanthine dehydrogenase (XDH) to the extremely insoluble 2,8-dihydroxyadenine (DHA), leading to urolithiasis and, in some cases, chronic renal failure that may require dialysis and/or transplantation [1].

## Prevalence

The prevalence of APRT heterozygotes is around 1%, but the prevalence of APRT-deficient individuals is much lower than expected, possibly due to mis- or under-diagnosis. The disorder is distributed worldwide and is not confined to any particular ethnic group. The prevalence is higher in Japan and Iceland due to founder effects [1,2].



**Adenine Phosphoribosyltransferase Deficiency. Figure 1** Role of APRT in removing adenine (a by-product of polyamine synthesis) and its conversion via XDH to DHA in APRT deficiency. HA, 8-hydroxyadenine; MTAP, 5Y-methylthioadenosine phosphorylase.

## Genes

Located on the long arm of chromosome 16 (16q24.3). The gene product is a dimer of identical subunits. The M136T mutation has been found only in Japan and is the most common mutation in that population. Fifteen mutations have been reported in non-Japanese populations, but D65V is the only mutation found in Icelandic patients to date. All mutations lead to enzyme deficiency in vivo, but two (M136T and V150F) show substantial (up to 25%) activity in vitro and thus may be mistaken for carriers of the defect.

## Molecular and Systemic Pathophysiology

APRT, a housekeeping gene expressed in all tissues, normally converts adenine into AMP, but in APRT deficiency adenine is oxidized by XDH in the liver to DHA. DHA is protein bound in vivo, but it can precipitate in the kidney leading to crystalluria and stone formation. Renal stones are not a common cause of renal failure, but chronic (and sometimes acute) renal failure can result due to DHA crystal deposition in the kidney of APRT-deficient patients. Several patients, in whom the disease went unrecognized, developed severe renal failure and have died. Others received dialysis or transplantation, but in some of these the defect was recognized only post-transplant, by the finding of the characteristic DHA crystals at biopsy following a rejection episode [3]. Symptoms may appear at birth or may not become apparent until the seventh decade and up to 50% of patients may be asymptomatic. This may account, at least in part, for the low prevalence of APRT deficiency. Studies in Aprt knockout mice indicate that DHA crystal deposition occurs first within tubular lumens, followed by deposition within epithelial cells and in the interstitium [4].

## Diagnostic Principles

The presence of round, brown crystals in urine deposits examined microscopically [2], or brownish spots on the diaper is suggestive of DHA, but this should be verified by the analysis of urine by HPLC or capillary electrophoresis. Routine stone analysis does not distinguish DHA from uric acid stones, which has led to misdiagnosis in the past. Plasma and urine uric acid are within normal ranges in this defect. APRT deficiency can be confirmed by enzyme assay in erythrocyte lysates, but the results can be misleading if (as in the majority of Japanese cases), the patient bears the M136T mutation that shows significant enzyme activity in vitro, or if the patient recently received a blood transfusion. APRT mutations can be readily detected by PCR and the functional significance of a mutation assessed by the ability of isolated lymphocytes to incorporate radiolabeled adenine into AMP [1].

### Therapeutic Principles

DHA synthesis, and hence stone formation, can be prevented by allopurinol, an inhibitor of XDH (adenine itself has no apparent toxicity in vivo). A low purine diet and high fluid intake are also suggested. Unlike uric acid stones, alkali administration is not beneficial, since the solubility of DHA is not altered within the normal physiological pH range. In patients with renal failure, the allopurinol dose must be adjusted to minimize the side effects of oxipurinol (the active metabolite of allopurinol). Invasive treatments have included extracorporeal shockwave lithotripsy and renal transplantation, but urolithiasis (and the ensuing renal damage) may recur if the underlying cause is not recognized [1].

## Adenomatous Polyposis Coli

►Adenomatous Polyposis, Familial

## Adenomatous Polyposis, Familial

Wolfgang Dietmaier[1], Arndt Hartmann[2]
[1]Institute of Pathology, University of Regensburg, Regensburg, Germany
[2]Department of Pathology, University Erlangen, Erlangen, Germany

### Synonyms

Adenomatous polyposis coli; Bussey-Gardner polyposis; Gardner syndrome; FAP

### Definition and Characteristics

Familial adenomatous polyposis is an autosomal dominantly inherited disorder characterized by numerous adenomatous polyps predisposing patients to the development of cancer. The disease is caused by germline mutations in the APC gene located at chromosome 5q21–22. The incidence of FAP is about 1:10,000 and it accounts for ~ 1% of all new colorectal cancer.

In FAP patients adenomas are endoscopically detectable between the age of 10 and 20 years. The progression of one or more adenomas to cancer is thereby a basic feature of FAP. The mean age of manifestations of colonic carcinomas in untreated FAP patients is about 40 years with an almost complete penetrance. However, cancer can arise at an early age and even in children with FAP. The colorectal cancer risk at the age of 20–25 years is 1–6%. Extracolonic manifestations like congenital hypertrophy of the retinal pigment epithelium (CHPRE), desmoid tumours or epidermoid cysts are further FAP characteristica which may serve as diagnostic markers of FAP.

A milder form of FAP, attenuated familial adenomatous polyposis (AFAP), is characterized by the presence of fewer than 100 adenomas, located more proximal and a delayed age of onset (about 15 years later than patients with classical FAP). Patients with AFAP have a cumulative risk of CRC by the age of 80 years of approximately 70%. Family history of polyps or CRC in AFAP patients may often be negative and secondary manifestations can lack. Underlying gene mutations are frequently located in the extreme proximal or distal regions of the APC gene.

### Prevalence

25:1,000,000

### Genes

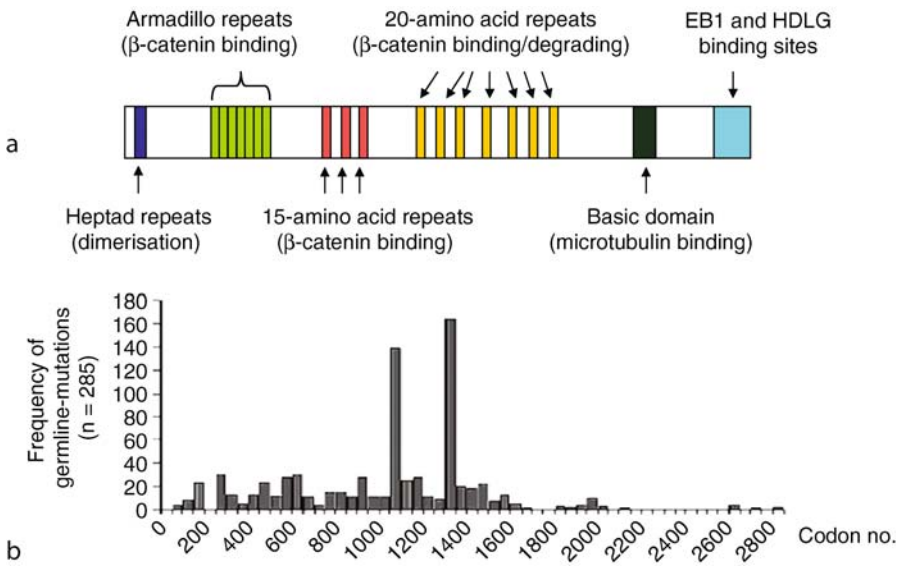
The APC gene (Fig. 1) is located on chromosome 5q21–22 [1,2] and spans over a region of 120 Kb.

Although the APC gene is composed of 15 exons encoding 2843 amino acids there are 21 exons, 7 of which are alternatively expressed [3]. Sixteen different APC transcripts are characterized with distinct 5′ regions due to alternative splicing.

Mutations are distributed throughout the gene and the vast majority of these introduce premature stop codons resulting in the production of a truncated APC protein. Germline mutations at the codons 1061 and 1309 are relatively frequent and account for 20% of all identified germline mutations in the APC gene. About 10% of APC mutations are large deletions which can comprise the entire gene. Missense mutations with unknown relevance are relatively rare.

### Molecular and Systemic Pathophysiology

The APC protein contains a couple of functional domains which are required for several biological



**Adenomatous Polyposis, Familial. Figure 1** a) Structure of the APC gene. b) Distribution and frequency of APC germline mutations (data were retrieved from the online APC mutation database at http://www.perso.curie.fr/Thierry.Soussi/APC.html.).

processes (Fig. 1). Central regions are required for binding and degradation of the β-catenin protein which causes the down regulating of the Wnt signal pathway. A carboxy-terminal located APC region mediates phosphorylation of glycogen synthase kinase 3β (GSK3β) and is required for stabilization of a complex of two proteins [4]. In unstimulated cells GSK3β promotes phosphorylation of conductin/axin which is added to the APC-GSK3β complex. This leads to the recruitment and phosphorylation of β-catenin which is thus targeted for degradation by the ubiquitin/proteasome pathway. If the Wnt pathway is stimulated, GSK3β is unphosphorylated and β-catenin accumulates. In the cytoplasma β-catenin binds to the cell adhesion protein E-cadherin and links E-cadherin to the actin cytoskeleton. Free β-catenin shuttles into the nucleus, binds to transcription factors of the TCF4/LEF family causing altered expression of genes affecting proliferation, migration and apoptosis (c-MYC, cyclinD1, matrilysin, ephrins, caspases). Thus, non-functional APC leads to accumulation of β-catenin and to uncontrolled expression of tumour promoting genes.

## Diagnostic Principles

The classical FAP is clinically defined by the presence of at least 100 colorectal adenomous polyps [5]. Histological confirmation requires examination of several polyps. In the case of a definite family history the detection of fewer adenomas at an early age is sufficient. Clear diagnosis of FAP is achieved by the detection of a pathogenic APC gene mutation which can be found in about 95% of FAP patients.

If clinical criteria are suspect and no APC mutation are detectable, FAP diagnosis is supported by the presence of extracolonic diseases like epidermoid cysts, osteomas or desmoid tumours.

Children of affected FAP parents should be examined by flexible sigmoidoscopy from the age of 10 to 12 and years and should be monitored at 1–2 years intervals until the age of 40 years if no adenomas are detectable. Mutation analysis can replace endoscopies in families where a pathogenic mutation has been identified.

## Therapeutic Principles

FAP patients or persons with proven pathogenic APC mutations should generally be treated by (prophylactic) colectomy or proctocolectomy when adenomas become detectable, and before the age of 20–25 years.

# Adenosine Deaminase Deficiency

Michael S. Hershfield
Department of Biochemistry, Duke University Medical Center, Durham, NC, USA

## Synonyms

ADA-deficient severe combined immune deficiency; ADA-SCID

## Definition and Characteristics

Autosomal recessive defect leading to profound depletion of T, B and NK lymphocytes [1]. Typical patients are infants with lymphocytopenia, failure to thrive and life-threatening opportunistic infections (SCID). Fifteen to 20% are less severely affected and present at 1–8 years of age; several adults have been diagnosed at 15–39 years. Some healthy children and adults with very low erythrocyte ADA activity but with significant ADA activity in nucleated cells have been identified by screening and have been designated "partial ADA deficiency."

## Prevalence

Estimated to occur in 1 per 250,000 to 1 per million live births. ADA deficiency is present in about 15% of all patients with SCID and in about 30% of those with autosomal recessive inheritance.

## Genes

The 12 exon, 32 kb ADA gene is located on chromosome 20q13.11 [2]. A G/C rich "housekeeping" promoter, which lacks TATA and CCAT sequences, allows basal transcription in all cells; an enhancer in the first intron determines high-level ADA expression in thymocytes. The 1.5 kb ADA mRNA is translated into a 363 amino acid, 41.7 kD protein [3].

## Molecular and Systemic Pathophysiology

The highest ADA activity occurs in lymphoid cells. Erythrocytes have about 0.1% of thymocyte activity. Erythrocyte ADA is a soluble protein of 41 kD, but in medullary thymocytes, activated T cells and epithelial cells of kidney, liver and some other tissues ADA also exists in complexes of >200 kD, due to binding of the 41 kD monomer to the cell membrane-associated glycoprotein CD26/dipeptidyl peptidase IV.

ADA catalyzes the deamination of adenosine (Ado) and 2′-deoxyadenosine (dAdo), producing inosine (Ino) and 2′-deoxyinosine (dIno). dAdo arises from DNA breakdown in lymphoid organs, including apoptosis of "negatively selected" immature thymocytes, antigen activation-induced apoptosis of T lymphocytes in lymph nodes and dissolution of the nuclei of erythroid progenitors in marrow.

Red blood cells of ADA-deficient SCID patients show (i) a marked elevation of dATP and total dAdo nucleotides (dAXP) and (ii) reduced activity of S-adenosylhomocysteine (AdoHcy) hydrolase (<5% of normal), due to "suicide-like" inactivation of ADA by dAdo. dAdo is also found in urine.

Toxic effects of dATP and AdoHcy, as well as elevated extracellular Ado acting through G-protein-coupled Ado receptors are thought to impair the viability, differentiation or function of lymphoid cells [1]. Specific pathogenic mechanisms include (i) allosteric inhibition by dATP of ribonucleotide reductase, blocking DNA replication and repair, (ii) induction of apoptosis resulting from the interaction of dATP with cytoplasmic cytochrome c, apoptosis activating factor-1 and procaspase-9 to form the "apoptasome" and (iii) inhibition by AdoHcy of S-adenosylmethionine-dependent transmethylation reactions.

More than 70 different ADA gene mutations, about 60% missense, have been identified. Among 52 phenotypically diverse patients and healthy subjects with "partial deficiency", whose 43 genotypes were derived from 42 different mutations, the total ADA activity expressed by both alleles of each genotype correlated well with red cell dAXP level and age at diagnosis [4].

## Diagnostic Principles

Erythrocyte ADA activity, measured by spectrophotometric or radiochemical assay, is <1% of normal and dATP (total dAXP) in erythrocytes, measured by HPLC, is elevated 30 to >1,000-fold. In patients transfused prior to testing, ADA deficiency is suggested by an elevation in erythrocyte dATP (dAXP). Although erythrocyte ADA activity is also very low in healthy subjects with "partial ADA deficiency", dATP (dAXP) is not elevated due to elimination of dAdo by residual ADA activity in non-erythroid tissues.

Because of genetic heterogeneity, ADA genotype analysis is used for diagnosis only if the mutations in a previously affected family member have been determined. Prenatal diagnosis is based on the absence of ADA activity in cultured amniocytes or fibroblasts from a chorionic villus biopsy.

## Therapeutic Principles

SCID is fatal within a year or two. Bone marrow or stem cell transplantation (BMT/SCT), enzyme replacement therapy and experimental gene therapy have all been used to treat ADA. BMT/SCT from an HLA-identical sibling is usually well tolerated and curative. Patients lacking such a donor may receive BMT/SCT from an HLA-haploidentical (usually parental) or HLA-matched unrelated donor, but morbidity is greater and immune reconstitution significantly less.

Enzyme replacement therapy (one or two weekly intramuscular injections of polyethylene glycol-modified bovine ADA (PEG-ADA is used for patients considered poor candidates for BMT/SCT from an HLA-mis-matched or unrelated donor. PEG-ADA is not curative and in most restoration of immune function is partial. However, it has been well tolerated, with survival comparable to or better than transplantation.

Clinical trials of gene therapy using retroviral vectors have been in progress for over a decade. Gene transfer and expression have been variable and concomitant treatment with PEG-ADA has complicated evaluation of clinical benefit. Greater efficiency of stem cell transduction, resulting in correction of immunodeficiency, has been reported in two patients not receiving PEG-ADA [5]. Gene therapy trials for ADA deficiency are currently on hold, following development of leukemia in 2 of 10 patients with X-linked SCID who had undergone successful stem cell gene therapy using a retroviral vector.

# Adenylosuccinate Lyase Deficiency

Georges Van Den Berghe, Jaak Jaeken
University of Leuven, Leuven, Belgium

## Synonyms

ADSL deficiency

## Definition and Characteristics

Autosomal recessive inborn error of purine nucleotide synthesis leading generally to severe psychomotor retardation, frequently accompanied by epilepsy and/or autistic features. Rare patients display only mild mental retardation, isolated muscle hypotonia or autism [1–3].

## Prevalence

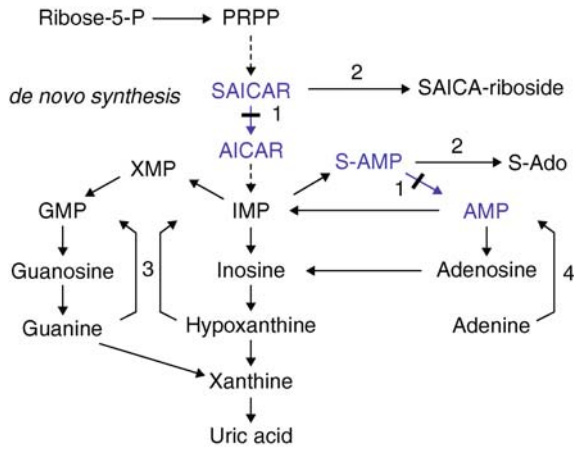
Unknown, but to date about 60 patients have been identified in 14 countries. Most cases have been diagnosed in The Netherlands, Belgium and the Czech Republic.

## Genes

The ADSL gene has been mapped to chromosome 22q13.1-q13.2. The 1452-nucleotide cDNA sequence encodes a 484-amino acid protein. The 4-subunit enzyme has a molecular weight of ~200,000. Thirty seven ADSL gene mutations have been identified. All are missense with the exception of a 39-bp deletion and a mutation in the 5'untranslated region. About half the patients are compound heterozygotes. Most frequently encountered, in about one-third of the alleles, is an R426H mutation.

## Molecular and Systemic Pathophysiology

Adenylosuccinate lyase catalyzes two steps in the synthesis of AMP and GMP (Fig. 1), the conversion of succinyl aminoimidazolecarboxamide ribotide (SAICAR) into aminoimidazolecarboxamide ribotide (AICAR) and the conversion of adenylosuccinate (S-AMP) into AMP. The deficiency results in accumulation in body fluids of SAICA-riboside and succinyl adenosine (S-Ado), the products of dephosphorylation, by 5'-nucleotidase(s), of the two substrates of the enzyme. Although ADSL deficiency might be expected to lead to decreased synthesis of adenine and guanine nucleotides, normal levels of the latter were measured in freeze-clamped liver, kidney and muscle of patients. This can be explained by residual activity of the enzyme and by circumvention of the defect by the purine salvage enzymes HGPRT and APRT. The symptoms of ADSL deficiency might thus be caused by neurotoxic effects of the accumulating succinyl purines. In most



**Adenylosuccinate Lyase Deficiency.**
**Figure 1** Pathways of Purine Metabolism. 1, ADSL; 2,5′-nucleotidase(s); 3, hypoxanthine-guanine phosphoribosyltransferase (HGPRT); 4, adenine phosphoribosyl-transferase (APRT)

patients, S-Ado/SAICA-riboside ratios are ∼1. The observation of milder mental retardation in patients with similar SAICA-riboside levels but S-Ado/SAICA-riboside ratios above 2, as compared to ∼1 in severely affected subjects [2], suggests that SAICA-riboside is the offending compound and that S-Ado could protect against its toxic effects. Hitherto however, all attempts to demonstrate neurotoxicity of the succinyl purines have failed.

### Diagnostic Principles

Due to the marked clinical heterogeneity in ADSL deficiency, screening for the defect should be performed in unexplained psychomotor retardation and neurological disease. Diagnosis is based on the presence of S-Ado and SAICA-riboside in urine and/or cerebrospinal fluid. Both are normally undetectable. A modified Bratton-Marshall test [4] on urine is the most practical. False positive results may be found in patients receiving medications, particularly sulfonamides or antiepileptics. Final diagnosis requires HPLC and UV detection [1].

### Therapeutic Principles

With the aim of correcting the hypothetical depletion of purine nucleotides in ADSL-deficient tissues, some patients have been treated with oral adenine and allopurinol, the latter to avoid conversion of adenine to the poorly soluble 2,8-dihydroxyadenine. No clinical or biochemical improvement was noted, with the exception of some acceleration of growth [2]. More recently, trials with ribose in a single patient showed a reduction of seizure frequency, which was not sustained.

### Synonyms

21-Hydroxylase deficiency-classical salt wasting (OMIM 201910) and 3β-Hydroxysteroid dehydrogenase deficiency classical (OMIM 201810); Steroidogenic acute regulatory protein deficiency (OMIM 201710); CAH

### Definition and Characteristics

Congenital adrenal hyperplasia is a group of autosomal recessive diseases whose common feature is an enzymatic defect in the steroidogenesis pathway. Three forms of congenital adrenal hyperplasia with salt wasting and hypotension have been described: (i) 21-Hydroxylase deficiency-classical salt wasting (OMIM 201910), which causes salt-wasting with life-threatening vomiting and dehydration occurring within the first weeks of life. It is also the most common cause of ambiguous genitalia due to prenatal virilization of genetically female (XX) infants; (ii) 3β-Hydroxysteroid dehydrogenase II (HSD 3β2) deficiency is an uncommon cause of CAH and results from loss of function of one of the key enzymes in adrenal cortisol synthesis. This form of CAH can cause salt wasting adrenal crises in infancy and is the only form that produces sexual ambiguity in both sexes; (iii) Congenital lipoid adrenal hyperplasia is the most severe form of congenital adrenal hyperplasia. Affected individuals do not synthesize any steroid hormones leading to a severe salt-wasting syndrome that is fatal if not treated in early infancy. All affected infants are phenotypic females because of the lack of production of testosterone.

### Prevalence

Rare disease.

### Genes

- 21 hydroxylase gene (CYP21 gene); Gene map locus 6p21.3; inheritance autosomal recessive;
- 3β-Hydroxysteroid dehydrogenase II gene (HSD3β2 gene); Gene map locus 1p13.1; Inheritance autosomal recessive;
- Steroidogenic acute regulatory gene (StAR gene), Cytochrome P450 side chain cleavage enzyme (P450scc); Gene map locus 8p11.2; Inheritance autosomal recessive.

### Molecular and Systemic Pathophysiology

Deficient activity of the enzyme 21-hydroxylase (21-OH) reduces cortisol and aldosterone synthesis leading to elevated ACTH levels and hyperplasia of the adrenal cortex. Aldosterone deficiency results in urinary salt loss with impaired $K^+$ and $H^+$ secretion and affected infants develop hypotension with hyperkalemia and metabolic acidosis in the first week of life. Ability to maintain systemic blood pressure is further compromised by cortisol deficiency. The early symptoms of this form of CAH are spitting and poor weight gain, but most infants with severe CAH develop vomiting and shock by the first two or three weeks of life. The steroid precursors, progesterone, 17-hydroxypregnenolone, and 17-hydroxyprogesterone (17OHP) are increased in the circulation. Since 21-OH activity is not involved in synthesis of androgens, a fraction of the elevated 17-hydroxypregnenolone is converted to dehydroepiandrosterone (DHEA), androstenedione, and testosterone beginning in the third month of fetal life. This results in virilization in female infants that is evident at birth.

3β-HSD II mediates three parallel dehydrogenase/isomerase reactions in the adrenal glands that convert Δ4 to Δ5 steroids: 17-Hydroxypregnenolone to 17-Hydroxyprogesterone, DHEA to androstenedione and pregnenolone to progesterone. 3β-HSD II also converts androstenediol to testosterone in the testes. Deficient activity of the enzyme reduces cortisol with or without aldosterone synthesis leading to elevation of ACTH levels. The increased ACTH results in large elevations of pregnenolone, 17-hydroxypregnenolone, and DHEA. Severe forms of 3β-HSD deficiency with combined aldosterone and cortisol deficiency can result in life-threatening salt-wasting crisis in early infancy. The excess fetal production of DHEA causes virilization in genetic females. Underproduction of testosterone in the testis causes sexual ambiguity in genetic males. It is the only form of CAH that can produce genital ambiguity in both sexes.

Most cases of lipoid adrenal hyperplasia are due to mutations of the gene for a protein called steroidogenic acute regulatory protein (StAR) which transports cholesterol into the mitochondria. Deficiency results in impaired synthesis of all three categories of adrenal steroids (cortisol, mineralocorticoids, and sex steroids) and testosterone in the testis. The absence of cortisol and aldosterone leads to salt wasting crisis in infancy. High levels of ACTH lead to adrenal hyperplasia with lipid accumulation and to hyperpigmentation. Lipid accumulation also damages the testes and ovaries so that even with appropriate adrenal hormone replacement, gonadal function and fertility cannot be preserved.

## Diagnostic Principles

Salt-wasting forms of adrenal hyperplasia are accompanied by low serum aldosterone concentrations, hyponatremia, hyperkalemia and elevated plasma renin activity (PRA) secondary to hypovolemia. Further diagnosis of specific types of salt wasting congenital adrenal hyperplasia depends on the demonstration of inadequate production of cortisol, aldosterone, or both in the presence of an excess of precursor hormones. High serum concentration of 17-hydroxyprogesterone (usually >1,000 ng/dL) and urinary pregnanetriol (metabolite of 17-hydroxyprogesterone) with classic clinical features like ambiguous genitalia in females, normal genitalia in males with precocious puberty, salt wasting and hyperpigmentation are suggestive of 21-hydroxylase deficiency. Diagnosis of 3β-HSD CAH is usually made because of the appearance of ambiguous genitalia at birth or by development of a salt-wasting crisis in the first month of life. In this form of CAH, pregnenolone, 17-hydroxypregnenolone, and DHEA, are elevated. Steroidogenic acute regulatory protein deficiency is suggested by the finding of an elevated ACTH, with decreased cortisol, DHEA and testosterone in the setting of salt wasting.

## Therapeutic Principles

Patients with volume depletion, hyponatremia, or hyperkalemia should receive an intravenous isotonic saline solution, as needed, to restore their intravascular volume. Dextrose may be necessary if the patient is hypoglycemic.After the patient's condition is stabilized, all patients should be treated with long-term glucocorticoid or aldosterone replacement (or both) as necessary. The goal of therapy of adrenal hyperplasia is the replacement of glucocorticoid and mineralocorticoids to prevent hypovolemia and hypotension and to suppress precursor hormones that cause virilization. Infants with ambiguous genitalia will require surgical evaluation.

# Adrenal Hypoplasia, Congenital

Manish Suneja, Christie P. Thomas
Division of Nephrology, Department of Internal Medicine, University of Iowa College of Medicine, Iowa City, IA, USA

## Synonyms

X-linked Addison's disease; Congenital adrenal hypoplasia with hypogonadotropic hypogonadism; Cytomegalic adrenocortical hypoplasia

## Definition and Characteristics

Congenital adrenal hypoplasia is a rare inherited disorder with genetic heterogeneity which generally presents within the first year of life with variable signs and symptoms, including vomiting and malaise, hypotension from hypovolemia and hyperpigmentation [1,2].

Three forms of congenital adrenal hypoplasia have been identified, as follows:

1. An X-linked form (OMIM 300200) is caused by a mutation or deletion of the DAX1 gene (dosage-sensitive sex reversal adrenal hypoplasia congenita critical region of the X chromosome, also called the AHCH gene) on the X chromosome. This form is usually associated with hypogonadotropic hypogonadism and failure to undergo puberty in boys. If the deleted region includes the contiguous glycerol kinase gene, psychomotor retardation and Duchenne type muscular dystrophy is also seen.
2. The autosomal recessive form (OMIM 184757) is from a mutation of the gene that codes for steroidogenic factor 1 (SF-1) on chromosome 9q33. This is associated with ambiguous genitalia in genetic males.
3. An autosomal recessive form of uncertain etiology (OMIM 240200) has also been identified.

## Prevalence

Rare disease.

## Genes

DAX1, steroidogenic factor (SF1), Gene map locus Xp21.3-p21.2, 9q33, Inheritance X linked, Autosomal recessive.

## Molecular and Systemic Pathophysiology

The roles of DAX1 and the undefined autosomal recessive gene in development of the adrenal cortex are not fully understood. DAX1 appears to be necessary for differentiation of the definitive adult adrenal cortex but not the fetal adrenal cortex, since the latter is preserved in patients who have deletions of DAX1. DAX1 acts as a transcriptional repressor for SF-1 and other genes involved in steroidogenesis. SF-1 is a transcriptional activator regulating steroidogenesis and male sexual differentiation and DAX1 is one of its principal targets.

## Diagnostic Principles

The most difficult aspect of adrenal insufficiency is clinical suspicion because signs and symptoms can be insidious or subtle. A cosyntropin stimulation test confirms the diagnosis of adrenal insufficiency. A spot urine or a 24-h urine for sodium, potassium, and creatinine, along with simultaneous serum sodium concentrations and creatinine concentrations, will determine whether inappropriate natriuresis is occurring. High-resolution karyotype may also be helpful.

## Therapeutic Principles

Patients are generally hypovolemic and may be hypoglycemic; therefore, initial therapy should consist of intravenous normal saline and dextrose. In cases of hypotension, a bolus dose of isotonic fluids over the first hour may be necessary to restore blood pressure. This can be repeated if the blood pressure remains low. Once electrolytes, blood sugar, cortisol, 17-hydroxyprogesterone and ACTH concentrations are obtained, the patient should be treated with glucocorticoids based on suspicion of adrenal insufficiency, since it may be life preserving.

# Adrenal Insufficiency

Holger S. Willenberg[1], Stefan R. Bornstein[2]
[1]Department of Endocrinology, Diabetes and Rheumatology, University Hospital Duesseldorf, Duesseldorf, Germany
[2]Medical Clinic III, University Hospital Dresden, Dresden, Germany

## Synonyms

Addison's disease; Morbus Addison (for primary forms of adrenal insufficiency); Adrenocorticotropic pituitary insufficiency (for secondary forms of adrenal insufficiency)

## Definition and Characteristics

Adrenal insufficiency (AI) is a heterogenous group of diseases leading to a functional impairment of the hypothalamic pituitary adrenal (HPA) axis. Eventually, there is a lack of glucocorticoids and/or mineralocorticoids. AI is termed "primary," when the disease process is located within the adrenal glands, "secondary" when the pituitary is the site of failure, or "tertiary" when the hypothalamus hosts the cause of the disease. In addition, there is a group of disorders that can not be classified within this scheme, but are characterized by relative hypocortisolism. In these cases, the need of glucocorticoids exceeds the capacity of the HPA axis, such as in critically ill patients when the strong feedback by cortisol prevents the adequate rise in ACTH secretion.

## Prevalence

Congenital adrenal hypoplasia, the demyelinating X-linked lipid metabolism disorders: adrenoleukodystrophy and adrenomyeloneuropathy, and other causes of primary adrenal insufficiency, such as unresponsiveness to corticotropin, have a low prevalence. On the other hand, iatrogenic forms of AI are frequent. Autoimmune adrenalitis is the most common cause of primary AI in developed countries (70%). Secondary AI compromises the largest patient population with AI.

## Genes

A monogenetic form of this syndrome, autoimmune polyendocrinopathie–candidiasis–ectodermal dystrophy (APECED, APS type I), is due to mutations in the autoimmune regulatory (AIRE) gene located on chromosome 21q22.3.

Isolated familial glucocorticoid deficiency may be due to ACTH resistance and consists of two distinct genetic syndromes, both of which being inherited as autosomal recessive traits. Inactivating mutations of the ACTH receptor (MC2R) gene or mutations in other

genes are causes for isolated resistance to ACTH. Allgrove syndrome (triple A syndrome) may be due to mutations in the AAAS gene on chromosome 12q13, which codes for the alacrima-achalasia-adrenal insufficiency-neurologic disorder (ALADIN) protein.

Hereditary or congenital adrenal dysfunction is particularly important in the pediatric patient population and is in the majority of cases due to steroid 21-hydroxylase deficiency. Isolated hypoaldosteronism can occur as a consequence of corticosterone 18-methyl oxidase II deficiency. Hyporeninemia and renal tubular acidosis type IV are also associated with hypoaldosteronism. Adrenal hypoplasia congenita (AHC) can occur in an X-linked trait due to a mutation in the DAX-1 gene. Hypogonadotropic hypogonadism or premature puberty can be combined with this disorder or the only clinical presentation.

Susceptibility to develop APS type II, a polygenetic disorder, is conferred by genes in the human leukocyte antigen (HLA) region on the short arm of chromosome 6. Different susceptibility and resistance alleles of the MHC class II have been identified so far. Other candidate genes include the cytotoxic T lymphocyte antigen 4 (CTLA4) coding region of chromosome 2 on q33.

## Molecular and Systemic Pathophysiology

In rare cases, AI is secondary to monogenic defects. The most important cause of AI is, however, autoimmune adrenalitis. It occurs isolated or in combination with other autoimmune diseases in autoimmune polyendocrinopathie syndrome (APS) (Table 1).

Other causes of AI include bilateral adrenal tumors due to chronic infectious, granulomatous or tumorous diseases, including postprimary tuberculosis, sarcoidosis, toxoplasmosis, histoplasmosis, or metastatic infiltration (e.g., lung or breast cancer, malignant melanoma). Destruction of the adrenal cortex can also be the result of hemorrhage during meningococcemia. Also adrenocortical glucocorticoid secretion is frequently impaired in chronic systemic diseases, including amyloidosis and AIDS.

Iatrogenic AI includes bilateral adrenalectomy and treatment with special drugs. Secondary AI most frequently results from suppression of the HPA axis by and subsequent correction or withdrawal of endogenous (Cushing's syndrome) or exogenous (iatrogenic) glucocorticoids. Other causes include hypopituitarism following neurosurgery or irradiation to control neoplastic lesions (pituitary adenoma, craniopharyngeoma). In addition, vascular lesions, trauma, Sheehan's syndrome, and apoplexy can also lead to impaired pituitary function. "Idiopathic" hypopituitarism is either due to mutations in genes expressed by the corticotrophs, such as prop-1, or due to hypophysitis, e.g., in autoimmune triple H syndrome.

Tertiary AI is a rare form of adrenal insufficiency and mostly due to irradiation, hemorrhage, tumors, and ischemia. The gucocorticoid resistance syndrome is an end-organ resistance, effectively presenting as glucocorticoid deficiency. Since aldosterone is not only stimulated via ACTH, secondary and tertiary AI is usually limited to glucocorticoid deficiency.

The clinical presentation of AI can vary, depending on age of manifestation and underlying disorder. While symptoms of primary AI in the majority of cases are determined by hypocortisolism and hypoaldosteronism, secondary and tertiary AI result only occasionally in hypoaldosteronism. On the other hand, in secondary and tertiary forms, AI is very often complicated by somatotropic, gonatotropic, and thyreotropic insufficiency, and often the last deficiency develops in hypopituitarism. All forms of adrenal insufficiency may present as an acute adrenal crisis or as chronic state with exacerbations. Symptoms include poor feeding in infants, weakness, failure to thrive, weight loss, fatigue, nausea and vomiting, diarrhea, orthostatic hypotension with dizziness from postural or persistent hypotension to hypovolemic shock due to dehydration. Other signs may be fever, abdominal pain, or hypoglycemia. Patients with chronic primary AI present with hyperpigmentation (creases of palms, nail lunulae, buccal mucosa, breast areolas and nipples, and scars), because of extensive ACTH levels. Enzyme deficiencies of CAH,

hyperandrogenism leads to virilization in girls and premature puberty or acne conglobata in boys.

## Diagnostic Principles

Early laboratory findings in AI may be lymphocytosis, eosinophilia, and neutropenia before hyperkalemia and hyponatremia develop. In addition, azotemia and metabolic acidosis may point to the diagnosis of AI. Hormone measurements are given in Table 2.

## Therapeutic Principles

Since routine laboratory studies do not necessarily demonstrate abnormalities, waiting for hormone analyses should not delay therapeutic intervention during adrenal crisis and be initiated immediately after the blood tests. Hypovolemic shock requires rapid replacement of sodium, glucose and water deficits. The therapeutic goal is an optimal and dynamic replacement of glucocorticoids and, if necessary, mineralocorticoids, depending on stress-related needs. All patients and their close relatives and friends need careful education. Usually, patients tolerate glucocorticoid therapy very well. Treatment of choice is hydrocortisone orally. To simulate the circadian rhythm of glucocorticoid secretion, split doses are given (Table 3).

Patients should take the first dose early in the morning and adopt their plan to the working time or sport excercises. In slight stress, before surgery, dental treatment, or during periods of intercurrent infection, the dosage has to be doubled or even tripled. During severe stress, such as infection or major surgery, replacement doses up to 200 mg hydrocortisone per day are required, sometimes, even continuous intravenous infusion. After overcoming this situation, the hydrocortisone doses should be returned to the normal replacement regimen within a few days. When doses higher of 60 mg hydrocortisone per day are given, no separate mineralocorticoid replacement is needed.

**Adrenal Insufficiency. Table 3** Example for glucocorticoid replacement therapy

| Glucocorticoid | Morning | Noon | Afternoon |
|---|---|---|---|
| ***Primary AI*** | | | |
| Hydrocortisone | 15 mg | 5–10 mg | 5 mg |
| Cortison actetate | 25 mg | – | 12.5 mg |
| Prednisone | 5 mg | – | – |
| ***Secondary and tertiary AI*** | | | |
| Hydrocortisone | 10 mg | 5 mg | – |

Otherwise, 0.05–0.1 mg fludrocortisone should be added in primary AI. Since these patients are frequently not quite able to conserve electrolytes, they should be put on a sodium-enriched diet. Treatment with corticotropin in subcutaneous injections conserves androgen secretion but bears the risk of allergic side effects and anaphylaxia. Therefore, female Addisonian patients have a better well-being when given DHEA in daily doses between 50 and 100 mg.

Adrenal crisis is often precipitated by acute stress. Therefore, appropriate increase in hydrocortisone replacement serves to restore glucocorticoid function. Slight elevation of TSH can be present in adrenal crisis and, independently, in autoimmune thyroid disease. If adrenal insufficiency is suspected, cortisol replacement has to be started earlier than treatment for hypothyroidism, because replacement of levothyroxin thrives the metabolism and may worsen the patient's condition in AI. Salt and volume loss are treated by intravenous infusion of 5% glucose in normal saline solutions lacking potassium. Cortisol should be administered, starting with a bolus of 100 mg.

# Adrenal Insufficiency, Secondary

Holger S. Willenberg
Department of Endocrinology, Diabetes and Rheumatology, University Hospital Duesseldorf, Duesseldorf, Germany

## Synonyms

Central hypocortisolism; Adrenocorticotropic insufficiency

## Definition and Characteristics

Adrenal insufficiency (AI) is a heterogenous group of diseases leading to a functional impairment of the hypothalamic pituitary adrenal (HPA) axis. AI is termed "secondary" when the pituitary is the site of failure, or "tertiary" when the hypothalamus hosts the cause of the disease. In clinical routine, very often the term *secondary adrenal insufficiency* is used for all pituitary or hypothalamic disorders and also for states of adrenal insufficiency after high-dose or long-term treatment with glucocorticoids.

## Prevalence

Secondary AI compromises the largest patient population with AI.

## Genes

"Idiopathic" hypopituitarism may be caused by mutations in genes expressed by the corticotrophs, such as prop-1, DAX-1, pit-1, and others.

## Molecular and Systemic Pathophysiology

Suppression of the HPA axis by and subsequent correction or withdrawal of endogenous (Cushing's syndrome) or exogenous (iatrogenic) glucocorticoids is the most common cause of secondary AI. Other causes include hypopituitarism following neurosurgery or irradiation to control neoplastic lesions (pituitary adenomas, craniopharyngeoma, menigeomas, metastasis) while tumors of the pituitary or adjacent structures themselves may impair the function of pituitary corticotrophs. In addition, granulomatous diseases (e.g., sarcoidosis and others), vascular lesions, trauma, Sheehan's syndrome, apoplexy, or hemorrhage into tumors can also lead to impaired pituitary function. "Idiopathic" hypopituitarism is either due to genetic defects of genes expressed by the corticotrophs or due to hypophysitis, e.g., in autoimmune triple H syndrome.

The clinical presentation of secondary AI can vary, depending on age of manifestation and the underlying disorder. Although aldosterone is mainly regulated by the renin-angiotensin-aldosterone system, secondary and tertiary AI are not necessarily limited to glucocorticoids and – in women – androgen deficiency. In addition, secondary AI is very often complicated by somatotropic, gonatotropic, thyreotropic insufficiency, and central diabetes insipidus and often the last to develop in hypopituitarism. Isolated forms of secondary AI exist and occur more frequently in idopathic forms of hypopituitarism. However, AI may present as an acute adrenal crisis or as a chronic state with exacerbations. Typical symptoms include poor feeding in infants and failure to thrive. Other symptoms are algor, weakness, arthralgias, fatigue, nausea and vomiting, abdominal pain, diarrhea, weight loss, and orthostatic hypotension with dizziness. Other features may be fever, hyponatremia, and hypoglycemia.

## Diagnostic Principles

Early laboratory findings in AI may be lymphocytosis, eosinophilia, and neutropenia before hyponatremia and hyperkalemia develop. In addition, azotemia, metabolic acidosis, and low plasma glucose may point to the diagnosis of AI. Hormone measurements are given in Table 1.

## Therapeutic Principles

Since routine laboratory studies do not necessarily demonstrate abnormalities, waiting for hormone analyses should not delay therapeutic intervention during adrenal crisis and initiated immediately after the blood tests. Salt and volume loss are treated by intravenous infusion of 5% glucose in normal saline solutions lacking potassium. Cortisol should be administered, starting with a bolus of 100 mg. Perspectively, the therapeutic goal is an optimal and dynamic replacement of glucocorticoids and, if necessary, mineralocorticoids and androgens, depending on stress-related needs. All patients and their close relatives and friends need careful education. Treatment of choice is hydrocortisone orally. To simulate the circadian rhythm of glucocorticoid secretion split doses are given, e.g., 10 mg–5 mg–0 mg, sometimes less, sometimes 12 mg per qm body surface or more, depending on symptoms,

| Cortisol 30 or 60 min after 100 μg CRH | <18 μg/dL | <18 μg/dL | <18 μg/dL |
| Plasma ACTH 30 or 60 min after CRH | High | Blunted response | Delayed or good response |
| Cortisol after insulin-induced hypoglycemia | <20 μg/dL | <20 μg/dL | <20 μg/dL |
| Plasma ACTH after insulin | High | Minor response | Minor response |

lymphocyte count, elecrolytes, electrolyte diuresis, and 24-h urinary excretion of cortisol.

Patients should take the first dose early in the morning and adopt their plan to the working time or sport exercises. In slight stress, before surgery, dental treatment, or during periods of intercurrent infection, the dosage has to be doubled or even tripled. During severe stress, such as infection or major surgery, replacement doses up to 200 mg hydrocortisone per day are required, sometimes even continuous intravenous infusion. After overcoming this situation, the hydrocortisone doses should be returned to the normal replacement regimen within a few days. Female patients with AI have a better well-being when given DHEA or low-dose testosterone.

## Synonyms

Formerly Schilder's disease

## Definition and Characteristics

X-linked recessive disease that primarily affects young boys with an onset between 3 and 10 years and exhibits progressive behavioral, cognitive, visual, auditory and gait abnormalities (juvenile or childhood cerebral

form). Death usually occurs within three years. Most develop clinical signs of adrenocortical insufficiency and after the onset of neurologic symptoms. Adolescent and adult forms also occur.

## Prevalence

1:25,000 in males.

## Genes

The ABCD1 (formerly ALD) gene on Xq28 has ten exons and encodes a peroxisomal integral membrane ABC half-transporter, ABCD1 or ALDP. A large number of mutations have been identified: about one-half are missense and one-quarter are frameshift mutations; exon 5 appears to be a mutational hot spot. Mutations in ABCD1 do not correlate with specific phenotypes in that the identical mutation can result in the AMN, ALD or Addisonian phenotypes in the same family. Modifier genes or environmental factors are suspected to contribute to the phenotypic variability [1].

## Molecular and Systemic Pathophysiology

The precise cellular role of ABCD1 is unclear. There is some evidence that ABCD1 can homodimerize or heterodimerize with other peroxisomal membrane proteins, and that overexpression of one may compensate for a deficiency of another. The expression of the ABCD1 transcript is highest in the adrenal gland and intermediate in brain. ABCD1 is most prominent in adrenal cortex, microglia, astrocytes, endothelial cells, and oligodendrocytes of the corpus callosum and internal capsule. How the absence of ABCD1 relates to the biochemical signature of all phenotypes: elevations in abnormal saturated very long chain (≥C22) fatty acids (VLCFA), is uncertain. The peroxisomal beta oxidation system is responsible for initiating the degradation of VLCFA. The abnormal VLCFA had been assumed to be due to decreased peroxisomal degradation primarily through decreased activity of its acyl-CoA synthetase (lignoceroyl-CoA ligase), but there is also evidence for increased synthesis by the microsomal elongation system. Recent data derived from knockout mice have cast doubt on the primacy of the former and the postulate that ABCD1 may transport VLCFA or its acyl-CoA synthetase across the peroxisomal membrane. These data also raise questions about the putative pathogenic role of VLCFA [2].

The systemic pathophysiology of ALD (or AMN) appears to be a complex pathogenetic fabric in which VLCFA, abnormal membrane fluidity, myelin instability, axonal dysfunction, inflammation/immune activation and perhaps age-related steroid fluctuations conspire to wreak havoc in the central nervous system (CNS). The endocrine failure is due to primary atrophy and apoptotic death of adrenocortical and testicular Leydig cells, presumably caused by the cytotoxic effects of free VLCFA.

We have proposed that dysmyelinative foci (loss of myelin and oligodendrocytes without an appreciable cellular reaction) constitute the initial myelin lesion of ALD and might be due to the incorporation of saturated VLCFA into myelin, which can lead to its spontaneous breakdown. Free saturated VLCFAs are extremely insoluble, particularly at normal body temperature; they adversely affect the viscosity of erythrocyte and adrenocortical cell membranes, disrupt model membranes, and are toxic to a number of cell types. The toxicity of free fatty acids varies directly with their length and degree of saturation. Most of the emphasis in ALD has been on C26:0 and C24:0, but longer chain lengths also occur. The sources for the VLCFA are both endogenous and exogenous. The greatest excess occurs in ganglioside, PLP, cholesterol ester and phosphatidylcholine fractions, the latter even in "normal" white matter. The cholesterol esters are found in macrophages of actively demyelinating areas, not in normal areas, which indicates that they are secondary players in the dysmyelination. VLCFA in any of the other three myelin components would be reasonable candidates to destabilize the myelin sheaths, once a certain threshold is reached. PLP is the most appealing candidate, both for the dysmyelination and particularly for the transition to inflammatory demyelination [3].

The inflammatory demyelination appears to involve an initial innate immune response to the insoluble lipids that may simulate a bacterial pathogen, in which macrophages and astrocytes produce cytokines, particularly TNF-α; this promotes a compromise of the blood–brain barrier and an influx of sensitized lymphocytes. An adaptive immune response then supervenes and several pathogenic elements seem to participate: an MHC-dependent TH-1 response, MHC-unrestricted CD1 lipid presentation, CD8 CTLs (probably unconventional), and oxidative damage by peroxynitrite and 4-hydroxynonenal, with resultant oligodendroglial lysis and loss of myelin. It is noteworthy that, despite biochemical and ultrastructural evidence for the involvement of brain, peripheral nerve, adrenal cortex, and testis, the only inflammatory site in ALD or AMN that converts to ALD is the brain. Hence, a CNS-specific antigen, such as PLP, is particularly appealing [4,5].

## Diagnostic Principles

Cerebral signs or symptoms with or without adrenocortical failure in a young male confirmed by an elevation of VLCFA, particularly C26:0, in plasma.

## Therapeutic Principles

Replacement therapy for adrenal insufficiency. Low fat diet combined with Lorenzo's oil (glyceryl trioleate–trierucate) can rapidly lower plasma VLCFA and may

be beneficial. Bone marrow, or stem cell at present, transplantation is effective in pre-clinical or mildly affected patients. Highly immunosuppressive protocols, including anti-oxidants such as N-acetylcysteine, are under study in more neurologically compromised patients. Gene therapy is in the developmental stage.

## Synonyms

Adult variant of adrenoleukodystrophy; ALD; AMN

## Definition and Characteristics

X-linked recessive disease in which men in their third to fourth decade, with or without adrenocortical or testicular dysfunction, develop difficulty walking due to spastic paraparesis and sensory ataxia that progresses slowly over years to eventuate in a wheelchair-bound existence; a milder peripheral neuropathy usually co-exists. Their neurological symptomatology may be restricted to this myeloneuropathy (pure AMN) or they may develop clinical signs or MRI lesions of cerebral white matter disease (cerebral AMN) that manifests as mild psychomotor deficits to visual or auditory abnormalities to dementia to a rapidly fatal ALD phenotype. Voiding abnormalities and impotence are common. Female heterozygotes may become symptomatic with a milder course and later onset of neurological deficits.

## Prevalence

1:20,000 in males and 1:15,000 in females.

## Genes

See ►Adrenoleukodystrophy.

## Molecular and Systemic Pathophysiology

See essay on ►Adrenoleukodystrophy.

The systemic pathophysiology of AMN (or ALD) appears to be a complex pathogenetic fabric in which Very long chain Fatty acids (VLCFA), abnormal membrane fluidity, myelin instability, axonal dysfunction, inflammation/immune activation and perhaps age-related fluctuations in steroid levels somehow conspire to wreak havoc in the central nervous system (CNS). In AMN the major CNS lesion is a myelopathy, but adrenal and testicular dysfunction usually co-exist. The endocrine failure is due to primary atrophy and apoptotic death of adrenocortical and testicular Leydig cells, presumably caused by the cytotoxic effects of free VLCFA.

The precise pathophysiology of the myelopathy is unknown, but neuropathologic and neurophysiologic data are most consistent with a primary “dying-back” axonopathy. The predominant spinal lesion is one of bilaterally symmetrical long tract degeneration, most commonly affecting the gracile tracts of the posterior columns (which carry the ascending large proprioceptive and vibratory sensation fibers of the dorsal root ganglia (DRG) from the legs) and the crossed lateral corticospinal tracts (which carry the descending large pyramidal fibers from the cerebrum). The tract degeneration consists of equivalent losses of axons and myelin sheaths that are greatest and seen earliest in the cervical gracile tracts and the lumbar

corticospinal tracts. That is, the axonal degeneration is most severe in the axonal compartment most distant from the parent cell body (e.g., DRG for gracile tracts) and progressively becomes equally severe in more proximal segments ("dying-back" toward the cell body) [1]. The parent neurons in the lumbar DRG, and presumably those of the pyramidal tracts, are atrophic but not appreciably lost at autopsy – which makes therapeutic intervention a realistic possibility if the pathophysiologic mechanism can been identified [2]. It has been postulated that, when VLCFA become incorporated into axonal membranes their viscosity/fluidity is adversely affected. An alternate, and perhaps not mutually exclusive, pathophysiologic mechanism would be an abnormality in axoplasmic transport. The recent discovery of abnormal mitochondria (lipidic inclusions) in DRG of AMN patients raises the possibility of decreases in energy needed for axoplasmic transport [2]. If ALDP were found to be transported down the axon, this could provide a most desirable pathophysiologic link between the gene defect and the neuropathologic data.

### Diagnostic Principles

Gait difficulties with or without adrenocortical, rarely testicular, failure in a young adult male. Confirmed by an elevation of VLCFA, particularly C26:0, in plasma.

### Therapeutic Principles

Replacement therapy is needed for adrenal insufficiency. Androgen replacement therapy is more controversial. Low fat diet combined with Lorenzo's oil (glyceryl trioleate-trierucate) can rapidly lower plasma VLCFA and may be beneficial. Bone marrow, or stem cell at present, transplantation is not recommended for AMN, but is being considered if AMN begins to convert to ALD. Gene therapy is in the developmental stage and not yet available [3].

## ALA Dehydratase Porphyria

Herbert L. Bonkovsky[1], Manish Thapar[2], Sishir Mathur[3]
[1]Research Cannon Research Center, Carolinas Medical Center, Charlotte, NC, USA
[2]Division of Gastroenterology and Hepatology, University of Missouri, Columbia, MO, USA
[3]Liver Billary Pancreatic Center, University of Connecticut Health Center, Farmington, CT, USA

### Synonyms

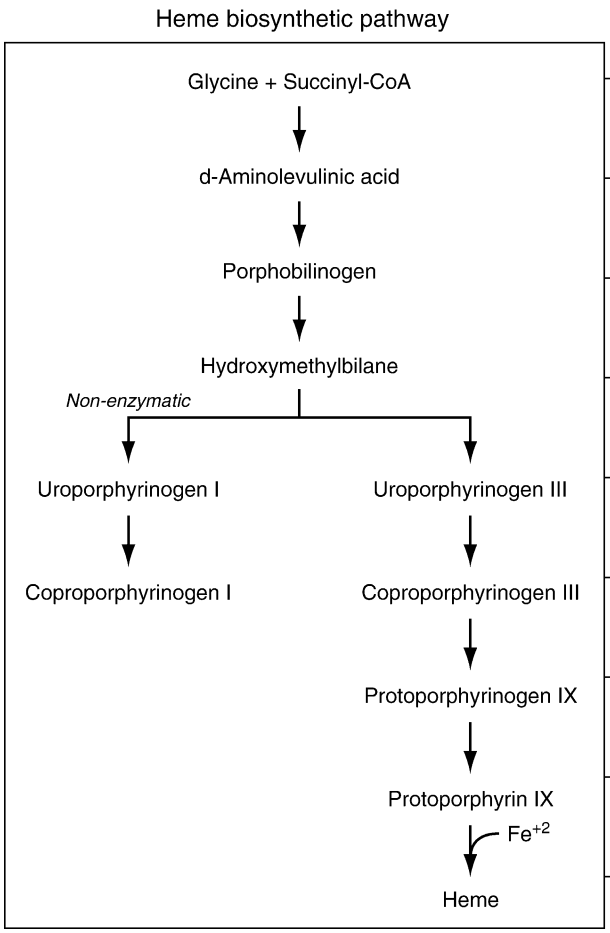
Doss porphyria; Plumboporphyria; ADP

### Definition and Characteristics

δ-aminolevulinic acid dehydratase porphyria (ADP) is a rare disorder caused by a profoundly decreased activity of δ-aminolevulinic acid dehydratase (ALAD), also known as porphobilinogen synthase (PBGS). ALAD catalyses the second step in the heme biosynthetic pathway, namely the condensation of two molecules of δ- aminolevulinic acid (ALA) into one of porphobilinogen (PBG) (Fig. 1).

ADP has an autosomal recessive inheritance and all of the well-documented cases thus far described have been males. Affected patients present with a variety of neurovisceral symptoms. Cutaneous manifestations have not been described in ADP [1]. The abdominal symptoms are very similar to those of the other acute porphyrias (acute intermittent porphyria, hereditary coproporphyria, variegate porphyria) and include episodes of colicky abdominal pain, nausea, vomiting, and constipation. Other neurologic manifestations include autonomic neuropathy, polyneuropathy, psychiatric symptoms or convulsions. Precipitating factors such as exposure to porphyrogenic drugs have not been evident in most reported cases.

Heterozygotes, who have ~50% of the normal activity of ALAD, are asymptomatic, but may have enhanced susceptibility to lead, and to the toxic effects of other chemicals such as 4,6-dioxoheptanoic acid (succinylacetone), iron, trichloroethylene, and styrene that can adversely affect the ALAD activity [2].



| Enzymes | Diseases |
|---|---|
| ALA synthase | |
| ALA dehydratase | ALA dehydratase deficiency |
| Porphobilinogen deaminase | Acute intermittent porphyria |
| Uroporphyrinogen III synthase (cosynthase) | Congentital erythropoietic porphyria |
| Uroporphyrinogen decarboxylase | Porphyria cutanea tarda hepatoerythropoietic porphyria |
| Coproporphyrinogen oxidase | Hereditary coproporphyria |
| Protoporphyrinogen oxidase | Variegate porphyria |
| Ferrochelatase | Protoporphyria |

**ALA Dehydratase Porphyria. Figure 1** The heme biosynthetic pathway.

## Prevalence

Fewer than a dozen cases have been reported so far. The prevalence of heterozygous ALAD deficiency is estimated to be less than 1% in Germany and 2% in Sweden.

## Genes

The human ALAD gene is found on chromosome 9 (9q34). It is 16 kb in length with two promoter regions and two alternative first exons, 1A and 1B, that generate housekeeping and erythroid-specific transcripts, respectively. Both transcripts encode the same amino acid sequence. The promoter region upstream of the housekeeping exon 1A is GC-rich and contains three potential Sp1 elements and a CCAAT box. Further upstream there are three potential GATA-1 binding sites and an AP-1 site. The promoter region upstream of the erythroid-specific exon 1B has several CACCC boxes and two potential GATA-1 binding sites [3]. These two promoter regions associated with human ALAD gene generate housekeeping and erythroid-specific transcripts by alternate splicing.

A common ALAD polymorphism, K59N, termed ALAD2, is seen in ~20% of Caucasians. ALAD2 retains normal enzyme activity but may be associated with increased susceptibility to lead toxicity.

Most, if not all, ADP cases described to date have inherited a different ALAD mutation from each unrelated parent and thus are compound heterozygotes. Eleven ALAD mutations, mostly point mutations, have been identified so far. (Cardiff; www.hgmd.cf.ac.uk).

## Molecular and Systemic Pathophysiology

ADP is often classified as an hepatic porphyria, although the site of overproduction of ALA is not established and would not be expected to be limited only to the liver. The human enzyme is believed to be a homo-octamer with a subunit size of 31-kDa. The enzyme requires an intact sulfhydryl group and one zinc atom ($Zn^{2+}$) per subunit for full activity.

Human ALAD exists as an equilibrium of functionally distinct quaternary structure assemblies, known as "morpheeins," in which one functional homo-oligomer has the ability to dissociate, change conformation and

reassociate into a different oligomer. A high activity octamer assembly and a low activity hexamer assembly have been described in human ALAD, which are in dynamic equilibrium. In ADP, the ALAD conformation has been shown to shift towards the less active hexamer assembly [4].

ALAD is the principal lead binding protein in erythrocytes, and inhibition of erythrocyte ALAD activity is a sensitive index of lead exposure. Succinylacetone (which accumulates in hereditary tyrosinemia type I) is the most potent inhibitor of ALAD, and ~40% of patients with this form of tyrosinemia develop signs and symptoms similar to ADP.

## Diagnostic Principles

Production, plasma levels, and urinary excretion of ALA are increased markedly in the face of near normal PBG levels. In contrast, other hepatic porphyrias show elevations in ALA and PBG to a similar extent.

All suspected cases should undergo a measurement of erythrocyte or lymphocyte ALAD activity. Erythrocyte ALAD activity is markedly reduced, and is not restored by the in vitro addition of dithiothreitol, which helps distinguish this disease from lead poisoning. Heterozygous parents have approximately half-normal activity of ALAD and normal urinary ALA [2]. All confirmed cases should ideally undergo mutational analysis, especially if they have first degree relatives.

Lead poisoning should be excluded by finding normal blood lead levels and showing that ALAD activity is not restored by dithiothreitol. Hereditary tyrosinemia should be excluded in young children.

## Therapeutic Principles

Hemin therapy was effective in most reported cases with acute attacks, as evidenced by clinical improvement along with decreases in urinary or serum levels of ALA. In one case weekly infusions of hemin were required to prevent recurrent attacks [5]. Limited experience shows that glucose is not very effective, but may be tried for mild symptoms. Porphyrogenic drugs should be avoided in all patients with ADP. Supportive care is similar as for other acute porphyrias [1].

There has been a single case report of liver transplantation in a Swedish child with severe disease. It is contentious whether liver transplant was of benefit or not.

# Alagille Syndrome

Lee A. Denson
Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

## Synonyms

AGS; Syndromic bile duct paucity; Arteriohepatic dysplasia; Watson-Miller syndrome

## Definition and Characteristics

Autosomal dominant developmental disorder which may include liver, heart, eye, kidney, craniofacial, skeletal, and central nervous system (CNS) abnormalities [1]. These include most commonly paucity of interlobular bile ducts, peripheral pulmonary artery stenosis, posterior embryotoxin, characteristic facies, and butterfly vertebrae.

## Prevalence

One in 100,000 live births. This may underestimate the true incidence with respect to phenotypically mild cases.

## Genes

Caused by mutations in the JAG1 gene, which encodes a cell surface ligand, Jagged1, for Notch family receptors. Most patients have null alleles, suggesting that JAG1 haploinsufficiency causes the disorder in these cases.

## Molecular and Systemic Pathophysiology

The disorder is caused by mutations in the JAG1 gene, leading to haploinsufficiency in most affected patients [2,3]. JAG1 encodes a cell surface ligand, Jagged1, for the Notch family receptors. While there is nearly complete penetrance, expression is quite variable. JAG1 mutations can be identified in 70% of patients, and are inherited in 30–50%. Mutations have been identified in almost all of the 26 exons of the gene, and include total gene deletions (6%) as well as

protein-truncating (insertions, deletions, and nonsense mutations) (82%) and missense mutations (12%). Most (72%) of the reported mutations lead to frameshifts and a premature termination codon. During both mouse and human development, JAG1 is strongly expressed in the regions of heart, kidney, eye, and developing nervous system which are ultimately affected. Interestingly, JAG1 is not expressed in developing hepatocytes or bile ducts, but rather the adjacent portal veins and hepatic arteries. This may link abnormal angiogenesis to the resulting bile duct paucity. Mice with homozygous deletion of Jag1 die during embryogenesis from defects in vascular remodeling, while Jag1+/− mice only exhibit abnormalities in eye development. Interestingly, mice doubly heterozygous for a Jag1 null allele and a Notch2 hypomorphic allele (expressed in adjacent hepatoblasts which may be bile duct precursors) exhibit a phenotype similar to Alagille syndrome; this work may give further insight into the variable phenotypic expression in humans [4].

## Diagnostic Principles

This diagnosis should be considered in all infants with neonatal cholestasis, as well as older patients with cholestatic liver disease and other features of the syndrome. The characteristic facies includes a broad forehead, deep-set eyes, mild hypertelorism, a straight nose, and a small pointed chin. The diagnosis may be made after using liver biopsy to identify paucity of interlobular bile ducts (defined as a ratio of bile ducts to portal tracts ≤0.9), combined with cardiac ultrasound, plain radiography, and ophthalmologic examination. It is generally accepted that, in addition to bile duct paucity, three of the following cardinal features should be present to make the diagnosis in a proband: cholestasis, characteristic facies, posterior embryotoxin, butterfly vertebrae, and consistent renal or cardiac disease. Family members with as few as one to two consistent clinical features should also be evaluated. JAG1 mutational analysis in the proband will facilitate this. Approximately 89% of patients who meet the overall criteria for AGS have bile duct paucity. Paucity may develop over time in infants with AGS, as the liver disease progresses.

## Therapeutic Principles

The majority of the morbidity in AGS is due to the cardiac and/or liver disease, and therapy is tailored accordingly. Most early mortality (before age 6) is related to the presence of complex congenital heart disease, while late mortality is primarily due to advanced liver disease. Recently, intracranial bleeding has also been reported in 12–14%. The subset of patients with chronic cholestatic liver disease tend to have the most severe clinical course, and will benefit from supportive care including medium chain triglyceride containing formulas as infants and fat soluble vitamin supplementation. Most presenting during infancy will remain jaundiced, with growth failure and pruritis; 10–50% will progress to cirrhosis. Pruritis can be extreme, and an indication for liver transplantation. Hypercholesterolemia is also common, and does not typically respond to medical therapy. Biliary diversion may significantly alleviate both pruritis and hypercholesterolemia, and should be considered prior to liver transplantation in patients who have not developed cirrhosis [5]. Indications for liver transplantation may include intractable pruritis, complications of cirrhosis, synthetic liver failure, or growth failure; this amounts to 21–50% of patients who present with liver disease in infancy. It should be noted, however, that growth failure may not improve after liver transplantation. Post-transplant survival has been reported in the range of 79–92%.

# β-Alanine-α-Ketoglutarate Aminotransferase Deficiency

André B. P. Van Kuilenburg[1],
Albert H. Van Gennip*
[1]Laboratory for Genetic Metabolic Diseases, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands

## Synonyms

BAKAT

*deceased

## Definition and Characteristics

Autosomal recessive? A nearly complete deficiency of BAKAT is hypothesized in patients with primary hyper-β-alaninemia. A partial deficiency of BAKAT is associated with Cohen's syndrome.

## Prevalence

The defect is very rare. Only one patient has been reported with a nearly complete deficiency [1] and one patient with a partial deficiency (50% of normal activity) [2].

## Genes

The gene locus is unknown.

## Molecular and Systemic Pathophysiology

The one reported boy with the putative nearly complete BAKAT deficiency suffered from hypotonia, hyporeflexia, generalized therapy-resistant tonic clonic seizures and intermittent lethargy and died in infancy. The patient with a proven partial deficiency of BAKAT had intermittent seizures, lethargy and Cohen's syndrome.

BAKAT is generally assumed to be the same enzyme as GABA transaminase (GABAT), but the clinical and metabolic phenotypes of deficiencies of these enzymes differ. Linear growth is normal or increased in GABAT deficiency but decreased in BAKAT deficiency. The β-alanine levels in the patient with the putative nearly complete BAKAT deficiency were two to three times normal, in plasma and CSF and 100 times normal in urine. Since the concentrations of malonic semialdehyde in urine were not increased, the block in the metabolic pathway is expected to be at the transamination step. In the patient with the partial deficiency, elevated levels of β-alanine were present in urine, but in plasma and CSF they were only seen after a 12 hours fasting period. The activity of BAKAT in the fibroblasts was decreased to 70% of control values. In the patients with GABAT deficiency, the β-alanine concentration in CSF was only eight times normal [3]. The symptoms in patients with hyper-β-alaninemia presumably reflect the agonistic effect of β-alanine on GABA receptors in the nervous tissue (see also the Fig. 1 in the chapter on ►β-aminoisobutyrate-pyruvate aminotransferase deficiency).

## Diagnostic Principles

Hyper-β-alaninemia in combination with increased concentrations of β-aminoisobutyric acid, GABA and taurine in urine are indicative of BAKAT as well as GABAT deficiency, but in BAKAT deficiency β-alanine in CSF is 100 times higher than in GABAT deficiency. Increased concentrations of the relevant amino acids in the body fluids can easily be identified by quantitative amino acid analysis.

## Therapeutic Principles

In the patient with presumed BAKAT deficiency, the metabolic but not the clinical abnormalities improved on treatment with 10 mg/day of pyridoxine orally. In the patient with proven partial BAKAT deficiency in fibroblasts, both the metabolic and the clinical symptoms improved dramatically on 100 mg/day of pyridoxine.

# Albers-Schönberg Disease

Wim Van Hul, Filip Vanhoenacker
Department of Medical Genetics, University of Antwerp, Antwerp, Belgium

## Synonyms

Marble bones disease [1]; Autosomal dominant osteopetrosis type II; Osteosclerosis fragilis generalisata

## Definition and Characteristics

An autosomal dominant form of osteopetrosis localized on chromosome 16p13.3.

## Prevalence

The prevalence of Albers-Schönberg disease is estimated at about 1/100,000 individuals [2].

## Genes

The ClCN7 chloride channel gene on chromosome 16p13.3 [3].

## Molecular and Systemic Pathophysiology

The CLCN7 chloride channel is a protein with several transmembrane domains. It has an important function in the bone resorbing cell (osteoclast). This multinucleated cell attaches to the bone thus creating an extracellular compartment. Acidification of this compartment is essential for the bone resorption process. The acidic environment is created by transfer of protons over the plasma membrane by a vacuolar-type ATPase

protonpump. The function of the CLCN7 chloride channel is to compensate for the potential generated over the membrane by transferring Cl-anions. Missense mutations in the gene encoding ClCN7 were found in patients with Albers-Schönberg disease. These mutations most likely resort a dominant-negative effect as ClCN7 are known to act as dimers.

### Diagnostic Principles

The clinical picture is highly variable ranging from individuals that are asymptomatic to patients with a very high fracture rate. Osteoarthritis of the hip and mandibular osteomyelitis can also occur. Radiologically it manifests with segmentary osteosclerosis mainly affecting the vertebral endplates ("rugger jersey spine"), the iliac wings with endobones and the skull base.

### Therapeutic Principles

No therapeutic intervention effective in increasing the bone resorption in these patients is currently available.

## Albinism

Markus Böhm, Thomas A. Luger
Department of Dematology, University Hospital of Muenster, Muenster, Germany

### Definition and Characteristics

Albinism defines a genetically and clinically heterogenous group of diseases characterized by reduction in melanin in the skin, hair and eye (oculocutaneous albinism, OCA, mostly autosomal recessive), or primarily in the eye (ocular albinism, OA, X-linked recessive).

### Prevalence

Among the different forms of albinism OCA2 has the highest prevalence of 1:37,000 in Caucasians, 1:15,000 in African-Americans, and 1:3,900 in Southern Africans with Bantu-speaking origin.

### Genes

Tyrosinase gene (Tyr), MIM 203100; P gene, MIM 203200; Tyrosinase-related protein-1 gene (TYRP1), 203290; Membrane-associated transporter protein (MATP), MIM 606574; HPS1 gene, MIM 604982; Beta-3 A-adaptin gene (ADTB3A), MIM 603401; HPS3 gene, MIM 606118; HPS4 gene, MIM 606682; HPS5 gene, 607521; HPS6 gene; MIM 607522; CHS1 gene; MIM 214500; OAI gene MIM 300500 (1).

### Molecular and Systemic Pathophysiology

Mutations of at least 12 different genes are responsible for albinism [1,2] (Table 1). Tyrosinase is the rate-limiting enzyme in melanin synthesis. Single base, missense, nonsense, frameshift and splice site mutations result in absent (in OCA1A) or reduced tyrosinase activity (in OCA1B). Mutations of OCA2 encoding the human homologue of the pink-eyed dilution gene cause OCA2. OCA2 encodes a transmembrane protein involved in generation and maintenance of the melanosomal pH. Mutations of TYRP1 result in OCA3. TRP-1 has DHICA oxidase activity and stabilizes tyrosinase and DOPAchrome tautomerase activity. Hermansky-Pudlak syndrome (HPS) is genetically heterogenous. HPS type 1 is caused by mutations of HPS1 encoding a transmembrane protein of 79 kDa which is involved in biogenesis of lysosomes and lysosome-related organelles. In other patients with HPS mutations in ADTB3A encoding the β3A subunit of AP3, an adaptor protein complex implicated in protein trafficking, were detected [3,4]. The gene associated with ►Chediak-Higashi syndrome (CHS), LYST, encodes a 430 kDa protein involved in fusion/fission events of lysosomes and related organelles. Mutations of OA1 cause OA1. The OA1 protein interacts with heterotrimeric $G_i$ proteins and appears to be involved in intracellular signaling, reorganization of the late endosomal compartment and melanosomal biogenesis [5].

### Diagnostic Principles

Albinism is most often detected by the characteristic ocular changes that are iris translucency, nystagmus and reduced visual acuity due to diminished amounts of retinal melanin and foveal hyoplasia. In OCA1A patients have white hair, skin and blue irides at birth and there is no pigment production throughout the life. Due to residual tyrosinase activity (detectable by the DOPA reaction of hair bulbs) the hair color of patients

**Albinism. Table 1** A selection of genes and loci of albinism

| Type of albinism | MIM# | Human chromosome | Human locus | Encoded protein | Murine locus | Functional role in pigmentation |
|---|---|---|---|---|---|---|
| OCA1 | 203,100 | 11q14–21 | *TYR* | Tyrosinase | *albino (c)* | Melanogenic enzyme |
| OCA2 | 203,200 | 15q11–13 | *OCA2* | Melanomsomal membrane protein[1] | *pink-eyed dilution (p)* | Stabilization of melanosomal pH |
| OCA3 | 203,290 | 9q23 | *TYRP1* | Tyrosinase-related protein (TPP-1) | *brown (b)* | Melanogenic enzyme/stabilizing factor |
| HPS | 604,982 | 10q24 | *HPS1* | Membrane protein | *pale ear (ep)* | Lysosome/melanosome structure/function |
| CHS | 214,500 | 1q43 | *CHS1* | Membrane protein | *beige (bg)* | Lysosome/melanosome structure/function |
| OA1 | 300,500 | Xp22.3–22.3 | *OA1* | Melanosomal membrane protein | *OA1 (oa)* | Intracellular signaling/melanosomal biogenesis |

[1]Modified from Oetting and King [2].

with OCA1B changes from white to blond during the first decade and may even become brown. These individuals may also tan and their visual acuity may improve. Prenatal and postnatal detection of genomic tyrosinase mutations is possible by allele-specific hybridization and PCR. Patients with the typical OCA2 have yellow hair, creamy skin and blue irides at birth. The ethnic background determines the final development of pigment. Individuals with OCA3 (formerly known as rufous albinism) have reddish skin and hair with minimal visual disturbance. Albinism associated with accumulation of ceroid-like pigment in the reticuloendothelial system and a bleeding diathesis due to a platelet storage pool deficiency is characteristic for HPS. CHS is a multisystemic disorder with features of OCA, haematologic, neurologic abnormalities, and problems with infection. Although OA primarily involves the eye it actually represents another form of OCA as cutaneous melanocytes display histologically giant melanosomes.

### Therapeutic Principles

Photoprotection is essential to minimize the risk of cutaneous cancers especially in patients with OCA1 and OCA2. Topical broad-spectrum sunscreens, physical sun protection and sunglasses are necessary and regular clinical examination on a yearly basis are advised.

# Alcohol Disorders

Karel Frasch, Markus Jäger
Department of Psychiatry II, University of Ulm, Guenzburg, Germany

## Synonyms

Acute alchohol disorders; Chronic alcohol disorders

## Definition and Characteristics

1. Alcohol intoxication: Acute alcohol-related psychopathological alterations.
2. Alcohol abuse: Repeated consumption pattern being associated with somatic and/or mental health problems.
3. Alcohol dependence ("alcoholism"): Repeated consumption pattern being associated with increase of tolerance, withdrawal symptoms, "craving," loss of control and preference of alcohol consumption compared with other activities.
4. Alcohol-related complicating transitory and chronic psychopathological syndromes: Any other psychiatric consequence being caused by alcohol consumption such as transitory or chronic alcohol-related psychotic, cognitive and/or affective syndromes.

## Prevalence

Substantial intercultural differences, highest in alcohol-"permissive" cultures such as Germany, France, Spain and Italy with a range of about 2–5% of the general population for both alcohol abuse and dependence.

## Genes

Alcoholism is a complex disorder with both genetic and environmental risk factors. Multiple genes have been demonstrated to modulate the susceptibility for alcoholism (Table 1). An important hypothesis is that people with alcohol dependence experience less aversive alcohol effects which is associated with (i) a genetically determined or environmentally caused serotonin neurotransmission deficit leading to reduced GABAergic sedation or (ii) a lack of a genetically determined slow alcohol metabolization (protective effect of the ALDH2–2 allele) [1,2].

**Alcohol Disorders. Table 1** Genes that may have an influence on alcohol use and dependence in humans [5]

| | |
|---|---|
| ADH | Alcohol dehydrogenase |
| ALDH2 | Aldehyd dehydrogenase |
| GABRA | Gamma-aminobutyric acid A receptor |
| OPRM | μ-opioid receptor |
| 5-HTT | Serotonin transporter |
| PER2 | Period gene |
| NPY | Neuropeptide Y |

## Molecular and Systemic Pathophysiology

Alcohol increases GABA and neurosteroid release and enhances the function of an extrasynaptically located GABA(A) receptor mediating inhibitory ionic currents [3]. Additionally, alcohol is an antagonist at the glutamatergic NMDA receptor which is upregulated in the course of alcohol dependence [2] whereas the GABA(A) receptor density declines (which is reversible in case of long-term sobriety); this results in typical glutamatergic withdrawal symptoms such as tremor, perspiration, agitation, nausea, vomiting, epileptic seizures and delirium, which is defined as additional clouding of consciousness, psychotic features, disorientation and autonomic nervous system dysfunction [3].

Acute alcohol consumption, similar to other psychotropic substances inducing dependence, increases the striatal release of dopamine ("reward system") which is associated with "craving" (via stimulation of μ-opiate receptors). Repeated dopaminergic stimulation leads to sensitization of the reward system and thus increases the attractiveness of alcohol and environmental cues being associated with its consumption, resulting in reduced capacity to control consumption [2].

Continued inadequate alcohol consumption can induce global atrophy of the brain most frequently affecting the frontal cortex and cerebellum [2] which is likely to be associated with deterioration in cognitive function and long term prognosis. Reduction in brain volume is at least partially reversible.

## Diagnostic Principles

Taking a drinking history (amount of alcohol consumed, time of the first alcoholic drink of the day, pattern of drinking, presence of withdrawal symptoms). Determining MCV, gamma-glutamyl transferase, blood alcohol level and CDT, which is considered as the most reliable indicator [4]. Reporting comorbid conditions (depression, anxiety or other neuropsychiatric symptoms, gastrointestinal and cardiovascular symptoms, sexual dysfunctions) and social problems.

## Therapeutic Principles

1. *Alcohol intoxication:*
   - Symptomatic treatment, sobering up.
2. *Alcohol abuse:*
   - Brief intervention by general practitioner (providing information, giving advice, "motivational interviewing").

3. *Alcohol dependence:*
   - Acute detoxification: Benzodiazepines and other *tranquilizers* (e.g. Clomethiazole) can be used to alleviate symptoms of acute alcohol withdrawal, they also prevent epileptic seizures.
   - Long term treatment: *Acamprosate* (NMDA-receptor antagonist) which is supposed to antagonize the (psychologically) conditioned central nervous system excitation. The blockade of μ-opioid receptors by substances such as *naltrexone* may help to reduce "craving" and "comfortable" effects of alcohol. Supporting evidence with regard to abstinence and relapse is weak for the alcohol aversive drug *disulfiram* (inhibitor of aldehyd dehydrogenase).

     Drug treatment should always be integrated with a comprehensive psychosocial (maintenance) therapy programe including institutions such as outreach clinics and self-help groups; thorough treatment of comorbid medical and mental disorders.
4. *Alcohol-related complicating transitory and chronic psychopathological syndromes:*
   - Symptomatic treatment.

### Synonyms

Alcalosis; Alkalemia

### Definition and Characteristics

Alkalosis is characterized by an arterial blood pH > 7.44. Metabolic alkalosis is due to a primary elevation of the plasma $HCO_3^-$ concentration. Respiratory alkalosis is defined by a primary reduction of $P_{CO2}$ due to hyperventilation (Fig. 1) [1].

Symptoms include peripheral paraesthesia, tetany and muscular cramps due to the fall in ionized calcium in serum (stronger binding of calcium to serum proteins). Primary respiratory alkalosis may lead to dizziness and fainting due to cerebral vasoconstriction [2].

### Prevalence

While alkalosis due to genetic defects is rare, metabolic alkalosis caused by volume depletion is a common side effect of natriuretic treatment.

### Genes

Mutations causing metabolic alkalosis without volume expansion [4]

Inactivating mutations in

- The renal $Na^+/Cl^-$ cotransporter NCC (SLC12A3): Gitelman's disease
- The renal $Na^+/K^+/2Cl^-$cotransporter NKCC2 (SLC12A1): type I Bartter syndrome
- The renal ROMK K-channel (KCNJ1): type II Bartter syndrome
- The renal CLC-Kb chloride channel (CLCnK): type III Bartter syndrome
- Barttin (BSND), a β-subunit of ClC-K-channels: type IV Bartter syndrome
- In the cystic fibrosis transmembrane conductance regulator, CFTR: Cystic fibrosis
- The intestinal down-regulated-in-adenoma, DRA (SLC26A3), chloride/bicarbonate exchanger
- Gain-of-function mutations in the calcium-sensing receptor (CaSR): type V Bartter syndrome

Mutations causing metabolic alkalosis with volume expansion [4]

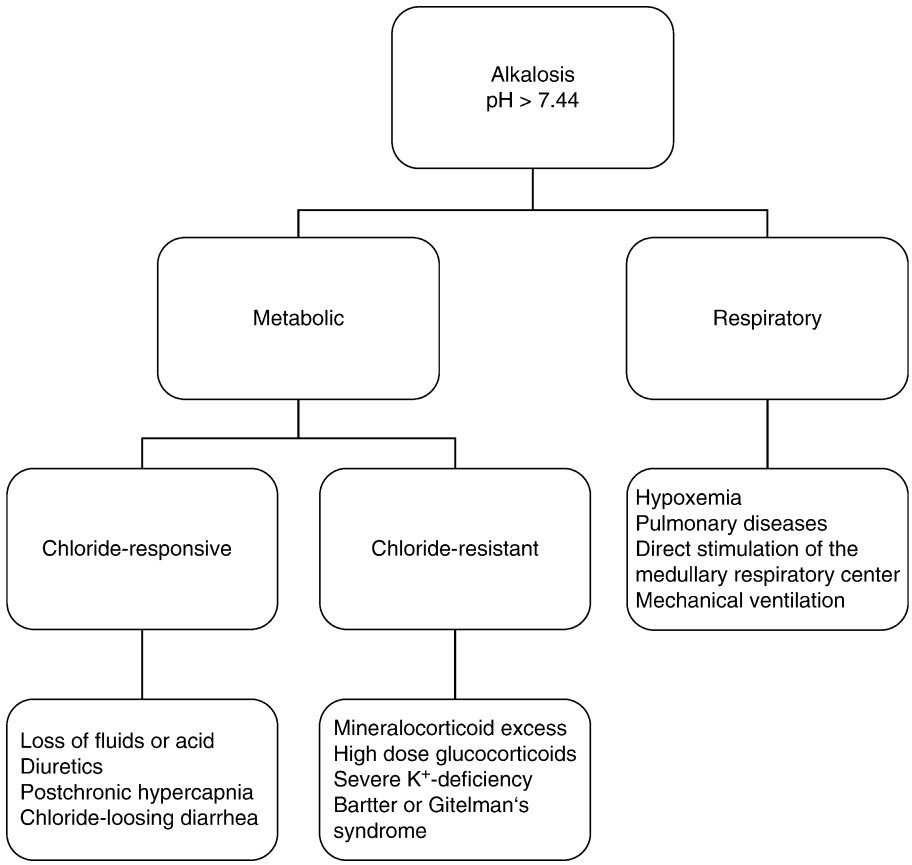
- Mutations in the steroid 11β-hydroxylase resulting in a chimeric gene with a 5′ promoter sequence of the 11β-hydroxylase gene fused to the distal 3′ aldosterone-synthase sequence: glucocorticoid remediable hyperaldosteronism
- Gain-of-function mutations in the β- or γ-subunits of the epithelial sodium channel ENaC: Liddle's syndrome
- Mutations in the 11β-hydroxysteroid dehydrogenase type 2 (11βHSD2): apparent mineralocorticoid excess

### Molecular and Systemic Pathophysiology

*Metabolic Alkalosis*: Metabolic alkalosis is caused by hydrogen ion loss from the gastrointestinal tract or in urine. Alkali administration or enhanced $HCO_3^-$ reabsorption due to volume-, potassium- or chloride depletion induce metabolic alkalosis [1].

*Chloride-responsive Alkalosis*: Primary loss of salt and consecutive extracellular (ECL) volume depletion activate the renin-angiotensin-aldosterone system, stimulate salt retention in kidney and other organs, and increase urinary potassium and acid excretion thereby promoting hypokalemia. Hypokalemia together with aldosterone stimulate renal acid excretion (ammoniagenesis and distal proton secretion). The most common causes are loop or thiazide diuretics reducing salt absorption. Loss of acidic gastrointestinal fluid (e.g. vomiting) causes higher plasma $HCO_3^-$ and ECL depletion. Chloride loss maintains metabolic alkalosis by enhancing proximal tubular $Na^+$ (and $HCO_3^-$) reabsorption, by lowering $HCO_3^-$ secretion from type B intercalated cells, and by increasing proton secretion. Excessive salt loss in sweat causes ECL depletion in cystic fibrosis [1,3].

*Chloride-resistant Alkalosis*: Primary hyperaldosteronism enhances renal salt reabsorption and potassium secretion as well as acid excretion. The syndromes of apparent mineralocorticoid excess share the features of hyperaldosteronism without aldosterone elevation.



**Alkalosis. Figure 1** Two major forms of alkalosis have to be distinguished, induced primarily by a change in metabolic functions or by a primary increase in respiration. Respiratory alkalosis can be initiated by a variety of events acting either directly on the respiratory center in the brainstem or stimulating peripheral chemo- or mechanosensors leading to increased respiratory drive. Metabolic alkalosis can be further subdivided in chloride-responsive and chloride-resistant forms. In general, chloride-sensitive forms are caused by an initial loss of salt and extracellular volume depletion which secondarily increases aldosterone activity, salt retention, potassium wasting and excessive acid excretion. This form of metabolic alkalosis can be treated with NaCl substitution. In contrast, chloride-resistant forms are due to an inappropriately increased aldosterone or aldosterone-like activity with similar mechanisms causing hypokalemia and alkalosis as in chloride-sensitive forms. However, alkalosis is treated by NaCl restriction and antagonizing aldosterone(-like) activity [1,3].

Gain-of-function mutations of the β and γ-ENaC subunits lead to excessive salt reabsorption. 11βHSD2 prevents activation of the mineralocorticoid receptor by cortisol and its absence results in hyperabsorption of salt and excessive excretion of potassium and acid [1,3,4].

*Respiratory Alkalosis*: $CO_2$-sensitive chemoreceptors in the brainstem and in the carotid and aortic bodies regulate respiratory drive. $PCO_2$ changing ambient pH is the most important stimulus for central chemoreceptors. Respiratory alkalosis arises from increased ventilatory drive due to hypoxemia or anemia, acidic cerebral pH or other stimuli such as pain, anxiety, stimulation of lung mechanoreceptors or direct stimulation of the respiratory center.

Physiologic compensation to hypocapnia involves acutely the fall in plasma $HCO_3^-$ by tissue buffering within few minutes and chronically by decreasing $HCO_3^-$ reabsorption and activating renal $HCO_3^-$ secretion. Hypoxic stimulation of peripheral chemoreceptors causes hyperventilation and rise in arterial and cerebral pH. Cerebral alkalosis limits hyperventilation unless arterial $PO_2$ falls below 50–60 mmHg or hypocapnia is not apparent because of pulmonary diseases.

Pulmonary disease (pneumonia, pulmonary fibrosis, pulmonary embolism) cause respiratory alkalosis by stimulating mechanoreceptors in the lung, chest wall, and airways causing hyperventilation. Direct stimulation of the medullary respiratory center is due to partly unknown mechanisms [1].

### Diagnostic Principles

Measurement of blood $HCO_3^-$, arterial pH and $P_{CO2}$. Urinary chloride concentration is an important parameter for differential diagnosis (95% of cases are caused by diuretics or chloride losses from the gastrointestinal tract). Chloride levels greater than 30 mmol/L suggest chloride-resistant forms such as primary hyperaldosteronism. Serum renin and aldosterone levels help to distinguish from apparent mineralocorticoid excess syndromes. Normotensive or hypotensive patients with chloride-resistant metabolic alkalosis may require genetic testing for Bartter or Gitelman's syndromes. Sweat tests when cystic fibrosis is suspected [1,3].

### Therapeutic Principles

*Metabolic Alkalosis*: Treatment of underlying etiology. In chloride-responsive forms, ECL volume has to be restored, potassium monitored, and potassium-sparing diuretics may be used. In chloride-resistant forms, NaCl should be restricted and mineralocorticoid activity reduced (mineralocorticoid receptor antagonists, ENaC inhibitors), suppression of ACTH in glucocorticoid-remediable with dexamethasone. In Bartter and Gitelman syndromes non-steroidal anti-inflammatory drugs may reduce renal chloride loss [1,2,5,3].

*Respiratory Alkalosis*: Treatment of the underlying etiology. In symptomatic patients with anxiety-hyperventilation syndrome rebreathing into a paper bag is the acute treatment of choice. In severe hypoxemia due to high altitude, oxygen should be supplied, symptoms can be ameliorated with acetazolamide [2,5].

### Synonyms

Type I hypersensitivity

### Definition and Characteristics

Allergic disease is caused by a dysregulated immune response against common, ubiquitous antigens, termed allergens, such as pollen, animal dander, pharmaceuticals or latex. The disorder is categorized by the organ

of disease manifestation and includes asthma, atopic dermatitis, allergic rhinitis, food allergy and anaphylaxis. The predisposition to produce IgE antibodies to allergens is termed atopy. Many factors affect the onset of allergic disease, including genetic susceptibility and environmental factors.

## Prevalence

Allergic disorders are common in affluent, western countries with a high degree of industrialization, affecting up to 40% of children and 30% of adults [1].

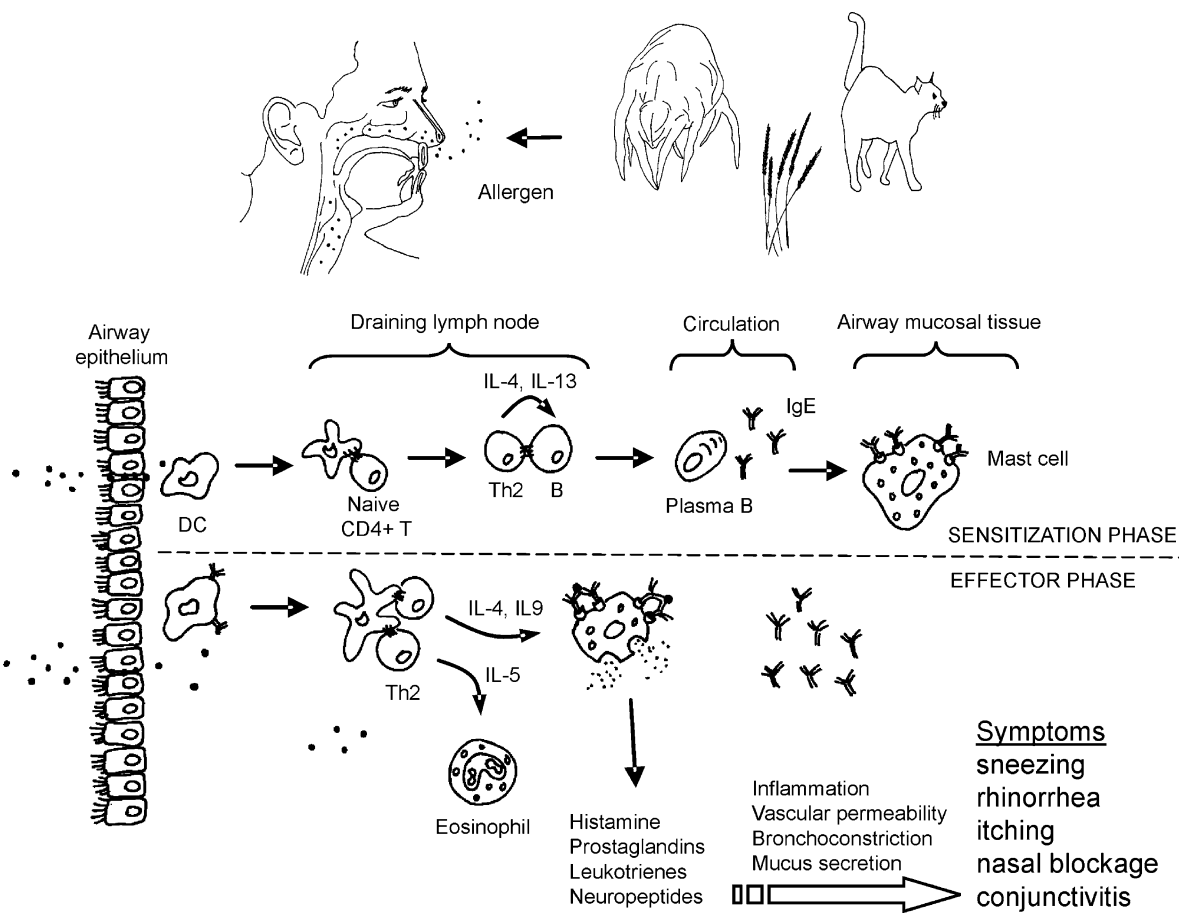
## Genes

Many genes may influence susceptibility to allergy, however, no single gene with complete penetrance has been identified. Rather, allergy occurs through complex interactions involving various genes and environmental risk factors. Among the genes associated with atopy are e.g., CTLA4 (2q33), IL-3, IL-4, IL-5, IL-9, IL-13, CD14 (5q23–q33), HLA-D, TNF-α(6p21.1-p23), FcεRIb (11q13), STAT6, SCF and IFN- γ(12q14–q24.33).

## Molecular and Systemic Pathophysiology

The allergic response is a consequence of complex signaling cascades and interactions between several cells of the immune system. Repeated exposure to allergenic compounds is required to trigger a hypersensitivity response, as exemplified by allergic rhinitis below. Allergic rhinitis is an inflammatory disorder of the upper airways, clinically characterized by inflammation of the nasal mucosa and symptoms such as sneezing, rhinorrhea, itching and nasal blockage [2]. The allergic response can be divided into two phases, the sensitization phase and the effector phase [3]. The first encounter with otherwise harmless antigens, such as inhalation of pollen or animal dander, results in sensitization and mounting of an inappropriate immune response towards the antigen (Fig. 1).

Allergens that cross the airway epithelial cells are taken up by nasal and bronchial mucosal antigen-presenting cells, mainly dendritic cells (DC), situated above and beneath the basement membrane of the respiratory epithelium [4]. The initial response to allergen in an atopic individual may be influenced by the local tissue environment, such as human thymic stromal



**Allergy. Figure 1** Cellular and molecular processes involved in the immune response in allergic rhinitis.

lymphopoietin (TSLP) or prostaglandin $E_2$ ($PGE_2$) produced by epithelial cells, which may influence the local balance of Th1/Th2 polarizing agents. DCs process the allergens and present them to allergen specific, naive $CD4^+$ T-cells in the draining lymph nodes, which subsequently become polarized proliferating effector T-helper type 2 (Th2) cells that produce cytokines such as IL-4, IL-5, IL-9 and IL-13. Within the Th2-cytokine environment, allergen specific B-cells switch their antibody production towards IgE upon cell–cell contact with T cells which involves recognition of allergen/MCH by the TCR, CD80/CD86 costimulation and ligation of CD40 by CD40L-expressing T cells. Circulating allergen specific IgE binds to various $Fc\varepsilon RI^+$ effector cells of the immune system, such as tissue mast cells and blood basophils. It is not until repeated exposure to allergens, during the effector phase, that the clinical symptoms emerge. In this phase, antigen-presenting cells, such as DCs, also process and present internalized allergens to specific memory $CD4^+$ T-cells generated during the sensitization phase. The activated effector memory T-cells further amplify the IgE production by producing Th2 cytokines. Simultaneously, intact allergen directly activates mast cells in connective tissues and basophils in blood by binding to surface IgE antibodies bound to FcεRI. Allergen induced cross-linking of FcεRI initiates a signaling cascade that cause exocytosis of preformed mediators, such as histamine, leukotrienes and prostaglandins, as well as production of various cytokines, e.g., IL-4 [5]. T-cell derived cytokines, such as IL-5, also promote eosinophil growth, differentiation and activation. Large numbers of activated eosinophils migrate into areas of allergen challenge and release, for instance, the toxic mediators major basic protein (MBP), eosinophilic cationic protein (ECP) and peroxidase (EPO), which may be responsible for tissue damage in later stages of the effector phase. Eosinophils also produce IL-4 and IL-13, which may further enhance the allergic response, as well as lipid mediators and chemoattractants. Production of Th2 cytokines and degranulation of mediators from mast cells and basophils, as well as activation of eosinophils etc. are all events that trigger the allergic inflammation. Other characteristics of allergic rhinitis include exudation of plasma proteins in the nasal and bronchial airways as a result of increased vascular permeability and the involvement of neuropeptides and nerve fibers in the nasal mucosa.

## Diagnostic Principles

The clinical diagnosis of allergic rhinitis depends on display and history of symptoms, which may be complemented with a skin prick test and detection of allergen specific IgE in blood.

## Therapeutic Principles

Allergen avoidance, drug therapy (such as antihistamines, corticosteroids) and allergen immunotherapy (vaccination with allergen extracts).

# Alopecia

Michala Bezdekova[1], Svetlana Brychtova[1], Zdenek Kolar[1], Tomas Brychta[2], Renata Kucerova[3], Martina Bienova[3]

[1]Department of Pathology and Laboratory of Molecular Pathology, Palacky University, Olomouc, Czech Republic

[2]SPEA Olomouc, s.r.o., Olomouc, Czech Republic

[3]Department of Dermatovenerology, Palacky University and University Hospital, Olomouc, Czech Republic

## Synonyms

Baldness; Hair loss

## Definition and Characteristics

Alopecia is characterized by partial or complete loss of hair. Hair loss is induced by various conditions such as hereditary disorders, aging, hormonal imbalance, internal and infectious diseases, intoxication and trauma. It is most noticeable on the scalp but can occur anywhere on the body where hair grows. Men are more frequently affected than women. Baldness can be classified into several types including androgenetic alopecia (AGA) referred to as female-pattern baldness (FPB) or male-pattern baldness (MPB), alopecia areata (AA), toxic alopecia (TA), scarring alopecia (SA) and

trichotillomania (TTM). Alopecia is generally caused by inactivation or destruction of the hair follicles preceded by a gradual shrinkage and miniaturizing. Until now, it has been believed that hair follicles can only form during embryonic development and that each individual is born with a fixed number of hair follicles. In 1998 Gat et al. reported findings on *de novo* hair follicle morphogenesis in adult skin and this has created possible strategies for the regeneration and reactivation of miniaturized hair follicles [1]. Increasing interest is being focused on β-catenin as a potential molecular candidate.

## Prevalence

By the age of 30, 30% of white men have androgenetic alopecia; by the age of 50, 50% do. White men are four times more likely than black men to develop premature balding.

## Genes

Some types of alopecia are considered to be genetically determined. In autosomal recessive alopecia universalis and papular atrichia a "hairless" gene (HR) has recently been cloned. In androgenic alopecia an initial autosomal dominant inheritance is superseded by polygenic inheritance. Functional mutations in the upstream promoter regions of the AR gene have been found and may alter transcription and translation in the affected scalp. Moreover, mutations of genes affecting plasma or tissue androgen concentration and/or alteration in the genes coding estrogen receptors, progesterone receptors, follicle stimulating hormone, sex hormone binding globulin and insulin like growth factor 1 are thought to be involved in the inheritance of AGA. The role of the HR gene in AGA development has not been proved. Recently, the loss of β-catenin has been postulated to have a major impact on hair follicle morphogenesis [2] and the precise link between androgenetic alopecia and catenin has been studied intensively. Changes to β-catenin regulation have been demonstrated mainly in cancer development, where mutations of the β-catenin gene CTNNB 1 result in disruption of a large number of cellular functions leading to loss of growth control and neoplastic change. However β-catenin mutations also induce benign tumor growth, as has been described for example in pilomatricomas and trichofolliculomas [3].

## Molecular and Systemic Pathophysiology

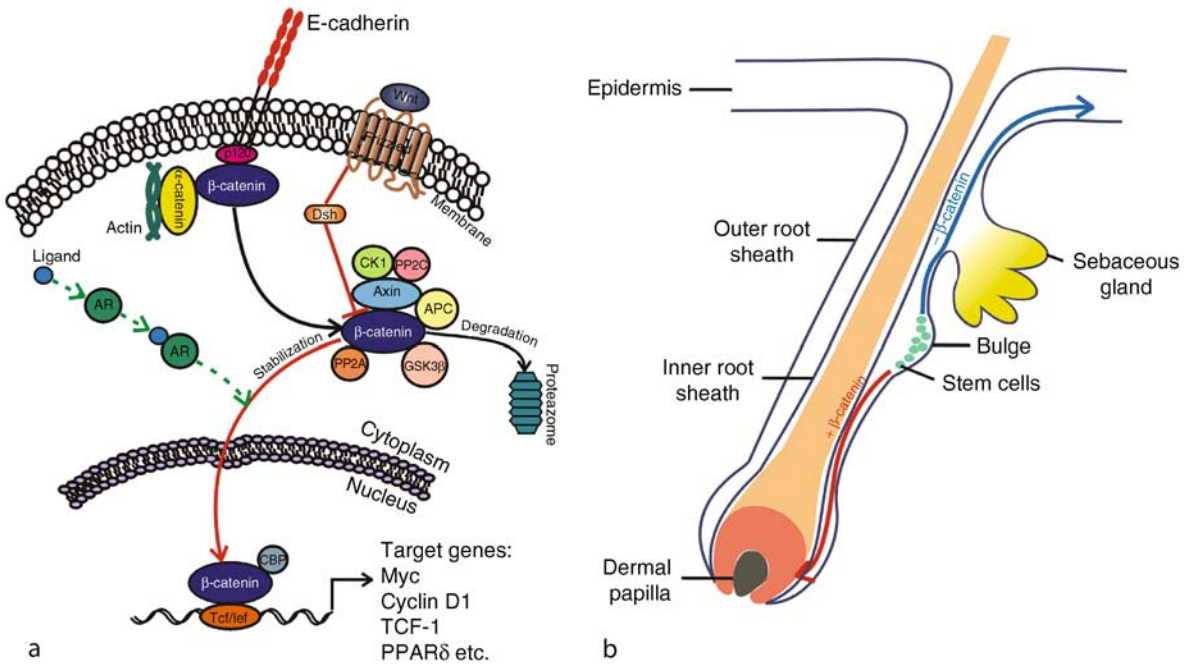
Catenins have emerged as molecular sensors that integrate cell-cell junctions and cytoskeletal dynamics with signaling pathways that govern morphogenesis, tissue homeostasis, and even intercellular communication between different cell types within a tissue [4]. Generally, β-catenin has a dual function. It plays a key role in cell-cell adhesion by linking cadherins to α-catenin and the actin cytoskeleton. In the absence of a Wnt signal, β-catenin is constitutively down-regulated by a multicomponent destruction complex containing GSK3β (glycogen synthase kinase 3 β), axin and a tumor suppressor APC (adenomatous polyposis coli). These proteins promote the phosphorylation of serine and threonine residues in the $NH_2$-terminal region of β-catenin. The β-catenin protein is then degraded by casein kinase CK1 and protein phosphatases PP2A and PP2C through the ubiquitin proteasome pathway. Wnt signaling inhibits this process, leading to an accumulation of β-catenin in the nucleus which promotes the formation of transcriptionally active complexes with members of the Tcf/lef family (T-cell factor/lymphoid enhancer factor) (Fig. 1a). In skin, the lef1/β-catenin complex is thought to regulate the differentiation of bulge stem cells to either hair follicles or epidermal cells (Fig. 1b): the complex of β-catenin and lef-1 forms a transcription factor that binds to the cell DNA activating the genes instructing the cell to become a hair follicle [1]. The absence or interference with Wnt seems to favor an epidermal or sebocyte cell fate. Moreover, it has been shown that mature skin cells expressing the constitutive form of β-catenin act like embryonic or stem cells, and start to produce aberrant new follicles throughout the interfollicular epidermis. Conversely, ablation of the lef1 gene or β-catenin expression impairs hair follicle morphogenesis. A study which investigated β-catenin in the scalp of patients suffering from AGA has revealed decreased expression of the protein compared to healthy individuals. Furthermore, the pattern of β-catenin expression showed membranous or weak cytoplasmic, but no nuclear protein location in the hair follicle [5]. Androgens and their receptors have been shown to influence β-catenin subcellular distribution and its translocation to the nucleus; however mechanisms of the nuclear translocation are not fully understood. It is possible that altered AR/β-catenin interaction might contribute to the hair follicle impairment.

## Diagnostic Principles

The diagnosis of alopecia is usually made clinically. Phototrichogram is a technique that analyzes the scalp under high-power magnification to give information on hair density, follicular unit composition and degree of miniaturization densitometrically. In case of diagnostic doubt, laboratory and histopathological examinations of scalp biopsies are sometimes necessary.

## Therapeutic Principles

So far scientists have sought how to decelerate further hair thinning and to increase scalp coverage with



**Alopecia. Figure 1** (a) Protein β-catenin connects actin filaments to the cadherins that make up adherens junctions that bind cells together. The axin/GSK3β/APC complex normally promotes the degradation of any cytoplasmic β-catenin excess. The stabilization of free pools of β-catenin by Wnt leads to entry into the nucleus and interaction with the Tcf/lef family of transcription factors to promote specific gene expression. In pathophysiological conditions aberrant β-catenin/Tcf signaling might be modulated by agonist-bound AR; (b) Hair follicle stem cells in the bulge differentiate in the presence of β-catenin into follicular keratinocytes.

limited success. This is in part because no way was known to induce the adult scalp to generate new hair follicles. Stabilization of the natural β-catenin within skin cells and activation of the Wnt pathway just long enough for formation of new follicles in alopetic scalp may open new possibilities for the treatment of alopecia based on gene therapy.

# Alopecia, Androgenetic

Tobias W. Fischer, Ralf Paus
Department of Dermatology, Venerology and Allergy, University Hospital Schleswig-Holstein, University of Luebeck, Luebeck, Germany

## Definition and Characteristics

Androgenetic alopecia (AGA; syn. male/female-pattern hair loss = MPHL/FPHL) is a clinically specific and pathogenetically fixed form of hair loss affecting both men and women of all ages during or after puberty.

AGA is a potentially reversible disease with hair growth reduction and resulting hair loss in androgen-dependent and genetically predetermined hair follicles in the fronto-temporal and vertex-region of the male scalp (defined as male pattern hair loss; MPHL), and preferentially in the cranio-parietal region of women (defined as female pattern hair loss; FPHL). Although the typical gender-specific pattern expression follows in ca. 85–90% the one that is characteristic for the

related gender, deceivingly, 5–10% each can show the pattern of the opposite gender or mixed patterns.

Both conditions, whose interpretation as a "disease" state is mainly justified by the substantial and widely underestimated individual degree of psychological suffering associated with it, develop over years in clinically observable phases: MPHL, as classified by Norwood-Hamilton, develops with thinning of the hair in the fronto-temporal area with slow retraction of the front-hair border into occipital direction and continuation in the vertex area with circular thinning of the hair and further confluence of both areas to almost complete baldness of the whole scalp except a small occipital "corona." In FPHL, thinning develops diffuse in the top-area of the scalp, classified in three grades by Ludwig, however, complete baldness is never observed [1].

## Prevalence

AGA commonly starts to develop at the age of 20–25 years, even though rare cases of much earlier start points are seen (usually coinciding with the onset of puberty and the associated surge in androgen production), and the prevalence increases up to 50% at the age of 50 years [1]. However, in the personal experience of these authors, the prevalence of at least minimal variants of AGA in both sexes at age 50 is considerably higher than customarily reported figures in the literature.

## Genes

The genetic involvement of AGA is undoubted, though poorly understood, in contrast to increasing knowledge gained about androgen involvement. Some information is available about genetic association of 5α-reductase type 1 and 2 genes with presence of AGA, and polymorphism of the AR gene is also associated with MPHL. However, the AR gene is located on the x-chromosome which makes it difficult to explain the strong penetrance of the baldness phenotype in fathers and sons. Also, no single gene has been identified so far convincingly as key genetic determinant of AGA, and polygenic inheritance with variable penetrance (e.g. on the basis of combinations of several mutations) is much more probable [1]. In addition, in FPHL, the importance of a relative lack of activity of locally produced estrogens (e.g. via insufficient aromatase activity) may have been underestimated [2].

## Molecular and Systemic Pathophysiology

The two basic pathogenesis mechanisms leading to AGA are widely appreciated to-date:

(i) increased conversion of circulating testosterone within the papilla of genetically predisposed hair follicles in androgen-sensitive scalp skin territorities to dihydrotestosterone (DHT) by intrafollicular 5α-reductase and (ii) overexpression of hair follicle related androgen receptor (AR) [1,3]. However, at least in FPHL, insufficient estrogen-stimulation may also be relevant (estrogens prolong anagen). Also, rather than abnormalities in local DHT production and/or AR expression, the target cell response to (normal) AR stimulation may be altered, e.g. by the excessive production of hair growth-inhibitory agents such as TGFβ2 [2].

Irrespective of the – as yet quite unclear – initial phases of AGA pathogenesis, the two characteristic pathophysiological events are shortening of the phase of active hair growth (anagen) e.g. by excessive AR stimulation, and hair follicle miniaturisation, likely by excessive emigration of inductive fibroblasts from the follicular dermal papilla. These events conspire to prematurely induce catagen, and thus to induce the characteristic, clinically appreciable telogen effluvium, and terminal-to-vellus conversion of hair follicles in androgen-sensitive scalp skin, transforming previously well-pigmented, thick, long hair shafts into tiny, non-pigmented, hardly visible, fibrous fluff [2,3]. It is important to emphasize that, even in the massively balding scalp, the actual number of hair follicles does not dramatically decline and that, in principle, vellus hair follicles permanently retain the full capacity to cycle and to reconvert into terminal follicles, and that they retain as many epithelial stem cells as are needed to achieve both.

The as yet unsolved key enigma remains how, when, and where exactly excessive AR stimulation and/or signalling shifts the intra- and perifolicullar balance between anagen-shortening/catagen-inducing agents (e.g. BMP2/4, FGF5, follistatin, TGFβ1, TGFβ2, prolactin, pro-NGF, BDNF and NT-3), and anagen-promoting/catagen-inhibitory agents (e.g. IGF-1, HGF, noggin) and how clinically undesired shifts in this local signalling balance, and in the subsequent imbalance in the trafficking of follicular papilla fibroblasts, can be therapeutically manipulated with highest efficacy and lowest risks [2,3].

## Diagnostic Principles

The diagnosis is largely clinical: hair thinning along the male or female pattern, increased terminal-to-vellus conversion, and telogen effluvium, positive family history for AGA. Sensible laboratory tests, especially in patients with FPHL, include DHEAS, free testosterone, SHBG, TSH, ferritin, iron, and zinc so as to detect and treat concommittant or aggravating factors, such as excessive adrenal androgen production, low iron and/or zinc stores, and abnormal thyroid dysfunction. Telogen effluvium-promoting drugs (e.g. beta-blockers,

lithium, androgens, thyrostatic agents, tamoxifen) must be recorded and, if possible, eliminated. Contrary to its common use in clinical practise, a routine trichogram (plucking of hairs with their roots and evaluation under light microscope for ratio of anagen/telogen/dystrophic hair) often provides only information of poor accuracy/reliability and is thus dispensable, while a professionally executed phototrichogram (evaluation of anagen/telogen ratio, hair count, hair density and cumulative hair shaft diameter by digital pictures taken with epiluminescence microscopy and digital software analysis) can be very useful, especially for objective follow-up of the response to treatment.

### Therapeutic Principles

Available therapeutic principles are still limited to two FDA-approved drugs, the oral 5-alpha-reductase inhibitor, finasteride (1 mg/day) and the topically applied potassium-channel opener, minoxidil (2–5%). While the latter can be used both in men and women, the former has been FDA-approved only for use in men. However, some recent case reports question the long-held dogma that finasteride is exclusively working in men [2]. Even though this has only been poorly examined in clinical studies, in the experience of the current authors, topical long-term application of 17-β-estradiol also is a very effective therapy for halting or slowing the progression of FPHL [2].

An ever-increasing array of topical agents has been suggested as alternative or supplementary therapy for AGA (incl. e.g. 17-alpha-estradiol, melatonin, caffeine, carnitine-tratrate, and a wide variety of plant/herbal extracts). However, for all these agents, professionally executed, long-term, prospective clinical studies with a randomized, prospective, double-blinded, crosss-over design remain to be performed so as to convincingly document efficacy and safety.

In addition, MPHL is ideally suited for corrective surgery with hair follicle autotransplants from androgen-insensitive occipital scalp skin. Even though hair transplants are increasingly advocated by some authorities also for use in women with AGA, the poor (if not impossible) demarcation of androgen-insensitive scalp skin territorities questions the justification of this approach. Also, growing hope that "hair follicle cloning" (i.e. for example, the *de novo* generation of hair follicles by injection of isolated and in vitro-propagated autologous hair follicle cell populations) may become a useful therapy for AGA, appear, in our view, ill-advised, since there is really no need at all to induce any new hair follicle in AGA, since the real challenge is to reconvert vellus follicles into terminal ones, and to counteract premature anagen termination [2].

## Alport Syndrome

Birgit Haack
Department of Molecular Pathology, University Hospital of Tuebingen, Tuebingen, Germany

### Synonyms

Nephropathy and deafness

### Definition and Characteristics

Disorder of basement membranes arising from mutations in different type IV collagens. The clinical picture is dominated by renal manifestations and malformations of the eye and the cochlea [1]. Alport syndrome shows considerable genetic and clinical heterogeneity. Occurrence and severity of the auditory and renal features vary in individuals. Different modes of inheritance have been described.

### Prevalence

Alport syndrome accounts for 1–2% of patients reaching end-stage renal disease (ESRD) in Europe. The prevalence is estimated to be 1:5,000 in the US [2]. The X-linked form accounts for approximately 85% of all Alport cases [3].

### Genes

COL4A3, COL4A4 or COL4A5.

### Molecular and Systemic Pathophysiology

The autosomally recessively inherited form of Alport syndrome can be caused by mutations in COL4A3 as well as in COL4A4. Collagen IV is the major structural component of the basement membranes of kidney, eye, lung, brain and cochlea. Patients show nephritis, often progressing to renal failure and end stage renal disease (ESRD), ocular abnormalities and/or hearing impairment, which is sensorineural, bilateral and initially affecting high frequencies, but spreading to other ranges later on.

An autosomally dominantly inherited form of Alport syndrome has also been reported to be caused by mutations in COL4A3 and COL4A4 [3]. Dominant Alport syndrome belongs to a group of nephropathies comprising e.g. benign familiar hematuria, Fechtner syndrome, Epstein syndrome and branchio-oto-renal (BOR) syndrome, thus aggrevating phenotype genotype correlations.

The major, X-linked form of Alport syndrome is caused by mutations in COL4A5 localized on Xq22 [4].

The mechanisms of pathogenesis in different forms of Alport syndrome and in different affected tissues are still obscure.

### Diagnostic Principles

According to clinical symptoms and biopsy of kidney. Due to the fact that type IV collagens are comprised of multiple exons (e.g., COL4A5: 51 exons spanning over 250 kb genomic DNA) and over 300 mutations are known so far, molecular genetic analysis is laborious and costly.

### Therapeutic Principles

So far, the only therapy is dialysis or kidney transplantation. Some studies on other therapeutic options have been published [5].

## Alzheimer Disease

Stefan Kins, Konrad Beyreuther
ZMBH, University of Heidelberg, Heidelberg, Germany

### Synonyms

Dementia of Alzheimer type; Alzheimer's disease

### Definition and Characteristics

Alzheimer's disease (AD) represents the most common neurodegenerative disease in the elderly. Clinically it is characterized by a progressive loss of cognitive functions. It begins with a fluctuating forgetfulness, and progresses to a pervasive loss of memory going along with declining activities of daily living, behavioral and personality changes. In late stages, the patients typically show muscle wasting and loss of mobility. The average duration of the disease is approximately 7–10 years.

Pathological hallmarks are neurodegeneration in selectively vulnerable brain regions accompanied by proteinaceous inclusions mostly associated with an inflammatory response [1]. The pathological inclusions consist either of abnormal phosphorylated tau protein, aggregating in form of neurofibrillary tangles (NFT), or deposits of the 40–42 amino acid long β-Amyloid (Aβ) peptides assembled in oligomers forming extracellular senile plaques. The distribution of neuritic plaques varies widely from one individual to another. Neurofibrillary tangles and neuropil threads, in contrast, exhibit a characteristic distribution pattern, going along with brain regions showing neurodegeneration, permitting the differentiation of six different stages (I–VI).

### Prevalence

Among people aged 65, 2–3% show signs of the disease, while 25–50% of people aged 85 have symptoms of AD. Approximately every five years after the age of 65, the probability of having the disease doubles.

### Genes

Alzheimer disease (AD) is a genetically complex and heterogeneous disorder. Established genetic factors implicated in AD include mutations in Amyloid precursor protein (APP) (chromosome 21), presenilin (PS) 1 (chromosome 14) and PS 2 (chromosome 1). Autosomal dominant mutations in these genes (familial AD) usually induce an earlier disease onset than in sporadic cases, with the majority of mutations affecting β- and γ-secretase cleavages of APP to increase the level of all Aβ species or the relative amounts of toxic Aβ42. Individuals with duplications of only the APP gene or with trisomie 21 develop AD relatively early in life. The presence of the ApoE4 allele (chromosome 19) is the only so far identified common risk factor for sporadic AD. Several lines of evidence suggest that additional susceptibility genes exist for both early- and late-onset AD, however, none of the more than three dozen putative AD loci proposed to date have been consistently replicated in follow-up analyses [2].

### Molecular and Systemic Pathophysiology

The first hypothesis trying to explain the pathogenic mechanisms underlying progressive neurodegeneration in AD was the "cholinergic hypothesis". It suggests that AD is mainly caused by reduction of acetylcholine

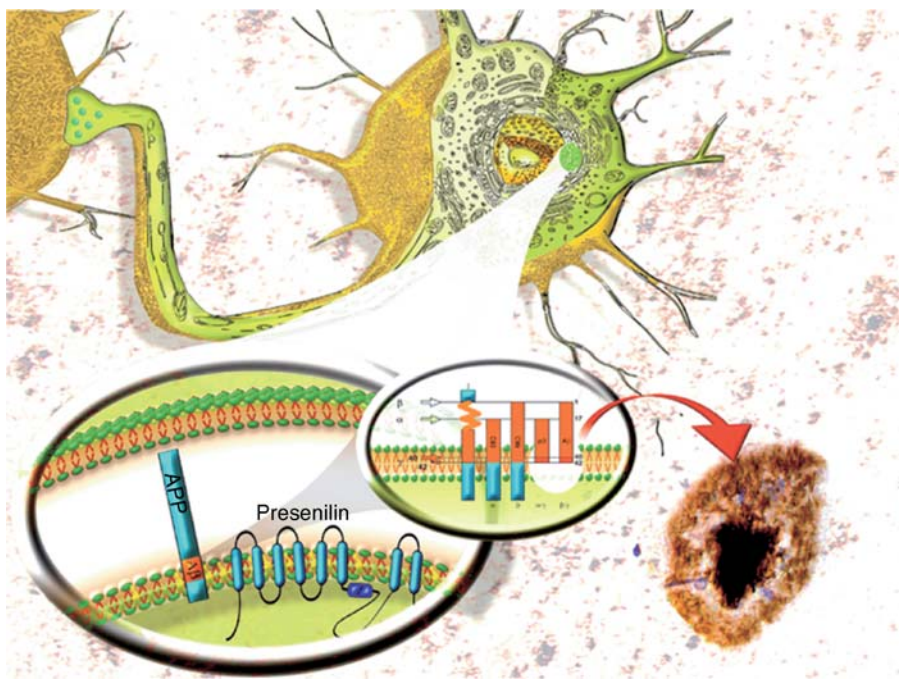
(a major excitatory neurotransmitter). As the medications with AChE-inhibitors, increasing ACh levels, have neither halted nor reversed the disease, the cholinergic hypothesis has not maintained widespread support.

The "tau hypothesis" is supported by the long-standing observation that the occurrence of NFT, but not the deposition of amyloid plaques correlates well with neuron loss. However, more recent data suggest that abnormal tau phosphorylation and tau aggregation is triggered by Aβ, whereas changes in tau pathophysiology have no major impact on Aβ generation or aggregation. Furthermore, genetic analyses did not serve any evidence that tau may affect the risk for AD so far.

At the moment, the majority of researchers support the amyloid hypothesis, suggesting that Aβ is the primary causative agent, whereby it is currently under debate which state of Aβ aggregates represents the toxic species: the mature aggregated polymer or any specific oligomeric species [4]. This hypothesis is strongly supported by genetic studies, showing that the majority of familial AD mutations are located in APP, PS1 or PS2 genes, causing an elevated generation of Aβ42.

APP is a type I transmembrane protein. During maturation it is processed by different secretases [5]. Cleavage by either α-secretase or, alternatively, the β-secretase, β-site APP-cleaving enzyme 1 (BACE1), results in membrane-retained C-terminal fragments, which are subsequently cleaved within the transmembrane region by the γ-secretase multiprotein complex containing presenilin. Cleavage of APP by α- and β-secretase results in the release of Aβ peptides and the APP intracellular domain (AICD) whereas α-cleavage prohibits Aβ generation (Fig. 1).

Although the molecular mechanisms of APP processing are well understood, it is still unclear which changes in normal cell physiology of elderly people cause the accumulation of Aβ. Plausible causes include alterations of subcellular transport, axonal transport damage, or changes in lipid or calcium homeostasis [6].



**Alzheimer Disease. Figure 1** The pathogenic role of APP in AD. Schematic structure of a neuron with synaptic contacts is shown. APP is a type I transmembrane protein localizing to different intracellular compartments, including the endoplasmatic reticulum (ER), Golgi apparatus, plasmamembrane and endosomal compartments in the cell soma, dendrites and axons. During maturation it is processed by different secretases. Cleavage by either α-secretase or, alternatively, the β-secretase, results in membrane-retained C-terminal fragments (C83 and C99), which are subsequently cleaved within the transmembrane region by the γ-secretase multiprotein complex containing presenilin (small and large insets). Cleavage of APP by γ- and β-secretase results in the release of Aβ, whereas α-cleavage prohibits Aβ generation (small inset). In the course of AD, Aβoligomerizes and aggregates in Amyloid plaques. Although it is clear that the generation of Aβ represents one of the key events in the course of AD, the mechanisms how Aβ causes neurodegeneration in specific vulnerable brain regions is not yet understood.

### Diagnostic Principles

Diagnosis of AD is primarily based on clinical tests of memory and intellectual abilities (for example the mini mental state examination). The accuracy of AD diagnosis is about 85–90%, but a definitive diagnosis must await post mortem examination of brain tissue. Physical tests, including blood and cerebrospinal fluid tests of phosphorylated tau and Aβ as well as neuroimaging (MRI and PET) are mainly performed to rule out differential diagnoses, but can provide a supporting role in diagnostic accuracy.

### Therapeutic Principles

Up to now, there is no treatment available to cure AD. Besides different psychosocial interventions, current medications include acetylcholinesterase (AChE) inhibitors or NMDA antagonists. Both have only a small benefit for the patients and do not slow disease progression. AChE-inhibitors cause an increase of acetylcholine (ACh) levels at the synapse, and are thought to partially rescue the loss of the cholinergic neurons. NMDA antagonists reduce the calcium influx at glutamatergic synapses, preventing neuronal excitotoxicity and thus possibly neuronal death in AD. Novel potential treatments for Alzheimer's disease with the potential to lower Aβ42 are currently under investigation. They include compounds inhibiting β- or γ-secretase, modulating γ-secretase in a way that less Aβ42 is generated and preventing oligomerization of Aβ. Vaccination with synthetic Aβ-species caused a dramatic reduction of β-amyloid plaques in animal models.

## β-Aminoisobutyrate-Pyruvate Aminotransferase Deficiency

André B. P. Van Kuilenburg,
Albert H. Van Gennip*
Laboratory for Genetic Metabolic Diseases,
Academic Medical Center, University of Amsterdam,
Amsterdam, The Netherlands

### Synonyms

BAIBPAT

### Definition and Characteristics

Benign polymorphism leading to a permanent hyper-β-aminoisobutyric aciduria (hyper-β–AIBuria) in healthy individuals.

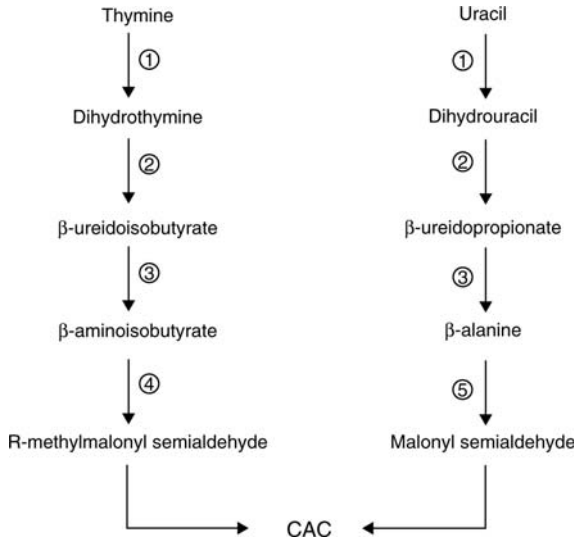
### Prevalence

Genetic high excretors of β-AIB are found with a frequency of 1–10% in Western European populations and up to 80% in Micronesian and Mongoloid populations in Southeast Asia.

### Genes

Hyper-β-AIBuria is thought to be a benign genetic polymorphism at a single locus with non-random distribution in human populations, the lowest frequencies being found in Caucasians, the highest in Micronesians. Inheritance is by an incompletely recessive gene (Fig. 1).

*deceased



**β-Aminoisobutyrate-Pyruvate Aminotransferase Deficiency. Figure 1** Scheme of the pyrimidine degradation pathway and the enzymes involved in the catalysis of each step. ① dihydropyrimidine dehydrogenase; ② dihydropyrimidinase; ③ β-ureidopropionase; ④ (R)-(-)-β-aminoisobutyrate-pyruvate aminotransferase; ⑤ β-alanine-α-ketoglutarate aminotransferase; CAC, citric acid cycle.

## Molecular and Systemic Pathophysiology

A permanent hyper-β-AIBuria (excretion in children above 79, in adults above 22 mmol/mol creatinine) is thought to be caused by a deficiency of R(-)β-aminoisobutyrate-pyruvate aminotransferase (BAIBPAT) in the liver [1]. The β-AIB found in urine is almost exclusively the R-isomer, which originates from thymine. In the kidney the R-isomer is both filtered by the glomerulus and secreted by the tubule cells. In plasma of Caucasians the concentration of the S-isomer, originating predominantly from valine and to a lesser extent from thymine, is usually fourfold that of the R-isomer due to active renal reabsorption. A linear relationship between the R- and S-enantiomers of β-AIB in urine has been reported [2]. R-β-AIB derived from thymine is transaminated by BAIBPAT to R-methylmalonyl semialdehyde (R-MMSA), which for the greater part is converted to propionyl-CoA and subsequently carboxylated. The methylmalonyl-CoA thus formed is isomerized to succinyl-CoA, an intermediate of the citric acid cycle. The smaller part of the R-MMSA may by racemized and the resulting S-MMA will be transaminated to S-BAIB presumably via aminobutyrate aminotransferase [2,3].

## Diagnostic Principles

Hyper-β-AIBuria can be identified by quantitative amino acid analysis of urine. The measurement of the activity of BAIBPAT in the liver of patients is not indicated. On the other hand, as hyper-β-AIBuria can also be caused by increased tissue-breakdown, it is important to exclude a neoplastic condition [4].

## Therapeutic Principles

Patients with BAIBPAT deficiency do not need to be treated.

## Synonyms

Renal amyloidosis

## Definition and Characteristics

Amyloidosis is a disorder of protein folding in which soluble proteins aggregate and deposit as insoluble fibrils in extracellular areas within various tissues. Renal involvement is quite common in systemic amyloidosis and frequently the major source of morbidity is amyloid nephropathy, which usually progresses to end-stage kidney disease [1].

The leading types of renal amyloidosis are immunoglobulin light chain (AL) and amyloid A (AA), and, rarely, familial or hereditary amyloidosis. AL amyloidosis, also known as primary amyloidosis, is derived from a fragment, or less frequently, from immunoglobulin light chain itself, whereas in a rare form of amyloidosis (AH) the deposits are truncated immunoglobulin heavy chains. AA amyloidosis, also called reactive or secondary amyloidosis, occurs in patients with chronic inflammatory disorders, including rheumatoid arthritis, familial Mediterranean fever (FMF), inflammatory bowel disease, and chronic infections [1–3]. The acute phase reactant serum amyloid A protein (SAA) forms AA amyloid fibrils through a process of cleavage, misfolding, and aggregation into a highly ordered abnormal β-sheet conformation.

In the kidney, amyloid deposition is primarily found in glomerular mesangium and capillary loops, but it may also be seen in the small arteries, arterioles, and tubular basement membranes. The clinical manifestations include proteinuria, ranging from nonnephrotic to massive (as high as 30 g/day), hypoalbuminemia, and renal insufficiency.

## Prevalence

The exact prevalence is unknown and seems to be quite variable throughout the world. The annual incidence rate is reported to be 2–12 per million population. Prevalence of renal amyloidosis is 1–4% in kidney biopsy series, 12–17% among patients with nephrotic syndrome, and <1% among patients with end-stage kidney disease undergoing renal replacement therapies.

## Genes

Genetic studies have revealed some abnormalities in amyloidogenic proteins: Polymorphisms, variant molecules caused by missense mutations, deletions, and premature stop codons, and genetically determined post translational modifications. Some mutations in genes coding nonamyloidogenic proteins can also play a permissive role in deposit formation. An increased risk for the development of AL amyloidosis has been reported for both Vλ3r and Vλ6a genes. Also, M694V and SAA1α homozygote genotypes have been found to be associated with AA amyloidosis in patients with FMF.

## Molecular and Systemic Pathophysiology

In contrast to the heterogeneous structures of the known amyloidogenic proteins, all amyloid fibrils have similar ultrastructural morphology and histochemical properties [4]. Marked refolding and highly ordered self-assembly into protofilaments of the various precursor proteins result in amyloid fibrils. Amyloid deposits are rich in restricted subsets of heparan and dermatan sulphated glycosaminoglycans and proteoglycans associated non-covalently with the fibrils. These are reported to play a role in amyloidogenesis, such as influencing protein folding and/or promoting fibril stability, since they are present universally, show close temporal relationship with the fibrils, and have restricted heterogeneity. Another universal constituent of amyloid deposits is the nonfibrillar normal plasma glycoprotein serum amyloid P, a member of the pentraxin family of calcium-dependent ligands and binding proteins that includes C-reactive protein, which is presumed to play a role in the pathogenesis and persistence of amyloid. Serum amyloid P protects fibrils from several proteases in vivo and prevents proteolytic reabsorption of the amyloid deposits.

The mechanisms of cellular injury and tissue damage are not completely understood. In addition to deleterious effects of physical substitution of parenchymal tissue by amyloid deposits, soluble prefibrillar aggregates may also exert cytotoxic effects through oxidative stress or apoptotic pathways [2].

## Diagnostic Principles

A kidney biopsy is often the method by which renal amyloidosis is identified. The absence of enlarged kidneys should not decrease suspicion of renal amyloidosis as the kidneys seem to be of normal size in most patients [1]. The histological demonstration of amyloid deposits, which is usually accomplished by staining with Congo red dye that produces an apple-green birefringence under polarized light, is required for the diagnosis. Electron microscopy shows that amyloid is composed of rigid, nonbranching fibrils of 8–12 nm in diameter [4,5]. Immunofluorescence or immunohistochemical staining of tissue, using antibodies that are directed against known amyloidogenic proteins, is used to differentiate the type of amyloidosis. In selected cases in which definitive typing cannot be made by the use of routine methods, microcharacterization by mass spectrometry and amino acid sequence analysis of the amyloid fibril proteins in the tissues may be considered.

## Therapeutic Principles

The successful treatment of amyloidosis should focus on reducing the supply of the amyloid precursor protein and supporting or replacing the function of the compromised organs. In order to select the appropriate

therapies, it is fundamental to identify the type and extent of the amyloid deposits. AL amyloidosis aims at the treatment of the underlying B cell dyscrasia to reduce the production of amyloid forming monoclonal immunoglobulin light chains (e.g., high-dose melphalan followed by autologous stem cell transplantation). In AA amyloidosis, therapeutic modality should address treatment of the underlying inflammatory process to keep SAA within normal range. Colchicine has been the most successful drug for this purpose, especially in patients with FMF. It is important to keep in mind that renal replacement therapies including dialysis and kidney transplantation, which are successfully performed in patients who have developed end-stage kidney disease secondary to amyloidosis, should not preclude administration of treatments against amyloid production.

# Amyloidoses, Cutaneous

Michael Emberger, Helmut Hintner, Thomas Hawranek
Department of Dermatology, Paracelsus Private Medical University, Salzburg, Austria

## Definition and Characteristics

Amyloidoses are rare disorders characterized by the extracellular deposition of amyloid in various organs leading to organic damage and dysfunction. The skin may be involved as the only organ – localized cutaneous amyloidosis – or in the course of systemic (generalized) amyloidosis. Within these two categories, several clinical variants can be distinguished and on pathogenetic grounds be classified as primary or secondary manifestations, and also be divided into hereditary and nonhereditary forms (see Table 1).

The various types of cutaneous amyloidoses differ in their clinical appearance, in the type of amyloid that is deposited, in the course of the disease and the patient's outcome, which in systemic amyloidosis depends on the internal organs involved.

## Prevalence

Amyloidoses are rare diseases and the prevalence and incidence differ dependent on the type of amyloidosis. The incidence of primary systemic amyloidosis is reported to be about eight patients per million per year.

## Genes

Genetic aberrations in hereditary syndromes associated with amyloidoses are still under investigation, but some are well documented: Familial Mediterranean fever with amyloidosis is a rare autosomal recessive disorder, caused by mutations in the MEFV gene (Mediterranian fever gene) on chromosome 16p. Muckle–Wells syndrome as an autosomal dominant disorder is reported to be linked to mutations in the CIAS gene on chromosome 1q. Familial primary cutaneous amyloidosis (lichen amyloidosus and macular amyloidosis) may be linked to chromosome 5p13.1–q11.2, and 1q23, at least in a subset of families.

## Molecular and Systemic Pathophysiology

Amyloid is a protein complex derived from many different precursor proteins. Ultrastructurally, it is composed of straight, nonbranching fibrils, measuring 6–10 nm, whose peptide component shows a β-pleated sheet pattern. Additionally, each amyloid molecule contains a nonfibrillary component, the serum amyloid P component (SAP), which binds to all types of amyloid deposits and protects them from degradation by proteolytic enzymes and phagocytic cells. Precursor proteins of amyloid among others are immunoglobulin light chains (amyloid L), polypeptide hormones (proinsulin, precalcitonin), prealbumins (i.e., transthyretin, senile amyloid), β2-microglobulin, keratin filaments (amyloid K), and serum amyloid A protein (Amyloid A) [1].

Histochemically amyloid shows specific staining properties with Congo red (apple-green birefringence in polarized light) and thioflavine T (yellow-green flourescence) and metachromatically stains with crystal violet and methyl violet [2]. Furthermore, immunohistochemical staining for cytokeratins may be used in cases of cutaneous amyloidosis in which amyloid K is suspected. In this context immunohistochemical identification of the SAP with antibodies might be of interest, but was demonstrated so far only in animals. In most cases of cutaneous amyloidosis, immunoglobulins, in particular $I_gM$, and complement C3 can be detected by immunofluorescence microscopy.

In primary localized cutaneous amyloidosis, which includes macular, papular [lichen amyloidosus (Fig. 1)]

**Amyloidoses, Cutaneous. Table 1** Classification of amyloid and biochemical nature of fibril proteins

| Clinical syndrome | Fibril proteins and precursors |
|---|---|
| *Systemic amyloidosis* | |
| Associated with immunocyte dyscrasia | |
| Primary systemic (occult dyscrasia) | AL fibrils form monoclonal immunoglobulin light chains |
| Myeloma associated | |
| Associated with chronic active diseases (secondary or reactive systemic amyloidosis) | AA fibrils from serum amyloid A protein (SAA) |
| Hereditary syndromes | |
| Predominantly neuropathic forms (autosomal dominant) | Transthyretin variant or apolipoprotein A1 or gelsolin |
| Familial amyloid polyneuropathy | |
| Nonneuropathic forms (autosomal dominant) | Apolipoprotein A1 or lysozyme or fibrinogen α-chain |
| Ostertag type | |
| Predominantly nephropathic forms | |
| Familial Mediterranean fever (autosomal recessive) | AA fibrils from SAA |
| Muckle–Wells type | AA fibrils from SAA |
| Predominantly cardiomyopathic forms | Transthyretin variant |
| Cardiomyopathy with persistent atrial standstill | Unknown |
| Senile systemic amyloidosis | Transthyretin from plasma |
| *Localized (organ-limited) amyloidosis* | |
| Hereditary syndromes | |
| Hereditary cerebral hemorrhage with amyloidosis | |
| Icelandic type | Cystatin C fibrils |
| Dutch type | β-Protein fibrils |
| Periarticular, bony, and renal amyloid in chronic hemodialysis patients | $\beta_2$-Microglobulin from plasma |
| Cerebral amyloid angiopathy and cortial plaques in Alzheimer's disease, senile dementia, Down's syndrome | β-Protein fibrils |
| Sporadic Creutzfeld-Jakob disease, kuru | Prion protein |
| Focal senile amyloidosis | |
| Heart atria | Atrial natriuretic peptide |
| Joints | Unknown |
| Seminal vesicles | Seminal vesicle exocrine protein |
| Prostate | $\beta_2$-Microglobulin |
| Ocular deposits (corneal, conjunctival) | Unknown |
| Endocrine amyloidosis (APUD organs, APUDomas) | |
| Elderly noninsulin-dependent diabetics, benign insulinomas of the pancreas, normal aged pancreas | Islet amyloid polypeptide fibrils (homology) with calcitonin gene-related peptides |
| Medullary carcinoma of the thyroid | Precalcitonin-related fibrils |
| Nodular (skin, lung, genitourinary tract) | AL fibrils derived from monoclonal immunoglobulin light chains |
| Primary localized cutaneous (macular amyloidosis and lichen amyloidosus) | Keratin-derived |
| Secondary localized cutaneous (microscopic deposits secondary to a variety of cutaneous lesional) | Keratin-derived |

Taken from [1].

and the rare nodular forms, two different kinds of amyloid – amyloid K and amyloid L – are deposited.

Except in the nodular form, in which fibrils are of amyloid L type and are thought to derive from local aberrant light chain material production by clonally expanded plasma cells in the course of extramedullary plasmocytoma, amyloid K is the protein deposited in all other cases of localized cutaneous amyloidosis

**Amyloidoses, Cutaneous. Figure 1** Primary localized cutaneous amyloidosis-lichen amyloidosus.

including secondary localized cutaneous amyloidosis, which occurs in association with benign and malignant neoplastic skin diseases. This can be demonstrated by the binding of antikeratin autoantibodies to the deposited proteins in direct immunofluorescence (DIF) (Fig. 2).

Furthermore, $I_gM$-antikeratin autoantibodies can be detected in the serum of patients, who suffer from localized cutaneous amyloidosis. The mechanism of amyloid K-deposition in these forms is still debated, but the basal epidermal keratinocyte seems to play the major role in the histogenesis. Basal keratinocytes show degenerative changes leading to the accumulation of modified keratin – tonofilaments in the upper dermis. It still remains unknown how tonofilaments transform into mature amyloid K by switching from an α-helical structure to a β-pleated sheet pattern, which is responsible for the binding of SAP and thereby for the resistance to degradation by proteolytic enzymes and phagocytes. Clinically, this mechanism leads to the formation of skin-colored and/or brownish, pruritic papules and plaques preferentially on the extensor surfaces of the patient's extremities and trunk.

In systemic amyloidoses (SA), many different kinds of amyloid (Table 1) are described to be deposited in the mesenchymal component of internal organs and sometimes also in the skin and mucosa. In this chapter, the authors want to dedicate attention to the most common forms of SA, amyloidosis L (AL) and amyloidosis A (AA). In AL (Fig. 3), which can be primary (primary systemic amyloidosis, occult dyscrasia) or associated with multiple myeloma, immunoglobulin light chains are the precursor molecules.

In AA, genetic mutations (like in Muckle-Wells syndrome) as well as chronic inflammatory or neoplastic processes lead to the deposition of amyloid that is derived from the serum amyloid A molecule, a

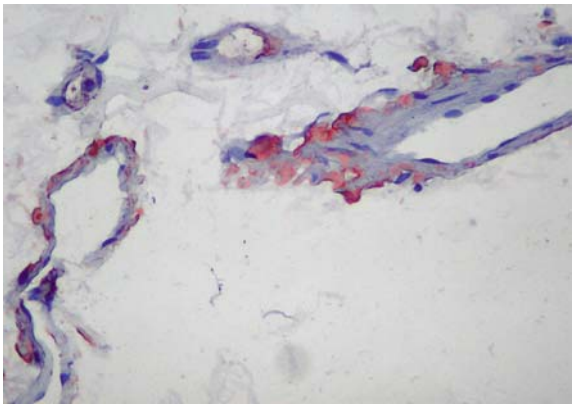
**Amyloidoses, Cutaneous. Figure 3** Periorbital and perional suffusions in a patient with systemic amyloidosis L.

mediator for inflammation. In detail, Il-1 is liberated in chronic inflammatory diseases, which stimulates hepatic cells for serum amyloid A production and secretion. Serum amyloid A is then phagocytized and



**Amyloidoses, Cutaneous. Figure 4** Deposits of amyloid in vessel walls of the subcutaneous fat in systemic amyloidosis (AL) (200×).

transformed to amyloid A by macrophages, which is finally exocytized and deposited in the mesenchyme. Because of the systemic oversupply of the amyloid precursor molecules in the circulation, they are preferentially deposited in vascular and perivascular structures (Fig. 4), causing dependent organic dysfunction (i.e., peripheral neuropathy, hepatomegaly, cardial and renal failure) by inhibition of nutritional supply and hemorrhage. Cutaneous involvement in systemic amyloidosis, when present, shows purpuric papular lesions at the sites of friction and characteristically suffusions in the periorbital region (Fig. 3).

## Diagnostic Principles

The clinical appearance of waxy, skin-colored and/or hemorrhagic papules or plaques, especially on the extremities and the face in periorbital areas (Fig. 3), as well as organ symptoms (i.e., congestive cardiomyopathy, renal failure with proteinuria, hepatosplenomegaly, and neuropathy) should refer to the diagnosis of amyloidosis. Histopathology and immunhistochemical stains on skin or organ biopsies should confirm the diagnosis. Only in special cases, direct immunofluorescence (with antikeratin autoantibodies) and electron microscopy are necessary to demonstrate amyloid deposition and to rule out differential diagnoses. Molecular biologic methods are necessary to characterize the type of deposited amyloid, if necessary. It is obligatory to investigate the patient for any inflammatory, neoplastic, or hereditary disease, which can be the source of amyloid production and deposition.

## Therapeutic Principles

In localized cutaneous amyloidosis therapy is difficult, and dermabrasion, carbon dioxide laser treatment, or surgical excision revealed recurrence. Retinoids (Etretinate) and dimethyl sulfoxide seem to be successful in some cases. Therapeutic options in systemic amyloidoses, which often run a catastrophic course, are the causal or symptomatic treatment of the underlying disease. In AL, a reduction of precursor molecules, i.e., circulating free immunoglobulin light chains, by more than 50% was shown to be associated with substantial survival benefit, regardless of the type of chemotherapy used [3]. Therapy that lowers the amyloidogenic precursor molecules in the serum of AL can stop further accumulation of amyloid deposits, but clinical improvement following chemotherapy seems to be delayed. As a rule, if the underlying disease is controlled or healed, systemic amyloidoses may show a benign course. A new therapeutic approach seems to be Ro 63–8695 (CPHPC), which is a competitive inhibitor of SAP binding to amyloid fibrils. Furthermore, CPHPC is described to crosslink and dimerize SAP molecules in the serum, leading to their rapid clearance by the liver. This mechanism should potentially remove SAP from amyloid deposits, which then can be degraded by proteolytic enzymes and phagocytes. Therefore, CPHPC could be a new therapeutic option for all forms of amyloidoses [4]. In addition, in hereditary forms of AA (especially in Muckle-Wells syndrome) systemic therapy with anakinra – an Il-1 receptor antagonist – may be a successful treatment, as patients treated with this drug have experienced a complete release of their symptoms and resolution of organ dysfunction [5].

# Amylopectinosis

►Glycogen Branching Enzyme Deficiency

# Amyotrophic Lateral Sclerosis

Ruth Danzeisen, Albert C. Ludolph
Department of Neurology, University of Ulm, Ulm, Germany

## Synonyms

Lou Gehrig's disease; Motor neuron disease; MND; ALS

## Definition and Characteristics

Amyotrophic lateral sclerosis (ALS) is the most common motor neuron disease in adults. The average age of onset is 50 years; rare juvenile cases are also observed. ALS was first described in 1869 by the French neurologist Jean-Martin Charcot as a progressive, late-onset, lethal motor neuron disease. Characteristics are the degeneration of upper and lower motor neurons, indicated by "myelin pallor" representing loss of the axons of upper motor neurons as they descend from the brain to connect onto the lower motor neurons within the spinal cord. The most typical feature of ALS is the degeneration of cortical, bulbar and spinal motor neurons, excluding those that control the bladder and the eye movement. This leads to generalized muscle weakness and atrophy, speech and swallowing disabilities, progressive paralysis and ultimately death caused by respiratory failure. About 90% of all cases are sporadic, with unknown etiology. The remaining cases are familial, about 20% of which are associated with mutations in Cu/Zn-Superoxide Dismutase (SOD1) [1]. Familial ALS cases are indistinguishable from sporadic ALS on the basis of clinical and pathological criteria. Generally, ALS patients show large heterogeneity as far as symptoms, age of onset and disease duration are concerned.

## Prevalence

Incidence: 1–2 per 100,000; prevalence: 4–6 per 100,000.

## Genes

Most common to date are mutations in the gene encoding Cu/Zn-superoxide dismutase (SOD1). Other genes associated with ALS encode alsin and dynein/dynactin. The alsin gene has been found to be mutated in families with juvenile onset ALS (recessive mode of inheritance). Mutations in the dynein/dynactin complex have also been suggested to be associated with ALS.

Further genes proposed to be associated with ALS are angiogenin, peripherin, senataxin, survival motor neuron gene (SMN), vascular endothelial growth factor (VEGF), vesicle associated protein B (VAPB).

## Molecular and Systemic Pathophysiology

The best studied cause of familial ALS are mutations in the SOD1 gene. SOD1 is 32-kDa homodimer, an anti-oxidant enzyme, located mainly to the cytoplasm and the mitochondria, but is also secreted. Over 130 different ALS-causing mutations are known, most of them point-mutations acting with a dominant mode of inheritance. Each mutation affects differently the biochemical and biophysical properties of SOD1 in vitro. The proposed toxic properties of mutant SOD1 vary from accumulation of protein aggregates, as a consequence of misfolding or protein oxidation, to promotion of pro-oxidant chemistry, possibly mediated by incorrect or loosened binding of metals.

To date no clear-cut correlation has been made between a given mutation and severity of disease. All mutations cause the same phenotype, possibly because they all cause the same mitochondrial damage [2]. Transgenic mice expressing mutant SOD1 ubiquitously display severe neurodegeneration, representing a commonly used model for ALS. Although it is expressed in all cells, SOD1 mutations results in the selective loss of motoneurons. Recent studies show that the neurotoxic effect of mutant SOD1 requires alteration of function of non-neural neighboring cells that enhance motoneuronal damage. Expression within motor neurons was shown to be a primary determinant of disease onset, while the presence of mutant SOD1 in microglia had effect on later disease progression. Onset and progression thus represent distinct disease phases defined by mutant action within different cell types to generate non-cell-autonomous apoptosis of motor neurons [3].

Other genetic defects have been shown to be associated with ALS (see above, "Genes"). Mutations in dynein/dynactin presumably cause a disruption of axonal transport, indicating one possible mechanism of ALS pathogenesis. The other genes implicated in ALS encode proteins involved in a wide range of cellular processes, from oxidation to RNA processing, vesicular transport and angiogenesis. In most cases, genetic analyses have been performed on relatively small populations and, although there have been many gene association studies in ALS, only a few have led to the identification of candidates with repeatable result [4].

Increasing evidence indicates that cellular functions impaired as a consequence of mutant SOD1 converge on pathways that could be activated by other toxic factors in non-SOD1 linked and in sporadic ALS. These pathways include oxidative damage, protein misfolding, mitochondrial dysfunction, defective axonal transport, excitotoxicity, insufficient growth factor signaling, and inflammation [3].

## Diagnostic Principles

A variety of diseases can resemble ALS in its early stages. The diagnosis is therefore primarily based on the

**Amyotrophic Lateral Sclerosis. Table 1** Revised El escorial criteria for diagnosing ALS

| ALS diagnostic category | Requirements |
|---|---|
| Definite ALS | LMN and UMN signs in three regions of the body |
| Definite familial ALS | LMN and UMN signs in one region of the body plus laboratory-supported identification of gene mutations associated with ALS |
| Probable ALS | LMN and UMN signs in two regions of the body (some UMN signs rostral to LMN signs) |
| Probable ALS (laboratory supported) | LMN and UMN signs in one region of the body plus electromyographic evidence of acute denervation of two or more muscles in two or more limbs |
| Possible ALS | LMN and UMN signs in one region of the body |

LMN – lower motor neuron; UMN – upper motor neuron.

**Amyotrophic Lateral Sclerosis. Table 2** Requirements for the diagnosis of ALS: A together with B

| A – the presence of | B – the absence of |
|---|---|
| (A:1) Evidence of *lower motor neuron (LMN) degeneration* by clinical, electrophysiological or neuropathologic examination, (A:2) evidence of *upper motor neuron (UMN) degeneration* by clinical examination, and (A:3) *progressive spread of symptoms or signs* within a region or to other regions, as determined by history or examination | (B:1) *Electrophysiological and pathological evidence of other disease processes* that might explain the signs of LMN and/or UMN degeneration, and (B:2) *neuroimaging evidence of other disease processes* that might explain the observed clinical and electrophysiological signs |

observed symptoms and signs in the patient, and a series of tests to rule out other diseases (see Tables 1 and 2). Symptoms are muscle weakness, atrophy of muscles, hyperreflexia, and spasticity with pyramidal signs, and the presence of upper and lower motor neuron signs in a single limb. If these symptoms are getting progressively worse, this is strongly suggestive. In order to exclude the possibility of other conditions, blood- and urine-tests and electromyography (EMG), nerve conduction velocity (NCV) or magnetic resonance imaging (MRI) testing may be needed [5].

## Therapeutic Principles

ALS cannot be cured. The first approved drug treatment for the disease is riluzole (Rilutek), which is believed to reduce damage to motor neurons by decreasing the release of glutamate. Treatments for ALS are designed to relieve symptoms and improve the quality of life for patients. Standard support therapy includes night-time breathing assistance early in the course of the disease and application of alternate feeding options once swallowing becomes difficult. Patients may eventually consider forms of mechanical ventilation (respirators). Medications to help reduce fatigue and depression, ease muscle cramps, control spasticity, and reduce excess saliva and phlegm can be considered [5].

# Analgesic Nephropathy

Michelle M. Estrella, Mohamed G. Atta
Department of Nephrology, Johns Hopkins University School of Medicine, Baltimore, MD, USA

## Synonyms

Phenacetin nephritis

## Definition and Characteristics

A slowly progressive decline in renal function secondary to chronic regular use of analgesic medications. Histology classically shows renal papillary necrosis and chronic interstitial nephritis.

## Prevalence

Phenacetin-containing analgesics were initially implicated as the cause of analgesic nephropathy; this led to the withdrawal of phenacetin from the market in many

industrialized nations during the 1980s. The general prevalence of analgesic nephropathy in these nations is estimated to be 1–5%. In nations such as Sweden in which over-the-counter sales of analgesic mixtures have also been banned, this prevalence is even lower. Eastern European countries are noted to have higher prevalence rates, presumably related to higher sales of analgesic mixtures. Though the majority of the epidemiological studies are methodologically flawed, lifetime cumulative intake of analgesics seems to correlate with increased incidence of end-stage renal disease.

## Molecular and Systemic Pathophysiology

The pathogenesis underlying analgesic nephropathy remains unclear although animal models and limited studies in humans have emphasized three main possible mechanisms: inhibition of prostaglandin production, renal medullary ischemia and direct cell injury.

Prostaglandins are hormones derived from arachidonic acid metabolism by two cyclooxygenase (COX) isoforms. COX-1 is expressed ubiquitously throughout the body while COX-2 has traditionally been viewed as inducible during inflammatory states. More recent data have demonstrated continuous low levels of COX-2 within the macula densa, thin ascending limb of the loop of Henle and endothelial cells of the kidney. In a state of low effective circulating volume, COX-2 expression is enhanced, leading to increased local prostaglandin production [1]. Prostaglandins, such as prostacyclin and PGE2, maintain proper renal hemodynamics in this setting by stimulating renin release and by attenuating afferent arteriolar vasoconstriction induced by angiotensin II and norepinephrine. The medullary pyramids are particularly at risk for ischemia given their delicate vascular supply that consists of tapering vasa recta capillaries derived from the efferent arterioles of juxtamedullary glomeruli. Non-steroidal anti-inflammatory drugs (NSAIDs) which inhibit both COX isoforms and selective COX-2 inhibitors disable the compensatory actions of prostaglandins. This results in reduced overall renal perfusion though these effects may be more profound in the renal medulla. Analgesics also cause relative renal ischemia despite normal renal perfusion by decreasing hemoglobin oxygen affinity. Aspirin reduces red blood cell 2, 3-diphosphoglyceric acid levels. Phenacetin produces methemoglobinemia [2].

The medullary counter-current multiplier system that modulates urinary concentration may accumulate harmful levels of analgesic metabolites within the medulla. Animal studies have demonstrated increased concentration gradients of acetaminophen metabolites and salicylate between the renal cortex and medulla. Direct cell injury likely occurs through free radical formation especially in the setting of combined acetaminophen and aspirin ingestion. Prostaglandin H synthase localized in the renal medulla transforms acetaminophen into reactive metabolites which in turn react with glutathione to form stable conjugated compounds. In the setting of concurrent aspirin use, the primary aspirin metabolite, salicylate, consumes glutathione supply resulting in increased free radical formation from acetaminophen metabolism. These free radicals react with oxygen to form superoxides that cause cellular membrane dysfunction [3]. COX inhibition may also shunt arachidonic acid metabolism to the lipoxygenase pathway. This process produces leukotrienes that instigate inflammation, resulting in chronic interstitial nephritis [4]. Recurrent insults lead to apoptosis of medullary interstitial cells and necrosis of the vasa recta. Eventually cortical interstitial fibrosis and tubular atrophy ensue.

## Diagnostic Principles

Analgesic nephropathy typically occurs in women suffering from chronic pain syndromes. Diagnosis is suggested by the presence of chronic kidney disease and positive history of daily analgesic intake for greater than one year; however, an accurate history of analgesic use is often difficult to obtain. Patients may suffer from recurrent urinary tract infections or renal colic secondary to urinary tract obstruction from sloughed necrotic papillary tissue. Urinalysis often demonstrates sterile pyuria and sub-nephrotic range proteinuria. Urinary concentration and acidification may also be impaired. Non-contrast computed tomography scans characteristically exhibit decreased renal size, “bumpy” renal contours and papillary calcifications [5].

## Therapeutic Principles

A more rapid decline in renal function has been noted in patients with ongoing analgesic use, underlying vascular disease and proteinuria at presentation. Preservation of renal function requires avoidance of further analgesic use and adequate control of possible concurrent diseases such as hypertension, diabetes and hypercholesterolemia. Prevention and prompt management of urinary tract infections and urinary tract obstructions are imperative.

## Androgen Insensitivity Syndrome

Kumarasamy Thangaraj, Singh Rajender
Centre for Cellular and Molecular Biology, Hyderabad, India

### Synonyms

Testicular feminization, 46,XY sex reversal; Reifenstein syndrome; Mild androgen insensitivity syndrome; MAIS; Partial androgen insensitivity syndrome; PAIS; Complete androgen insensitivity syndrome; CAIS; AIS

### Definition and Characteristics

AIS manifests in an array of phenotypes from mild to partial or complete androgen insensitivity [1]. Complete androgen insensitivity syndrome (CAIS) is characterized by female external genitalia, usually

with small labial folds, a short blind ending vagina (3–10 cm), absence of Wolffian duct derived structures and prostate, absent/rudimentary uterus, gynecomastia, scanty/absent pubic/axillary hairs. In partial androgen insensitivity syndrome (PAIS), several different phenotypes are evident with predominantly female phenotype to ambiguous genitalia (determined by the extent of clitoromegaly and fusion of labia) or predominantly male phenotype with micropenis, perineal hypospadias and cryptorchidism. The later group of the patients is also termed as Reifenstein syndrome [2]. Males with mild androgen insensitivity syndrome (MAIS) usually have normal male genitals and internal male structures; however, during puberty they may experience breast enlargement, sparse facial and body hair, and inadequate enlargement of penis [3]. Some affected males may also have impaired sperm production resulting in oligozoospermia or azoospermia [4].

## Prevalence

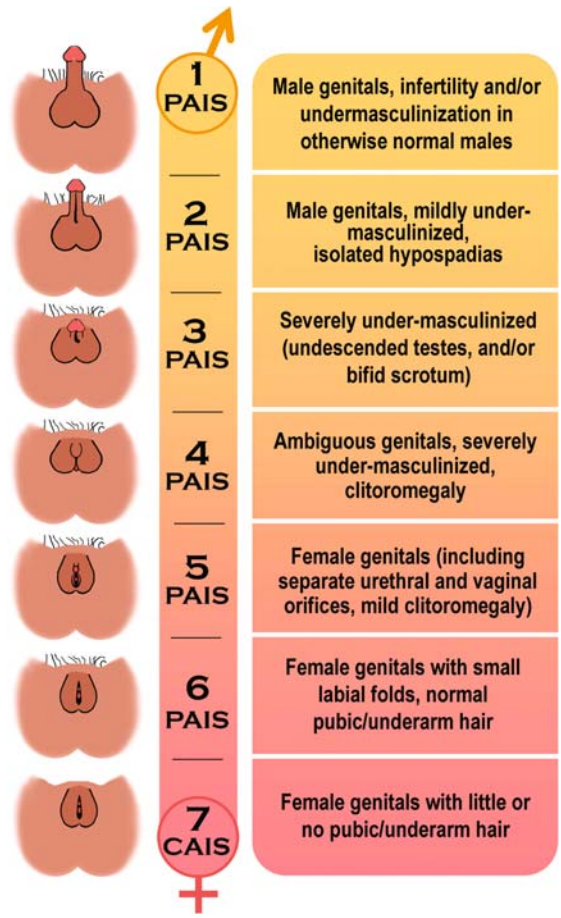
*CAIS*: The estimate of the incidence varies from 1 in 20,000 to 1 in 64,000 individuals with a 46,XY karyotype.
*PAIS*: The incidence of PAIS is estimated to be 1 in 30,000 individuals with a 46,XY karyotype.
*MAIS*: The incidence is much lesser than CAIS and PAIS, however, the incidence has not been measured as yet.

## Genes

Deletions/point mutations in androgen receptor (AR) gene, mapped on Xq11–12, have been frequently reported in AIS (web: http://www.mcgill.ca/androgendb/) [5]. Mutations have been reported throughout the gene with deletions predominantly in exons 1 and 2, and substitutions in exons 2–8 of the gene. Certain nucleotide positions have been identified as mutation hotspots. Mutations in SRD5A2 gene in the background of AR mutations may result in phenotypic variations among the affected siblings sharing the AR mutation [1].

## Molecular and Systemic Pathophysiology

AIS results from the imperfect secondary sexual differentiation as a result of defective AR. The complete loss of the androgen action in CAIS results in the default development of the ovaries, followed by the breast development at puberty leading to overall female phenotype. The partial loss of androgen action in PAIS results in various phenotypes (Fig. 1), depending upon the overall exposure of the fetus to the androgens. The mild loss of androgen action in MAIS results in failure of proper enlargement of penis and testicular growth, and/or inadequate sperm production leading to infertility.



**Androgen Insensitivity Syndrome . Figure 1** Different grades of Androgen Insensitivity Syndrome (AIS) along with phenotypic appearance of external genital organ and clinical features. PAIS 1 is also referred as MAIS. AIS 6 and AIS 7 (also called as CAIS) differ only by the presence and absence of pubic hair, respectively.

## Diagnostic Principles

The diagnostic features of AIS are the presence of female external genitalia, ambiguous genitalia or undermasculinization in association with 46,XY karyotype, normal/elevated levels of androgens, elevated levels of LH and/or FSH. The individuals with CAIS are difficult to distinguish from their normal female counterparts at birth, however, the absence of menstruation onset and the absent/scanty pubic/axillary hair at puberty may indicate CAIS. The diagnosis is confirmed by the evaluation of hormone levels, followed by the confirmation of the abdominal testes by needle biopsy. The highest grade of PAIS (grade 6) can also be diagnosed in a similar way with the difference that pubic/axillary hair is of higher density. The presence of the ambiguous external genitalia at birth may indicate PAIS. This is confirmed by evaluation of hormone

levels, poor/normal breast development, appearance of normal pubic/axillary hair at puberty, and needle biopsy confirming testicular tissue. However, the PAIS should be distinguished carefully from the male pseudohermaphroditism arising as a result of inadequate androgen metabolism due to defective 5-α reductase enzyme. The undermasculinization resulting in smaller testicular volume, micropenis, reduced sperm count or the development of certain feminine characters such as gynecomastia, high-pitched voice and behavioral differences, in the otherwise normal looking males, may help to detect MAIS. The sequence analyses identifying a mutation in AR gene would confirm AIS.

### Therapeutic Principles

Therapeutic principles focus mainly on three aspects: surgical reconstruction of external genitalia, removal of abdominal gonads due to the risk of neoplasia, and the choice of appropriate hormone therapy. The development of external genitalia is one of the main aspects of sex differentiation taking place *in utero*. Therefore, it is not possible to initiate normal differentiation of external genitalia and fertility in the affected individuals. However, surgical reconstruction of the external genitalia may help to restore the normal sexual life in many patients. The individuals with CAIS have female external genitalia with short vaginal length, which may be inadequate for sexual intercourse. These individuals are invariably raised as girls after surgical restoration of the normal vaginal length. The gonads are surgically removed and estrogen therapy may be given to help the development of female secondary sexual characters. However, most of the patients do not need hormonal therapy because in the absence of androgen action, female secondary sexual characters develop by default. In PAIS, the restoration of the external genitalia involves more extensive manipulation. The external genitalia resembling female genitals or the ambiguous genitalia are surgically manipulated to construct the female genitals. Hypospadias or the micropenis may be reconstructed to male genitals, followed by the removal of gonads and testosterone therapy to favor male secondary sexual differentiation. In MAIS, surgical intervention is usually not required, except the correction of the gynecomastia in certain cases; however, androgen therapy may be advised to achieve masculinization.

## Anemia

John-John B. Schnog[1], Victor E.A. Gerdes[2]
[1]Department of Internal Medicine, Slotervaart Hospital, Amsterdam, The Netherlands
[2]Amsterdam Vascular Medicine Group, Department of Vascular Medicine, Academic Medical Center, Amsterdam, The Netherlands

### Definition and Characteristics

Reduced hemoglobin concentration**.** Weakness, shortness of breath, palpitations, and headaches are common complaints. In elderly patients' heart failure, angina pectoris, intermittent claudication, or mental deterioration may occur. Clinical manifestations depend on the speed of onset and the severity of anemia. Pallor of the skin or mucous membranes and resting tachycardia may be present.

### Prevalence

It is a common clinical condition, with a wide variety of causes. No precise prevalence is available. In developing countries iron deficiency due to helminthic infections and malnutrition are major causes of anemia. There are considerable differences in the occurrence of hemoglobin disorders and red cell membrane disorders that leads to anemia in different parts of the world.

### Genes

Genes associated with hemoglobin disorders such as sickle cell anemia and thalassemias, red cell membrane defects and enzymatic defects, paroxismal nocturnal hemoglobinuria, Fanconi anemia, and Diamond–Blackfan syndrome are specified in the chapters on these topics.

## Molecular and Systemic Pathophysiology

Anemia can be classified according to the underlying pathological condition. There are three classes of anemia; however, it should be stated that in many clinical situations more than one class coexist.

1. Anemia due to a reduced production of erythrocytes in the bone marrow as a result of bone marrow damage or reduced erythropoietin production. Red blood cells usually have a normal volume (normocytic anemia). Bone marrow may be infiltrated by malignant cells or it may be fibrotic, for instance due to myelofibrosis or radiation therapy. Erythropoietin production may be reduced in case of renal insufficiency. In case of inflammatory diseases the production of erythropoietin is suppressed by cytokines, which have a direct suppressive influence on the bone marrow as well. In hypothyroidism the oxygen need of tissue is reduced, also leading to a reduced erythropoietin production. Mild iron deficiency may also lead to bone marrow hypoplasia.
2. Anemia due to a maturation disorder of erythrocytes. Maturation defects are associated with an altered red cell volume: decreased when the hemoglobin production is impaired (microcytic), increased when there are nuclear defects in erythroid progenitor cells (macrocytic). Hemoglobin production is reduced in moderate and severe iron deficiency. There are many clinical conditions leading to iron deficiency. Hemoglobin production is impaired in thalassemias as a result of defective globin chain production. Defective heme synthesis occurs in sideroblastic anemia. Defects in the nucleus of erythroid progenitor cells may be the result of a variety of clinical conditions. Deficiencies of hydroxycobalamin (vitamin B12) or folate (vitamin B11) lead to macrocytic anemia, and can be the result of reduced intake, or a reduced uptake from the gut, for instance after bowel surgery or as a result of malabsorption. Intrinsic factor, which is produced in the stomach, is an essential factor for the uptake of B12 in the ileum. Antibodies against intrinsic factor cause B12 deficiency and macrocytic anemia in the case of pernicious anemia. Drugs that have an influence on DNA metabolism cause macrocytic anemia as well. Well-known examples are alkylating agents, methotrexate, and antiretroviral therapy. Alcohol has the same effect. The myelodysplastic syndrome is another possible cause of macrocytic anemia.
3. Anemia due to an increased turnover or loss of erythrocytes. In contrast to the other types of anemia the number of reticulocytes, young erythrocytes, is high in most conditions of this group. Exceptions are acute and chronic blood loss. In the first, erythrocyte production has not been upregulated yet, while in the latter iron is lost along with the erythrocytes which limits erythrocyte production (in fact, a combination of blood loss, reduced red cell production, and a maturation defect due to iron deficiency). The red blood cells have a normal or slightly increased mean volume depending on the percentage of reticulocytes (which are larger than erythrocytes). Hemolytic anemia, which leads to an increased erythrocyte turnover, may be caused by membrane defects, enzymatic defects, hemoglobin disorders, autoimmune processes as well as mechanical factors. Membrane defects may be congenital (hereditary spherocytosis and elliptocytosis) or acquired (paroxismal nocturnal hemoglobinuria). Examples of enzymatic defects are glucose 6 phosphate dehydrogenase deficiency and pyruvate kinase deficiency. Autoimmune hemolysis is seen in patients with systemic autoimmune disease, but also in patients with hematologic malignancies or infections. Hemoglobin disorders, sickle cell disease and thalassemias, may present with hemolytic anemia. A prostetic heart valve is a well-known mechanical cause of hemolysis.

## Diagnostic Principles

Medical history, physical examination, and screening laboratory examination lead to the diagnosis in most patients. Screening laboratory examination should include measurement of hemoglobin concentration, mean corpuscular volume of erythrocytes, reticulocyte, leucocyte, and platelet counts. Examination of the blood film is often helpful. A higher bilirubin and a lower haptoglobin concentration are indicative for hemolysis. Bone marrow examination may be needed in case of unexplained reduced erythrocyte production. Additional tests for the diagnosis of hemoglobin disorders, enzymatic defects, membrane defects are mentioned in the chapters on these disorders.

## Therapeutic Principles

The treatment is dependent on the underlying condition.

## Synonyms

Anemia; AIHA; Idiopathic autoimmune hemolytic; Cold agglutinin disease; Paroxysmal cold hemoglobinuria

## Definition and Characteristics

Autoimmune hemolytic anemia (AIHA) is a disease in which the patient is producing antibodies against antigens present on his own red blood cells, causing them to be destroyed prematurely. The disorder can be classified by the isotype and temperature at which the antibodies react optimally with the red cell antigen: in warm AIHA the antibodies are mostly IgG and react at normal body temperature (37°C); in cold-reacting AIHA IgM antibodies are seen and react best at temperatures below 37°C. Cold AIHA can be further subdivided into cold agglutinin disease (CAS, cold hemagglutinin disease) and paroxysmal cold hemoglobinuria (PCH). Rarely, patients have mixed warm and cold autoantibodies. AIHA can occur by itself (primary or idiopathic) or in combination with another disease, or as a result of drug therapy (secondary) [1].

## Prevalence

AIHA has a prevalence of 1 in 100,000; warm type AIHA is the most common type [1]. CAS represents approximately 16–32% of AIHA cases, whereas PCH is reported in 2–10% of cases of hemolytic anemia. In 50% of the cases, AIHA is primary or idiopathic since its cause cannot be determined.

Approximately half of secondary warm and cold AIHA cases are associated with lymphoproliferative disorders. Autoimmune disorders are the next leading cause of warm AIHA, whereas infections are the most common cause of secondary cold AIHA. Primary CAS is mostly seen in older adults (70 years and above), affecting more females than males.

## Genes

In humans, there is conflicting data as to the role of HLA-A1, B7 and B8 for susceptibility to this disease. Genetic studies in a certain strain of mice known as the New Zealand black (NZB) [2], which develop warm AIHA spontaneously in 25% of the cases, have revealed that the development of AIHA is under multigenic control and a combination of several susceptibility genes and modifying alleles with suppressive activities determine the outcome of disease features in the progeny. Susceptibility loci for development of AIHA mapped thus far include autoimmune hemolytic anemia (Aha), autoimmune anemia 1 (Aia 1), and Aia2, although none of the genes or gene products responsible for the associated phenotypes have yet been identified.

## Molecular and Systemic Pathophysiology

Several mechanisms are thought to result in the loss of tolerance to red cell antigens, including: (i) cryptic determinants, a result of conformational change on self red cells, or cross reactive foreign antigens mimicking epitopes on red cells leading to polyclonal T and B cell activation, (ii) genetic defects in central tolerance such as mutations in apoptotic machinery (mutations associated with Fas/Fas ligand), (iii) immunoregulatory disorders resulting in errors in peripheral tolerance such as depletion of CD4+CD25+ T regulatory cells or imbalance of cytokine (Th1/Th2) networks such as increased production of Th2 (IL-4 and IL-10) versus reduction in Th1 (IFN-gamma) cytokine production or downregulation of IL-12 [3,4,5].

Most warm autoantibodies are directed against the Rhesus blood group antigen complex. The presence of autoantibodies on the patient's red cells results in recognition and binding of the Fc portion of the antibody molecule to the Fc-receptors on splenic macrophages and subsequent ingestion of the sensitized erythrocytes. In most cases the sensitized cells are only partially ingested, leaving characteristic cells of AIHA referred to as microspherocytes. These spherocytes are trapped in the splenic sinusoids and removed from circulation. If in addition to autoantibodies, the red cells are also coated with complement factor C3 split product (C3b), there is enhanced clearance through complement receptors present on the macrophages.

Cold IgM autoantibodies bind to the red cells in the extremities where the temperature can be lower, activate complement, and deposit C3b on the cell surface. These complement sensitized cells are cleared

extravascularly by the macrophages of the liver. In severe cases, the complete complement cascade is activated on the cell surface, resulting in intravascular hemolysis.

## Diagnostic Principles

Low hemoglobin, increased reticulocyte count and positive direct antiglobulin test (DAT) are the main diagnostic features of AIHA. Patients may develop symptoms such as fatigue and dizziness as a result of anemia. In cases of intravascular hemolysis, decreased haptoglobin, hemoglobinemia and hemoglobinuria can also be seen. Eluate studies and indirect antiglobulin tests are some of the additional assays used to define the antibody.

## Therapeutic Principles

In mild AIHA no treatment may be required. When intervention is necessary, corticosteroids (prednisone) represent the first line of treatment. Splenectomy may be considered in certain cases. Intravenous gammaglobulin has been used with mixed results. Rituximab (anti-CD20 antibody) has been used successfully in pediatric cases. Immunosuppressive therapy may be used if the other agents are ineffective. Blood transfusions may be necessary, although they are complicated because the autoantibodies are panagglutinins, so that crossmatching of red blood cells may be difficult.

If the hemolysis is thought to be drug-induced, the offending drug needs to be discontinued.

In cases of cold AIHA, keeping the patient warm may be sufficient. For more severe cases, corticosteroids are rarely effective. Splenectomy is not useful because the liver is the main site for clearance of complement-coated cells.

# Anemia, Sideroblastic Acquired Idiopathic

Norbert Gattermann
Deparment of Hematology, Oncology and Clinical Immunology, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

Refractory anemia with ringed sideroblasts; RARS; AISA

## Definition and Characteristics

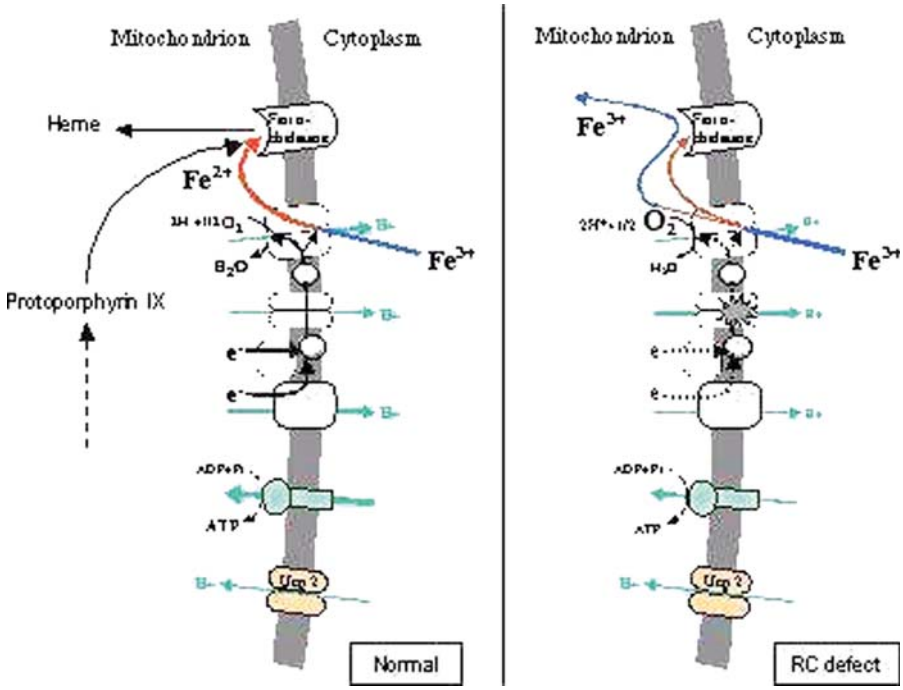
Clonal bone marrow disease arising from a multipotent hematopoietic stem cell. Red cell precursors show large abnormal iron granules surrounding the cell nucleus ("ringed sideroblasts") [1]. This finding corresponds to massive iron accumulation in the mitochondria.

## Prevalence

Like other types of myelodysplastic syndrome (MDS), the incidence of AISA is strongly age-dependent. The majority of cases occur after age 65. Crude annual incidence is about 1/100,000 (Fig. 1).

## Molecular and Systemic Pathophysiology

Ferrochelatase utilizes only ferrous iron ($Fe^{2+}$) for heme synthesis. In sideroblastic anemia, iron accumulates in the ferric form ($Fe^{3+}$). This appears to be attributable to a failure of the respiratory chain (RC) to remove oxygen from the mitochondrial matrix efficiently. Oxygen consumption is stimulated in erythropoietic cells by uncoupling protein-2. A low oxygen concentration in the mitochondrial matrix helps to keep iron in the reduced form. A respiratory chain defect will decrease $O_2$ consumption and will thus increase $O_2$ in the mitochondrial matrix. If iron, which crosses the inner mitochondrial membrane as $Fe^{2+}$, becomes re-oxidised ($\rightarrow Fe^{3+}$), it will be rejected by ferrochelase and will thus accumulate in the mitochondrial matrix. RC dysfunction can be explained by mutations in mitochondrial DNA (mtDNA), because important RC subunits are encoded by mtDNA. Clonal mtDNA mutations, changing conserved nucleotides/amino acids, have been discovered in the bone marrow of patients with AISA [2,3]. They affect protein genes as well as mitochondrial transfer RNAs and mitochondrial ribosomal RNAs. They are acquired in the bone marrow and show heteroplasmy, i.e., coexistence of mutant and wild type mtDNA, which is typical of mitochondrial DNA disorders. Besides interfering with iron metabolism and heme synthesis, mitochondrial dysfunction can explain



**Anemia, Sideroblastic Acquired Idiopathic. Figure 1**

other features of AISA [4], like increased apoptosis of bone marrow cells [5] and megaloblastic changes in red cell precursors (because de novo pyrimidine nucleotide synthesis depends on a functioning respiratory chain).

## Diagnostic Principles

Bone marrow cytology, including iron staining, reveals ringed sideroblasts and other dysplastic changes. Reversible causes of sideroblastic anemia (e.g., alcoholism or lead poising) must be excluded. Clonal chromosomal abnormalities are detectable in up to 50% of patients. They apparently provide the growth advantage to the clone harboring the mitochondrial defect. There are no chromosomal changes specific for the sideroblastic phenotype.

## Therapeutic Principles

The only curative approach is allogeneic stem cell transplantation. Treatment with erythropoietin and G-CSF can diminish apoptosis of bone marrow cells, thereby improving blood counts. Because of secondary hemosiderosis, patients require iron chelation therapy.

# Aneurysm, Aortic and Arterial

Michael L. H. Ma[1], Patrick T. S. Ma[2], Alexander K. C. Leung[3]
[1]Trinity College, Dublin, Ireland
[2]Heart Health Institute and Department of Cardiac Science, The University of Calgary, Calgary, AB, Canada
[3]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

An aneurysm (AN) is defined as a widening of the vessel that is greater than 50% of its normal size [1]. An AN is classified as fusiform or secular. A fusiform

AN affects the entire circumference of the segment of the vessel resulting in a symmetric dilatation, whereas a secular AN involves only a portion of the circumference resulting in an outpouching of the vessel wall. Mycotic or infected ANs are arterial dilatations secondary to an infected embolus adhering to the wall of the AN. A dissecting aneurysm (DA) is defined as a hematoma that extends to or dissects the medial wall of a vessel secondary to a tear in the intima. DA can be classified (Stanford) as type A, in which the dissection involves the ascending aorta; type B, when the dissection is limited to the descending aorta. Aortic ANs are classified as thoracic, abdominal and thoracoabdominal. The sinus of Vasalva is a dilatation of one of the aortic sinuses between the aortic valve annulus and the sinotubular ridge; a common location is the right coronary sinus, which may rupture into the right ventricle. Other important ANs include the intracranial aneurysms which are usually secular (or berry) aneurysms located at the terminal internal carotid artery, middle cerebral artery bification, and the top of the basilar artery. Aortic and arterial ANs commonly produce no symptoms and are usually detected on routine examinations as a palpable, pulsatile and nontender mass, or may present as an incidental finding on an imaging test performed for other reasons. The speed of AN growth can be unpredictable, and may enlarge steadily or exponentially with time and age. As it reaches a critical size, which is specific for each location, the chance of rupture is greatly increased and site specific symptoms start to occur. Rupture and dissection of ANs are often accompanied by sharp, excruciating pain and carries a high morbidity and mortality rate when it happens in the aorta and intracranially. Other complications include thromboembolism and compression of adjacent structures. Aortic dissection can result in occlusion of major arteries, compression of adjacent structures, acute aortic regurgitation and myocardial infarction [2].

## Prevalence

Studies found that 4.8% of men aged 65–69 had an AN and 10.8% of men aged 80–89 had an aortic AN. Prevalence of AN in the intracranial arteries is 2%, the abdominal aorta 1%, the iliac artery 0.003%, femoral artery 0.004%, and popliteal artery 0.008%.

## Genes

Mutations of the genes encoding fibrillin-1 and type III procollagen have been implicated in some cases. Linkage analyses have identified loci in chromosome 5q13–14 and 11q23.3–q24 in several families with familial clustering of aortic ANs.

## Molecular and Systemic Pathophysiology

In familial cases such as in Marfan and Ehlers-Danlos syndromes, cystic medial necrosis leads to the degeneration of collagen and elastic fibers in the tunica media of the aorta as well as the loss of medial cells that are replaced by multiple clefts of mucoid material. This results in circumferential weakness and dilatation and the development of fusiform AN and dissection ANs. Aortic rupture and dissection may follow. Furthermore, the dilatation of aortic annulus may cause significant aortic insufficiency. Recently, it has been shown that excessive transforming growth factor-β (TGF-β) contributes to progressive aortic rest enlargement [3]. Both polyclonal TGF-β neutralizing antibody and losartan, an angiotensin receptor inhibitor that limits TGF-β actin, may prevent aortic enlargements in Marfan syndrome [3]. For non-familial cases, the underlying causes of ANs are likely multifactorial which may include systemic causes, inflammation, and atherosclerosis. It is hypothesized that AN formation and rupture are the result of elastin and collagen degradation by proteases such as plasmin, matrix metalloproteinases and cathepsin S and K [4]. These proteases are derived from the endothelial and smooth muscle cells locally, and also from immigrated inflammatory cells. Vasculitides that are associated with arterial ANs include Takayasu's arteritis, giant cell arteritis, polyarteritis nodosa, Kawasaki disease, Behcet's syndrome and spondyloarthropathies. Congenital aortic aneurysms may be primary or associated with bicuspid aortic value or aortic coarctation.

## Diagnostic Principles

Aneurysms are suspected by a localized pulsatile mass and are usually diagnosed incidentally from an imaging test such as routine x-ray, ultrasound, CAT scan or MRI. Ultrasonography is the preferred modality for screening except for intracranial aneurysms. The diagnosis can be confirmed with CT scan, MRI and/or angiography.

## Therapeutic Principles

Medical therapy consists of cessation of smoking and treatment of hypertension and dyslipidemia. Surgical consideration depends on the general health of the patient as well as the chance of rupture of the particular aneurysm [5]. Once the aneurysm has reached a critical diameter and when symptoms start to occur, surgery is indicated.

# Angelman Syndrome

Alessandra Baumer
Institute of Medical Genetics, University of Zurich, Zurich, Switzerland

## Synonyms

MIM 105830; Former designation (now in disuse): "Happy puppet syndrome"

## Definition and Characteristics

Angelman syndrome (AS) is a neurogenetic disorder caused by genetic defects at 15q11–13. Characteristic features include severe mental retardation, lack of speech, unmotivated laughter, and ataxia.

## Prevalence

The disorder occurs in approximately 1/15,000–20,000 live births.

## Genes

E6-associated protein ubiquitin-protein ligase gene: UBE3A (MIM: 601623); Small nuclear ribonucleoprotein polypeptide N: SNRPN (MIM: 182279).

## Molecular and Systemic Pathophysiology

The genetic basis of AS is complex. The majority of patients (approximately 70%) have an interstitial deletion at 15q11–q13 affecting the maternally inherited chromosome 15. Approximately 5% of AS patients have an imprinting defect [1] and 3–5% have a paternal UPD15 [2]. Furthermore, mutations in the imprinted gene UBE3A account for approximately 10% of AS cases [3–5]. The genetic defect underlying the remaining 10% of cases remains unknown to date.

Patients with a deletion generally appear to be more severely affected than those with a patUPD15 or an imprinting defect; patients with a mutation in the UBE3A gene also present with severe and typical AS features [6]. On the basis of these observations it is thought that the functional loss of the maternal UBE3A gene alone appears to cause the major features of AS.

## Diagnostic Principles

Some typical clinical symptoms of AS become more and more evident after the first 2 years of life (e.g. seizures, lack of speech and movement disorders), however, experienced physicians would usually diagnose AS also in new-borns. A number of other syndromes may mimic some of the AS features, particularly the RETT syndrome, which can be considered as the main differential diagnosis.

The molecular diagnosis of AS is based on the analysis of the methylation status at SNRPN. An abnormal methylation pattern is detected in AS patients with the 15q11–q13 deletion, patUPD15 and imprinting defects. Microsatellite analysis allows to differentiate between these classes of genetic defects. Conventional methods are usually used for the detection of UBE3A mutations (such patients have normal methylation patterns at SNRPN).

The 15q11–13 deletion can also be detected by FISH analysis; and in rare cases a UPD can be detected by conventional cytogenetic investigations, i.e. if either A) a clear polymorphism is present on both chromosomes 15, or B) the two chromosomes 15 are replaced by a 15;15 Robertsonian translocation chromosome.

## Therapeutic Principles

No therapy is available. Severe seizures may be treated with anticonvulsive drugs. Physiotherapy and ergotherapy are recommended.

# Angina

►Coronary Artery Disease
►Tonsillitis

# Angina Pectoris

Wolfgang Schillinger, Gerd Hasenfuss
Department of Cardiology and Pneumology, Heart Center, Georg-August-University of Goettingen, Goettingen, Germany

## Synonyms

Stenocardia

## Definition and Characteristics

Angina pectoris is chest pain or discomfort due to coronary heart disease (CHD) and is a symptom of myocardial ischemia. It occurs when the blood supply to the heart muscle does not meet its demand. This usually results from obstruction or spasm of the coronary arteries. In less frequent cases, angina can be caused by valvular heart disease, hypertrophic cardiomyopathy or uncontrolled high blood pressure.

## Prevalence

The prevalence of angina pectoris increases with age, being twice as common in men as in women. In men, the prevalence is 2–5% in the 45–54 year-old age-group and 11–20% in the age group 65–74; in women the respective prevalence is 0.5–1% and 10–14%. It can be estimated that the prevalence of angina pectoris in Europe is as high as 30,000–40,000 per one million total populations.

## Genes

Most common forms of CHD are believed to be multifactorial and to result from many genes, each with a relatively small effect working alone or in combination with modifier genes and environmental factors. Well described examples include familial forms of hypercholesterolemia often caused by mutations in the low-density lipoprotein (LDL) receptor or the apolipoprotein (apo) B gene (APOB). Table 1 specifies candidate gene variants for CHD.

Recently, a 58-kilobase interval on chromosome 9p21 was found to be associated with CHD in more than 23,000 individuals. This interval contains no annotated genes and is not associated with established CHD risk factors. Homozygotes for the risk allele make up 20–25% of Caucasians and have an approximately 30–40% increased risk of CHD [1].

## Molecular and Systemic Pathophysiology

Inflammation plays a major role in all stages of atherosclerosis and CHD and participates in the local, myocardial, and systemic complications of atherosclerosis. As a response to diverse factors like bacterial

products, vasoconstrictor hormones, proinflammatory cytokines, dyslipidemia, and others, the endothelial cells of the artery express adhesion molecules that promote adhesion and transmigration of blood leukocytes. The blood leukocytes communicate with endothelial and smooth muscle cells (SMCs) depending on mediators of inflammation and immunity such as prostanoids and other derivates of arachidonic acid, and protein mediators, including cytokines and complement components.

As a consequence of the inflammatory ferment, SMCs migrate from the tunica media to the intima, proliferate and build a complex extracellular matrix. Moreover, they secrete matrix metalloproteinases (MMPs) which modulate various functions of vascular cells. As the lesion progresses, calcification may occur. In addition, cell death (including apoptosis) commonly occurs in the atherosclerotic lesion. Death and coalescence of lipid-laden macrophages can form the classic, lipid-rich "necrotic" core of atherosclerotic plaque [2,3].

## Diagnostic Principles

An accurate history is important and should routinely demand cardiovascular risk factors like hypertension, diabetes mellitus, smoking, and hypercholesterolemia and family history. Typically, angina is induced by effort or conditions that increase myocardial oxygen demand. General physical examination is often unremarkable, but can show findings suggesting lipid disorders (e.g. xanthelasma). Resting 12-lead ECG is normal in 50% of cases or can show unspecific findings. However, the detection of pathologic Q/QS waves strongly suggests an ischemic origin of symptoms. Treadmill or bicycle exercise stress test during 12-lead ECG monitoring which may reveal stress-induced ST-segment depression is the test of choice to diagnose myocardial ischemia in the majority of patients with suspected stable angina. Additional non-invasive stress tests can be obtained by myocardial perfusion scintigraphy, echocardiography, and cardiac magnetic resonance imaging. Multislice CT angiography is an attractive technique for non-invasive detection of coronary artery stenosis, but its diagnostic accuracy is still uncertain. By definition, obstructive CHD is ultimately diagnosed by documenting flow-limiting coronary artery stenosis at angiography [2].

## Therapeutic Principles

The aims of treatment are to minimize or abolish symptoms and also improve prognosis by preventing myocardial infarction and death. Identifying and treating risk factors is a priority in patients with CHD. Interventions for secondary prevention include smoking cessation, dietary modification, and correction of adiposity, as well as treatment of dyslipidemia (e.g. with statins), diabetes and hypertension. Drugs to improve outcomes in angina are antiplatelet agents such as acetyl salicylic acid and clopidogrel. β-adrenergic receptor antagonists reduce myocardial ischemia, improve exercise tolerance and provide symptomatic relieve in angina. ACE inhibitors are vasodilators and improve endothelial dysfunction and other properties that could translate into benefits in ischemic heart disease. Calcium antagonists have been shown to be effective in the treatment of coronary artery spasm. Also, they exhibit antianginal effect through reduction of myocardial oxygen demand secondary to decreased afterload and myocardial contractility. A new therapeutic class, called If inhibitor, has recently been made available: Ivabradine provides pure heart rate reduction, leading to major anti-ischemic and antianginal efficacy. All patients with angina pectoris and established CHD should be evaluated whether they might benefit from revascularization therapy by coronary bypass surgery or percutaneous coronary intervention. Criteria for prognostic indications have been developed. Moreover, patients with refractory angina pectoris despite optimal medical treatment should be evaluated for this option [2].

# Angiodysplasia

►Lymphedema Syndromes

# Angiodysplasia of the Colon

Matthias Wenning
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

Vascular ectasia of the colon; Colonic arteriovenous malformation; Colonic angioma

## Definition and Characteristics

Angiodysplasia is a degenerative lesion of previously healthy blood vessels found most commonly in the cecum and proximal ascending colon. Seventy-seven percent of angiodysplasias are located in the cecum and ascending colon, 15% are located in the jejunum and ileum, and the remainder are distributed throughout the alimentary tract. The lesions are small (less than 5 mm), impalpable and are not associated with skin or other visceral lesions [1]. Phillips, in a letter to the London Medical Gazette in 1839, first described a vascular abnormality causing bleeding from the large bowel. An association between colonic angiodysplasia and aortic stenosis was described by Heyde in 1958. In 1960, Margulis and colleagues identified a vascular malformation in the cecum of a 69-year-old woman who presented with massive bleeding. This diagnosis was accomplished by mesenteric arteriography. Galdabini first used the name angiodysplasia in 1974 [1]. Angiodysplasia occurs predominantly in those aged between 60 and 69 years although cases as young as 19 years have been reported. Patients with colonic angiodysplasia may present with hematochezia (0–60%), melena (0–26%), hemoccult-positive stool (4–47%) or iron deficiency anemia (0–51%). Bleeding is usually low grade but can be massive in approximately 15% of patients. Iron deficiency anemia and stools that are intermittently positive for occult blood can be the only manifestations of angiodysplasia in 10–15% of patients. Bleeding stops spontaneously in over 90% of cases but is often recurrent [1].

## Prevalence

The prevalence of angiodysplasia in the United States is 0.8% in healthy patients older than 50 years who are undergoing screening colonoscopy. Foutch et al. noted the prevalence of angiodysplasia to be 0.93% from three prospective studies in which screening colonoscopies were performed in 964 asymptomatic individuals (mean age, 61 years). Patients with von Willebrand's disease may have an increased incidence of gastrointestinal bleeding from colonic angiodysplasia [2].

## Genes

Sato et al. reported in 2004 a point mutation in the exon 28 of the von Willebrand's factor gene in some patients with von Willebrand's disease complicated with gastrointestinal angiodysplasia. Studies confirming the role of this gene defect have not been reported to date [2].

## Molecular and Systemic Pathophysiology

Angiodysplasias typically are irregularly shaped clusters of ectatic small arteries, small veins, and their capillary connections. Microscopically, angiodysplastic lesions are dilated, distorted, thin-walled vessels. The amount of smooth muscle in the vessel wall is variable. The vessel wall can become so thinned that it appears to be composed only of endothelium [1]. The exact mechanism of development of angiodysplasia is not known. One prominent hypothesis accounts for the high prevalence of these lesions in the right colon is based on the Laplace law. The Laplace law relates wall tension to luminal size and transmural pressure difference in a cylinder whereby the wall tension is equal to the pressure difference multiplied by the radius of the cylinder. In the case of the colon, wall tension refers to intramural tension, pressure difference is that between the bowel lumen and the peritoneal cavity, and cylinder radius is the radius of the right colon. Wall tension is highest in bowel segments with the greatest diameter, such as the right colon. This theory suggests that repeated episodes of colonic distention are associated with transient increases in lumen pressure and size. This results in multiple episodes of increasing wall tension with obstruction of submucosal venous outflow, especially where these vessels pierce the smooth muscle layers of the colon. Over many years, this process causes gradual dilation of the submucosal veins and, eventually, dilation of the venules and arteriolar capillary units feeding them. Ultimately, the capillary rings dilate, the precapillary sphincters lose their competency, and a small arteriovenous communication forms. This accounts for the characteristic early filling vein observed during mesenteric angiography. Of note, the aforementioned pathophysiological mechanisms responsible for the development of cecal lesions are unlikely to apply to lesions in the upper GI tract, despite being morphologically identical. Recently, a link between a deficiency of high molecular-weight multimers of von Willebrand factor, aortic stenosis, and colonic angiodysplasia has been proposed. Bleeding from angiodysplastic lesions in the upper and lower GI tract has been reported in patients with von Willebrand disease [2,3]. Because factor VIII complex is synthesized partly in vascular endothelial cells, patients with von Willebrand disease and angiodysplasia have been proposed to have an

underlying endothelial defect that may be related to the subsequent development of the two disorders (accelerated clearance of von Willebrand factor from plasma) [4]. However, as with renal failure, the coagulopathy more likely is responsible for bleeding than for the development of the lesions. Roskell et al. demonstrated a relative deficiency of collagen type IV in the mucosal vessels in angiodysplasia compared to controls. The authors propose that this deficiency may be related to the patients' susceptibility to ectasia and hemorrhage. In a small study, Junquera et al. noted an increased expression of angiogenic factors in human colonic angiodysplasia [5]. This study observed vascular immunoreactivity for basic fibroblast growth factor was observed in seven (39%) specimens from patients with colonic angiodysplasia, whereas either very limited or no immunostaining was found in sections from specimens of patients with colonic cancer and healthy margins.

## Diagnostic Principles

The diagnosis can be made radiologically, endoscopically, at operation or by the histopathologist. Selective mesenteric angiography is a useful diagnostic technique, especially in patients with massive bleeding in whom a colonoscopic diagnosis is difficult. Helical CT angiography can detect extravasation from angiodysplasia and potentially is an important noninvasive test in patients with obscure bleeding sites. Capsule endoscopy has been reported to detect cecal angiodysplasias in selected cases, but its role as a diagnostic test for the colon is still experimental. Endoscopy is the most common method of diagnosing angiodysplasia in both the upper and lower GI tract.

## Therapeutic Principles

Angiodysplasia of colonic origin has been managed by endoscopic obliteration. Argon plasma coagulation, heater probe and laser photocoagulation has been successful in controlling bleeding from colonic angiodysplasia. Endoclips have been used in anecdotal case reports for bleeding angiodysplasia of the cecum and right colon. Angiodysplasia that presents with acute hemorrhage can be controlled effectively with angiography, although it seldom is needed. Angiography is appropriate in severely ill patients who are not candidates for surgical intervention. In these patients, transcatheter embolization of selected mesenteric arteries has been quite effective. Surgical resection is the definitive treatment. Current data do not support the use of hormonal therapy or in patients with colonic angiodysplasia. Somatostatin analogs and thalidomide have been reported to decrease the rate of bleeding from intestinal angiodysplasia. Octreotide should be first choice in patients with portal hypertension.

# Angioedema, Angiotensin-converting-Enzyme-Inhibitor-induced

Murat Bas[1], Georg Kojda[2]
[1]HNO, Technische Universitaed Munich, Munich, Germany
[2]Institute for Pharmacology and Clinical Pharmacology, University Clinic Duesseldorf, Duesseldorf, Germany

## Synonyms

Quincke edema; Kinine-induced angioedema; ACEi

## Definition and Characteristics

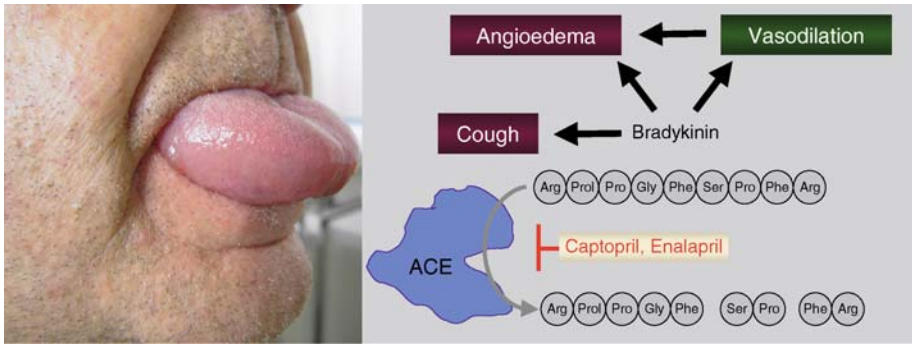
Sudden occurrence of subcutaneous or submucosal swelling (Fig. 1), so-called angioedema, is an established and – in case pharynx or larynx are involved – potentially life-threatening side effect of angiotensin-converting enzyme inhibitors (ACEi). The duration of ACE-inhibitor treatment at the onset of angioedema ranges from 1 day to 8 years with a median of 6 months [1].

## Prevalence

The incidence of ACEi-induced angioedema is 0.4–0.7%. The mortality is world wide 0.1% of these cases. Black people may have an increased risk to develop an ACEi-induced angioedema [2].

## Molecular and Systemic Pathophysiology

ACE catalyses the generation of the important cardiovascular mediator angiotensin II from angiotensin I and substantially contributes to the inactivation of bradykinin (BK) (Fig. 1). Hence, inhibitors of ACE inevitably account for increased BK plasma levels. BK is a mediator of inflammation, activates nociceptors, increases vascular



**Angioedema, Angiotensin-converting-Enzyme-Inhibitor-induced. Figure 1** Clinical manifestation (right panel) and the possibly underlying pathophysiology (left panel) of ACEi induced pathophysiology of angioedema.

permeability, and causes endothelium-dependent vasodilatation. High levels of BK have been demonstrated ($n$ = 4) in plasma during an acute episode of angioedema [3] and both the amount and the activity of peptidases involved in the bradykinin metabolism such as aminopeptidase P [4] and dipeptidyl peptidase IV [5] are reduced.

These observations are consistent with the hypothesis that ACEi-induced angioedema is related to accumulation of bradykinin. However, the role of BK on angioedema is not completely understood. BK degradation is blocked in all patients treated with ACEi, but only a small percentage experience a single attack or recurrent angioedema [1]. Patients with ACE dysfunction are characterized clinically by low potassium serum concentrations, alkalosis, and high plasma levels of renin, angiotensin I, and BK, but the high plasma BK levels do not release an angioedema. Also, patients with the syndrome of idiopathic high levels of BK do not develop angioedema. Likewise, many patients experience ACEi-induced angioedema after many years of uneventful treatment with ACEi. Taken together, increased plasma bradykinin levels appear to play a role in the course of ACEi-induced angioedema but additional factors are likely involved in the underlying pathological process. For example, recent data suggest an involvement of acute phase proteins such as fibrinogen and C-reactive protein [1].

## Diagnostic Principles

Sudden swelling of lips, tongue, oropharynx, and larynx may be caused by a variety of pathophysiologic events. Most importantly, the diagnosis of ACEi-induced angioedema should be preceded by exclusion of other pathologies such as allergic reactions, deficiency of C1-esterase inhibitor, infection, inflammation, tumors, and diseases of large salivary glands. Furthermore, other drugs are known to induce angioedema with an incidence >1% including rituximab, alteplase, fluoxetine, laronidase, lepirudin, and tacrolimus. It is important to know that many patients can develop angioedema even after many years of uneventful ACEi treatment.

## Therapeutic Principles

Patients with acute angioedema should be hospitalized for at least 12–48 h. Any treatment with ACE inhibitors and other drugs known to induce angioedema (see above) must be discontinued. To maintain ventilation particularly in severe obstructive upper airway swelling, intubation and in rare cases tracheotomy has to be performed. In addition, oxygen may be necessary. In many cases of angioedema, emergency treatment includes intravenous corticosteroids, e.g., 250–500 mg prednisolone and inhalation of epinephrine before final diagnosis. It should be emphasized that none of these interventions are evidenced based strategies to treat ACEi-induced angioedema. A new option for pharmacologic treatment with a strong biologic rationale is the blockade of bradykinin B2-receptors, e.g., by icatibant.

# Angioedema, Hereditary

Randolf Brehler
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Hereditary angioneurotic oedema; HAE

## Definition and Characteristics

It is an inherited, autosomal dominant disease of episodic, non-itching and non-inflammatory edema of the subcutaneous and submucosal tissue that completely resolves in 1–5-days. A major attack is frequently preceded by a prodromal rash, which consists of annular erythema and wheals. Edema of the skin can form monstrous deformities of the face; affected gastrointestinal mucosa leads to pain, vomiting and diarrhea and can be easily misdiagnosed as a surgical emergency. Involvement of oral mucosa, pharynx and larynx is common; larynx edema can lead to life threatening reactions resulting in death by asphyxia. The edema of the urinary tract mucosa leads to dysuria and the involvement of the ZNS to headache, dizziness and paralytic symptoms. The first symptoms of HAE occur in >50% of the patients before they are 10 years old, but the disease is mostly diagnosed in patients older than 20 years.

Quantitative or qualitative C1 esterase inhibitor (C1 INH) deficiency is the biochemical cause of HAE. Acute attacks of HAE can be related to dental treatments and surgical interventions. The therapy with corticosteroids is ineffective in the treatment of all types of HAE; the administration of C1 INH is the therapy of choice.

## Prevalence

The prevalence of HAE in the common population is two cases in 1,000–10,000; 85% suffer from type 1 HAE (quantitative deficiency of C1 INH) and 15% from type 2 HAE (dysfunctional C1 INH protein).

## Genes

The 17,159 kb long C1 inhibitor (C1 INH) gene (accession number X54486) is located on the chromosome 11 subregion q11.2–q13. Mutations were detected in all gene regions; at present nearly 100 different mutations have been reported. In about 20% of the patients with HAE the mutations are spontaneous and therefore relatives are not affected.

## Molecular and Systemic Pathophysiology

C1 INH is a serine protease inhibitor central to the regulation of the complement system. It forms complexes with C1 and inhibits C1r and C1s in the complement system as kallikrein in the kinin-forming contact system. The defective inhibition of the target proteases (C1r, C1s, kallikrein) is clinically silent under normal circumstances but becomes clinically significant if triggering factors like trauma activate the complement components of the classical pathway. They cleave high-molecular-weight kininogen in the contact system and generate plasmin, leading to the release of peptides, increasing the vascular permeability responsible for edema.

## Diagnostic Principles

The diagnostic serologic parameters of the different types of HAE are given in Table 1.

# Angiomatous Hamartoma

Engin Sezer[1], Atilla Şenayli[2]
[1]Department of Dermatology, Gaziosmanpaşa University School of Medicine, Tokat, Turkey
[2]Department of Pediatric Surgery, Gaziosmanpaşa University School of Medicine, Tokat, Turkey

## Synonyms

Eccrine angiomatous hamartoma; EAH; Sudoriparous angiomatous hamartoma; Functioning sudoriparous angiomatous hamartoma; Nevus of the sweat gland; Cavernous angiomatosis of the sweat ducts

## Definition and Characteristics

Hamartoma is a non-neoplastic proliferation of cells and tissue components that occurs in an affected area. In its EAH form, there is an increased number of eccrine secretory and ductal elements within the angiomatous channels.

## Prevalence

Although adult onset has been reported, the disease is most commonly seen during early childhood. There is no apparent gender preference. EAH is a rare disorder with approximately 50 cases reported in the literature.

## Genes

The genetic characteristics have not been demonstrated.

## Molecular and Systemic Pathophysiology

EAH is a rare cutaneous hamartoma appearing histologically as a proliferation of eccrine sweat glands with angiomatous vascular elements that are of capillary origin. A deficiency between the mesenchyme and differentiating epithelium causes EAH. These layers cause the proliferation of the epithelial elements and an abnormal biochemical interaction is the main disturbance [1]. Histologic features of EAH are hyperplastic eccrine structures, increased proliferation of vascular structures, and variable presentations of increased lymphatic, smooth muscle, and pilar structures. An acanthotic epidermis is evident on hematoxylin and eosin-stained tissue sections. In the deeper part of the dermis, mature eccrine sweat glands aggregate and numerous thin-walled blood vessels are detected. Unusual histological variants including the infiltration of adipose tissue, apocrine glands, hyperplastic nerve bundles and intercellular mucin deposits have been reported. Using immunohistochemical staining techniques, carcinoembryonic antigen, S100, and CD44 are stained in tissues derived from patients with EAH. CD34 is also strongly stained in the surrounding stroma, but not the pericytes or vascular endothelium. In other studies, the vascular elements have been shown to stain positively for anti–*Ulex europaeus* and anti–factor VIII antigens [2]. The secretory portions of the eccrine glands are positive for S100, carcinoembryonic antigen, epithelial membrane antigen, and Cam5.2. Characteristics of the tumor include tubular and glandular masses within a richly vascular stroma. Hamartoma occurs during early organogenesis which is thought to represent an abnormality of heterotypic dependency. According to this theory, the main problem rests with deficient biochemical interactions between differentiating epithelium and the underlying mesenchyme, which in turn causes malformation of adnexal and vascular structures.

## Diagnostic Principles

EAH lesions are characterized by solitary or multiple flesh-colored, blue-brown or pinkish-red slow growing nodules or plaques, and are mainly located on the limbs [3]. The disease manifests mainly at birth or in childhood. The lesions are often asymptomatic, but pain and hyperhidrosis are reported in one-third of the patients. Rapid growth of EAH has been reported during pregnancy and puberty, suggestive of hormonal influences. Osteolytic changes and destruction of the nail matrix with vestigial nails has been described (Fig. 1).

**Angiomatous Hamartoma. Figure 1** Eccrine angiomatous hamartoma lesions on the toes resulting in nail matrix destruction and vestigial nails.

Histological features including dermal proliferation of vascular channels, generally of capillary nature in close association with well-differentiated eccrine elements help to identify the disease. The main differential diagnosis is sudoriparous angioma, in which the angiomatous component with vessels of large calibre predominates and the eccrine elements show dilatation rather than proliferation.

## Therapeutic Principles

Surgical excision is curative and is reserved for painful or cosmetically unacceptable lesions. Occasionally, the pain may remit spontaneously without treatment after several years. Spontaneous regression of the disease is exceedingly rare [4].

# Angiosarcoma

Michael Stürzl[1], Peter Klein[2], Christian Zietz[3]

[1]Division of Molecular and Experimental Surgery, Department of Surgery, University of Erlangen-Nuremberg, Erlangen, Germany

[2]Department of Surgery, University of Erlangen-Nuremberg, Erlangen, Germany

[3]Department of Pathology, Technical University of Dresden, Dresden, Germany

## Synonyms

Hemangiosarcoma; Lymphangiosarcoma; Malignant hemangioendothelioma; Malignant angioendothelioma; Hemangioblastoma

## Definition and Characteristics

Angiosarcomas are rare malignant tumors with the tumor cells variably recapitulating the morphologic and functional features of normal endothelium. Consequently, the tumors present with varying degrees of differentiation (Fig. 1a, b).

Specifically undifferentiated tumors show high mitosis rates and high rates of metastasis. Reported tumor-related 5 year survival rates are below 20%.

## Prevalence

Angiosarcomas develop with similar frequency in females and males and constitute less than 1% of all sarcomas. One-third of the tumors occur in the skin, about one-fourth in soft tissue, and the remainder at other sites (e.g., breast, liver, bone, spleen). Approximately 50% of cutaneous angiosarcomas occur in the head and neck. Risk factors are radiation (angiosarcoma of the skin), exposure to vinyl chloride, arsenic, and thorium dioxide/thorotrast (angiosarcoma of the liver) as well as chronic lymphedema (Stewart-Treves-Syndrome) [1].

## Genes

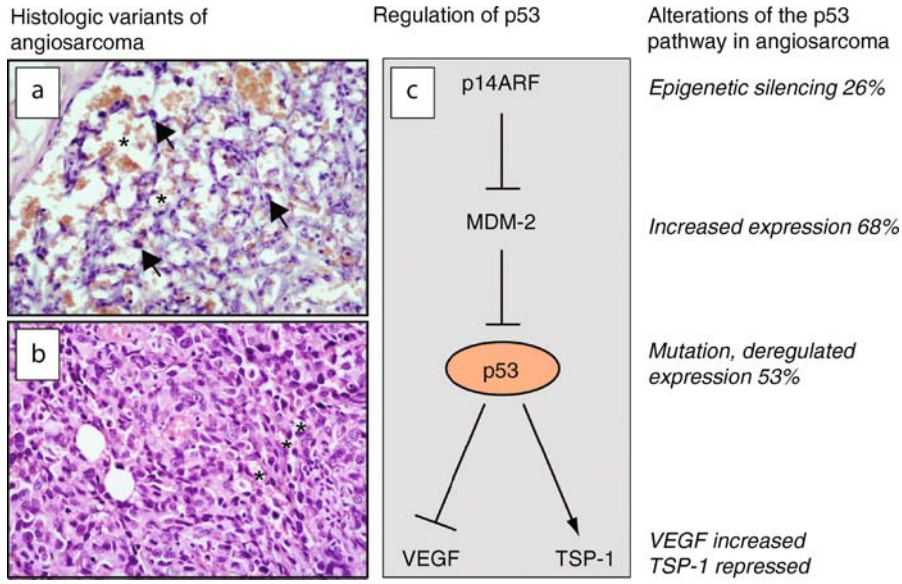
TP53, MDM-2, p14ARF, VEGF, FGF2.

## Molecular and Systemic Pathophysiology

The tumor suppressor p53 plays a key role in the pathogenesis of angiosarcoma (Fig. 1c). P53 deficiency leads to development of angiosarcomas in mice. In humans mutations and deregulated expression of p53 have been detected in up to 53% of angiosarcomas. In addition, two major regulatory molecules of p53 activity, namely the murine double minus-2 protein (MDM-2) and p14ARF, are aberrantly expressed in many angiosarcomas. MDM-2, which inhibits p53 activity, is expressed in increased amounts in 68% of the tumors [2]. P14ARF, which inhibits MDM-2, has been found to be repressed by epigenetic silencing in 26% of the cases investigated [3]. In normal endothelial cells p53 inhibits angiogenic activation *via* suppression of pro-angiogenic vascular endothelial cell growth factor (VEGF) and activation of anti-angiogenic thrombospondin-1 (TSP-1) [4]. Impaired activity of p53 in angiosarcoma cells increases VEGF and represses TSP-1 expression. Both events activate the growth of the endothelial cell-derived tumor cells of angiosarcoma. In addition, a second pro-angiogenic factor, basic fibroblast growth factor (bFGF), and its receptor are upregulated in angiosarcoma cells and bFGF serum concentrations are increased in angiosarcoma patients. Altogether, a shift of the angiogenic balance in the course of deregulated p53 activity is a key event in the pathogenesis of angiosarcoma. Besides this, it may be of therapeutic relevance that the c-kit proto-oncogene, a tyrosin kinase receptor of stem cell factor, is expressed in more than 50% of angiosarcomas.

## Diagnostic Principles

Localization and extension of the primary tumor is commonly detected with magnetic resonance tomography.



**Angiosarcoma. Figure 1** Differentiation and molecular regulation of angiosarcoma. (a) Moderately differentiated angiosarcoma with numerous blood filled vessels with irregular size (*) and atypical endothelial cells (arrows). (b) Low differentiated angiosarcoma with epitheloid structure and only few blood vessel channels (*) between the neoplastic endothelial cells. (c) Schematic presentation of p53 regulation (*left*) and relative frequency of alterations of this pathway in angiosarcoma (*right*).

Distant metastases in the lung are commonly investigated with computer tomography. Histological staining of biopsies for CD31 and FLT1 demonstrates the endothelial cell origin of the tumor cells. In few morphologically questionable cases negativity of the human herpesvirus-8 latency associated nuclear antigen-1 (HHV8-LNA1) may be used to differentiate angiosarcoma from Kaposi's sarcoma.

### Therapeutic Principles

Gene directed molecular approaches for treatment of angiosarcoma are not available, as yet. The most widely used treatment at present is surgical resection with wide excision in combination with postoperative radiotherapy. The likelihood of local regional failure is high as is the risk of distant relapse. Chemotherapy may be used for short term medication [5].

# Ankylosing Spondylitis

Steven Mumm
Division of Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO, USA

## Synonyms

Marie-Strumpell spondylitis; Bechterew syndrome; Rheumatoid spondylitis

## Definition and Characteristics

Ankylosing spondylitis (AS) [Online Mendelian Inheritance in Man (OMIM) #106300] literally means "fusion of the vertebrae due to inflammation." AS is characterized by progressive back pain and stiffness, caused by recurring cycles of inflammation and new bone growth, resulting in fusion of vertebrae [1,2]. The process usually starts at the sacroiliac joints between the sacrum and pelvis. Progression can occur throughout the spine, however, there is considerable variation among individuals. Onset of AS usually occurs in the second or third decade of life. Other joints can also be affected and include the hips, knees, and ankles. The most serious complication is spinal fracture. Secondary features, outside the skeleton, may include inflammation of the eye (uveitis, iritis) and in the heart (around the aortic valve), psoriasis, and inflammatory bowel disease (Crohn's disease and ulcerative colitis).

## Prevalence

AS is a common disorder, but the prevalence varies among ethnic groups and between males and females, with males having a higher incidence. The prevalence of AS is estimated at 0.5% in men and 0.2% in women in Britian, approximately 2% in men and 0.5% in women in Norway, and as high as 2.5% in the adult Eskimo population in Alaska, USA [1]. Conversely, the incidence of AS in Japan is very low (~0.01%). Worldwide, the prevalence of AS approaches 0.9% [1].

## Genes

The gene(s) responsible for AS has not yet been positively identified. AS is a complex genetic disorder with several genes (and corresponding genetic defects or polymorphisms) contributing to the disease. A variety of genetic studies have implicated the human leukocyte antigen B27 (HLA B27) to be directly involved in the disorder [3,4]. Additionally, other genes within the HLA genetic locus on chromosome 6p, are also likely involved, possibly tumor necrosis factor α (TNFα). Other genes, near the HLA locus, are also likely involved. Recurrence risk modeling suggests a total of 5 genes will probably account for AS. Genome-wide scans have identified additional candidate loci on chromosomes 1p, 2q, 6p, 9q, 10q, 16q, and 19q [3,4]. Candidate genes include interleukin 1 (IL-1 on chromosome 2) and the cytochrome P450 2D6 gene (debrisoquine hydroxylase, CYP2D6) on chromosome 22q [3,4]. Defects in CYP2D6 may disrupt metabolism of a natural toxin or antigen, increasing susceptibility to AS.

## Molecular and Systemic Pathophysiology

The pathogenesis of AS is not completely understood, but will likely turn out to be a complex disorder with genetic, immunological, and environmental components [1,2]. AS is caused by recurring cycles of inflammation and new bone growth that eventually lead to fusion of the spine. The process starts with inflammation at the site of attachment of tendons to bone (enthesis) and progresses with deterioration of the bone at these sites (enthesopathy). This inflammatory process is promoted by HLA B27, which has a direct role in antigen presentation. Likewise, defects or polymorphic variants in CYP2D6 may have an effect on normal processing of antigens. Further, polymorphic variants in the cytokines TNFα and IL-1, also modulate the inflammatory process. As the inflammation subsides, new bone growth occurs. TNFα, IL-1 and other cytokines involved in inflammation also stimulate normal bone turnover (osteoclastogenesis and coupled osteoblastogenesis). Hence, cytokines appear to have a dual role in AS, inflammation and bone turnover–both processes that contribute to the pathophysiology of AS. Only when the additional genetic factors are identified, will the precise pathogenesis of AS be elucidated.

## Diagnostic Principles

Symptoms usually start in late adolescence or early adulthood, and include low back pain and stiffness, commonly occurring in the morning and improving with exercise. There is also loss of spinal mobility. Laboratory testing for HLA-B27 is positive in most cases of AS. Diagnosis is confirmed when there is inflammatory back pain with radiological evidence of sacroiliitis (either grade II bilaterally or grade III unilaterally) [1].

## Therapeutic Principles

Non-steroidal anti-inflammatory drugs (NSAID) are commonly used to reduce the pain and stiffness associated with AS, although they are ineffective at retarding the progression of the disease. NSAID use is often associated with gastrointestinal side effects, which may limit its use [5]. These may be avoided by use of NSAIDs that inhibit cyclo-oxygenase-2 (COX-2

inhibitors). Some of the disease-modifying antirheumatic drugs (DMARDs), such as sulfasalazine, are the secondary approach to AS, although controlled studies are limited [5]. Two new anti-TNFα agents (infliximab, a TNFα monoclonal antibody, and etanercept, a TNFα receptor fusion protein) are in clinical trials and show promise in treating AS [5]. Regular exercise and physical therapy are also important components in treatment of AS [2].

# Annular Pancreas

Guido Adler
Department of Internal Medicine I, Ulm University, Ulm, Germany

## Synonyms

Pancreas annulare

## Definition and Characteristics

Annular pancreas is an embryologic malformation characterized by the presence of a ring of pancreatic tissue completely or partially surrounding the second part of the duodenum. Its major clinical symptom is complete or partial duodenal obstruction. Several anatomic classifications have been proposed according to the fusion pattern of ventral and dorsal pancreatic duct, the intra- or extramural position of pancreatic tissue in the duodenal wall, the place of drainage of the annular duct and the origin of the annulus from the different biliopancreatic ducts [1,2] (Fig. 1a).

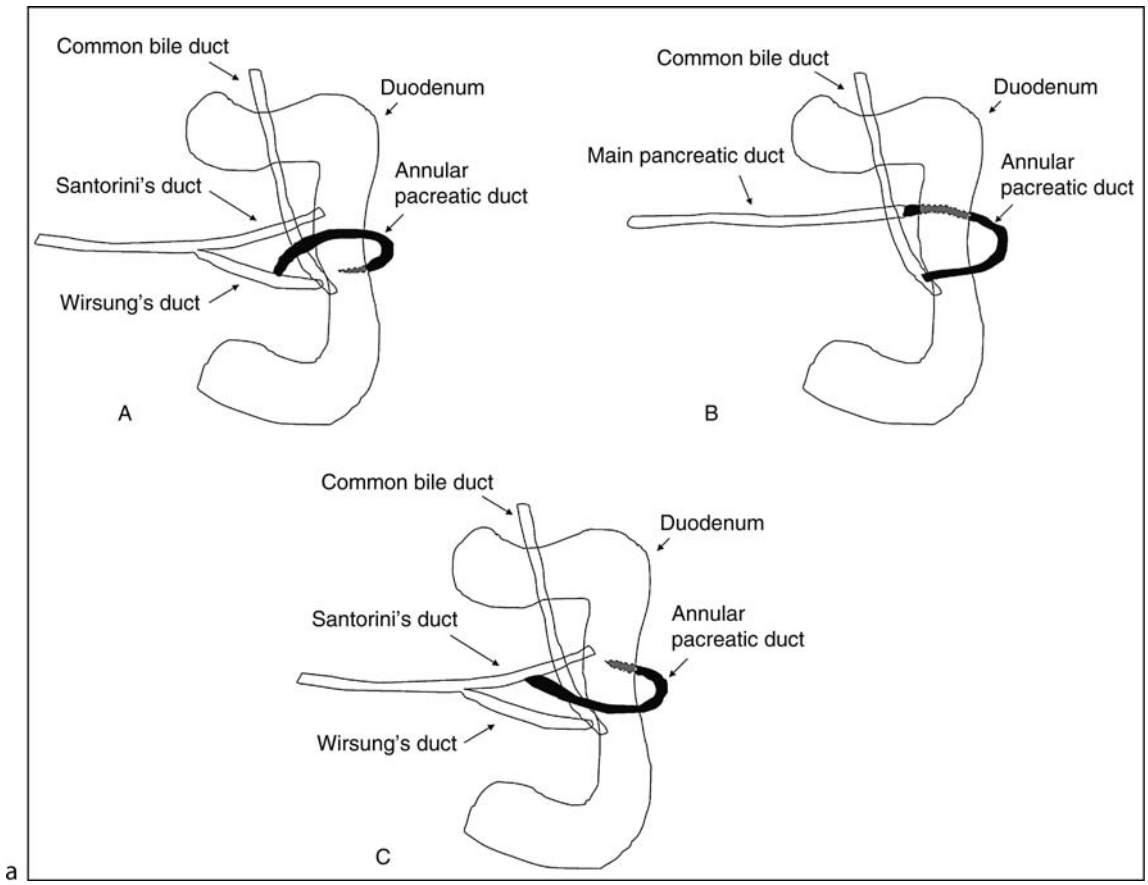
The disease was diagnosed during childhood in 51.5% and in adults in 48.5% of all published cases. In up to 70% of newborn children annular pancreas is associated with other congenital anomalies like duodenal atresia, Down's syndrome, esophageal atresia, congenital heart defects, imperforate anus, chromosome 1p36 deletion syndrome and other structural birth defects. In patients with Down syndrome the risk for annular pancreas is increased 430 times [3]. The spectrum of symptoms and clinical presentations varies with the degree of duodenal obstruction due to annular pancreas. In children, duodenal obstruction is the most common presenting complaint which makes vomiting the leading clinical symptom. Annular pancreas often does not become symptomatic until later in life, mainly in the third and forth decade. In adults the major clinical though unspecific symptoms suggestive of annular pancreas are abdominal pain (70%) and nausea and vomiting (60%). Peptic ulcer disease, obstructive jaundice and pancreatitis are less common.

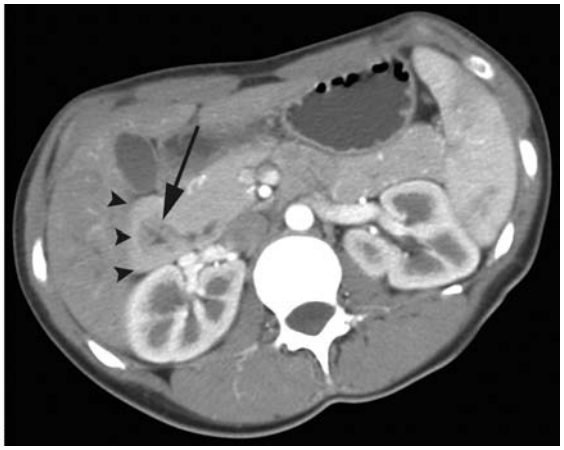
## Prevalence

No exact data exist on the prevalence. In surgical and autopsy series the incidence was three cases in 24,519 and three cases in 20,000 respectively. In different ERCP series the incidence was between 1 in 160 and 1 in 250 cases. It appears to be more frequent in males than in females with a ratio of about 2:1. The occurrence of annular pancreas in successive generations of a family argues for an autosomal dominant or X-linked inheritance.

## Molecular and Systemic Pathophysiology

The ectopic tissue of annular pancreas is a remnant of the developing head of the pancreas during embryonic development. In pancreatic organogenesis two members of the hedgehog family of cell signals – Indian hedgehog (Ihh) and Sonic hegdehog (Shh) – regulate crucial developmental processes. In an experimental model in mice the inactivation of Ihh or Shh caused overgrowth of ventral pancreatic tissue resulting in an annulus around the duodenum [4]. The results from this study demonstrated that the annulus is derived from the ventral pancreas by asymmetric lateral branching of the ventral duct and symmetric branching of the ventral bud. This experimental phenotype is strikingly similar to the annular pancreas in humans. Different other hypotheses were mainly descriptive but were not supported by experimental evidence [1]. They include both dorsal and ventral bud hypertrophy resulting in a complete ring. Another theory suggests that the ventral bud of pancreatic anlage adheres to the duodenal wall and stretches to form a ring during rotation.





**Annular Pancreas. Figure 1** (a) Scheme of three types of annular pancreas. (A) annular duct develops from the Wirsung duct, (B) main pancreatic duct surrounds the duodenum, (C) annular duct develops from Santorini duct or common bile duct (Ref. [2], with permission). (b) Ct scan from a 26 year old female. Pancreatic tissue (arrowheads) surrounds the duodenum (arrow) (by courtesy of A. Aschoff, Dep Radiology, University Hospital Ulm, Germany).

## Diagnostic Principles

Different imaging techniques are available to demonstrate an annular pancreas. Nevertheless in up to 40% final diagnosis requires surgery for confirmation. A complete duodenal obstruction causing dilated stomach and proximal duodenum may result in the "double bubble" sign on an abdominal radiograph. Transabdominal ultrasound may demonstrate a fluid filled dilated descending duodenum encircled by pancreatic tissue and is increasingly used to make

prenatal diagnosis. Pancreatic parenchyma surrounding the duodenum can be visualized by CT or MR imaging (Fig. 1b).

Endosonography, ERCP and MRCP can demonstrate the typical circular structure of pancreatic duct.

## Therapeutic Principles

Symptomatic annular pancreas should be treated operatively. There is no single operative procedure of choice. Published experience clearly argues against direct intervention on the offending annulus. Resection of the annulus has been associated with numerous complications including persistent duodenal obstruction, pancreatitis and pancreatic fistula. In pediatric and adult patients side-to-side duodenoduodenostomy, gastrojejunostomy or duodenojejunostomy are the treatments of choice. In adults a further variety of surgical, laparoscopic and interventional endoscopic procedures have been mentioned to be effective [5].

# Anorexia

►Anorexia Nervosa

# Anorexia Nervosa

Kirsty Kiezebrink
University of Abertay, Dundee, UK

## Synonyms

Anorexia; Eating disorder; Self-starvation

## Definition and Characteristics

Anorexia nervosa is a psychiatric disorder that according to the Diagnostic and Statistical Manual for Mental Disorders, Fourth Edition (DSM-1V), is defined as "the refusal to maintain body weight about 85% of predicted, an intense fear of gaining weight, undue influence of body shape or weight on self image, and missing at least three consecutive menstrual periods." Individuals with anorexia nervosa aim to control body weight and or shape by voluntary starvation, alongside this starvation there is often inappropriate compensatory behaviors such as vomiting, excessive exercise, abuse of diet pills, diuretic drugs, laxative pills, and thyroid hormone abuse. Anorexia nervosa is a complex condition involving psychological, neurobiological, physiological, sociological and genetic components.

## Prevalence

The group with highest prevalence of Anorexia nervosa are young females between the ages of 15 and 25 from social classes one and two. In this group the prevalence is about 1%. Males also develop anorexia nervosa with estimates of 1:10, male: female ratio. It is estimated that about 10% of females in the general population are affected by some form of eating disorder (including those that just fail to meet the full diagnostic criteria, eating disorders not otherwise specified, EDNOS).

## Genes

Theander [1] first considered the possibility of a genetic influence in AN in 1970. He noted an increased prevalence of AN in the sisters of sufferers, prevalence rates of 3–7% and 1–6% have been observed in siblings of affected individuals and first-degree relatives respectively, and the propensity for a particular illness to group within relatives is in general a characteristic of intergenerational family transmission. More recent studies have suggested that the prevalence of AN in relatives of sufferers is more than 11 times greater than that in the general population.

AN is unlikely to be caused by a defect in a single gene. It is more likely that subtle variation in several genes and their interaction with the environment will result in increased susceptibility to AN. A candidate gene approach has been employed to attempt to identify genes which may be associated with AN. Genes are selected on the basis of their believed roles in traits such as perfectionism, obsessive behaviors, maturity fears, low self-esteem overall anxiety, mood and eating behavior. To date analyses on 16 different candidate genes association studies with AN have been published. Of these six of the genes are related to the serotoninergic system. The most promising of these is the HTR2A receptor polymorphism (−1,438G > A), however there is mixed evidence of this association [2]. A further area that has received a great deal of attention is the catecholamine system, three genes have been investigated in this system these are DRD3, DRD4 and COMT. These genes have been shown to be associated

with other psychiatric disorders (schizophrenia and substance abuse). However, the published reports failed to show any evidence of association with AN. The final group of genes that has received attention are the neuroendocrine genes, these are involved in appetite regulation and energy metabolism. The genes investigated within this group include DRD3, DRD4, COMT, AGRP, LEP, MCH4, UCP [1–3] ESR and HLA-A. Of these some evidence of association has been shown with UCP, ESR1 and HLA-A. Currently the most promising associations appear to be with OPRD1 and HTR1D, these associations were first identified through a genome scan which identified 1p33–36 as a hot spot. Both these genes were identified within this region and were reported to be associated with AN [3]. This finding has since been confirmed in a second cohort [4].

## Molecular and Systemic Pathophysiology

AN has one of the highest morbidity and mortality rates of any psychiatric disorder. The health consequences of long term maintenance of extreme body weight are many and varied, ranging from an increased risk of premature death to several non-fatal but debilitating complaints that impact on the immediate quality of life [5]. Macro and micro-nutrient deficiencies and disruption of multiple organ systems is brought about through starvation. In addition to hypoglycemia and vitamin deficiencies, starvation results in the suppression of thyroid function, in hypercortisolemia, and in release of endogenous opioids, which may contribute to reduction in hunger described by patients with AN.

Starvation results in many biochemical changes such as hypercortisolemia, nonsuppression of dexamethasone, suppression of thyroid function and amenorrhea. Computerized tomographic (CT) studies of the brain have revealed enlarged sulci and ventricles in underweight patients, which return to normal size with weight gain.

Neuroendocrine disturbances are responsible for delayed puberty, amenorrhea, anovulation, decreased oestrogen levels, increased growth hormone, decreased antidiuretic hormone, hypercarotenemia, and hypothermia.

Self-induced vomiting can lead to swelling of salivary glands, electrolyte and mineral disturbances, and enamel erosion in teeth. Laxative abuse can lead to long lasting disruptions of normal bowel functioning. Complications such as tearing the esophagus, rupturing the stomach, and developing life-threatening irregularities of the heart rhythm may also result.

## Diagnostic Principles

Physical signs and symptoms can include constipation, abnormally low heart rate, dizziness, disturbances of vision, abdominal pain, hypotension, lanugo and disruption of menstrual cycle.

## Therapeutic Principles

Psychosocial problems abound both within the individual sufferer and also in their families. The complexity of this disorder underpins the problems of devising the best treatment plan for patients. The first stage of treatment will often involve treating medical complications in order to stabilise a patient. Following this, the major aims of treatment are to restore patients nutritional status and establish healthy eating patterns, address dysfunctional thoughts related to the eating disorder. These treatment aims are best achieved through psychotherapy. There is limited use of pharmacotherapy whilst weight is still low. Drugs are more commonly administered after weight has been restored in order to help maintain weight and normal eating behaviors as well as treat associated psychiatric symptoms. These include: Antidepressants: Serotonin-specific reuptake inhibitors are commonly administered to treat depressive, obsessive or compulsive symptoms that persist in spite of or in the absence of weight gain. Antipsychotics may also be used to treat agitation and psychotic thinking. In some cases anti-anxiety medications may be used to reduce anticipatory anxiety.

# Antibody Deficiency with Normal Immunoglobulins

Alan P. Knutsen
Division of Allergy/Immunology, Department of Pediatrics, Saint Louis University Health Sciences Center, St. Louis, MO, USA

## Synonyms

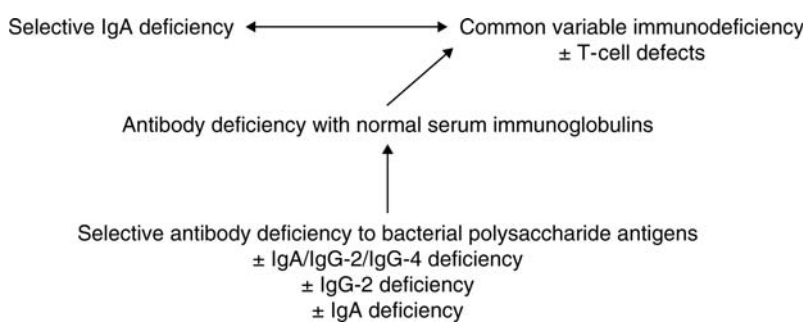
Antibody deficiency with normal serum immunoglobulins; Selective antibody deficiency; IgG subclass deficiency

## Definition and Characteristics

Antibody deficiencies are the most common of primary immunodeficiency disorders. The spectrum of B-cell deficits range from profound hypogammaglobulinemia and antibody deficiency, such as in the B negative agammaglobulinemia states, common variable immunodeficiency (CVID), and hyper-IgM deficiency syndrome (HIGM def) to antibody deficiency disorders with normal and/or near normal serum immunoglobulin levels. The later antibody deficiency disorders are comprised of a spectrum: [1] antibody deficiency with normal or elevated immunoglobulins, [2] selective antibody deficiency to bacterial polysaccharide antigens, and [3] IgG subclass deficiency (Fig. 1).

The hallmark of antibody deficiency with normal immunoglobulins is a profound antibody deficiency to multiple protein and polysaccharide antigens with normal or elevated serum immunoglobulin IgG, IgA, and IgM, and normal T-cell numbers and function. However, with the exception of immunoglobulin levels, this B cell immune deficiency clinically- and laboratory-wise is similar to CVID. Thus, it is speculated that some patients with antibody deficiency may evolve into CVID. In addition, some of these patients may be diagnosed as having an IgG subclass deficiency. Though in the later, antibody responses to protein antigens are typically normal and have a selective antibody deficiency to polysaccharide antigens. If there is a profound T-cell immune deficiency associated with the antibody deficiency, these patients are categorized as a combined T- and B- cell immunodeficiency (CID), Nezelof syndrome or thymic dysplasia.

Antibody deficiency with normal immunoglobulins needs to be differentiated from [1] selective antibody deficiency to bacterial polysaccharide antigens, [2] IgG subclass deficiency, and [3] antibody deficiency with associated T-cell deficiency (Fig. 1). In selective antibody deficiency, there is a deficiency of antibody responses to bacterial polysaccharide antigens, such as to Streptococcus pneumoniae, but antibody responses to protein antigens, serum IgG, IgA, IgM, and IgG-subclasses are normal. In IgG subclass deficiency, there is usually decreased IgG-2 levels, sometimes associated with IgG-4 and/or IgA deficiency, IgG-2, IgG-2/IgG-4, IgA/IgG-2/IgG-4 deficiencies, and these are associated



**Antibody Deficiency with Normal Immunoglobulins. Figure 1** Proposed relationship of IgG subclass deficiency, selective antibody deficiency, antibody deficiency with normal immunoglobulins with common variable immunodeficiency and selective IgA deficiency.

with defective antibody responses to bacterial polysaccharide antigens. In antibody deficiency with normal immunoglobulins associated with defects of T-cell numbers and function, this is categorized as a combined immunodeficiency (CID) or Nezelof syndrome.

## Prevalence

The spectrum of disorders of antibody deficiency with normal immunoglobulins include selective antibody deficiency and IgG subclass deficiency. In studies examining patient populations with increased susceptibility to infections, IgG subclass deficiency is a common finding. Aucouturier et al reported an IgG subclass deficiency frequency of 24%, with a predominance of IgG2 deficiency, in a group of 229 patients with abnormally frequent and/or prolonged or severe infections recruited from three departments of clinical immunology between 1983 and 1987. This same group screened a similar population of 254 patients in a subsequent study, this time recruited from departments of pediatrics or infectious diseases throughout France between 1988 and 1990. Using similar laboratory techniques and diagnostic criteria, the frequency of IgG subclass deficiency was 18% though IgG3 isotype deficiency predominated rather than IgG2. The IgG3 deficiency predominance remained a highly significant finding when both studies were analyzed as a whole series of 483 patients. The findings of these studies correlated with the results of a preceding large series of patients by Oxelius et al in which IgG3 was also found to be the most frequently defective isotype. The frequency of IgG subclass deficiency may also vary by age and sex. Studies carried out in Scandinavia suggested that children were more likely to have IgG2 subclass deficiency whereas adults were more likely to have IgG3 deficiency.

The prevalence of selective antibody deficiency is unknown; however, it is more common in younger children compared to older children and adults. Selective antibody deficiency in children <6 years old may be akin to transient hypogammaglobulinemia of infancy (THI) representing a maturational delay in which the children "outgrow". The exact frequency of THI is unknown; although it has been estimated at 1 per 10,000. In this author's experience, THI and selective antibody deficiency are relatively common diagnoses in young children referred for evaluation of recurrent infections. On the other hand, antibody deficiency with normal immunoglobulins appears to be a rare immunodeficiency.

## Genes

No specific gene defects have been identified in antibody deficiency with normal immunoglobulins, selective antibody deficiency, and IgG subclass deficiency. However, a number of genetic defects have been reported in CVID: CD19 deficiency, inducible costimulator (ICOS), transmembrane activator & calcium-modulator and cytophilin ligand interactor (TACI), B cell activating factor receptor (BAFFR) deficiency. These have not been studied in antibody deficiency with normal immunoglobulins, selective antibody deficiency, and IgG subclass deficiency.

## Molecular and Systemic Pathophysiology

The immunopathogenesis of antibody deficiency with normal immunoglobulins is unknown. However, it appears to be an intrinsic B cell defect, similar to common variable immunodeficiency (CVID). We have observed that memory B cells, $CD27^+$ B cells, may be decreased in selective antibody deficiency and CVID and may precede the development of CVID (personal observation). Similar to CVID, inadequate T helper cell activity for B-cell immunoglobulin synthesis and increased T-suppressor activity have been described. Decreased $CD4^+$ $CD45RA^+$ naïve T helper cells have also been observed. We have observed decreased IL-2 synthesis, similar to that seen in some patients with CVID; this has not been evaluated in antibody deficiency with normal immunoglobulins.

## Diagnostic Principles

*Infections*: The susceptibility to infections in antibody deficiency with normal immunoglobulins is similar to that of patients with CVID. These include primarily respiratory infections with polysaccharide encapsulated bacteria. Thus, these patients have recurrent/chronic sinusitis, otitis media, pneumonia, and pharyngitis. Recurrent pulmonary infections may lead to bronchiectasis. These patients are also susceptible to bacterial sepsis and meningitis. The microorganisms responsible are similar to those seen in CVID, namely Streptococcus pneumoniae, non-typable Hemophilus influenzae, Moraxilla catarrhalis, and Staphylococcus aureus. Indeed, Higuchi et al [4] reported two brothers with recurrent infections resembling toxic shock syndrome with absent antibody response to *S. aureus* toxic shock syndrome toxins.

*Other features*: Allergic diseases, usually asthma and allergic rhinitis, occur in approximately 55% of children with selective antibody deficiency. As seen in patients with CVID, persistent lymphodenopathy may also be present. In addition, Knutsen et al described intestinal lymphoid nodular hyperplasia (ILNH) in a girl with this syndrome. ILNH has been reported in CVID and selective IgA deficiency.

## Therapeutic Principles

The treatment of antibody deficiency with normal immunoglobulins is similar to that with patients with CVID, namely antibody replacement therapy with

intravenous immunoglobulin (IVIG) infusions [5]. Since IgG levels remain elevated, IVIG dose depends upon clinical improvement. In addition, there appears to be increased catabolism of IgG with IVIG therapy, which may necessitate using higher and/or more frequent doses of IVIG. Alternatively, subcutaneous gammaglobulin (SCGG) therapy may be used on a weekly basis that maintains steady state IgG levels. Both IVIG and SCGG therapy result in reduction of sinopulmonary infections.

# Anti-glomerular Basement Membrane Antibody Disease with Pulmonary Hemorrhage

►Goodpasture Syndrome

# Antiphospholipid Syndrome

Cord Sunderkötter
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Definition and Characteristics

A systemic syndrome characterized by presence of antiphospholipid antibodies (aPLA) (lupus anticoagulant, antibodies against cardiolipin or/and β2-glycoprotein I (β2-GPI)), and recurrent vascular thrombosis, causing complications in pregnancy, deep venous thrombosis, pulmonary emboli, livedo reticularis, and thrombocytopenia. In primary antiphospholipid syndrome (APS), there is no evidence of underlying disease, whereas the frequent association with systemic lupus erythematodes or less commonly with other disorders is referred to as secondary APS.

## Prevalence

aPLA are found among young subjects at a prevalence of 1–5%. There is a rise in elderly patients with chronic diseases. Among the patients with systemic lupus erythematodes, prevalence of antibodies ranges between 12 and 34%. There are no sufficient data to determine what percentage of persons with aPLA develop complications consistent with APS. However, 50–70% of patients with systemic lupus erythematodes and aPLA will develop the syndrome. About 20–30% of all deep vein thromboses are also due to APS (reviewed in [1]).

## Molecular and Systemic Pathophysiology

*Formation of aPLA*: These heterogeneous antibodies show simultaneous reactivity against several β2-GPI peptides. Recent studies identified a hexapeptide (TLRVYK) as one epitope on β2-GPI antibodies and showed that microbial pathogens (Haemophilus influenzae, Neisseria gonorrheae, and tetanus toxoid) carried sequences related to this hexapeptide and that they could induce formation of corresponding antibodies and disease symptoms in mice [2]. Similarly, aPLA were formed after immunization of mice with peptides from Cytomegalievirus that had structural similarity to one binding site on β2-GPI. Thus, molecular mimicry between infecting agents and autoantigens could be an underlying mechanism.

*Thrombotic disease*: three major molecular mechanisms are proposed:

1. aPLA may act in vivo by disrupting the kinetics of the normal procoagulant and anticoagulant reactions of phospholipids on cell membranes: upregulation of tissue factor, inhibition of protein C pathway, β2-GPI anticoagulant activity, antithrombin III activity, or annexin V anticoagulant activity. The membrane protein annexin V (formerly called lipocortin) has anticoagulant activity as it impairs via crystallization the formation of the coagulatory complex of enzyme, substrate and cofactor on anionic surfaces. Binding of aPLA to annexin counteracts this impairment [3].
2. aPLA may enhance platelet aggregation and they may activate endothelial cells and neutrophils resulting in increased adherence and release of damaging or proinflammatory agents. In mouse experiments,

aPLA-induced damage of cells, especially in the placenta, was dependent on activation of complement and C5a–C5aR-mediated recruitment of neutrophils [4].
3. For thromboembolic events to be induced by aPLA, alterations leading to damage of endothelial cells may be additionally required, e.g., via oxidized LDL ("second hit" hypothesis).

On histology, there is thrombotic microangiopathy involving the venous and arterial vascular beds, but no vasculitis.

## Diagnostic Principles

According to international consensus [1], at least one of the clinical criterion (vascular thrombosis, pregnancy complications) and one laboratory criterion (lupus anticoagulant, by at least two phospholipid-dependent coagulation assays, and/or moderate or high levels of antibodies against cardiolipin or β2-GPI) should be present on at least two occasions, 6 weeks apart for diagnosis of APS. Almost any organ and tissue may be involved in the disease, including the brain, the heart, the placenta, the skin, the endocrine system, the blood, or the kidneys (refer to ▶Sneddon syndrome for further diagnostic measures).

## Therapeutic Principles

Prophylactic anticoagulation is not mandatory in patients with high titer anticardiolipin antibodies, but no history of thrombosis. As however may be justified. General measures to prevent thrombosis and other vasoprotective actions should be taken.

When a history of recurrent deep vein thrombosis or pulmonary embolism is established, long-term anticoagulant therapy is needed with international normalized ratio (INR) of ~2.0–3.0 [5]. Treatment for pregnant patients with APS includes low molecular weight heparin (LMWH) and low dose aspirin (325 mg). Women with previous thromboses may receive doses for full anticoagulation. Warfarin can also be used from 14 to 34 weeks for the patients with previous stroke or severe arterial thromboses. The use of intravenous immunoglobulin (IVIG) seems to be restricted to the patients with pregnancy losses despite conventional treatment. For contraception, oral oestrogens should not be used.

# Antisocial Personality/Psychopathy Disorder

Henrik Larsson[1], Essi Viding[2]
[1]Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden
[2]Department of Psychology, University College, London, UK

## Synonyms

ASPD

## Definition and Characteristics

According to the DSM-IV, antisocial personality disorder (ASPD) is characterized by a pervasive pattern of disregard for social norms and violation of the rights of others [1]. The APSD criteria are broad and encompass a heterogeneous population of antisocial individuals. Psychopaths form a particularly severe subgroup of ASPD. Psychopathy is most commonly assessed using the Psychopathy Checklist - Revised (PCL-R) [2]. The PCL-R defines psychopathy with a cluster of interpersonal and affective characteristics in addition to overt antisocial behavior. These include superficial charm, deceitfulness and callousness. The overlap between ASPD and psychopathy is asymmetric; that is individuals identified as psychopathic most often receive a diagnosis of ASPD, but the reverse is not true [2].

## Prevalence

Approximately 3% of men and 1% of women in the general population meet the DSM-IV criteria for ASPD [1]. There is no information available on the prevalence

of psychopathy in the general population. Data from prison samples suggest that only approximately 25% of ASPD diagnosed men meet the PCL-R criteria for psychopathy [2].

## Genes

Genes regulating serotonergic neurotransmission, in particular monoamine oxidase A (MAOA), have been associated with antisocial behavior. These may interact with environmental risk factors to increase risk for antisocial behavior [3]. The affective-interpersonal dimension of psychopathy has received little attention in molecular genetic studies. Twin and adoption studies confirm that this core psychopathic dimension is heritable. The possibility of different genetic bases for antisocial behavior and the affective-interpersonal dimension of psychopathy have not been investigated in molecular genetic studies, even though results from twin studies indicate a substantial genetic overlap [2].

## Molecular and Systemic Pathophysiology

So far no monocausal pathophysiological origin is known for ASPD or psychopathy. Several brain areas and cognitive functions associated with perception and regulation of emotions have been found to correlate with antisocial behavior. Most studies concentrate on frontal and temporal abnormalities in antisocial behavior. Neuropsychological functions associated with these brain regions, such as perception of threat and modulation of affective response are compromised in antisocial individuals. Toxic environments may contribute to this association by inducing hyperreactivity of the brain's emotional circuitry in ASPD in general. Psychopathic individuals show the opposite pattern at the neural level [4]. Data indicate that psychopaths show hyporeactivity to emotional stimuli. At the neurochemical level there is some data suggesting a relationship between reduced central serotonergic activity and increased levels of aggressive antisocial behavior. Unfortunately, none of these studies have differentiated between psychopathic and non-psychopathic antisocial behavior. Psychophysiological data suggest that electrodermal reactivity is positively associated with aggressive antisocial behavior and negatively related with psychopathy. Low resting heart rate and high heart rate reactivity are associated with aggressive antisocial behavior, but not with psychopathy [2].

## Diagnostic Principles

Diagnosis of ASPD is based on detailed psychiatric exploration and classification according to DSM-IV diagnostic criteria. Individuals diagnosed with ASPD must be at least 18 years old and have had a history of conduct disorder before age fifteen. Three or more of the following criteria are required: failure to conform to social norms with respect to lawful behaviors, deceitfulness, impulsivity or failure to plan ahead, irritability and aggressiveness, reckless disregard for the safety of self or others, consistent irresponsibility or lack of remorse [1]. The PCL-R consists of 20 items. Each item is scored on a 3-point scale (0, 1, 2) according to the extent to which the rater judges that it applies to a given individual. Total scores can range from 0 to 40, reflecting the degree to which the individual matches the prototypical psychopath. A score of 30 or above is typically used as a cut score for diagnosis of psychopathy, but other cut scores have been used, depending on the purpose of the assessments and the context in which they are made. The actual diagnosis is made based on a semi-structured interview, file and collateral information and specific scoring criteria [2].

## Therapeutic Principles

Some efforts have been made to identify medications that effectively treat behavioral correlates of psychopathy, such as aggression and impulsivity or comorbid disorders such as substance abuse. For example, selective serotonin reuptake inhibitors have shown efficacy in impulsive aggression [2]. Very little research has examined the pharmacological treatment of psychopathy per se. In addition, there is no evidence that any non-pharmacological treatments yet applied are successful for use with psychopaths. Nevertheless, recently developed guidelines for treatment of institutional psychopathy, suggest that a cognitive-behavioral program that incorporates relapse prevention to combat substance abuse, anger management to control aggression, prosocial modeling to break down antisocial thinking and values and motivation interviewing to enhance commitment to treatment may be effective if implemented systematically [5]. The literature supporting this approach is still scarce [2].

# Antithrombin III/AT3

►Antithrombin Deficiency

# Antithrombin Deficiency

Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, Maastricht University, Maastricht, The Netherlands

## Synonyms

Deficiency of AT-III SERPINC1; Antithrombin III; AT3

## Definition and Characteristics

First described by Egeberg in a pedigree in which persons in three generations had thrombophlebitis and other thrombotic disease associated with about half-normal levels of antithrombin III [1]. The molecule is presently described as "antithrombin" (AT). Subsequent, numerous publications, including several large kindreds have been described, establishing AT deficiency as a risk factor for venous thrombosis. The mature AT molecule has a molecular weight of 58,200 with 432 amino acids. AT is a member of the serine protease inhibitor (SERPIN) superfamily. It is the principal inhibitor of a number of coagulation proteases including thrombin, factors Xa and IXa. It forms a covalent 1:1 complex with the serine protease, called suicide substrate inhibition. About 10% of the AT molecules have a high affinity for heparin, and possibly also for some of the natural anticoagulant glycosaminoglycans.

## Prevalence

AT deficiency is rare, in a recent review of literature data the population estimates range from 0.2/1,000 to 11/1,000 [2]. In patients with venous thrombosis the prevalence ranges from 1–8%.

## Genes

The gene spans 13.4 kb and has seven exons. Males and females are equally affected. Heterozygous deficiency is associated with an increased risk of venous thrombosis; homozygous deficiency is extremely rare and thought to be incompatible with life [2].
*Gene Map Locus*: 1Q23–Q25.

## Molecular and Systemic Pathophysiology

The first mutation linked to antithrombin deficiency was described in 1983. Since then an array of mutations have been identified. AT deficiency is divided into:

*Type I*: low plasma levels of both functional and immunological AT.

*Type II*: variant AT in plasma, further divided in RS (defective reactive site), HBS (defective heparin-binding site) and PE (pleiotropic, i.e. multiple functional effects). The most recent updated database of AT mutations contains 256 entries [3].

A reduced plasma concentration (of about 50% of normal) is associated with an increased level of thrombin generation, which may explain the greater risk of thrombosis. In specific young individuals AT deficiency has been associated with either venous thrombosis at specific sites such as mesenteric veins, or with arterial thromboembolism. In the majority of congenital AT deficient individuals there is a risk of venous thromboembolism; this predisposition is similar in individuals with an *acquired* AT deficiency (see below).

*Clinical Features*: The risk of venous thromboembolism is increased by an estimated fivefold in patients with a heterozygous deficiency, while mortality is not increased [2].

## Diagnostic Principles

In individuals with (an increased risk of) venous thromboembolism AT deficiency is usually identified by a functional, amidolytic assay. The normal range in adult individuals is quite high (83–128%). In the case of a deficiency, verification of antigen levels is obtained to determine the type of deficiency [4]. It is imperative to rule out any acquired types of AT deficiency such as those associated with DIC or nephrotic syndrome. Thus, information of overall clotting times, platelet count, routine chemistry and urine may be required for proper interpretation.

## Therapeutic Principles

In individuals with a congenital AT deficiency, adequate thrombosis prophylaxis is warranted in high risk for thrombosis conditions such as following surgery. In specific situations such as pregnancy, the use of low molecular weight heparin prophylaxis throughout pregnancy and postpartum is presently indicated. Replacement with purified or recombinant AT preparations is usually not indicated, except for high risk for thrombosis situations such as may occur in pregnant women who suffer pre-eclampsia or sepsis.

In patients with an *acquired* AT deficiency due to protein loss or depletion in the course of DIC, incidental reports have mentioned the application of AT replacement therapy. In general, the high costs and doubtful benefit should restrict the general use of replacement

therapy. A recent large randomized controlled trial in patients with sepsis did not show any benefit from AT administration over placebo on mortality [5].

# α-1 Antitrypsin Deficiency

James K. Stoller[1], David A. Lomas[2]
[1]Department of Pulmonary and Critical Care Medicine, Section of Respiratory Therapy, Cleveland Clinic; Cleveland Clinic Lerner College of Medicine, Cleveland, OH, USA
[2]Department of Medicine, University of Cambridge, Cambridge Institute for Medical Research, Cambridge, UK

## Synonyms

Alpha-1 antiprotease deficiency; "Genetic emphysema"; AAT

## Definition and Characteristics

Clinical features of alpha-1 antitrypsin (AAT) deficiency may involve several organs (lung, liver, skin, and blood vessels) and include emphysema, hepatitis, cirrhosis, panniculitis, and an association with C-anticytoplasmic antibody positive (C-ANCA) vasculitis. Different pathophysiologic mechanisms underlie these various manifestations. Specifically, emphysema results from inflammation and unopposed proteolytic damage to alveolar walls when serum and lung levels of AAT fall below a "protective threshold value" (11 μM in the serum). Individuals with severe deficiency of AAT (i.e., serum levels below this protective threshold value) are at risk for developing accelerated airflow obstruction; other known risk factors for airflow obstruction include cigarette smoking and dusty occupational exposure.

Liver disease associated with AAT deficiency (AATD) may occur in individuals with variants associated with intra-hepatocyte accumulation of AAT, which has been called "loop-sheet polymerization." Such variants include Z, Mmalton, and Siiyama in which structural instability of the protein allows polymerization within the hepatocyte and accumulation of the unsecreted protein within the endoplasmic reticulum of the cell. While the pathophysiologic mechanism of liver disease remains unclear, it appears that inadequate protein trafficking and clearance of the abnormal unsecreted AAT protein causes liver inflammation, cirrhosis, and the possibility of hepatoma.

Panniculitis in AATD results from unopposed proteolytic damage, manifesting histologically as lobular panniculitis. Panniculitis is uncommon in AATD.

Though the association of AATD with vasculitis is perhaps least well-characterized, the prevalence of abnormal AAT phenotypes among individuals with C-ANCA positive vasculitis is clearly higher than in the general population.

## Prevalence

PI*ZZ homozygotes – 1/1639 to 1/5097; PI*MZ – 1.9 to 5.2%.

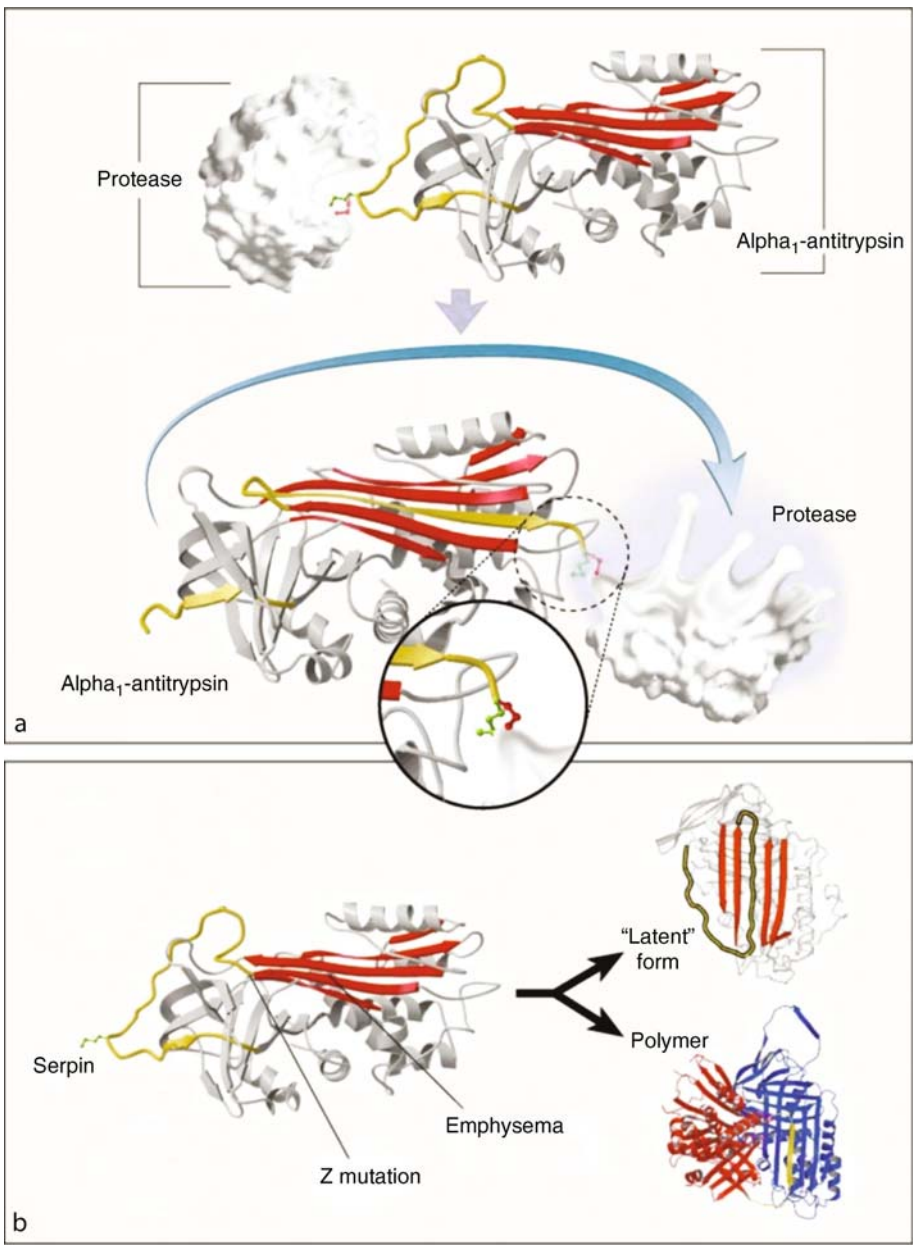
## Genes

AAT is encoded by the 12.2-kb, 7-exon SERPINA1 gene on the long arm of chromosome 14 (14q32.1). Over 100 allelic variants have been classified using the PI (protease inhibitor) nomenclature that assesses AAT mobility in isoelectric focusing analysis. Normal AAT migrates in the middle (M) and variants are designated A (anodal) to L, if they migrate faster than M, and N to Z, if they migrate more slowly. The most common variants are the Z (Glu342Lys) and S alleles (Glu264Val). Point mutations are inherited as a simple Mendelian trait; the normal genotype is designated PI MM or PI M, a heterozygote for the Z gene is PI MZ, and a homozygote is PI ZZ or PI Z. AAT alleles are co-dominantly expressed; each allele contributes to the plasma level of protein. Thus, each of the deficiency alleles causes a characteristic decrease in the plasma concentration of AAT; the S variant forms 60% of the normal M concentration and the Z variant 10–15%. Null alleles produce no AAT. Thus, combinations of alleles have predictable effects, the MZ heterozygote has an AAT plasma level of 60% (50% from the normal M allele and 10% from the Z allele), the MS heterozygote 80% and the SZ heterozygote 40%.

## Molecular and Systemic Pathophysiology

*Liver Disease*: The Z mutation (Glu342Lys) results in normal translation of the gene, but 85% of the Z AAT is

retained within the endoplasmic reticulum with only 10–15% entering the circulation. The Z mutation distorts the relationship between the reactive-center loop (that binds to the target proteinase) and β-pleated sheet A that forms the major feature of the molecule. The consequent perturbation in structure allows the reactive-center loop of one AAT molecule to lock into the A sheet of a second molecule to form a dimer which then extends to form chains of loop-sheet polymers (Fig. 1).



**α-1 Antitrypsin Deficiency. Figure 1** Mechanism of inhibition of proteases by $\alpha_1$-antitrypsin and of polymerization in serpinopathies. (a) (*Upper*) Docking of the protease to the reactive centre loop of $\alpha_1$ antitrypsin. (*Lower*) The protease has cleaved the reactive centre loop, releasing it from its metastable high energy state. The reactive loop swings with the protease in tow into a more stable conformation within the main β-sheet. The process distorts and alters the structure of the protease. (b) Mutations of serpins can result in several diseases. In the case of $\alpha_1$-antitrypsin deficiency caused by a *Z* mutation, a substitution of lysine for glutamic acid at position 342 widens the β-sheet A. The gap in the β-sheet A can either accept its own loop to form a latent conformation or proceed to polymerization in an irreversible process. Adapted from Carrell RW, Lomas DA (2002) Alpha$_1$-antitrypsin deficiency: a model for conformational diseases. N Engl J Med 346:45–53.

These polymer chains become interwoven to form the insoluble PAS-positive aggregates that are the hallmark of AAT liver disease. The process of intrahepatic polymerization also underlies the severe plasma deficiency of the rare Siiyama (Ser53Phe) and Mmalton (deletion of residue 52) deficiency alleles and the mild plasma deficiency of the S (Glu264Val) and I (Arg39Cys) variants.

There is a strong genotype-phenotype correlation that can be explained by the molecular instability caused by the mutation and, in particular, the rate at which the mutant forms polymers. Those mutants that cause the most rapid polymerization cause the most retention of AAT within the liver. This in turn correlates with the greatest risk of liver damage and cirrhosis, and the most severe plasma deficiency.

*Lung Disease*: The quantitative deficiency of AAT in the serum is compounded by a fivefold reduction in association rate kinetics with neutrophil elastase caused by the Z mutation and the polymerization of secreted Z AAT within the airways and alveoli. The formation of polymers inactivates AAT (thereby further reducing the protein available to inhibit neutrophil elastase) and the polymers themselves may be chemotactic and drive excessive inflammation.

## Diagnostic Principles

AATD is clearly under-recognized by clinicians, with evidence of long diagnostic delays (3–7 years) between patients' initial symptom and the initial diagnosis. Furthermore, available evidence suggests many patients may see multiple healthcare providers with attributable symptoms before the initial diagnosis is made.

Once suspicion is established, diagnostic tests include measuring the serum level (often by nephelometry) and determining the phenotype, often by isoelectric focusing after using allele-specific probes in polymerase chain reaction assays, particularly for the Z and S alleles.

Pulmonary function testing, including spirometry with bronchodilators and diffusing capacity measurements, are important in assessing the presence of obstructive lung disease and in monitoring disease progression.

## Therapeutic Principles

Therapy of lung-affected individuals with AATD includes all of the standard treatments for chronic obstructive pulmonary disease, e.g., including bronchodilators, preventive vaccinations, supplemental oxygen when indicated, pulmonary rehabilitation, and lung transplantation, when indicated. Available data suggest that lung volume reduction surgery is a relatively unappealing option for individuals with emphysema due to AATD.

Specific therapy for AATD currently consists of the infusion of purified pooled, human plasma AAT, for which three preparations are currently available in the United States. Many therapies are currently under investigation and include gene therapy for transfecting the normal human AAT gene (e.g., using an adeno-associated virus vector system), administration of purified or recombinant AAT by inhalation, administration of small molecular elastase inhibitors, and development of small molecules to prevent polymerization of aberrant AAT protein.

# α-1 Antitrypsin Deficiency Panniculitis

►Panniculitis at Alpha-1 Antitrypsin Deficiency

# Anxiety Disorders

Daniela Eser, Rainer Rupprecht
Department of Psychiatry, Ludwig-Maximilian-University Munich, Munich, Germany

## Definition and Characteristics

Anxiety disorders are frequent and disabling disorders with great socioeconomic impact. They are most frequently seen in primary care and there is a great degree of underdiagnosis and even more undertreatment. According to ICD-10 [1] and DSM-IV [2] generalized anxiety disorder (GAD), panic disorder with and without

agoraphobia, social anxiety disorder, specific phobias and posttraumatic stress disorder (PTSD) are classified as anxiety disorders. Panic disorder is characterized by suddenly occurring panic attacks, which are accompanied by an intense vegetative reaction. The leading symptom of generalized anxiety disorder is continuous worry together with inner tension. The predominant symptom of social anxiety disorder is anxiety in social situations where subjects are observed by others. Specific phobias are strictly related to a specific situation or a specific object. PTSD is a later occurring reaction to a trauma or a severe life event. The exact diagnostic criteria are given in the ICD-10 [1] or the DSM-IV [2], respectively.

## Prevalence

Panic disorder 2.7%, specific phobia, 8.7%, social anxiety disorder 6.8%, GAD 3.1%, PTSD 3.5%.

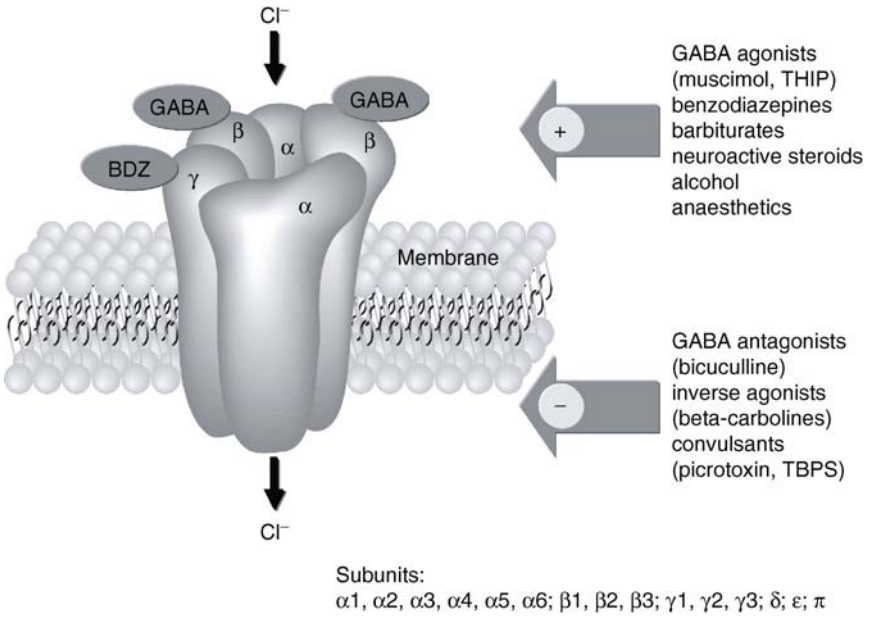
## Genes

Although various genetic association studies have been published for anxiety disorders such as panic disorder, so far no specific anxiety gene has been identified.

## Molecular and Systemic Pathophysiology

So far no monocausal pathophysiological origin is known for any of the anxiety disorders. Most pathophysiological studies have been performed in panic disorder and suggest that there is a dysfunction of the GABAergic system. There is evidence from spectroscopy studies that GABA levels are decreased in the cortex of patients with panic disorders. This is in line with neurophysiological studies suggesting changes in the control of saccadic eye velocity and alterations in the equilibrium of GABAergic neuroactive steroids. Moreover, benzodiazepines, which target $GABA_A$ receptors, are powerful anxiolytic agents. $GABA_A$ receptors belong to the family of ligand-gated ion channels with four transmembrane spanning domains and share considerable homology with nicotinic acetylcholine, serotonin type 3 and glycine receptors. They consist of various subunits, which usually form a pentamer containing α, β, and γ subunits [3] (Fig. 1).

Besides the most abundant α, β and γ subunits, other subunits (δ, ε, π, and θ) are known [4] which are important for tissue specific receptor expression. A variety of different compounds act at $GABA_A$ receptors, e.g., agonists for the GABA binding site and allosteric modulators such as benzodiazepines. The differential pharmacology of benzodiazepines is largely determined by variations in the expression of α subunits [3]. Currently, six α subunits (α1–α6) are known. For the development of novel anxiolytic compounds it is intriguing that the various α subunits confer distinct pharmacological properties on benzodiazepines with regard to their anxiolytic, anticonvulsant, sedative or muscle relaxant effects. Such differential effects of benzodiazepines are in part determined by



**Anxiety Disorders. Figure 1** Pharmacology of the $GABA_A$ receptor complex. The $GABA_A$ receptor consists of various subunits, which usually form a pentamer containingα, β, and γ subunits. Besides the most abundant α, β and γ subunits, other subunits (δ, ε, π, and θ) are known [3]. A variety of different compounds act at $GABA_A$ receptors, e.g. agonists for the GABA binding site and allosteric modulators such as benzodiazepines. TBPS: t-butylbicyclophosphorothionate.

a single amino acid. For example, a histidine at position 101 in the α1 subunit is crucial for the GABA enhancing effects of benzodiazepines, whereas an arginine at position 101 as present in α6 leads to a decrease in the GABA response to benzodiazepines [3]. Moreover, transgenic mouse models have suggested that the sedative effects of benzodiazepines are conferred via the α1 subunit, whereas their anxiolytic effects are mediated through α2 and α1 subunits [3]. The GABA binding site can be labeled by muscimol and is located within subunits of the β type. In spite of the importance of α subunits for benzodiazepine pharmacology the presence of a γ subunit appears to be important for the binding of benzodiazepines to $GABA_A$ receptors [3].

## Diagnostic Principles

Anxiety disorders have to undergo thorough physical and neurological examination to exclude a somatic cause of the disorder. This is usually accompanied by routine laboratory screening, electrocardiogram (ECG), electroencephalography (EEG) and neuroimaging methods such as cranial computer tomography or magnetic resonance tomography (MRT). Diagnosis is based on detailed psychiatric exploration and classification according to accepted diagnostic criteria such as the International Classification of Diseases (ICD-10) [1] or the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) [2] after exclusion of a somatic disorder.

## Therapeutic Principles

Anxiety disorders are treated by pharmacotherapy, psychotherapy or a combination of both. Specific phobias are usually treated by cognitive behavioral therapy (CBT). CBT is also the best-studied psychotherapy for the treatment of other anxiety disorders. With regard to pharmacotherapy, antidepressants, especially selective serotonin reuptake inhibitors and selective serotonin-norepinephrine reuptake inhibitors, represent first line treatment options. However, due to their slow onset of action, the addition of benzodiazepines is frequently required during treatment initiation. Benzodiazepines should not constitute a long-term treatment option in view of their abuse liability and withdrawal problems. Novel treatment developments focus on GABA-analogues, subtype specific benzodiazepines, modulators of neuroactive steroids, drugs targeting the GABA binding site of the $GABA_A$ receptor and on neuropeptides. Detailed guidelines for the treatment of anxiety disorders have been provided recently [4,5]. It has to be emphasized that every pharmacotherapy of anxiety disorders has to be accompanied by at least psychoeducation, even if a systematic psychotherapy is not provided.

# Aortic Aneurysm

►Aneurysm, Aortic and Arterial

# Aortic Coarctation

►Coarctation of the Aorta

# Aortic Dissection

Matthias Siepe, Friedhelm Beyersdorf
Department of Cardiovascular Surgery, University Medical Center Freiburg, Freiburg, Germany

## Synonyms

Dissecting aneurysm of the aorta

## Definition and Characteristics

Aortic aneurysms and dissections are the major diseases affecting the aorta, and a leading cause of morbidity and mortality in industrialized countries. The most common locations for aneurysms are the ascending thoracic aorta and the infrarenal abdominal aorta. Aortic dissections are closely associated with aortic aneurysms and typically begin with a tear in the aortic inner layer, the intima; blood then penetrates the diseased medial layer and dissects along the plane of the aortic wall. The dissection usually proceeds antegrade from the site of the intimal tear, but can also proceed retrograde. More than 95% of aortic dissections originate either in the ascending aorta within several centimeters of the aortic valve or in the descending aorta just distal to the origin of the left subclavian artery. Thoracic aortic aneurysms and aortic dissections are related conditions as indicated by the fact that progressive enlargement of the aorta leads to dissections in the absence of prophylactic surgical repair of the aneurysm.

## Prevalence

For a very long time, this pathology was considered uncommon and carried such a hopeless prognosis that it received little attention except as a medical curiosity. However, the incidence of the pathology had been underestimated since there are 5–30 cases per million population of aortic dissections per year.

The average age of patients with a thoracic aortic aneurysm is 65 years, and men are at a slightly increased risk compared to women (1.7:1). However, every fourth dissection affects patients younger than 40 years of age. The reason for this discrepancy is the different pathomechanism of the aortic disease in younger and older subjects. While genetic syndromes with connective tissue disorders lead to aortic aneurysms and dissection early in some patients, most aortic aneurysms in older subjects are caused by slow degenerative processes explained in detail below.

## Genes

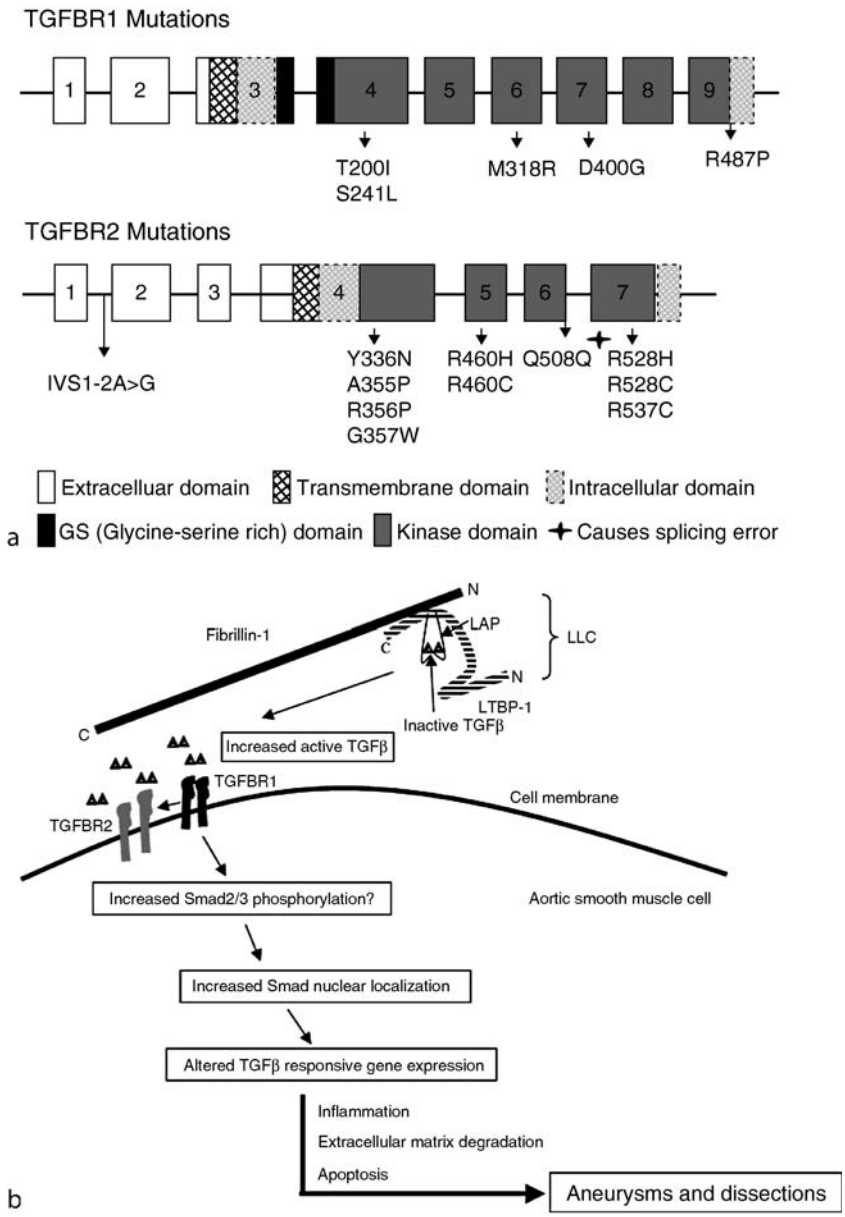
The genetic basis of aortic aneurysms and aortic dissections is being investigated only relatively recently. It has been recognized for some years that aortic dissections occur in conjunction with several genetic syndromes, in particular Marfan syndrome (MFS) and Loeys-Dietz syndrome (LDS), and research initially focused on the genetic basis of syndromic aortic dissections. More recently, research has focused on defining the genetic component for non-syndromic dissections, and identifying genes for this condition. The identification of disease genes causing both syndromic and non-syndromic aortic dissections have advanced rapidly and facilitated the progress in understanding the disease.

Thoracic aortic dissections are the major cardiovascular complication associated with the well-known genetic syndrome known as Marfan syndrome (MFS), a disorder with skeletal, ocular, and cardiovascular manifestations that is inherited in an autosomal dominant manner. The progressive dilation of the aortic root terminating in dissection is a major cause of mortality and morbidity in Marfan patients. As described mainly by the group of Dietz in 1991, aortic disease in MFS is the result of defects in the fibrillin-1 (FBN1) gene that localizes to chromosome 15q15–31 [1]. FBN1 is a major component of the microfibrils that build the elastic fiber and has a repetitive domain structure containing calcium-binding epidermal growth factor precursor-like and transforming growth factor-ß-binding motifs. More than 700 mutations in the FBN1 gene have been identified to date. In addition to MFS, FBN1 mutations can also result in other clinical manifestations, including isolated ocular or skeletal defects on the one hand or cardiovascular features of MFS without fulfilling the diagnostic Gent criteria described by de Paepe et al. [2] on the other hand. Metabolic labeling and immunohistochemical studies have shown that the majority of fibroblasts explanted from MFS patients have a decrease in fibrillin-1-containing microfibrils in the extracellular matrix far below the 50% level. The analysis of the FBN1-deficient mouse models of MFS has provided a linking pathway between decreased formation of microfibrils and the manifestations of MFS. Fibrillin-1-deficient mice demonstrated increased active transforming growth factor-beta (TGF-ß) in tissues when compared with wild-type mice, suggesting that reduced microfibrils increased the bioavailability of active TGF-ß in tissues. Furthermore, antagonism of TGF-ß signaling prohibited the pulmonary parenchymal abnormalities, mitral valve anomalies, and aortic dilatation observed in the transgenic mouse models of MFS, suggesting a crucial role for TGF-ß signaling in MFS.

Recently, DNA from nine MFS families with no identified mutations in FBN1 was also sequenced, and TGF-ß receptor 2 (TGFBR2) missense mutations were identified in three of these families. These TGFBR2 mutations in MFS patients involved the intracellular serine-threonine kinase domain of the receptor, and have been determined to reduce receptor signaling induced by TGF-ß when co-expressed with a TGF-ß responsive promoter in an *in vitro* assay system.

TGFBR1 and TGFBR2 mutations have also been described in a syndrome associated with cleft palate, craniosynostosis, congenital heart disease, arterial aneurysms, and mental retardation as part of the phenotype, termed Loeys-Dietz syndrome (LDS) [3] (Fig. 1a).

Most mutations observed were germline heterozygous missense mutations that affect amino acids in the functionally important intracellular kinase domain



**Aortic Dissection. Figure 1** (a) Heterozygous germline TGFBR1 and TGFBR2 mutations in syndromic and nonsyndromic aortic disease. Genomic and protein structure of the TGFBR1 and TGFBR2 genes showing known mutations previously identified in MFS, LDS, and others. (b) Dysregulated TGF-β signaling leading to aneurysms and dissections. TGF-β is secreated in an inactive form and stored in the extracellular matrix in a complex termed the large latent TGF-β complex (LLC), consisting of a latency-associated peptide (LAP) and a latent TGF-β-binding protein-1 (LTBP-1). Dysregulation of TGF-β signaling results from fibrillin-1, TGFBR1, or TGFBR2 mutations, leading to altered transcription of TGF-β-responsive genes, resulting in the clinically relevant medial degeneration leading to aneurysms and dissections (Figs. 1a and b are obtained from Pannu H et al. Ann NY Acad Sci 2006 with permission of Blackwell Publishing).

of the proteins. Surprisingly, tissues from affected patients showed increased expression of collagen and connective tissue growth factor in addition to nuclear enrichment of phosphorylated Smad2, both observations suggesting enhanced TGF-ß signaling in these tissues. This suggests a common pathway of dysregulated TGF-ß signaling in the pathogenesis of aortic disease, either due to the presence of amplified active TGF-ß as observed in Marfan or by disruptions in signaling due to TGF-ß receptor mutations (Fig. 1b).

The bioavailability of active TGF-ß is recognized to be strongly regulated and dependent on its release from a large latent complex to which TGF-ß is non-covalently associated with its propeptide fragment, labeled the latency-associated peptide, and covalently linked to latent TGF-ß-binding protein (LTBP) (Fig. 1b). This complex associates with fibrillin-1-containing extracellular microfibrils and fibrillin-1 mutations lead to impaired amounts of microfibrils in the extracellular matrix, and thereby to enlarged amounts of bioavailable TGF-ß in the patients' tissues with relevant FBN1 mutations. This mechanism of increased TGF-ß signaling caused by relevant FBN1 mutations, while difficult to resolve with the putatively kinase-inactivating TGFBR1 and TGFBR2 mutations identified in Loeys-Dietz syndrome, appears to be the origin of aortic disease in both these syndromes as enhanced TGF-ß signaling is observed in aortic tissue from LDS patients as well. These observations are remarkably similar to previous investigations demonstrating fibroblast-specific expression of a kinase-deficient TGFBR2 in a transgenic mouse model, causing paradoxical upregulation of the TGF-ß signaling pathway. The biological mechanism following the TGF-ß signaling upregulation observed in aortic disease remains to be clarified. Interestingly, the angiotensin-1 antagonist losartan known for TGF-ß antagonism was able to reverse the clinical manifestations of Marfan, including the aortic manifestation when administered in a transgenic mouse model of MFS. Moreover the TGF-ß-induced failure of muscle regeneration is attenuated in disease-related myopathy using Losartan in the mouse model. Possibly, the use of losartan can replace beta-blockers in the first line as preventive and antihypertensive treatment of genetically disposed patients in the future.

Familial aggregation studies of patients referred for surgery of ascending aneurysms or dissections, who did not have an associated genetic syndrome, have shown that 11–20% of these patients have a first-degree relative with a history of aortic dissections, providing evidence that genetic predisposition plays a key role in the etiology of this disease. Screening for aortic aneurysms of individuals at risk for inheriting the defective gene often identifies individuals with asymptomatic ascending aortic aneurysms and supports the confirmation of autosomal dominant inheritance of the disorder. Families with inherited forms of aortic dissections display a wide range of first onset of the familial disease (variable expression); the age of acute dissections has ranged from adolescence to octogenarians within a single family. In families with inherited forms of aortic dissections, the pathology in the aortic wall of aneurysms and dissection is mainly medial degeneration.

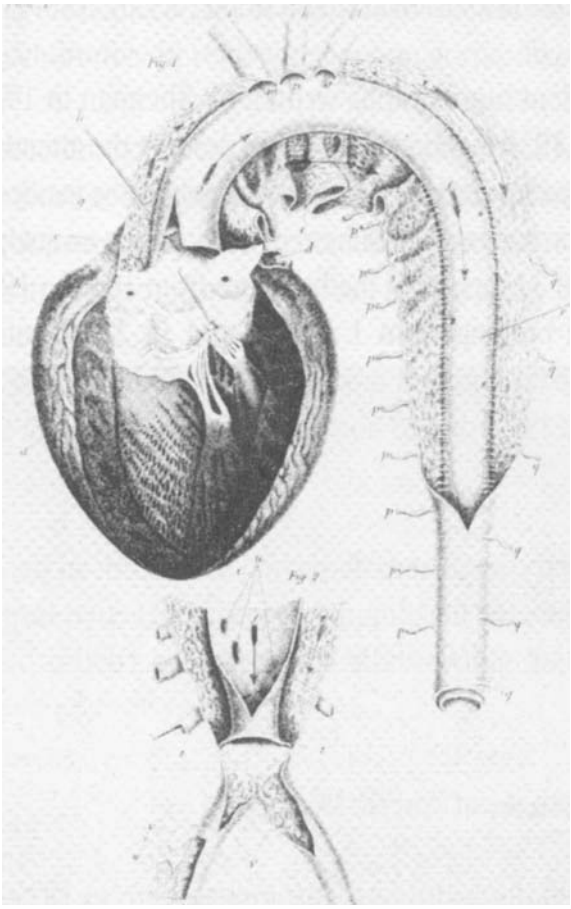
Several families were genetically studied in detail. Interestingly one identified defect (MYH11) involved the smooth muscle cells. In the family, there was a co-existing risk of persistent ductus arteriosus (PDA) due to failing smooth muscle cell action. In addition to the isolated aortic dissections in families, there are aortic dissection families described with associated features such as bicuspid aortic valve, cervicocephalic arterial dissections, cerebral aneurysms, and coarctation of the aorta, suggesting that these malformations result from a single developmental disposition and are potentially due to different genes for each noted familial form of aortic dissection associated with a specific gene defect (Fig. 1). The successful identification of MYH11 as the gene responsible for PDA in conjunction with aortic dissections lends support to this hypothesis. In addition, familial aggregation studies have established the co-existence of aortic dissections and bicuspid aortic valve. Additionally, an increased prevalence of aortic root enlargement has been noted in patients with bicuspid aortic valve, suggesting another common genetic basis for aortic dissections and bicuspid aortic valve.

## Molecular and Systemic Pathophysiology

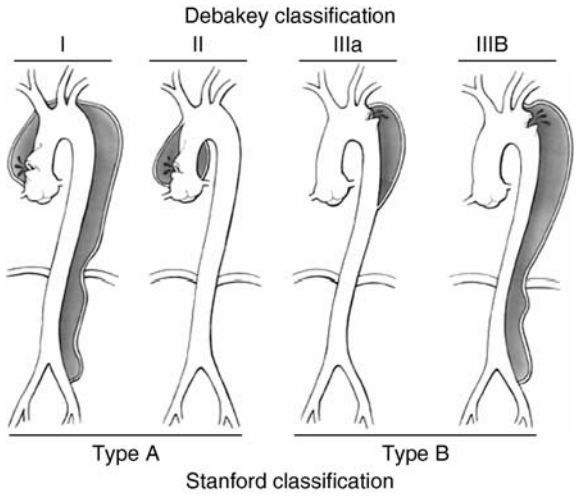
Dissecting aneurysms have neither a common etiology nor a common pathology. The most common pathology associated with thoracic aortic aneurysms is medial degeneration, a poorly understood pathologic process previously termed *cystic medial necrosis* by Erdheim [4], which will be dealt with in greater detail later. It might be caused by an irregular reconstruction of the aortic wall in response to stressors like hypertension.

Aortic dissection has been recognized as a clinical and pathologic entity for 250 years. F. Nicholls was the first to describe an aortic dissection after his autopsy on King George II in October, 1760. The king's surgeon tried everything to save His Majesty's life, but in vain. At necropsy the next day, Nichols, physician to his Majesty, described the lesion as a blood collection under the external coat together with a rupture of the right ventricle. Forty years later, in 1802, Jean-Pierre Maunoir from Geneva termed the phenomenon of the infiltration of blood in the arterial wall "dissection" and introduced the term anévrysme disséqué (dissected aneurysm). Around 1840, Pennock identified that the dissections take place in the laminae of the media. At that time, J. Hope published the first precise illustration of an acute dissection of the entire aorta (see Fig. 2).

At the end of the nineteenth century, B. Paecock revealed the cough mechanism in a review of 80 cases from multiple centers around the world and divided the dynamics of the disease into three still valid stages: rupture of the internal coat, dissection and possible external rupture, and recanalization. He also noted the high mortality of the disease within the first day.



**Aortic Dissection. Figure 2** First illustration of dissection from the aortic valve to the bifurcation. From J. Hope (1842) with permission of J. B. Lippincott.



**Aortic Dissection. Figure 3** DeBakey's classification and Stanford classification of aortic dissection.

In the beginning of the twentieth century, Krukenberg and others speculated that an involvement of a rupture of the vasa vasorum in the media and consecutive media weakening by intramural hematoma would cause the intimal tear as the starting point of the dissection. More recently, the interest in dissecting aneurysms of the aorta was stimulated by the development of reconstructive surgery in the 1960s and endovascular surgery in the 1990s. Indications for surgery are based on the symptomatology and the morphology of the dissection. Several morphological classifications have been proposed; the DeBakey classification from 1961 and the Stanford classification from 1970 are commonly used.

DeBakey and colleagues classified aortic dissections according to their origin and extent (Fig. 3).

A dissection beginning in the proximal aorta that involves most of the entire aorta was classified as type I (12% of the cases). Type II (6%) involves only the ascending aorta and is the most common type in Marfan syndrome. In type III (60%), the dissecting process originates immediately distal to the left subclavian artery and continues well below the diaphragm. Type IV (22%) is similar to type III, except that the dissection remains confined to the descending thoracic aorta.

In 1970, Daily et al. [5] from Stanford University Medical School introduced the Stanford classification (Fig. 3): dissections involving the ascending aorta, regardless of the site of primary intimal tear and extent of distal propagation of the dissection are type A; those without involvement of the ascending aorta are type B. This classification is based on the difference in management: any type A dissections were (and still are) considered an indication for emergency surgery, while medical treatment should be the preferred treatment for a large subset of patients with type B dissections. This Stanford-classification is still the most common nomenclature for dissections around the world.

In his initial description of aortic dissection in 1819, Laennec comments on the cause of dissection. In addition to "high impetus of blood," he listed bony incrustations within the arterial wall, tears and ulcerations in the intimal membrane, and, occasionally, tubercles and small abscesses within the fibrinous membrane. It appeared much later that this speculation was right. Nicholls demonstrated in 1728 that experimental over-distension of an artery at the autopsy table results in the bursting of the intima with the formation of an aneurismal outpouching of the external layer. He had already interpreted the observation that high intravascular blood pressure might lead to distention without rupture or a rupture of the internal coat. This internal layer was less resistant and is more likely to give way because of the anatomic disposition of fibers, he believed. This concept is still valid almost 300 years later.

Atherosclerosis is the next major cause of aortic dissection. In 1893, the pathologist Joseph Coats concluded that atheromas were of critical importance in the pathogenesis of aneurysms and consecutive dissection. He performed several autopsies and found small aneurysms commencing in 6 cases and, in all of them, atheromatous thickening of the intima and wasting of the media with atrophy and even wasting of the elastic fibers in the sections of the commencing aneurysms. The elastic lamina ended fairly abruptly. According to Coats, the atrophy of the media was the most important causative factor in aneurismal formation. To include the causative effect of hypertension he postulated that the atheromatous patch was projected by the pressure of blood against the media in every systole of the heart.

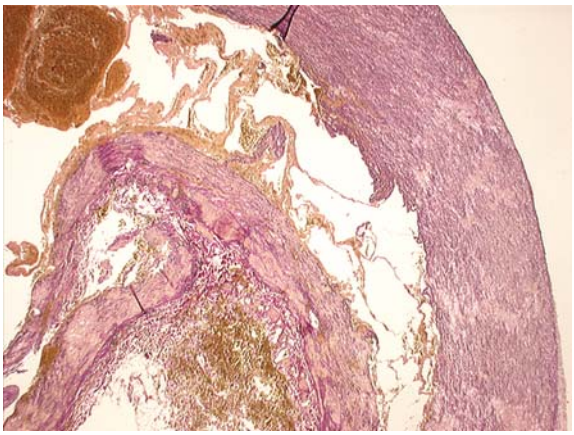
More specifically, and modern concepts expand the previous description of the atherosclerotic aorta, the thickened intima shows massive fibrosis and calcification and increased amounts of intracellular fatty acids. The extracellular matrix is degraded by histiocytic cells and can compromise the integrity of the intima. Additionally, degenerative changes might develop within fibrous tissue with reduced cellularity and collagen-fiber hyalinization. Both mechanisms may result in intimal rupture, most often at the onset of the plaque (see Fig. 4).

Degeneration of the media is a predisposing factor for aortic dissection. The microscopic aspects of the typical lesions of dystrophy within the media were first described by Otto Gsell in 1928. He described necrosis of muscle cells in the wall of dissected aortas, followed by degeneration of elastic tissue and production of collagen, which finally resulted in cleft formation. The clefts were filled with mucoid ground substances. A year later, Jakob Erdheim called this alteration "medionecrosis aortae idiopathica cystica" emphasizing the predominant role of mucoid changes within the media [4]. The loss of muscular cells combined with mucoid degeneration is very frequent in elderly people and might be induced by sclerosis of the vasa vasorum with resulting ischemia within the arterial wall. In 1970, Carlson et al. reported the histological findings in 250 autopsies of human ascending aortas. This study revealed that the incidence of mucoid degeneration increases progressively with age: from 10% in the first two decades (genetic syndromic patients were excluded) to 60 and 64% in the seventh and eighth decade, respectively. Among patients with hypertension the incidence of cystic mucoid necrosis is consistently higher than in normotensive patients of the same age.

Histologically, aortic aneurysms are characterized by the degradation of elastin in the media and adventitia, smooth muscle cell loss with thinning of the medial wall, infiltration of lymphocytes and macrophages, and revascularization (see Fig. 5).

The pathogenesis of aneurysms is, therefore, complex and multifactorial. There appear to be environmental, genetic, inflammatory, and structural factors. It seems to be not a specific disease process but rather the metabolic end-effect to which age and hypertension may strongly contribute.

**Aortic Dissection. Figure 4** Macroscopic view of a post mortal aorta. Aortic dissection is located near the aortic arch (formalin fixed) showing the real lumen (forceps) and the false lumen filled with thrombotic material. Note that the false lumen has a wider appearance than the original one.



**Aortic Dissection. Figure 5** Microscopic specimen of a recent case (from Pathological Institute of the University Medical Centre Freiburg, EvG, 25×). Aortic dissection seen in the outer third of the media with interposed thrombus and fibrin exudation. There is a clear disruption of the wall texture, with interruptions of the elastic lamellae in the media, which leads to instability of the aortic wall from shear stress and pressure.

Aortic dissection is not exclusively observed in older subjects. Schnikter and Bayer reviewed the literature in 1944 and found that 141 of 580 (24%) cases of proven aortic dissections occurred in patients less than 40 years of age. The high incidence of elastic tissue lesions in the younger age group suggests a relationship to hereditary defects, which have been discussed earlier. Other predisposing factors to aortic dissections were pregnancy, bicuspid aortic valve, and coarctation of the aortic isthmus.

The first isolated case of aortic dissection during pregnancy was reported in 1832. Later studies showed that the frequency of dissections in pregnancy is highest in the third trimester and occurs seldom during labor or shortly afterwards. In 2003, Immer et al. reviewed the recent literature (1983–2002) on this topic and collected 57 cases of pregnancy and aortic dissection. As reasons for the number of dissections during pregnancy multiple factors are discussed, especially, that the coexisting hemodynamic alteration during the third trimester plus the physiologic changes in extracellular matrix architecture by hormonal factors may predispose to dissections. Additionally, Marfan syndrome meeting the Gent criteria was diagnosed in 40% of the cases, and 10% of the Type-A dissections had a bicuspid aortic valve – another predisposing factor.

Indeed, a bicuspid aortic valve appears to be related in some way to a structurally weaker aorta. The abnormal elastic properties, similar to the findings in Marfan syndrome, have been described in the aortic wall of patients with bicuspid aortic valves.

Aortic coarctation is also clearly associated with a higher frequency of aortic dissections. In the series of Schnikter and Bayer, 32% of the 141 young patients with aortic dissection presented aortic coarctation. This high frequency is related to the often developed systemic hypertension and also to the frequent association of aortic coarctation with a bicuspid aortic valve. In the autopsy series of Reifenstein, in the 104 patients who died from the complication of aortic coarctation, the bicuspid aortic valve accounted for the most common associated anomaly (42% of the cases).

Blunt trauma has occasionally been reported as a cause of aortic dissection. Traumatic dissection is lined typically between the intact adventitia and the media, and not within the media as commonly seen in patients with spontaneous dissection of other etiology. Often, the dissection starts at the level of the ligamentum arteriosum, where most traumatic ruptures are localized as well. Wilson and Hutchins found 3 out of 204 aortic dissections caused by trauma. The dissection rarely progresses retrograde to the ascending aorta and more frequently involves the distal parts of the aorta. This is often complicated by thrombosis within the false or true lumen, followed by malperfusion injury like paraplegia.

## Diagnostic Principles

In patients at risk for aortic dissection, routine imaging of the aortic anatomy is warranted to identify situations with the need for prophylactic surgical treatment (see Therapeutic Principles).

The typical presentation of a patient suffering from an acute aortic dissection is severe chest pain and pain in the back. Some compare their pain with a knife in the back. Only a few patients recognize a caudal moving pain which is likely to be linked to the proceeding dissection. Patients suffering from malperfusion might present with the respective symptomatology. These reach from obstruction of a peripheral artery with acute leg ischemia or abdominal pain from mesenterial ischemia to severe neurological dysfunction from carotid occlusion. The notion of a chronic aortic dissection without the history of pain as an incidental finding is rare.

In physical examination on presentation of the patients, special care is warranted to realize malperfusion and distinguish it from other diagnoses with chest pain, especially myocardial infarction. In the era of widespread distribution of 24 h catheter laboratories for emergency coronary angiograms, it is not unusual that patients with aortic dissections are transferred to the catheter lab first and the features of normal coronaries and an intimal flap in the aorta are found.

In the first minutes after presentation of the patient, a powerful monitoring should be implemented as soon as possible, without losing time in transportation to an emergency CT scan. Whenever the patient needs to be transported to a facility with CT scan, the hospital with the ability to treat all entities of aortic dissection will be the best choice. The CT scan with contrast medium represents the Gold-Standard diagnostic feature for aortic dissection. To identify an involvement of the ascending aorta and omit misinterpretations from movements with the heart rhythms, an ECG-triggered CT of the thoracic aorta should be performed. As alternative investigations in circumstances when CT-scans are impossible (e.g., broken machine or pregnant women), the MRI is the next best choice. However, in most hospitals an emergency MRI is not easy to obtain.

Additionally, the involvement of the ascending aorta might be diagnosed by transesophageal echocardiography.

## Therapeutic Principles

Treating patients with aneurysms needs to be discussed separately for the group of patients at risk for an aortic dissection presenting with genetic syndromes or non-syndromic aortic aneurysms and for the other group of patients with concrete dissection.

In general, prophylactic surgical treatment of aortic aneurysms should be performed when the risk for dissection or rupture is higher than the risk for prophylactic

surgery. In patients with connective tissue disorders and a history of aortic dissection in their families, many centers operate aneurysms of the aorta with a diameter of between 40 and 45 mm prophylactically. In patients without genetic disorders, 50 mm diameter is the most common threshold for prophylactic aortic surgery of an aneurysm. Patients known to be at risk or with existing aneurysms below the threshold for surgery need to be reevaluated in accurate time intervals and optimal blood pressure management including ß-Blocker therapy is needed.

The main principle in the treatment of an acute (and chronic) dissection is that type A dissections need an emergency operation and prosthetic treatment of the ascending aorta and most of the type B dissection can be managed without operations. The reason to treat dissected ascending aortas surgically is the high fatal complication rate within the first hours after onset of symptoms. Within the first hours after the initial event, 5% mortality per hour was observed. This notion explains that a delay of treatment is no option in type A dissections. Causal factors for the high complication rate in type A dissections are hemorrhagic pericardial tamponade or severe aortic valve incompetence from proximal ascending aortic lesions together with malperfusion events of the aortic arch's branches, with subsequent brain damage or aortic rupture.

Originally, these patients with type A dissections were operated in deep hypothermic circulatory arrest with arterial canulation of the femoral artery and vein. Recently, most centers use selective cerebral perfusion with moderate cooling during arch or distal ascending aorta repair to protect the patients from brain damage from deep hypothermia. For the selective cerebral perfusion, it is possible to canulate the right subclavian artery (and perfuse the brain through the brachiocephalic trunk and right carotid artery) or one or both carotid arteries. The aortic resection can include resection of only the ascending aorta or concomitant resection of the aortic valve with valve replacement and reconstruction and reinsertion of the coronaries in the artificial graft. Concomitant arch repair or replacement is needed in some cases as well. Importantly, the entry of the dissection needs to be resected during the operation. In most cases, the distal portion of the dissected aorta will be treated with a glue to allow only antegrade flow in the true lumen and close the false lumen.

Patients with type B dissection are typically treated without the need for urgent operations. The important component in the first week of treatment is proper control of pain and hypertension, with regular physical and CT-scan control of possible malperfusion of organs or body parts. Arterial pressure control, especially, might be challenging and sometimes multiple intravenous antihypertensive drugs are necessary within the first weeks. Monitoring in an intensive care unit for the first few days is needed for most patients.

For some patients, a surgical treatment is mandatory. Indications for surgery are impossible control of pain or hypertension, rapid growth of the dissected aorta and occlusion of arteries from the dissection membrane. Recent technological developments have made endovascular treatment possible in the majority of patients using stent-grafts to enlarge the true lumen and occlude the false lumen and fenestration of the dissection membrane in malperfusion events. Using a hybrid approach in some cases, surgical revascularization of stent-graft occluded arteries is needed. Endovascular treatment is not recommended in patients with connective tissue disorders, which should preferentially be treated with open surgery.

In all patients suffering from dissections, strict follow-up investigations are needed to identify pathological changes such as enlargement, beginning penetration and others.

## Synonyms

ARHS

## Definition and Characteristics

The three most common causes of aortic root to right heart shunts (ARHS) are sinus of Valsalva aneurysm with fistula (SVAF), coronary arterial venous fistula (CAF), and anomalous pulmonary origin of the left coronary arteries (APOCA). SVAF consists of a separation or lack of fusion between the media of the aorta (Ao) and the annulus of the aortic valve (AV). Approximately 90–95% of congenital aneurysms originate in the right or noncoronary sinus, and project into the right ventricle (RV) or right atrium (RA), respectively. Rupture usually occurs in the third or fourth decade of life. An abrupt sizable rupture causes chest pain, bounding pulse, elevated jugular venous pressure with prominent tall A and V waves, a continuous thrill and murmur accentuated in diastole, aortic regurgitation murmur, pulmonary arterial hypertension (PAH) and volume overload of the heart. A small perforation that progresses slowly may at first go unnoticed, and congestive heart failure (CHF) may occur after months or years. The natural history of APOCA is characterized by the origin of the coronary artery arising from the pulmonary artery (PA). The most common variant is an anomalous origin of the left coronary artery (LCA) from the PA. APOCA has three general patterns: (i) 80–90% suffer from acute progression to myocardial infarction (MI) or CHF in early infancy, with death before the first year of life; (ii) early illness followed by improvement in childhood; and (iii) asymptomatic. Clinically, the symptomatic patient is usually an acutely ill infant with pulsus alternans, elevated jugular venous pulse, or a third heart sound, and mitral regurgitation (MR) murmur. The characteristic cardiac murmur across the shunt that connects the right and left coronary artery can be systolic, diastolic, continuous or absent. CAF consists of a communication between a coronary artery and another cardiac chamber: the coronary sinus, right atrium (RA) or right ventricle (RV). The shunt is usually of small magnitude, and myocardial blood flow is not usually compromised. Potential complications include infective endocarditis, thrombus formation with occlusion or distal embolization of the fistula, rupture of an aneurysmal fistula, and rarely PAH and CHF. A loud superficial continuous murmur usually occurs at the lower or midsternal border.

## Prevalence

APOCA occurs approximately 1 in 300,000 life births. SVAF and CAF are both very rare.

## Molecular and Systemic Pathophysiology

The pathophysiological consequence of ARHS depends chiefly on three factors: the amount of blood flowing through the abnormal communication from the aortic root, the rapidity through which the shunt develops, and the chamber that receives the shunted blood: RA, coronary sinus (CS), RV or the pulmonary artery (PA). Shunted blood must flow through the pulmonary bed, left atrium (LA) and left ventricle (LV) on its way back to the Ao. Hence, volume overload occurs in the left heart chambers and the lungs, and causes PAH and CHF. The recipient cardiac chambers of the shunt as well as the downstream cardiac structures are all dilated secondary to volume overload. In SVAF, an acute rupture gives the heart little chance to adapt and acute progression to CHF occurs; whereas a small perforation is much better tolerated and the progression to CHF is much more gradual. In patients with APOCA, high pressure in the pulmonary trunk (PT) in the fetal and early neonatal provides a perfusion gradient for flow into the anomalous coronary artery. The Ao perfuses the normally originating coronary artery, e.g. right coronary artery (RCA). The subsequent fall in neonatal PA pressure is accompanied by a parallel fall in flow through the LCA. When the pressure in the anomalous LCA falls below the pressure in the RCA, blood then flows from the RCA to LCA via intercoronary anastomosis. The LCA drains into the PA and does not receive blood from it. This causes severe myocardial ischemia, infarction, extensive LV scarring and dilatation. The ischemic cardiomyopathy and the presence of ischemic MR would result in CHF and arrhythmic sudden death.

## Diagnostic Principles

When present, a continuous murmur and its location trigger the suspicion of ARHS. In ARHS, the electrocardiogram (ECG), chest x-ray, transthoracic Doppler echocardiogram (TTE), transoesophageal echocardiogram (TEE), and cardiac magnetic resonance (CMR) may reveal chamber dilatation of the left heart as well as the recipient (and downstream) right-sided heart chambers or structures of a significant shunt. TTE, TEE and CMR may locate the shunt as well as ventricular wall motion abnormalities. EKG may locate the site of MI

and ischemia, especially in APOCA. Cardiac catheterization (CC) with retrograde thoracic aortography and selective coronary angiography locate and quantify the left to right shunt and confirm the diagnosis.

### Therapeutic Principles

Medical management in ARHS consists of measures to relieve CHF, and to treat coexistent arrhythmias and endocarditis. In SVAF, corrective surgery with cardiopulmonary bypass consists of direct closure of the defect and repair of the aneurysm. All efforts should be made to preserve the aortic valve in children because aortic valve replacement greatly increases the operative risk in small patients. Rarely, device closure of the ruptured aneurysm is successful [1]. Small CAF have an excellent long-term prognosis, whereas untreated larger CAF may cause premature coronary artery disease. Hence, for large CAF, coil embolization at the time of CC is the treatment of choice [2] but surgical treatment is still needed in selective cases [3]. Once diagnosed, coronary artery bypass surgery is indicated in APOCA because of the likely progression to malignant arrhythmias, cardiomyopathy and sudden death [4].

## Aortic Septal Defect

►Aortopulmonary Septal Defects

## Aortic Stenosis

Volker Liebe, Jens J. Kaden
1st Department of Medicine, Faculty of Clinical Medicine Mannheim, University of Heidelberg, Heidelberg, Germany

### Synonyms

Calcific aortic stenosis

### Definition and Characteristics

Calcific aortic valve disease is a slowly progressive disorder ranging from fibro-calcific valvular thickening without obstruction of blood flow (aortic sclerosis) to severe calcification of the aortic valve cusps with impaired leaflet motion (aortic stenosis).

### Prevalence

Calcific aortic valve stenosis is the most common heart valve disorder in the elderly in developed countries. The prevalence of this condition increases with age, and is reported for American populations aged ≥65 years to exceed 2%, and for American/Finnish populations aged ≥75 years to range from 2.6 to 12.4%.

### Genes

The following genes have been proposed to predispose for the development of calcific aortic stenosis: the B allele of the vitamin D receptor; interleukin ten polymorphisms –1082, –819, and –592; connective tissue growth factor polymorphism –447, and 32-bp deletion polymorphism of the chemokine receptor 5, respectively. Furthermore, a shorter leukocyte telomere length is associated with the development of calcific aortic stenosis.

### Molecular and Systemic Pathophysiology

The aetiologies of calcific aortic stenosis include degeneration, bicuspid aortic valves, familial hypercholesterolemia, hyperuricaemia, hyperparathyroidism, Paget's disease, ochronosis, Fabry's disease, systemic lupus erythematosus, and drug induced valve disease.

For decades, degenerative calcific aortic stenosis was believed to be a primarily age-dependent disease of the valve tissue with passive calcium deposition. Newer studies have pointed out, however, that the pathologic changes in calcific aortic stenosis are based on an actively regulated cellular process of valvular matrix remodelling and biomineralization. On the basis of histopathological, experimental and clinical studies, pathogenesis of the disease is considered as follows: Underlying genetic and cardiovascular risk factors as well as mechanical stress are likely to contribute to the histolopathologically demonstrated valvular macrophage and lymphocyte infiltration. An "early lesion" with deposition of lipids that has much in common with the early lesion in atherosclerotic plaques has been described. The leukocytes induce a chronic inflammatory tissue milieu followed by an activation of myofibroblasts and increased cell proliferation by release of pro-inflammatory cytokines, such as interleukin-1β and tumour necrosis factor (TNF)-α. TNF-α mediates the formation of an osteoblast phenotype of local myofibroblasts in stenotic aortic valves. The concomitant expression and activation of

matrix metalloproteinases promotes the profound conversion of the valvular tissue. Tissue calcification and bone formation is further promoted by the release of bone-associated cytokines such as bone-morphogenetic protein-2 and -4, and the activation of osteoblast-specific transcription factors such as Cbfa-1, respectively. Recent studies also suggest neoangiogenesis to be involved in the pathogenesis of aortic valve stenosis (for reference, see also 1).

Valve leaflet thickening, calcific nodule formation, and bone formation might be the end stage of the active disease process described above, and eventually lead to aortic stenosis with an obstruction to left ventricular outflow and an increase in left ventricular afterload. With severe aortic stenosis, left ventricular hypertrophy occurs leading to a loss of myocardial cells, subendocardial ischemia, and fibrosis. Initial symptoms are often due to diastolic left ventricular dysfunction. Eventually, the classical symptoms of angina, non-Q wave myocardial infarction, exertional syncope, and heart failure occur. However, many patients present with more subtle symptoms, typically decreased exercise tolerance, or dyspnoea on exertion.

## Diagnostic Principles

The standard diagnostic evaluation of aortic stenosis includes echocardiographic assessment of leaflet anatomy and the extent of valvular calcification. The severity of aortic stenosis can be graded on the basis of antegrade velocity, mean pressure gradient, and continuity equation valve area [1] (Table 1).

Cardiac catheterization for measurement of the transvalvular gradient is recommended for the rare patient in whom noninvasive tests are inconclusive or when there is a discrepancy between noninvasive tests and clinical findings regarding severity of aortic stenosis. However, coronary angiography is recommended before valve surgery in patients with aortic sclerosis at risk for coronary artery disease to determine whether concurrent coronary artery bypass surgery is needed [2]. Exercise testing in asymptomatic patients with aortic stenosis can elicit exercise-induced symptoms and abnormal blood pressure responses [2]. Additionally, serum neurohormone levels, such as brain natriuretic peptide (BNP), show an association of increased levels with disease severity.

**Aortic Stenosis. Table 1** Degrees of severity in aortic valve stenosis

| | Transvalvular maximal flow velocity, m/sec | Aortic valve area, $cm^2$ |
|---|---|---|
| Mild aortic stenosis | 2.5–3.0 | >1.5 |
| Moderate aortic stenosis | 3.0–4.0 | 1.0–1.5 |
| Severe aortic stenosis | >4.0 | <1.0 |

## Therapeutic Principles

Current guidelines recommend surgical aortic valve replacement in patients with severe aortic stenosis once cardiac symptoms (e.g. angina, congestive heart failure, and syncope) are present [3]. The age-corrected survival postoperatively is nearly normalized [4]. The percutaneous implantation of a self-expanding aortic valve bioprosthesis as an alternative to valve surgery is currently subject to research. A future possibility to delay timing of surgical aortic valve replacement may be slowing the disease progression with medical therapy (e.g. statins, [5]).

# Aortic Valve Regurgitation

Raffi Bekeredjian, Norbert Frey
Department of Cardiology, University of Heidelberg, Heidelberg, Germany

## Synonyms

Aortic regurgitation; Aortic (valve) insufficiency

## Definition and Characteristics

Aortic valve regurgitation is defined as diastolic reflux of blood from the aorta into the left ventricle due to malcoaptation of the aortic cusps. The regurgitant blood leads to volume overload of the left ventricle. Depending on the acuity of onset, severity of regurgitant volume, etiology of cusp malcoaptation and concomitant cardiac diseases, clinical presentation may vary from absence of symptoms to rapid death [1].

## Prevalence

The exact prevalence of aortic regurgitation is not known. It is estimated that chronic aortic regurgitation has a prevalence of up to 10% in the adult population.

## Genes

In most cases aortic regurgitation is currently considered to be an acquired disease. However, several inherited connective tissue disorders are associated with aortic regurgitation, including Marfan syndrome (mutations of the fibrillin gene), Ehlers-Danlos syndrome (mutations in collagen and procollagen genes), as well as osteogenesis imperfecta (mutations in procollagen genes). More recently, a link between specific genes regulating aortic valve development and aortic regurgitation has been unraveled: Mutations of the transcriptional regulator NOTCH1 have been identified in families with aortic valve diseases, such as bicuspid valves, which facilitate valvular degeneration and subsequent regurgitation [2].

## Molecular and Systemic Pathophysiology

Two major pathophysiologic entities can be distinguished in aortic regurgitation: dilation of the aortic root vs. genuine diseases of the aortic valve.

Clinically, it is critical to differentiate acute and chronic onset of aortic valve regurgitation. *Acute* aortic regurgitation is commonly caused by acute infectious endocarditis, aortic dissection, or blunt chest trauma. Due to the rapid onset and the typically severe degree of regurgitation, the myocardium cannot adapt to the massive volume overload of the left ventricle. Therefore, acute aortic regurgitation often leads to rapid cardiac decompensation and – if not treated in time – death due to cardiogenic shock. In contrast, *chronic* aortic regurgitation may be asymptomatic for many decades. The most common causes for chronic aortic regurgitation include aortic valve calcification/degeneration (correlating with age), aortic root dilation (often accompanied by arterial hypertension), congenital abnormalities (i.e., bicuspid aortic valves), as well as (subacute) infectious endocarditis. While valve calcification/degeneration has been considered to be purely an age-dependent process, it is increasingly recognized that it is also influenced by genetic factors. Mutations of the NOTCH1 gene impair embryonic aortic valve development and have been shown to cause aortic valve calcification in patients [2]. Activation of osteoblast-specific genes seems to be a key mechanism by which NOTCH1 mutations facilitate aortic valve calcification.

In chronic aortic regurgitation, compensatory mechanisms such as eccentric hypertrophy result in preservation of diastolic compliance and ejection fraction, thereby delaying the onset of clinical symptoms. However, in chronic severe regurgitation, left ventricular dilation and hypertension may further increase wall stress and volume/mass ratio, eventually resulting in decompensation with systolic and diastolic heart failure.

## Diagnostic Principles

On physical examination several signs may indicate aortic regurgitation such as a diastolic decrescendo murmur and high blood pressure amplitudes. The most important diagnostic tool is echocardiography, allowing for measurements of left ventricular dimensions, determination of systolic and diastolic function, morphologic evaluation of the aortic valve and visualization of diastolic regurgitation in Doppler color flow mapping and continuous wave Doppler imaging (Fig. 1). Cardiac catheterization should be applied if preoperative evaluation of the coronaries is mandated and additionally permits grading of aortic regurgitation by supravalvular aortography as well as direct cardiac pressure measurements. More recently, cine magnetic resonance imaging has been introduced to visualize and grade aortic regurgitation noninvasively.

## Therapeutic Principles

In acute aortic regurgitation, rapid aortic valve replacement is the only treatment option for the patient. In chronic aortic regurgitation, a more conservative strategy may be applied. As long as aortic regurgitation is quantified as mild to moderate and ventricular function is not impaired, surgical treatment can be postponed. Pharmacologic treatment does not influence outcome of chronic aortic regurgitation [3]. If severe aortic valve regurgitation is symptomatic and/or left

**Aortic Valve Regurgitation. ventricular function is impaired, the patient should be referred for aortic valve replacement [4].

# Aortitis

Pavel Fencl
Department of Nuclear Medicine, PET Centre,
Na Homolce Hospital, Prague, Czech Republic

## Definition and Characteristics

Aortitis comprises rare disorders of unknown primary cause. Based on clinical features, the primary, non-infectious, granulomatous inflammation of the aortic wall splits into three types: aortitis in Takayasu arteritis (TA), vasculitis of younger patients. Aortitis in giant cell arteritis (GCA), vasculitis of older patients aged 40 or over. Isolated aortitis (IA) contributing to the fever of unknown origin (FUO) syndrome. It is not evident, GCA and IA are two separate entities, but their clinical courses differ substantially. Other similar aortitis are assumed to be secondary.

## Prevalence

The prevalence is unknown; its incidence is low, with geomorphic, racial, age, and gender affiliation. For TA, the incidence is 0.26/100,000/year, with the male/female ratio (1:8) higher among persons of Asian origin. For GCA, the incidence is 0.17/100,000/year, with the male/female ratio 1:3, in patients aged 50 or over, the incidence is approximately ten times higher. The incidence is higher in Caucasians, in Northern Europeans is more frequently associated with polymyalgia rheumatica. The incidence of IA has not been traced.

## Genes

The effect of any single gene is modest. A risk of GCA was proven in association with different HLA-DRB1 genes, while the risk of TA was associated with HLA-B genes. HLA-B52, B54, HLA-B51, B52, HLA-B52, B39 and HLA- B52, A31. In identical twins, concordance for aortitis is lower than 100%, so the pathogenetic factors must be both genetic and environmental [1]. An environmental impact on the incidence of GCA indicates the proven seasonal fluctuation.

## Molecular and Systemic Pathophysiology

It is not evident that the molecular pathophysiology differs between individual granulomatous inflammations of the aortic wall. For the chronic stage, it is evident that the histological patterns of primary and secondary aortitis are similar.

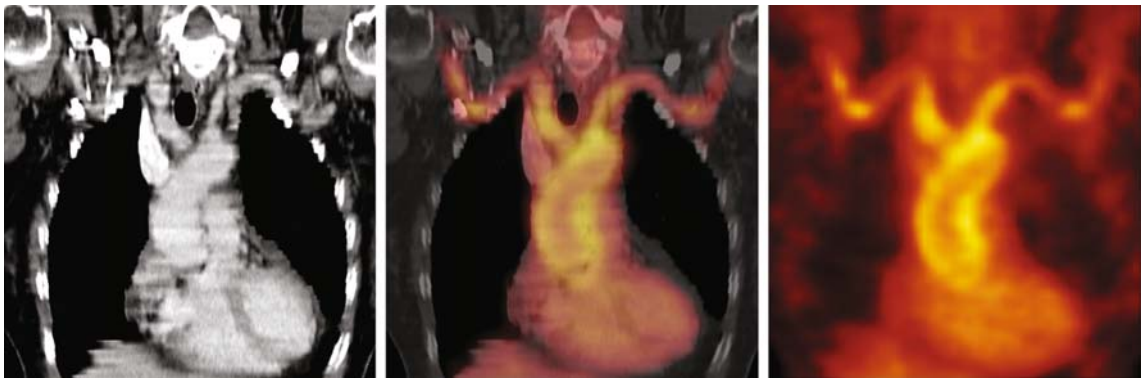
The recent theory of the formation of GCA in noninfectious medium-sized arteries clarifying documented observations is limited because some parts remain unexplained [2]. Information concerning the pathophysiology of aortitis is less comprehensive, based only on the examination of the specimens of surgically treated aortic aneurysms. In contrast to arteritis, the chronic stage of the granulomatous inflammation of the aortic wall is not associated with medial hyperplasia, but with weakening due to medial degeneration and laminar medial necrosis, followed by the dilatation of the diameter of the aorta.

The granulomatous inflammation of the vessel wall is the result of two different immunopathogenetic processes. The inflammation is ignited by the activation of innate immunity and develops into a loss of self-tolerance in the artery wall [2].

The innate immune system is represented by immature and quiescent myeloid dendritic cells (mDCs) in the adventitia. The cells express Toll Like Receptors (TLR) TLR2 and TLR4, ready to bind to PAMPs (pathogen-associated molecular patterns); when triggered by PAMPs, undergo maturation, turn into chemokinine-producing cells. Acute-phase responses are generated via a cascade of signals with Interleukin-1 (IL-1) and IL-6 as a main stimulator of acute-phase proteins. Matured mDCs bridge innate and adaptive immunity, developing into professional antigen presenting cells (APC), activating CD4+ T cells. CD4+ T cells release IL-2 and IF-γ, and regulate the differentiation and function of tissue-infiltrating macrophages. Macrophages residing in the adventitia stimulate T-cell production by pro-inflammatory cytokines IL-1β, IL-6, and TGF-β (transforming growth factor). Macrophages in the smooth-muscle cell layer are responsible for oxidative stress and the production of matrix metalloproteinase, the principal instruments evident in the lipid per-oxidation, injury of the smooth-muscle cells, the fragmentation of the internal elastic lamina, and the thinning of the media. The role of the nitric oxide synthetase-2 released by macrophages residing in the adventitia is not understood. As a result of the immune impairment of the vessel wall, macrophages release mediators (e.g., growth- and angiogenic-factors, endothelial growth factor), inducing the angioneogenesis, the proliferation, and migration of myofibroblasts, accompanied by a deposition of intracellular matrix [2].

## Diagnostic Principles

The acute phase of aortitis is clinically not characterized by any disease-specific symptom (headaches, malaise, fatigue, weight loss, anorexia, night sweat, and fever). Laboratory tests commonly show an



**Aortitis. Figure 1** FDG-PET/CT imaging of ascending aorta, aortic arch and its branches. CT imaging on the left, PET imaging on the right, fused imaging PET/CT in the middle. No systemic or local infection was found in a 60-year-old woman who had been complaining of fever for 6 weeks. Elevated CRP, erythrocyte sedimentation ratio, malaise, and fatigue were observed. The complaint diminished spontaneously during the last 2 weeks before the FDG-PET/CT investigation without any therapy. A slightly wider, hypodense aortic wall was detected on CT scan. PET revealed a significantly increased FDG uptake in the wall of aorta and its main branches as a sign of inflammation. The spontaneous decrease of clinical symptoms with the gradual normalization of laboratory tests makes isolated aortitis the obvious cause of FUO in this patient. The main advantage of FDG information is the vivo imaging of glucose metabolism, the main disadvantage is its inability to translate the signs of hypermetabolism into proper histopathology. It is difficult to differentiate high consumption of glucose in malignant and inflammation processes. Furthermore, in the diagnostics of aorta wall inflammation, the primarily noninflammation hypermetabolic processes (e.g., high metabolic activity of macrophages in vulnerable atherosclerotic plaques or higher uptake of FDG in lamina musculars in patients with arterial hypertension) are potential pitfalls.

abnormally elevated erythrocyte sedimentation ratio, a high white cell count, elevated alkaline phosphatase levels, and anemia. The chronic phase of aortitis is clinically silent until the dilatation of the aorta, or aortic valve regurgitation. In the histological differential diagnosis, it is still unclear whether histological features exist to separate clinically distinguishable types of aortitis [3]. CT images correctly the lumen of the aorta. MRI proves the inflammation changes by an enhancement in the aorta wall. To the diagnosis of inflammation, the in vivo imaging of glucose metabolism (Fig. 1) by FDG-PET or FDG-PET/CT contributes substantially [4,5]. But, in the diagnostics of aorta wall inflammation, the primarily non-inflammation hypermetabolic processes (e.g., high metabolic activity of macrophages in vulnerable atherosclerotic plaques or higher uptake of FDG in lamina muscularis in patients with arterial hypertension) are able to cause pitfalls.

### Therapeutic Principles

In the acute phase, almost all patients respond to initial doses of prednisone. Depending on residual clinical activity, the dose is titrated to lower levels. In an unknown number of patients with FUO, the symptoms of aortitis can subside spontaneously, without prednisone therapy. The use of the immunosuppressive agent methotrexate is not superior to prednisone. The chronic stage of aortitis manifested by dilatation or aneurysm of the aorta, or aortic valve regurgitation, has to be treated surgically.

### Synonyms

Aortopulmonary window; Aortopulmonary fenestration or fistula; Aortic septal defect; Partial persistent truncus arteriosus; APSD

### Definition and Characteristics

Aortopulmonary septal defect (APSD) is a rare congenital cardiac abnormality defined as a communication between adjacent portions of the ascending aorta (AAo) and the pulmonary artery (PA), with the presence of separate semilunar valves. APSD may exist as an isolated lesion, the rest (47−77%) are found in conjunction with other congenital heart disease, including patent ductus arteriosus, ventricular septal defects (20%) tetralogy of Fallot (6%), right aortic arch (5–20%), transposition of the great arteries (10%), interrupted aortic arch (8%), coarctation of the aorta (13–20%) and coronary artery anomalies (23%) [1]. APSD is subdivided into three subtypes. Type I occurs between the origin of the main PA and the posteromedial wall of AAo immediately above the sinus of Valsalva. Type II describes a communication between the AAo and the origin of the right PA. It involves the anomalous origin of the right PA from the aorta. Type III is a defect between the PA and the majority of the AAo together with a Type II defect; here the right PA arises from the posterior or posterolateral AAo, and is completely separate from the main PA trunk. Most APSD is large and the blood flow is from left to right after birth. The common presentation is that of early congestive heart failure (CHF), irreversible pulmonary hypertension (PH), acute decompensation from intercurrent infections and death. Only a minority of patients with uncorrected APSD reaches their teens or young adulthood. The patients with smaller APSD are underdeveloped, tachypnoeic and have a tendency toward recurrent respiratory infections. Physical signs include bounding arterial pulse with wide pulse pressure, cardiac enlargement with a prominent apical impulse. The murmur of APSD is loud and harsh, and can be holosystolic or early systolic. Alternatively it can

be continuous in restrictive APSD which accounts for 20% of all APSD cases. The murmur is usually loudest in the third left intercostal space. Other murmurs include Graham Steell murmur resulting from a dilated pulmonary trunk, and an apical mild diastolic mitral murmur caused by increased flow. When the flow across the APSD shunt is reversed from the development of suprasystolic PH, patients would develop increasing generalized cyanosis, a loud pulmonic ejection murmur, a loud single second beat, the stigmata of the Eisenmenger complex, and the disappearance of the systolic murmur across the defect.

### Prevalence

APSD is a rare defect consisting of about 0.1−0.6% of congenital heart disease. The male to female ratio is about 1.8:1 and no racial trend exists.

### Molecular and Systemic Pathophysiology

The aberrant embryogenesis of APSD originates from the incomplete fusion and/or malalignment of the right and left conotruncal ridges which may cause defective and unequal partitioning of the aortopulmonary (AP) trunk (Type I) and a more posterior and dorsal aorta. The abnormally positioned aorta may then connect to the right sixth aortic arch, which is the precursor of the right PA. Hence, the right PA may connect to the main PA as well as having an orifice into the aorta (Type II), giving rise to the anomalous origin of the right PA from the AAo. The pathophysiology of APSD is closely related to the size of the defect, the direction of blood flow across the shunt and the development of pulmonary hypertension. Regardless of the size, APSD does not affect the fetus. After birth, the fall in pulmonary vascular resistance (PVR) causes progressive shunting of blood from the systemic to the pulmonary circuit across the APSD. This results in PH, CHF and the development of pulmonary vascular obstructive disease which eventually would progress to shunt reversal and the Eisenmenger complex. The above progression is also highly dependant on the nature of the other congenital heart lesions if present.

### Diagnostic Principles

The diagnostic features of APSD are dependant on the size and direction of the shunt, the presence of PH and associated congenital abnormalities. Differential diagnosis includes coronary artery anomalies, large patent ductus arteriosus, truncus arteriosus, pulmonary arteriovenous fistula, ruptured sinus of Valsalva aneurysm, and ventricular septal defect. Echocardiogram is usually the method of choice for the diagnosis of APSD [2]. It shows enlarged cardiac chambers and measures PA pressure; the APSD can best be delineated with color flow Doppler. Cardiac magnetic resonance angiography can accurately visualize and measure the size of the APSD. Cardiac catheterization performed before surgery can identify a shunt at the level of the PA and assess the extent of PH and related congenital abnormalities. Selective aortography and manipulation of the catheter from the main PA directly to the AAo confirm the diagnosis.

### Therapeutic Principles

As most APSD are large, irreversible PH occurs early. Hence, surgical closure is ideally performed in the first few months of life [3]. Currently, the procedure of choice involves transaortic closure of the APSD by direct suture (small defects) or by using a prosthetic patch (large defects) while providing cardiopulmonary bypass [4,5]. Stenosis of grafts or surgical sites of the APSD repair are the most common long term complications. Patients should also receive bacterial endocarditis prophylaxis for life.

## Synonyms

Acrocephalosyndactyly

## Definition and Characterisitics

Apert syndrome (AS) represents one of the most common and severe syndromic forms of craniosynostosis (premature fusion of one or more cranial sutures). Unlike other craniosynostosis syndromes, AS is additionally characterized by syndactyly (fusion of one or more digits) and dermatological manifestations. Central nervous system, cardiovascular, respiratory, urogenital, and other visceral defects occur less frequently.

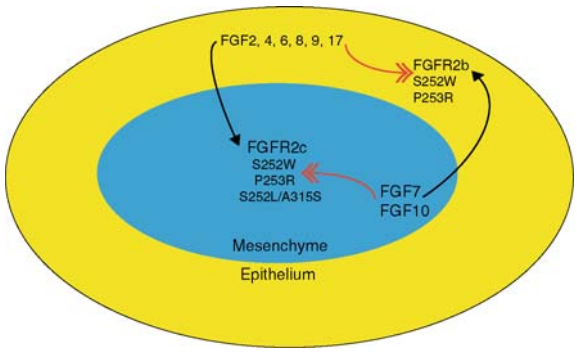
## Prevalence

Apert syndrome (AS) is inherited in an autosomal dominant fashion with a prevalence of about 1 in 70,000 births [1]. The incidence of AS increases with advanced paternal age and is believed to result from mutations arising in the male germ cells that confer a selective survival advantage on sperm cells [2].

## Genes

AS results from mutations in the gene encoding fibroblast growth factor receptor 2 (FGFR2), located on chromosome 10q26 [3]. Mutations in FGFR2 are also responsible for other craniosynostosis syndromes including Crouzon syndrome (CS), Pfeiffer syndrome (PS), and Jackson-Weiss syndrome (JWS). FGFR2 is one of four members of the FGFR family (FGFR1–4) of receptor tyrosine kinases and consists of an extracellular portion composed of three immunoglobulin-like domains (D1–D3), a single transmembrane helix, and an intracellular portion with tyrosine kinase activity. A tissue-specific alternative splicing event in D3 creates epithelial FGFR2b and mesenchymal FGFR2c, each of which binds selectively to a unique subset of the eighteen human FGFs that are expressed in the opposite tissue as their respective FGFR2 isoform [4]. This leads to the establishment of a paracrine signaling circuit between mesenchyme and epithelium that is fundamental for organogenesis and tissue homeostasis (Fig. 1). Both crystallographic and biochemical data demonstrate that FGFs interact with D2, D3 and the short interconnecting D2–D3 linker region.

Two canonical missense mutations, S252W and P253R, which map to the D2–D3 linker region of FGFR2, account for 67 and 32% of AS cases, respectively [3]. Rare cases of AS result from a S252F mutation and Alu-element insertions in the intron preceding or within the "c" isoform specific exon of the FGFR2 gene. A S252L/A315S double mutation in FGFR2 results in an atypical form of AS, characterized by syndactyly in the absence of craniosynostosis. Consistent with the location of the canonical AS mutations, which precede the alternatively spliced region of FGFR2, the AS mutations have been detected in both FGFR2c and FGFR2b splice isoforms. However, because many of the related craniosynostosis syndromes, including CS and PS, are caused by mutations in the "c" specific exon of FGFR2, it is likely that the AS mutations predominantly act by affecting FGFR2c, and not FGFR2b [5].



**Apert Syndrome. Figure 1** Schematic of the FGFR2 epithelial-mesenchymal paracrine signaling loop in normal human development (black arrows). AS mutations short circuit normal signaling mechanisms (red double headed arrows) by creating autocrine signaling loops.

## Molecular and Systemic Pathophysiology

Biochemical analysis of several CS mutations demonstrates that these mutations activate FGFR2c constitutively (in the absence of FGF) by inducing the formation of intermolecular disulfide-bridged FGFR2c dimers. In contrast, in vitro binding and cellular studies showed that FGFR2c harboring the AS mutation retained FGF-dependency. Interestingly, AS patients with the S252W mutation have a more severe craniofacial phenotype, whereas AS patients with the P253R mutation present with more severe syndactyly. This, taken together with the observation that craniosynostosis and syndactyly can either occur in combination or individually, has led to the hypothesis that distinct pathophysiological mechanisms give rise to craniofacial and limb abnormalities in AS. Indeed, recent structural and biochemical studies have shed light onto how the dissociation of craniofacial and limb phenotypes occurs in AS [4,5].

The crystal structures of S252W FGFR2c and P253R FGFR2c bound to FGF2 have revealed the molecular basis by which these AS mutations lead to FGF-dependent FGFR2c gain-of-function. Each AS mutation is shown to create additional but distinct ligand-receptor interactions, thereby leading to enhanced FGFR2c-FGF binding affinity. Ser252Trp FGFR2c makes additional hydrophobic contacts with the N-terminal region of FGF2 [4]. In contrast, Pro253Arg FGFR2c makes additional hydrogen bonds with the core loop region of FGF2 [4]. Analysis of the effect of the AS mutations on ligand binding affinity/specificity of FGFR2c revealed that the two canonical AS mutations increase the binding affinity of FGFR2c to all FGFs, including FGF10, an FGF ligand that normally does not bind to wild-type FGFR2c [5]. In contrast, the atypical S252L/A315S double mutation leads to an increase in binding to FGF10 mainly [5]. Based on these data, the syndactyly phenotype in AS is proposed to manifest from illegitimate autocrine FGFR2c-FGF10 binding and signaling in the mesenchyme (Fig. 1) [1,5].

This hypothesis also accounts for the more severe syndactyly in P253R AS patients than in S252W patients, as P253R FGFR2c binds with greater affinity to FGF10 than S252W FGFR2c does. This model of syndactyly is also consistent with the finding that Alu-insertions (responsible for rare cases of AS) lead to the ectopic mesenchymal expression of FGFR2b, and thus also permit illegitimate autocrine FGF10 signaling in the mesenchymal tissue of these patients [1,5].

These binding studies also reveal a direct correlation between the severity of craniosynostosis phenotype in AS and the differential ability of the AS mutations to cause an overall increase in FGFR2c binding affinity towards multiple FGFs. The S252W mutation, which is associated with more a severe craniofacial phenotype, results in greater enhancement in FGFR2c binding to most FGF ligands, relative to the P253R mutation. Moreover, the inability of the S252L/A315S double mutation to confer a widespread increase in FGFR2c-FGF binding explains the lack of craniosynostosis in patients harboring the S252L/A315S double mutation. The widespread enhancement of FGF binding by the AS mutations will lead to a global elevation of mutant FGFR2c signaling that is parallel to the FGF-independent increase in FGFR signaling causing CS and nearly all cases of PS [5].

## Diagnostic Principles

The diagnosis is suggested by craniosynostosis in the presence of syndactyly patient and confirmed by mutational analysis.

## Therapeutic Principles

AS and other craniosynostosis syndromes are currently managed using a multidisciplinary approach relying primarily upon multiple surgical interventions to repair craniofacial and hand/foot anomalies. With the recent advances in our understanding of the molecular basis for FGFR2 gain-of-function in AS, the non-surgical management of AS with inhibitors of FGFR signaling may soon be an exciting possibility [5].

## Synonyms

APOC2 deficiency; Hyperlipoproteinemia type Ib; C-II anapolipoproteinemia

## Definition and Characteristics

Autosomal recessive defect of apolipoprotein C-II (apo C-II), the cofactor of lipoprotein lipase (LPL), leading to excessive fasting hypertriglyceridemia and chylomicronemia.

As a result of the hypertriglyceridemia the patients may suffer from pancreatitis, eruptive xanthomas, lipemia retinalis, and hepatosplenomegaly. Heterozygous carriers are typically normolipidemic. Clinically and biochemically, apo C-II deficiency closely mimics LPL deficiency.

## Prevalence

Extremely rare, $<1:10^6$.

## Genes

APOC2, localized on chromosome 19q13.2, contains four exons, overall length 3,570 bp, a single transcript of 717 bp. An overview of published mutations is shown in Table 1.

## Molecular and Systemic Pathophysiology

The mature apo C-II is a 79 amino acid exchangeable apolipoprotein. In humans, the major site of expression is the liver, a minor site is the intestine. Apo C-II is always lipid-bound and can be found on the surface of chylomicrons, chylomicron remnants, very low density (VLDL), intermediate density (IDL) and high density lipoproteins (HDL). Amphipathic helices, responsible

for lipid binding, were predicted for residues 14–39 and 43–55 [1].

Apo C-II is the requisite cofactor of LPL (EC 3.1.1.34), an enzyme catalyzing the hydrolysis of triglycerides on lipoproteins, and therefore plays an essential role in plasma triglyceride metabolism. The structures needed for activation of LPL reside within the C-terminal one-third of apo C-II, concentrated in a third helix [2,3]. Activation of LPL by apoC-II depends on the ability of apoC-II to bind LPL and stabilize a ternary complex with the lipoprotein substrate. In addition to this bridging function apo C-II binding may also induce a change in LPL conformation to expose the active site of the enzyme, normally covered by a lid-domain.

Interestingly transgenic mice overexpressing the human apo C-II gene are hypertriglyceridemic, suggesting that apo C-II has functions in the metabolism of plasma triglycerides beyond activating LPL [4].

### Diagnostic Principles

Absence of apo C-II in serum/plasma; missing or extremly low activity of LPL in post heparin plasma, which can be restored by exogenous heat inactivated plasma as a source of apo C-II.

### Therapeutic Principles

There is no gene therapy and no pharmacological therapy available. Fibrates upregulate LPL but there exist no data whether enhanced LPL mass may improve the condition. Dietary therapy exists in the form of a low fat diet, supplemented with medium chain fatty acids. Other treatments include infusion of plasma as apo C-II source [5].

## Apoptosis

Sebastian Wesselborg, Björn Stork
Department of Internal Medicine I, University of Tuebingen, Tuebingen, Germany

### Synonyms

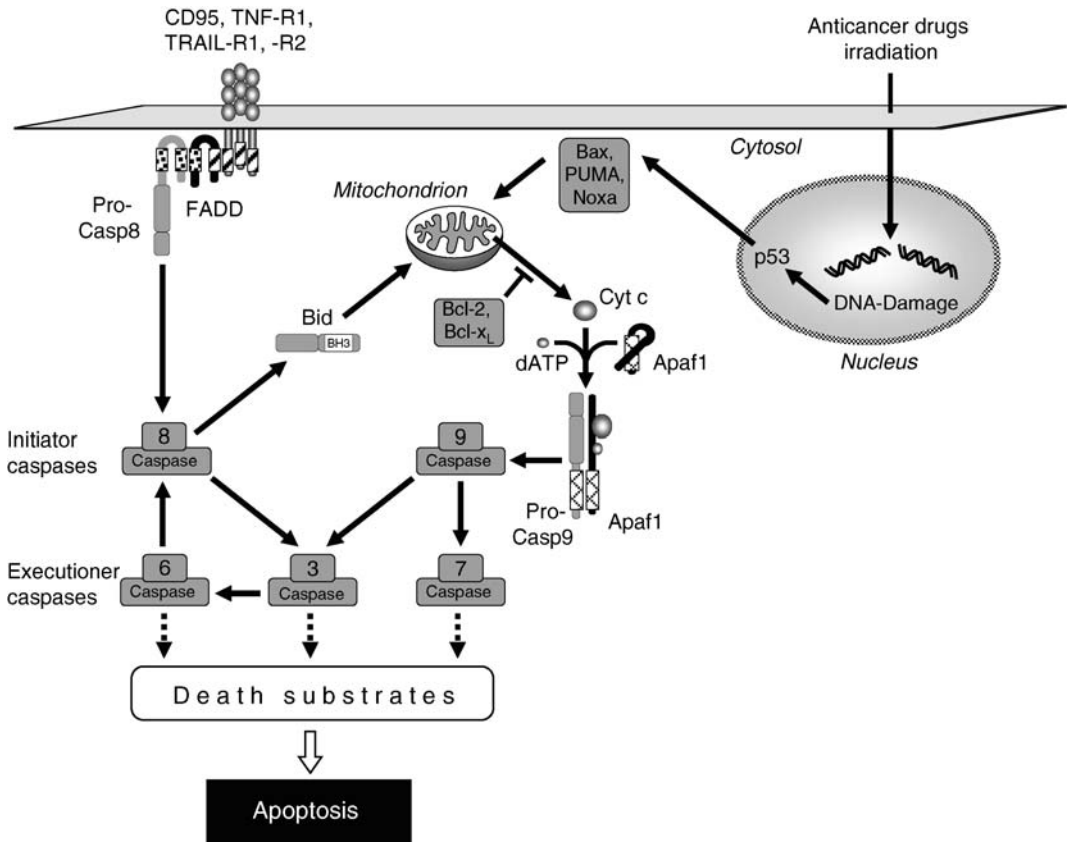
Programmed cell death type 1

### Definition and Characteristics

Apoptosis plays a major role during embryonic morphogenesis and in tissue homeostasis in the adult organism. The major executioners of the endogenous suicide program are cysteine proteases of the caspase family that are activated upon partial proteolysis. Usually initiator-caspases are activated in high molecular weight complexes and activate downstream located effector-caspases. There exist two major apoptosis signaling pathways – the extrinsic death receptor pathway that enables cytotoxic T lymphocytes to eliminate virus-infected cells and tumor cells and the intrinsic mitochondrial death pathway that is activated upon cellular stress and is the major executioner of DNA damage-induced cell death in tumor cells upon radio- and chemotherapy (Fig. 1) [1].

### Prevalence

Embryonic morphogenesis. In the adult organism: elimination of autoreactive thymocytes, downregulation of the immune response, elimination of tumor cells and virus-infected cells. As an antagonist of mitosis responsible for cell homeostasis.



**Apoptosis. Figure 1** The two major signaling pathways of apoptosis. The death receptor pathway *(left)* is initiated upon receptor ligation, resulting in the recruitment of the adapter protein FADD. FADD in turn recruits the initiator-caspase-8 which undergoes autoproteolytic activation at the receptor complex. The mitochondrial death pathway *(right)*, could be activated by many apoptotic stimuli, such as DNA-damaging agents (anticancer drugs or irradiation). DNA-damage can activate the tumor suppressor p53 that in turn induces the expression of pro-apoptotic Bcl-2 members (Bax, Puma and Noxa) which induce the release of cytochrome c into the cytosol. Cytochrome c, after hydrolysis of (d)ATP, binds to the adaptor Apaf-1 and in turn activates the initiator-caspase-9. Expression of anti-apoptotic Bcl-2 proteins (Bcl-2 or Bcl-xL) inhibits the release of cytochrome c from the mitochondrion and thus the activation of the mitochondrial death pathway. Activation of both pathways via initiator caspase-8 or -9 leads to the activation of effector-caspases (caspase-3, -6 and -7) that after cleavage of vital death substrates induce the final demise of the cell. Because caspase-8 cleaves the Bcl-2 protein Bid and generates a truncated, pro-apoptotic BH3-containing fragment that induces cytochrome c release, both pathways are interconnected.

## Genes

See Table 1.

## Molecular and Systemic Pathophysiology

Defects in apoptosis signaling can affect cell homeostasis. Thus, tumors tend to inhibit the apoptotic machinery (e.g., by inactivation of p53, Apaf-1, Bax, Bak or overexpression of Bcl-2, Bcl-xL, Mcl1) and thereby develop resistance to radio- and chemotherapy. Defects in apoptosis signaling are also associated with autoimmune diseases (e.g., rheumatoid arthritis). Defective elimination of apoptotic cells (defects in C1q, C4) can also contribute to autoimmune diseases, such as lupus erythematosus [2]. An excess of apoptosis occurs during hepatitis, neurodegeneration (multiple sclerosis, Alzheimer disease, Parkinson disease), apoplexy and cardiac infarction.

## Diagnostic Principles

So far, parameters in apoptosis signaling have not entered routine diagnosis. However, since tumors with a defective mitochondrial death pathway comprise resistance to radio- and chemotherapy, the function and expression levels of pro-apoptotic Bcl-2 members (such as Bax, Bak, Bim, Puma, Noxa) and anti-apoptotic Bcl-2 members (such as Bcl-2, Bcl-xL,

Mcl-1) or Apaf-1 might serve as valuable diagnostic parameters for tumor therapy in the future. In addition, annexin V is used as a tracer for molecular imaging of tumor apoptosis in preliminary clinical studies in order to evaluate the response to radio- and chemotherapy.

## Therapeutic Principles

Commonly, chemo- and radiotherapy eliminate tumors by induction of apoptosis. Death receptor ligands (TRAIL, TRAIL-receptor agonists (mapatumumab, lexatumumab), TNFα), and activators of the mitochondrial apoptosis pathway like BH3-mimetic inhibitors of Bcl-2 proteins (ABT-737) are used in first clinical trials [3].

## Synonyms

AGAT deficiency; Creatine deficiency syndrome

## Definition and Characteristics

Autosomal recessive deficiency of creatine synthesis [1]. Main clinical manifestations include mental retardation and epilepsy. Affected patients appear normal at birth and develop first symptoms within the first months or years of life [2,3].

## Prevalence

The true prevalence is unknown. Since its first description in 2001, only four patients from two different families have been diagnosed. Three cases have been published [1–3].

## Genes

The human AGAT gene (OMIM#602360) has been mapped to chromosome 15q15.3. The AGAT genomic DNA is 16,858 bp long (genomic DNA: GenBank accession no. 1432573), and consists of nine exons (mRNA: GenBank accession no. S68805). AGAT [2.1.4.1] is localized in the mitochondrial intermembrane space and has also been found in the cytosol. AGAT is expressed at high levels in kidney, liver, and pancreas and is detectable also in other organs such as muscle, brain, and testis.

## Molecular and Systemic Pathophysiology

Creatine is synthesized mainly in liver, kidney, and pancreas by two enzymatic reactions catalyzed by arginine:glycine amidinotransferase (AGAT) and by guanidinoacetate methyltransferase (GAMT). Creatine is transported via the blood stream to tissues including skeletal muscle and brain and taken up against a large concentration gradient via an active sodium dependent creatine transport system (CRTR). AGAT catalyzes the first of the two reactions in creatine biosynthesis, effecting the transfer of the amidino group from arginine to glycine and formation of ornithine and guanidinoacetate, the immediate precursor of creatine.

Deficiency of AGAT activity results in deficiency of both, creatine and guanidinoacetate, mainly in brain and body fluids. In humans with AGAT deficiency, no substrate accumulation (glycine and arginine) could be demonstrated [2,3]. This points to the fact that only minor amounts of both amino acids are substrates for creatine synthesis, while major amounts are utilized in other metabolic pathways. Deficiency of creatine in the brain results in loss of capacity of the creatine/creatine-phosphate system to store and transmit phosphate bound energy. In the three cases published so far, a point mutation resulting in a stop codon on exon 3 (T149X) has been found [1,3]. AGAT deficiency is a model of brain creatine deficiency. Animal models for AGAT deficiency do not exist so far, but as soon as available, they will provide an ideal tool for the investigation of the potential neuroprotective effects of creatine.

## Diagnostic Principles

Lower than normal levels of guanidinoacetate in body fluids is characteristic of AGAT deficiency. Therefore determination of this compound in urine, plasma, and/or CSF is the first diagnostic hint. Methods for determination of guanidinoacetate are mainly based on gas chromatography–mass spectrometry and tandem mass spectrometry. For diagnosis of AGAT deficiency, these methods must be sensitive enough to detect lower than normal levels. Additional diagnostic clues are deficiency of creatine/creatine phosphate in the brain as determined by in vivo proton magnetic resonance spectroscopy, and abnormally low urinary creatinine excretion, which is directly proportional to the intracellular body creatine pool. Diagnosis is confirmed by mutation analysis. Determination of AGAT activity is possible in fibroblasts and virus transformed lymphoblasts. So far, no experience is available with prenatal diagnosis.

## Therapeutic Principles

Oral substitution of creatine corrects brain creatine deficiency and leads to considerable but incomplete clinical improvement [2,5]. It is not known so far, if early recognition (e.g., by newborn screening) and presymptomatic treatment might lead to a better outcome.

are now reaching adulthood. Increased survival of these patients has been associated with an increasing number of arrhythmic problems (Table 1). Atrial arrhythmias are most common, but ventricular arrhythmias may also be seen. Arrhythmias may occur as a result of structural changes, due to the effects of pressure or volume overload, or may be a result of reentrant circuits created by suture lines and/or patches placed. Atrial stretch as a result of pressure or volume overload affects atrial refractoriness potentiating the vulnerability to induction of atrial arrhythmias such as atrial flutter or fibrillation. Progressive fibrosis of the right ventricle with areas of slow conduction, coupled with the presence of scars and patches from corrective surgical procedures leads to anatomic substrates required for sustaining ventricular tachycardia (VT). Right ventricular dilatation and stretch with areas of slowed ventricular activation may contribute to the creation of reentrant circuits within the right ventricle.

## Prevalence

*Atrial Septal Defect (ASD)*: The most common arrhythmias seen in adults who have had surgical repair of atrial septal defects are atrial flutter and atrial fibrillation [1]. Approximately 60% of these patients will develop atrial flutter or atrial fibrillation, particularly those older than 40 years of age.

*Ebstein's Anomaly*: About one third of patients with Ebstein's anomaly have an arrhythmia, most commonly AV reentrant tachycardia, Wolff-Parkinson-White Syndrome related tachycardias and to a lesser extent, atrial tachycardia, atrial flutter, atrial fibrillation, and VT. Atrial arrhythmias are encountered more frequently with increasing age and duration of follow-up [2].

*Tetralogy of Fallot*: Sustained VT has a prevalence of 4–7% and usually has left bundle branch block-like morphology secondary to a reentrant rhythm originating from the right ventricular outflow tract. Non-sustained ventricular arrhythmias detected by Holter monitoring is present in up to 60% of patients. It has low predictive value for subsequent sustained VT or sudden cardiac death (SCD) in these patients. There is a small, but persistent risk of late SCD in patients following Tetralogy of Fallot surgery, with an estimated incidence of 0.5–6%. Older age at initial repair, moderate or severe pulmonary regurgitation, a history of sustained VT, moderate or severe left ventricular dysfunction, a QRS duration of 180 ms or greater and a rapid increase in QRS duration are predictive of risk for sudden cardiac death [4].

Risk factors for sudden cardiac death in patients with repair of Tetralogy of Fallot:

- Older age an initial repair
- Moderate or severe pulmonary regurgitation
- History of sustained ventricular tachycardia
- Moderate or severe left ventricular dysfunction
- QRS duration of 180 ms or greater
- Rapid increase in QRS duration

*Transposition of the Great Arteries (TGA)*: In the adult patient post Mustard repair, there is a high incidence of systemic right ventricular dysfunction associated with late atrial arrhythmias. Also present, is a higher risk of SCD, reported at 7% on long-term follow-up, attributed to ventricular arrhythmias or atrial flutter with 1:1 AV conduction degenerating into ventricular fibrillation, and asystole. An increased QT dispersion is a marker for the presence of heterogeneity of ventricular repolarization, with rapid heart rates due to physical stress, atrial flutter and ectopic ventricular beats serving as triggers for reentrant ventricular arrhythmias. Increased QT dispersion and the loss of sinus rhythm have been associated with SCD in these patients. At long-term follow-up of adult patients post Mustard repair, only one-third remained arrhythmia-free. A progressive loss of sinus rhythm has been observed at a rate of 2.4%/year with sinus rhythm present in 77% at 5 years and 40% at 20 years. Loss of sinus rhythm has been associated with previous septectomy,

postoperative bradycardia, late atrial flutter, and preoperative arrhythmias. The loss of sinus rhythm in patients after Mustard repair is in contrast to the long-term maintenance of sinus rhythm in 95–98% of patients who have undergone an arterial switch operation.

A large population based study has estimated the incidence of late *sudden cardiac death* (SCD) in patients with congenital heart disease who have undergone surgery to be 0.9/1,000 patient-years. There is an increased incidence of SCD in patients with tetralogy of Fallot, transposition of the great arteries (TGA), coarctation of the aorta and congenital aortic stenosis. The event rate for the group of patients with obstructive left heart lesions and cyanotic defects is 2.2/1,000 patient-years compared to a rate of 0.14/1,000 patient-years in those with left to right intra-cardiac shunt lesions or pulmonic stenosis. While the most common cause of SCD is arrhythmic in origin, embolic events, aneurysm rupture, and acute ventricular failure have been reported as well. The risk of SCD after repair of transposition of the great arteries starts early after repair and remains high thereafter. The rate of SCD is approximately 4% at 10 years and 9% at 20 years. In contrast, the risk of SCD after repair of tetralogy of Fallot is 2.2% at 20 years, 4% at 25 years and 6% at 30 years.

## Molecular and Systemic Pathophysiology

*Atrial Septal Defect (ASD)*: Early closure of an ASD has been shown to reduce long-term occurrence of atrial arrhythmias. Predictors of late post-operative atrial arrhythmias include older age at repair, pre-operative atrial flutter or fibrillation and the presence of atrial fibrillation, atrial flutter or junctional rhythm post-operatively. Atrial flutter following surgical ASD repair is usually due to macro-reentry. The re-entrant circuit may be right sided involving the common flutter isthmus (caval-tricuspid isthmus), may involve an atriotomy scar or both. The former is seen more frequently. Occasionally, circuits with a "figure of eight" configuration may be present. Atrial flutter circuits may also be left atrial in origin.

*Ebstein's Anomaly*: In ebstein's anomaly, there is apical displacement of one or more tricuspid valve leaflets from the atrioventricular (AV) ring into the right ventricle. This is associated with a diminution in size of the functioning right ventricle. The deformity with displacement of the tricuspid valve can result in tricuspid insufficiency and right atrial dilatation. These abnormalities, along with the frequent coexistence of an ASD, predispose to the development of atrial arrhythmias. In addition, there is a high prevalence of accessory pathways in these patients. Accessory pathways may be present anywhere along the right sided-AV ring or in the postero-septal region and often multiple pathways are present. This is presumed to be a consequence of the discontinuity of the central fibrous body and septal AV ring, resulting in persistence of fetal accessory AV pathways. Accessory pathway variants, such as Mahaim fibers, are also more common in this condition.

*Fontan Operation*: The Fontan operation is a palliative surgical procedure employed in patients with tricuspid atresia, pulmonary atresia, complex single ventricle and double-inlet ventricle. Older variants such as the right atrium-pulmonary artery connection have given way to newer modifications that reduce the distention of the right atrium, such as the lateral tunnel and external conduit. In response to chronic stretching secondary to persistent pressure overload, the Fontan right atrium remodels and dilates. This is associated with a change in the electrophysiological properties of the right atrium manifest by atrial conduction delay and an increase in conduction heterogeneity in the atrium. Risk factors for early postoperative arrhythmias (Table 3) include preoperative AV valve regurgitation and an anatomically abnormal AV valve.

Risk factors for the development of arrhythmias after the Fontan operation:

- Preoperative atrioventricular valve regurgitation
- Older age at operation
- Poor functional status preoperatively
- Previous atrial septectomy
- Atrial tachyarrhythmias preoperatively
- Pulmonary artery reconstruction
- Atriopulmonary anastamosis
- Postoperative sinus node dysfunction
- Length of follow-up

Older age at the time of repair is a risk factor for the development of arrhythmias as these patients will have experienced long periods of hypoxia, volume overload, ventricular hypertrophy and often have abnormal diastolic filling prior to surgery. Risk factors for development of late atrial arrhythmias include poor preoperative functional status, previous atrial septectomy, preoperative atrial tachyarrhythmias, older age at operation, need for AV valve replacement, pulmonary artery reconstruction, atriopulmonary anastamosis, early postoperative atrial tachyarrhythmias, postoperative sinus node dysfunction, and length of follow-up [3].

*Tetralogy of Fallot*: This condition is composed of four features: subpulmonary infundibular stenosis, Ventricular septal defect (VSD), overriding aorta and right ventricular hypertrophy. These patients are predisposed to both atrial and ventricular arrhythmias. The combination of moderate or severe left ventricular systolic dysfunction and QRS duration greater than 180 ms has a positive predictive value of 66% and negative predictive value of 93% for sudden cardiac death. QRS duration

greater than 180 ms has been shown to have 100% sensitivity and 95% specificity for sustained VT and SCD in tetralogy of Fallot patients. QRS prolongation reflects damage to the right bundle branch during surgical repair and late progressive QRS prolongation, secondary to RV dilatation, the result of chronic pulmonary regurgitation. Moderate to severe pulmonary regurgitation and aneurysmal dilatation of the RV outflow tract are observed with a greater frequency in patients with sustained VT. Programmed electrical stimulation is often used to risk stratify patients, as patients with inducible arrhythmias are probably at the highest risk. One-third of tetralogy of Fallot patients manifest atrial arrhythmias, with both congestive heart failure and recurrent atrial arrhythmias observed on follow-up. Risk factors for development of atrial arrhythmias include older age at operation, increased atrial size, tricuspid or pulmonary regurgitation and ventricular dysfunction. Atrial flutter and atrial fibrillation is more common in patients with long-lasting pulmonary artery shunts, early operations for residual hemodynamic lesions, older age at repair and moderate to severe tricuspid regurgitation. Tricuspid regurgitation leads to right atrial dilatation from volume and/or pressure overload that prolongs atrial refractoriness and creates the substrate for atrial arrhythmias. Patients usually present with palpitations, though occasionally atrial arrhythmias may manifest as syncope or presyncope.

*Transposition of the Great Arteries (TGA)*: This malformation occurs when the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle. At birth, a patent foramen ovale and a patent ductus arteriosus allow for mixing of blood to sustain life. The Mustard and Senning operations were developed to correct the physiologic abnormality by forming a baffle within the atria to switch the flow of blood at the inflow level. The Mustard repair requires extensive incisions and suture lines in the atria. This results in intra-atrial conduction delay and abnormalities in atrial refractoriness, creating the substrate for atrial flutter. The arterial switch operation was subsequently created to enable the left ventricle to become the systemic ventricle.

## Diagnostic Principles

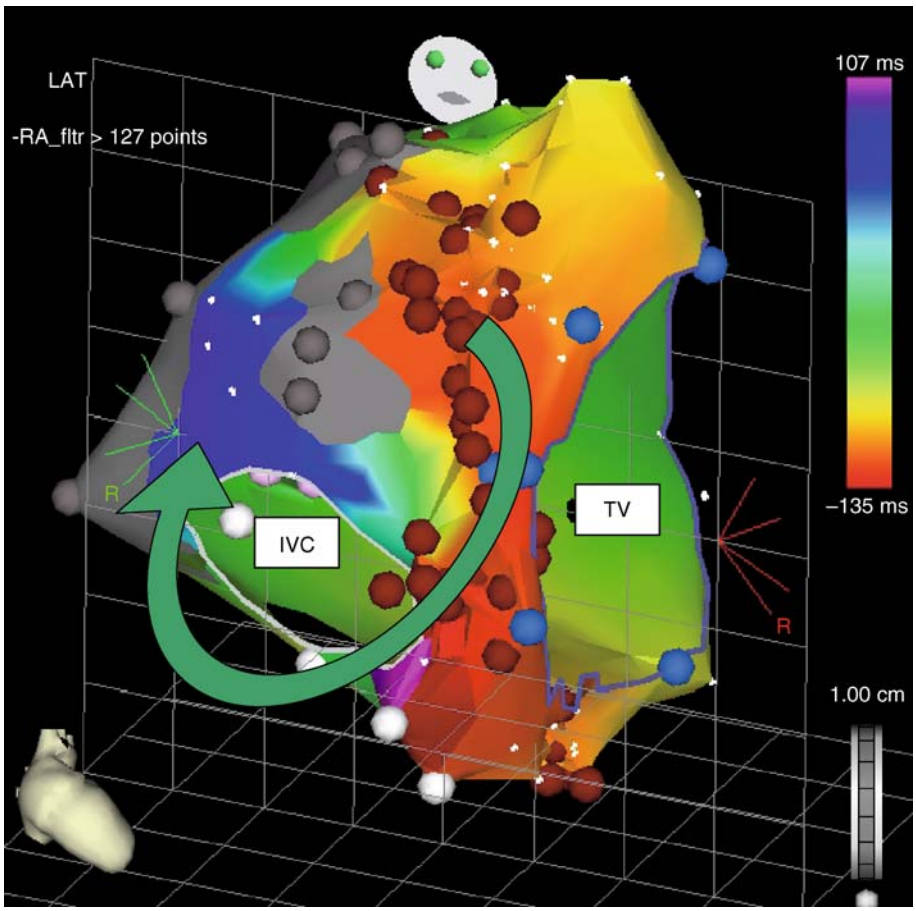
Cardiac arrhythmias are diagnosed by ECG. In patients with paroxysmal arrhythmias, Holter monitoring or Event monitoring is often required. The diagnosis may also be confirmed by electrophysiologic studies.

## Therapeutic Principles

*Atrial Septal Defect (ASD)*: Catheter mapping techniques can be used to definitively determine the location of the reentrant circuit. Activation mapping, entrainment mapping, and 3D electro-anatomical mapping techniques are essential for localizing the reentrant circuits and areas of slow conduction. Employing entrainment techniques as well as mapping with three-dimensional electro-anatomic systems is essential when treating atrial arrhythmias in the setting of surgical repair of an ASD. Catheter ablation of critical isthmuses and regions of slow conduction necessary for maintenance of the reentrant rhythm is then feasible (Fig. 1). Success rates of radiofrequency ablation of these circuits vary, but approach 80% and ablation is considered the treatment of choice in these patients. Occasionally, patients are referred for ASD closure as an adult. If the patient has a prior history of atrial fibrillation, a MAZE procedure can be performed at the time of ASD closure with excellent results. When the standard MAZE procedure has been performed at the time of ASD closure, results are excellent with no recurrence of atrial fibrillation. Long-term incidence of arrhythmias after catheter-based techniques of ASD is unclear as these are relatively new but is expected to be low.

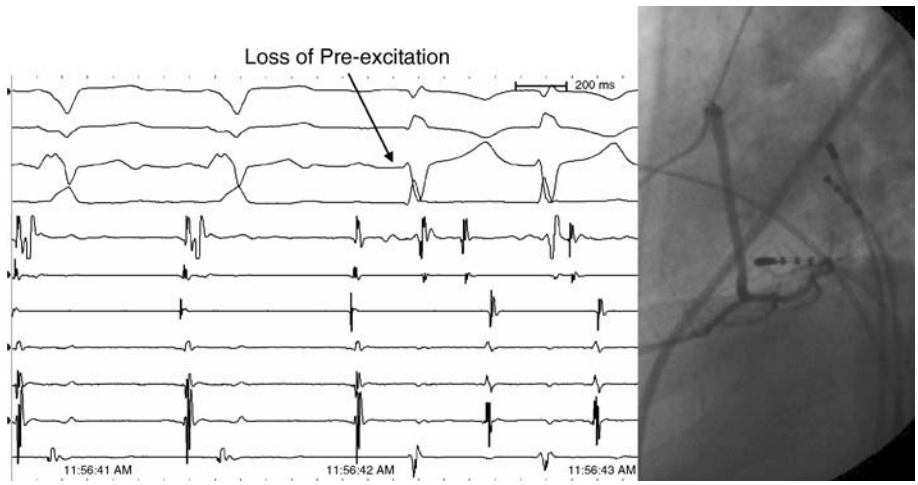
Radiofrequency ablation is the treatment of choice for all arrhythmias in patients with *Ebstein's anomaly*, however success rate is lower (76%) compared to rates of 95% in patients without the anomaly. Factors that contribute to decreased success include the complex geometry of the accessory pathway due to the anomalous AV ring anatomy, location of the pathway along the atrialized portion of the right ventricle, abnormal endocardial activation potentials confounding identification of the accessory pathway, distorted anatomy of the AV ring, and the presence of multiple pathways (Fig. 2). In addition to a low success rate, radiofrequency ablation in Ebstein's anomaly is associated with a 25% risk of recurrence. Refractory arrhythmias are an indication for surgical repair in these patients. In patients undergoing tricuspid valve repair or replacement surgical cryoablation for accessory pathways, as well as right atrial or biatrial MAZE may be performed for atrial flutter or atrial fibrillation. Surgical intervention for accessory pathway-mediated tachycardia and atrioventricular node reentrant tachycardia (AVNRT) has had excellent long-term results. In contrast, surgical intervention for atrial flutter or atrial fibrillation has been less effective, with a recurrence rate of 40%.

Atrial arrhythmias develop in 41–61% of post-Fontan procedure patients [3]. Management of the atrial arrhythmias in patient population after the Fontan Operation generally entails a combination of antiarrhythmic drugs, permanent pacemakers, radiofrequency ablation, and reoperation. Anti-arrhythmic drugs must be used cautiously, as many patients have underlying sinus node disease and are at risk of developing severe bradycardia. Furthermore, anti-arrhythmic drugs may cause slowing of atrial rates during tachycardia facilitating 1:1 conduction. Finally, proarrhythmia is always



**Arrhythmia, Cardiac in Adults with Congenital Heart Disease. Figure 1** Electro-anatomical mapping of a right atrial flutter in a patient 20 years after surgical correction of an atrial septal defect. Grey areas represent areas of scar. The arrow represents the circuit for the scar related atrial flutter. A line of radiofrequency lesions (red dots) from scar to IVC resulted in termination of atrial flutter. A line of radiofrequency lesions was also given along the TV to IVC isthmus. *IVC* inferior vena cava; *TV* tricuspid valve.

a concern when prescribing anti-arrhythmic agents, especially in the setting of ventricular dysfunction. Permanent pacing may be required in the presence of sinus node and/or AV disease. Due to the anatomic constraints present, atrial and ventricular leads may have to be implanted surgically via an epicardial approach. Antitachycardia pacing has been combined with medical therapy with some success. Atrial rate-responsive pacing is preferred due to the high incidence of sinus node dysfunction. Rapid pacing prevents bradycardia and atrial extrasystoles and may eliminate initiation of reentrant tachycardias. Radiofrequency ablation of atrial arrhythmias is associated with immediate success rates of 83%, but a fairly high recurrence rate of 20% at short term follow-up. Potential causes of recurrence include persistently abnormal hemodynamics, massive right atrial dilatation with distorted anatomic landmarks, stasis related to low flow resulting in poor catheter tissue contact, and the inability to create deep lesions in markedly thickened and fibrotic atria. More common ablation sites often include the region of the Fontan anastamosis, the lateral right atrial wall and the inferior right atrium. Refractory atrial arrhythmias are an indication for reoperation. Surgical conversion from an atrio-pulmonary anastamosis to a total cavo-pulmonary anastamosis along with electrophysiologically guided cryoablation has excellent results in preventing recurrent arrhythmias and reducing symptoms. Surgical cryoablation and antitachycardia pacing results in 83% of patients being arrhythmia-free without medications. Cryoablation is targeted at predominantly three locations: the infero-medial right atrium between the inferior vena cava and the coronary sinus, the superior rim of the ASD patch and along the lateral right atrial wall corresponding to the length of the crista terminalis. For patients with atrial flutter, cryoablation is employed as part of the modified right atrial MAZE procedure, along with excision of the right



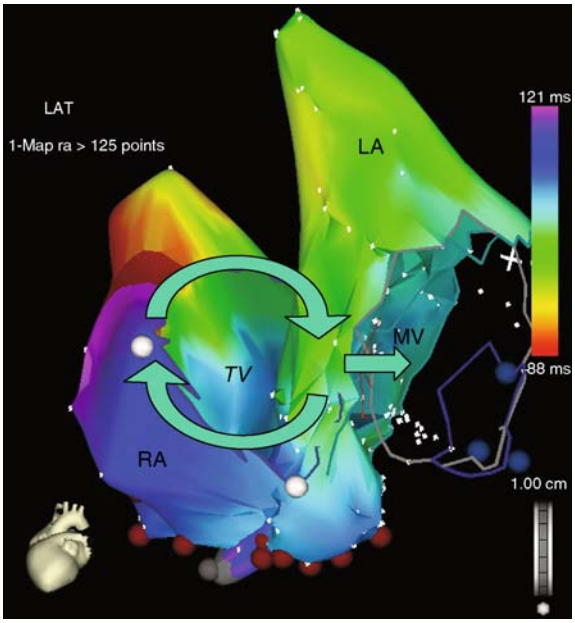
**Arrhythmia, Cardiac in Adults with Congenital Heart Disease. Figure 2** Intracardiac electrograms during radiofrequency ablation in a patient with Ebstein's anomaly and dextrocardia. Due to the complex anatomy of the tricuspid valve annulus, coronary angiography (*left lateral view*) was used to locate the AV ring. The accessory pathway was located in a postero-lateral location of tricuspid ring. Radiofrequency lesions at that site resulted in the loss of pre-excitation (*arrow*).

atrial appendage and placement of an atrial pacemaker. In patients with atrial fibrillation, the MAZE-Cox III procedure combines lesions of the right-sided maze with cryoablation lesions extending from the pulmonary veins toward the posterior mitral or tricuspid valve annulus, and from the isolated pulmonary veins to the edge of the excised left atrial appendage.

*Tetralogy of Fallot*: RFA has been successfully employed for atrial flutter and VT. A large area of scar seen as low-voltage electrograms, can usually be identified along the free wall of the right atrium, and successful ablation can be accomplished by creating a line of radiofrequency lesions between the lower margin of the scar and the inferior vena cava. Prerequisites for VT ablation include inducibility on programmed electrical stimulation, hemodynamic stability during the tachycardia to enable adequate mapping, and monomorphic morphology of the VT. VT has been localized to the right ventricular outflow tract and the infundibulotomy scar or the septal surface of the VSD patch repair, with a high immediate success rate and low rate of recurrence. Patients with VT that cannot be ablated are treated with an implantable cardioverter defibrillator (ICD).

Surgical re-operation to correct the hemodynamic substrate has been attempted. A significant reduction in preexisting VT and QRS duration stabilization has been reported following valve replacement for severe pulmonary regurgitation, while concomitant intraoperative electrophysiological-guided cryoablation prevents recurrence of preexisting tachyarrhythmias. For patients requiring re-operation, a modified maze procedure should be considered, if recurrent atrial tachyarrhythmias exist. In addition to recurrent atrial and ventricular tachyarrhythmias, sinus node dysfunction has been reported in approximately 36% of patients.

*Transposition of the Great Arteries (TGA)*: Approximately 20% of adult patients who have had a Mustard repair will require permanent pacing in long-term follow-up for symptomatic sinus node dysfunction, atrioventricular block or to facilitate treatment of tachyarrhythmias. Careful evaluation of individual anatomy and exclusion of baffle leaks must be performed prior to determining pacemaker lead placement. The majority of supraventricular arrhythmias (73%) following Mustard repair are due to atrial flutter. Risk factors for development of supraventricular tachycardias include pulmonary hypertension, systemic ventricular dysfunction, and childhood junctional rhythm. Given the high prevalence of arrhythmias in this population, radiofrequency ablation has been employed with a 73–83% success rate, and a 12% rate of recurrence. The common flutter isthmus (tissue between the tricuspid valve and inferior vena cava orifice), the area around the os of the coronary sinus, and the region extending from the tricuspid annulus are critical components of the reentry circuit [5]. Intra-atrial reentry may involve either atrium and may require a retrograde aortic approach to facilitate ablation in the pulmonary venous atrium. (Fig. 3). In addition, focal atrial tachycardias have been localized adjacent to baffle suture lines. Typical AVNRT can also occur although infrequently. The incidence of supraventricular tachycardia is also significantly less with a rate of 5% in patients who have undergone an arterial switch operation compared to 48% in patients who have had a Mustard operation. The arterial switch operation is likely to be



**Arrhythmia, Cardiac in Adults with Congenital Heart Disease. Figure 3** Electro-anatomical mapping of an atrial flutter 20 years after a Mustard operation in a patient with d-transposition. Arrows indicate the activation sequence. The flutter circuit (clock-wise) is due to reentry around the tricuspid valve annulus (anterior and systemic AV ring). Activation in the left atrium (venous atrium) follows right atrial activation. A retrograde approach was used to perform catheter ablation (red dots) with restoration of sinus rhythm. *LA* left atrium (venous); *RA* right atrium (systemic).

associated with a lower incidence of long-term atrial arrhythmias because there are no atrial scars.

Identification of patients at highest risk, the correction of hemodynamic defects and use of implantable cardioverter defibrillators, will avoid sudden cardiac death. Use of implantatable defibrillators in adults with corrected congenital heart disease is safe and effective in reducing mortality from malignant ventricular arrhythmias.

[1]Heart Health Institute and Department of Cardiac Science, The University of Calgary, Calgary, AB, Canada
[2]Trinity College, Dublin, Ireland
[3]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Arrhythmias in acute myocardial infarctions (MI) can be classified as supraventricular or ventricular (below the atrioventricular node), early MI (0–48 h post-MI) or late (over 48 h post-MI). Supraventricular arrhythmias include sinus bradycardia (SB, rate < 60 b/m) sinus tachycardia (ST, rate >100 b/m), paroxysmal supraventricular tachycardia (PSVT, conduction of supraventricular impulses arising from pacemakers other than the SA node with a rate of >100 b/m), atrial flutter and fibrillation (AFL, AFB), and junctional dysrhythmias which include AV junctional rhythm at a rate of 35–60 b/m or non-paroxysmal junctional tachycardia (NPJT) with a rate of 70–130 b/m. Myocardial infarction (MI) is classified as ST elevation MI (STEMI) or non-ST elevation MI (NSTEMI). Ventricular arrhythmias include ventricular premature beats (VPB), accelerated idioventricular rhythm (AIVR, a monomorphic consecutive wide QRS rhythm with a rate between 50 and 100 b/m), ventricular tachycardia (VT, three or more consecutive wide QRS complex beats with a rate greater than 100 b/m, and is considered sustained if it lasts more than 30 s, VT is considered monomorphic if it has a single consistent QRS morphology), and ventricular fibrillation (VF, irregular QRS undulations of varying width, contour and amplitude). Primary VF occurs < 48 h of MI, and is generally not associated with recurrent ischemia or heart failure, hence likely a primary event. Non-primary

or secondary VF is associated with hypotension, respiratory or cardiac failure and is agonal and resuscitation usually fails. VF is the most frequent mechanism of sudden cardiac death. Without treatment, asystole occurs invariably. VT is often associated with palpitations, worsening ischaemic symptoms and hemodynamic collapse. VT may degenerate into VF. The increase in ventricular rate that is associated with ST, PSVT, AFL and AFB may also aggravate ischemia and heart failure.

## Prevalence

VPB (10–93%), AIVR (0–50%), ST (30–40%), SB (15–25%), PSVT (0–10%), AFL (0–5%), AFB (10–15%) VT (STEMI: 3.5%, NSTEMI: 0.8%), sustained VT (STEMI: 2–5% during 0–48 h); non-sustained VT (1–7%), polymorphic VT (0.3%). VF (STEMI: 4.1%, NSTEMI: 1%; 3.1% between 0 and 4 hrs post MI with 11% recurrence, 0.6% between 4 and 48 h with 15% recurrence). Primary VF (2.1%; with 60% episodes between 0 and 4 h and 80% episodes between 0 and 12 h), non-primary VF (3.6%). In the pre-thrombolytic era: VPB (10–93%), VT (3–39%), VF (4–20%).

## Molecular and Systemic Pathophysiology

The mechanisms of early and late post-MI ventricular arrhythmias differ. In the early stage, VPB and VF result from transient arrhythmogenic phenomena in ischemic and infarcting tissue such as abnormal automaticity induced by left ventricular wall stress or increased catecholamine release, triggered activity, and reentrant circuits created by heterogeneous conduction and repolarization. While such early ventricular dysrhythmias are associated with a higher in-hospital mortality, the long-term out-of-hospital mortality is not increased [1]. On the other hand, late VT which reflects myocardial scar and permanent arrhythmic substrate is capable of developing reentrant circuits. Late VT occurs more commonly in large transmural MI with left ventricular dysfunction, and is associated with both an increased hospital and long-term mortality [2]. Sustained monomorphic VT could be a marker of permanent arrhythmic substrate even early after an MI [3], as it may reflect a permanent substrate from a prior silent MI. Polymorphic VT is usually due to abnormal automaticity or trigger activity associated with ischemia or reperfusion. There are no clinical features (including VPB) that would predict VF. Factors that increase the risk of VF includes large STEMI, hypotension, hypokalemia, male gender and smoking history. Ventricular arrhythmias, e.g., AIVR, occurring within a period of minutes after reperfusion can be related to reperfusion injury caused by the influx of calcium, oxygen and oxygen free radicals that can further damage the reperfused ischemic myocytes. Occlusion and reperfusion of coronary vessels supplying the infero-posterior myocardium, trigger the Bezold-Jarish reflex which causes vagotonia and results in hypotension, bradyarrhythmias, and heart blocks. On the other hand, activation of the symphatic nervous system, and SA or AV nodal ischemia may increase the likelihood of supraventricular tachyarrhythmias such as ST, AFL, and AFB.

## Diagnostic Principles

The 12-lead electrocardiogram, continuous telemetry in the CCU and holter monitoring remain the main tools for the diagnosis of post-MI arrhythmias.

## Therapeutic Principles

The acute treatment of post-MI life-threatening ventricular tachyarrhythmias (VF, VT) is immediate electrical defibrillation [4]. Hemodynamically stable patients with VT can be treated with intravenous (IV) amiodarone followed by synchronized electrical cardioversion with brief anesthesia. Intravenous procainamide is an alternative to amiodarone. Patients who develop sustained VF more than 48 hrs after MI may have to receive an intracardiac defibrillator as well as optimal revascularization and medical therapy. It is important to emphasize that the antiarrhythmic treatment is just an adjunct to the treatment of underlying ischemia with medical or invasive therapy. Other reversible causes such as hypokalemia and hypomagnesemia, adrenergic overstimulation and heart failure should be optimally treated (e.g., with electrolyte replacements, beta-blockers). There is no specific treatment needed for VPB other than beta-blockers. The management of peri-infarction supraventricular tachyarrhythmias includes rate control and pharmacological or electrical conversion [5]. For sustained AFL or AFB with hemodynamic compromise, prompt electrocardioversion is indicated. If this fails, the use of intravenous amiodarone or digoxin may be required. For more stable patients rate control with intravenous beta blockers such as metoprolol or intravenous diltiazem may suffice. PSVT may be treated with intravenous adenosine.

# Arrhythmias, Supraventricular

Jens Seiler, Martin Rotter
Swiss Cardiovascular Center Bern, University Hospital, Bern, Switzerland

## Synonyms

Narrow complex tachycardias

## Definition and Characteristics

Group of cardiac rhythm disturbances, which require atrial, atrioventricular (nodal) tissue and/or the tissue of the adjacent veins for their initiation and maintenance. The term encompasses sinus tachycardia, inappropriate sinus tachycardia, sinus nodal reentrant tachycardia, atrial tachycardia, multifocal atrial tachycardia, ectopic and persistent junctional tachycardia, atrioventricular nodal reentrant tachycardia, atrioventricular reentrant tachycardia (e.g. Wolff-Parkinson-White syndrome), atrial flutter and atrial fibrillation. These arrhythmias are paroxysmal or persistent and hardly ever life threatening due to hemodynamic impairment or induction of ventricular arrhythmia. If persistent they can cause tachycardia-induced cardiomyopathy. Atrial flutter and atrial fibrillation carry the risk of arterial thromboembolism [1].

## Prevalence

Supraventricular arrhythmias are common. Atrial fibrillation is the most common clinically significant cardiac arrhythmia with a prevalence estimated at 0.4%, increasing with age [1]. The prevalence of paroxysmal supraventricular tachycardia is estimated at 0.225% [2].

## Genes

Most of the supraventricular arrhythmias are sporadic. Exceptions are familial forms of atrial fibrillation and the Wolff-Parkinson-White-Syndrome. In contrast to some ventricular arrhythmias to date there is no clear and consistent picture of a certain type of supraventricular arrhythmia and causative genes and their respective mutations.

## Molecular and Systemic Pathophysiology

The underlying cause of arrhythmias is abnormal impulse formation, abnormal impulse conduction, endless loop formation or a combination of these. There are three major pathophysiologic mechanisms of arrhythmias: increased automaticity, triggered activity and re-entry. Cells with increased automaticity exhibit enhanced phase-4-depolarization with an increased discharge rate compared to pacemaker cells. Abnormal automaticity can arise from cells with reduced maximum diastolic potentials [3]. If the discharge rate exceeds that of the sinus node, the sinus node will be overdriven and the ectopic focus will be the predominant pacemaker. Triggered activity is associated with repolarization disturbances of the cell. Depolarization is triggered by oscillations in the membrane potential called after depolarizations that may reach the threshold potential leading to a consecutive discharge. Reentry is the conduction of an impulse around an anatomical or a functional area of conduction block. The classification of supraventricular arrhythmias is based on the ECG appearance, the proposed or clarified electrophysiologic mechanism and the involved morphological and functional substrate. Reentry is the most common cause of supraventricular arrhythmias. Supraventricular arrhythmias can affect otherwise healthy patients with no detectable structural abnormality as well as patients with structural heart disease. Extracardiac physiological and pathological factors, e.g. increased sympathetic tone, hyperthyroidism and drugs, can cause, precipitate and/or worsen supraventricular arrhythmias [1,4].

## Diagnostic Principles

Diagnosis is established by 12 lead ECG recording in the majority of the cases [5]. The usual presentation of supraventricular arrhythmia is a narrow-complex tachycardia (QRS-duration less than 120 ms), but in some cases supraventricular arrhythmias may have wide QRS-complexes due to bundle-branch-block or preexcitation, i.e. premature excitation of the ventricles by an accessory muscle bundle connecting the atria and the ventricles. Electrophysiological testing usually allows the exact delineation of the mechanism of the arrhythmia, but is generally performed only if catheter ablation is considered [4].

## Therapeutic Principles

Therapy is guided by the type of arrhythmia, the associated risks, the symptoms, frequency and duration of the arrhythmia. The basic therapeutic principles are rhythm control (restoration and maintenance of sinus rhythm), or rate control (mitigation of symptoms by slowing the heart rate). The therapeutic spectrum encompasses patient information, vagal maneuvers, treatment with adenosine, beta blockers, calcium channel blockers, digoxin, class I and class III antiarrhythmic drugs, catheter ablation of the arrythmogenic substrate or – in combination with the implantation of a permanent pacemaker – catheter ablation of the atrioventricular node as well as the prevention of thromboembolic complications. The most common treatment strategies are drug treatment and catheter ablation [1,2,4].

# Arrhythmias, Ventricular

Alexander Leaf
Harvard Medical School, Charlestown, MA, USA

## Synonyms

Ventricular tachycardia; Venrtricular flutter; Ventricular fibrillation

## Definition and Characteristics

Ventricular arrhythmias include both ventricular tachycardia (VT) and ventricular fibrillation (VF).

## Prevalence

Ventricular tachycardia is a frequent complication of myocardial infarction, a leading cause of death in Europe and North America.

## Genes

A wide variety of genetic defects and polymorphisms predispose to the occurrence of ventricular tachycardia and fibrillation including those causing long QT syndrome (see ►Long QT syndrome).

## Molecular and Systemic Pathophysiology

VT is characterized by very rapid but regular heart beats (~150 bpm). Because of the very rapid heart rate, if persistent over 30 s, hemodynamic collapse of circulation may occur. In contrast, VF has a totally chaotic rhythm, which makes the heart unable to function as a pump, and again hemodynamic collapse of the circulation occurs but more promptly than with VT. Both VT and VF have a very high correlation with coronary heart disease, acute myocardial infarctions, large chronic scars in the heart, and sudden cardiac death. Both can be caused by a dysfunctional state of the fast, voltage-dependent $Na^+$ channel, which initiates an action potential and may cause a fatal reentry arrhythmia as it transmits through the nonhomogeneous conduction pathway in the ischemic myocardium [1]. Excessive fluctuations of ionized $Ca^{2+}$ in the cytosol of heart cells causing after-potential discharges, which, if of sufficient magnitude, can trigger ectopic $Na^+$ currents that also initiate fatal arrhythmias [2].

## Diagnostic Principles

Ventricular tachycardia is diagnosed by ECG.

## Therapeutic Principles

For many years the pharmaceutical industries have been trying to synthesize an effective antiarrhythmic drug. Despite the expenditure of hundreds of millions of dollars they have been unable to produce a drug, which is both effective and safe. The most effective of their drugs todate cause severe adverse reactions with some 30% morbidity. Most antiarrhythmic medications by their very effect on cardiac ion channels may have proarrhythmic effects. By contrast the n-3 (ω-3) long chain, polyunsaturated fish oil fatty acids have been a regular part of the human diet for hundreds of thousands of years during which our genes were adapting to our environment, including our diet, that was high in n-3 fish oil fatty acids and low in plant seed n-6 proarrhythmic fatty acids. They are now known to be safe. These n-3 fish oil fatty acids are also potent antiarrhythmic agents as clearly demonstrated now by epidemiologic, observational [3], and clinical trials in humans [4].

Today the most effective prevention recommended by cardiologist is to have an implanted cardioverter-defibrillator (ICD) placed in patients requiring minimal surgery, who are at high risk for fatal VT or VF. An ICD will sense the presence of a ventricular arrhythmia and defibrillate it. However, the ICD is not perfect in successfully defibrillating all potentially fatal arrhythmias, so even with an ICD some patients will die. In a clinical trial [5] all patients enrolled in the study had ICDs and were randomized to either a supplement of fish oil fatty acids or to a placebo olive oil which has no

antiarrhythmic action. After each patient had completed the 12 months in the study, there was still a marked benefit in those receiving the fish oil supplement compared with those receiving the placebo [5]. So we can conclude that the fish oil fatty acids are more effective in preventing fatal ventricular arrhythmias than are ICDs.

# Arrhythmogenic Right Ventricular Cardiomyopathy

Srijita Sen-Chowdhry[1,2], Deirdre Ward[1], William J. McKenna[1]

[1]Inherited Cardiovascular Disease Group, The Heart Hospital, University College London Hospitals, NHS Trust and Institute of Cardiovascular Science, University College London, London, UK

[2]Imperial College, London, UK

## Synonyms

Arrhythmogenic right ventricular dysplasia; ARVD; Right ventricular dysplasia; Arrhythmogenic cardiomyopathy; ARVC

## Definition and Characteristics

Genetically inherited heart muscle disease characterized pathologically by progressive myocyte loss with fibrofatty replacement.

The classic form shows early predilection for the right ventricle and left ventricular involvement with disease progression.

Variants that preferentially affect the left ventricle are increasingly recognized (left-dominant arrhythmogenic cardiomyopathy).

Clinical manifestations include ventricular arrhythmia and sudden cardiac death. Heart failure is less common but well documented [1].

## Prevalence

Most recently estimated at 1 in 1,000 but remains underrecognized.

## Genes

Commonly transmitted as autosomal dominant trait.

Recessive syndromic variants associated with woolly hair and cutaneous disease (e.g., Naxos disease and Carvajal syndrome).

Identification of causative mutations in plakoglobin (Naxos), desmoplakin, plakophilin-2, and desmoglein-2 has defined ARVC as a disease of the desmosome.

Additional putative mutations in transforming growth factor beta3 (TGF-β3), known to stimulate production of extracellular matrix components and modulate stability of intercellular junctions.

ARVD2 has an atypical phenotype and is linked with mutations in the cardiac ryanodine receptor, the major calcium release channel of the sarcoplasmic reticulum in cardiac myocytes, also isolated in familial catecholaminergic polymorphic ventricular tachycardia [2].

## Molecular and Systemic Pathophysiology

Desmosomes are specialized cell adhesion junctions in cardiac and epithelial tissues that link intermediate filaments with the cyclasmic membranes of adjacent cells, thereby conferring mechanical strength. Cardiac myocytes are constantly exposed to shear stress, and a defect in any component of the desmosome may compromise cell junction stability. Consequent myocyte detachment and death may be accompanied by inflammation; fibrofatty repair follows [2].

Ventricular arrhythmia may arise from one of the following mechanisms: (i) macro-reentrant circuits caused by islands of fibrofatty tissue, (ii) gap junction remodeling secondary to impaired mechanical coupling of cells, and (iii) bouts of myocarditis occurring in conjunction with myocyte loss [2].

**Arrhythmogenic Right Ventricular Cardiomyopathy. Table 1** Task Force Diagnostic Criteria for ARVD/C

| | Major | Minor |
|---|---|---|
| Family History | Familial disease confirmed at necropsy or surgery. | Family history of premature sudden death (<35 years of age) due to suspected ARVD/C Family history (clinical diagnosis based on present criteria). |
| ECG depolarisation/ conduction abnormalities | Epsilon waves or localized prolongation (>110 ms) of QRS complex in right precordial leads (V1–V3). | Late potentials on signal-averaged ECG. |
| ECG repolarisation abnormalities | | Inverted T waves in right precordial leads (V2 and V3) in people >12 years of age and in absence of right bundle branch block. |
| Arrhythmias | | Sustained or nonsustained LBBB–type ventricular tachycardia documented on ECG or Holter monitoring or during exercise testing. Frequent ventricular extrasystoles (>1000/ 24 hours on Holter monitoring). |
| Global or regional dysfunction and structural alterations | Severe dilatation and reduction of right ventricular ejection fraction with no or mild left ventricular involvement. Localized right ventricular aneurysms (akinetic or dyskinetic areas with diastolic bulgings). Severe segmental dilatation of right ventricle. | Mild global right ventricular dilatation or ejection fraction reduction with normal left ventricle. Mild segmental dilatation of right ventricle. Regional right ventricular hypokinesia. |
| Tissue characteristics of walls | Fibrofatty replacement of myocardium on endomyocardial biopsy. | |
| The presence of two major, one major plus two minor, or four minor criteria from different categories is considered diagnostic. After ref 31. | | |

## Diagnostic Principles

Clinical diagnosis is difficult owing to the nonspecific nature of associated findings and subtle or absent abnormalities in early "concealed" phase.

Task Force diagnostic criteria (Table 1) are highly specific but lack sensitivity for early and familial forms.

Modifications to the original criteria have been proposed to enhance sensitivity in the diagnosis of familial ARVC [1].

## Therapeutic Principles

Implantation of cardioverter defibrillator recommended for patients at high risk of sudden death. Indicators of adverse prognosis include prior cardiac arrest, sustained ventricular tachycardia with hemodynamic compromise, unexplained syncope, and early onset of structurally severe disease [3].

# Arrythmogenic Right Ventricular Dysplasia

Jens Mogensen
Department of Cardiology, Aarhus University Hospital, Skejby, Denmark

## Synonyms

Arrythmogenic right ventricular cardiomyopathy; ARVC; ARVD

## Definition and Characteristics

Arrythmogenic right ventricular cardiomyopathy, (ARVC), is a hereditary cardiac condition most commonly transmitted by autosomal dominant inheritance. Less frequently autosomal-recessive variants of ARVC have also been reported in association with skin and hair disorders. The cardiac manifestations are characterised by progressive fibrofatty replacement of the myocardium. Structural abnormalities of the right ventricle predominate and include myocardial wall thinning, aneurisms and cavity dilatation [1]. Recent investigations suggest that the condition may also present with biventricular or isolated left ventricular dilatation [2]. In addition ARVC is a major cause of sudden death during adolescence and early adulthood. Disease expression is heterogeneous even within families and penetrance is incomplete [3]. The condition has been diagnosed at all ages although it very rarely occurs before adolescence.

## Prevalence

The prevalence of ARVC is largely unknown. Diagnosis is often difficult because many affected individuals have no or limited symptoms in addition to subtle clinical disease manifestations. Many cases are first revealed post-mortem.

## Genes

The condition is a genetically heterogeneous. Disease causing mutations have so far been identified in desmoplakin, (DSP), plakophilin, (PKP2), desmoglein, (DSG2), and desmocollin, (DSC2). These proteins are all constituents of the specialized adhesive junctions between cells known as desmosomes (Table 1).

Results of genetic investigations have suggested that mutation analysis of these genes will uncover a disease causing mutation in 40–70% of all ARVC cases. Autosomal-recessive variants of ARVC have also been described in association with skin and hair disorders [4]. Naxos disease, a triad of ARVC, palmoplantar keratoderma, and woolly hair, is caused by homozygous mutations in plakoglobin, (JUP), which is another component of the desmosomal plaque. Recessive mutations in DSP have been identified in an Arab family with ARVC and a pemphigus-like skin disorder and in an Ecuadorian family with a Naxos like cutaneous phenotype and apparent dilated cardiomyopathy, the so-called Carvajal syndrome (Table 1).

## Molecular and Systemic Pathophysiology

The discovery of mutations in DSP, PKP2, DSG2, DCS2, and JUP has led to the hypothesis that ARVC is a disease of the desmosome which consists of 3 major protein families: cadherins (desmocollins and desmogleins), armadillo repeat proteins (plakoglobin and plakophillins) and plakins (desmoplakin, plectin, etc). Desmosomes are protein structures situated in cell membranes that maintain adhesion between neighbouring cells and serve as anchoring sites for the intermediate filaments. They are found in tissues that experience mechanical stress, including epidermis and myocardium. In addition to cell adhesion they are involved in cell communication, tissue morphogenesis and differentiation. Much has been learnt about pathophysiology from studies of genetically modified mice. For instance mice lacking plakophilin are stillborn with profound cardiac abnormalities. They develop abnormal cardiac desmosomes and their desmoplakin dissociates and accumulate in cytoplasmatic aggregates. Recent investigations of mice haploinsufficient of desmoplakin who thereby lack about half of the protein compared to wildtype mice develop an age dependent ARVC like phenotype with cardiac enlargement and ventricular arrhythmia [5]. Their myocardium is dominated by fibrosis and fatty tissue. Apparently, shortness of desmoplakin causes nuclear translocation of plakoglobin and upregulation of genes implicated in formation of adipose and connective tissue.

**Arrythmogenic Right Ventricular Dysplasia. Table 1** Disease genes in ARVC

| Autosomal dominant inheritance | Gene symbol | Clinical characteristics |
|---|---|---|
| Desmoplakin | *DSP* | All disease genes associated with primarily ARVC but with highly heterogeneous disease expression including isolated involvement of the left ventricle. No specific genotype-phenotype correlation is apparent |
| Plakophilin | *PKP2* | |
| Desmocollin | *DSC1* | |
| Desmoglein | *DSG2* | |
| Autosomal recessive inheritance | | |
| Plakoglobin | *JUP* | Naxos disease: ARVC, woolly hair, palmoplantar keratoderma |
| Desmoplakin | *DSP* | Carvajal syndrome: Dilated cardiomyopathy, woolly hair, palmoplantar keratoderma |

### Diagnostic Principles

The diagnosis is based on major and minor diagnostic criteria proposed by The International Task Force of the European Society of Cardiology and International Federation of Cardiology that includes morphological changes, histology, electrical abnormalities, rhythm disturbance and family history [1]. Magnetic resonance imaging, (MRI), is a valuable tool in diagnosing right ventricle abnormalities as well as fatty tissue replacement of the myocardium. Recent genotype-phenotype studies have suggested that the disease expression is very heterogeneous and that the phenotype may even overlap with idiopathic dilated cardiomyopathy, (DCM). Furthermore these studies have indicated that current diagnostic task force criteria lack sensitivity for early disease when clinical findings are subtle. This limitation has prompted proposal of modified diagnostic criteria for ARVC and suggest a key role for genetic analysis identifying individuals with early disease since sudden cardiac death is a frequent first manifestation of the condition.

### Therapeutic Principles

The clinical manifestations of the condition are variable including asymptomatic individuals, palpitations, syncope, hearth failure and sudden death. Treatment of the condition is available and includes antiarrhythmic medications, implantable cardiac defibrillator, (ICD), heart failure therapy and percutaneous catheter ablation of arrhythmias refractory to drug treatment.

## Arteriohepatic Dysplasia

►Alagille Syndrome

## Arteriosclerosis

►Atherosclerosis

## Arteriovenous Fistula

Christopher K. Zarins
Division of Surgery, Stanford University School of Medicine, Stanford, CA, USA

### Synonyms

AV fistula; AVF; AV shunt

### Definition and Characteristics

An arteriovenous (AV) fistula is an abnormal high flow connection between an artery and vein which allows blood to flow directly from an artery into a vein, thus bypassing the capillary bed.

Normally, oxygenated blood flows from arteries into the capillary bed, where oxygen is released into the tissues. Deoxygenated capillary blood then flows into veins and returns to the heart. When there is a direct connection between a high-pressure artery and low-pressure vein, a short circuit is created which bypasses the high resistance capillary bed. This results is in a high flow situation and pulsatile blood flow in the veins. This can cause the veins to bulge and enlarge and become varicose. If the AV communication is very large, tissues downstream may receive insufficient blood supply. In some cases, the volume of diverted blood may be so great that heart failure may occur.

AV fistulas may be present at birth (congenital fistula), or develop after birth (acquired fistula). Congenital arteriovenous fistulas are birth defects and are also known as arteriovenous malformations (AVMs). AVMs may occur anywhere in the body, including intracranially. Acquired arteriovenous fistulas may result from a penetrating knife or bullet injury that damages both an

artery and an adjacent vein. Arteriovenous fistulas may also develop as a complication of arterial and venous punctures performed during angiographic catheterization procedures. In patients with kidney failure who require hemodialysis, arteriovenous fistulas and shunts are surgically created in the wrist or arm in order to increase blood flow and pressure in the veins of the forearm. This enlarges the veins and creates a high flow situation in order to allow sufficient blood to flow through the dialysis machine.

## Prevalence

Congential AVMs are uncommon and occur with equal frequency among males and females. AVMs are present at birth, may regress after birth and may progress during puberty or pregnancy. Surgically created AV fistulas and shunts are very common in kidney failure patients undergoing hemodialysis. Traumatic and angiographic catheter induced fistulas are being increasingly recognized.

## Genes

Experimental studies reveal that high flow arteriovenous fistulas result in up-regulation of candidate genes involved in cullular proliferation and differentiation. In animals with patent AVF 168 genes with significantly increased expression ($p \leq 0.05$) were identified, including APBA1, PRKDC, TAP1, NEK2, GC, TGFβ1, GBA, F8, IMPDH2, AFM, NBL1, LECT2, ANGPT1, KHDRBS1, ITGAM, and RAD52.

## Molecular and Systemic Pathophysiology

A direct connection between a high pressure artery and a low pressure vein short circuits the capillary bed and results in a marked increase in blood flow in the afferent artery. This results in high wall shear stress and compensatory enlargement of the afferent artery with ultimate normalization of wall shear stress levels as the artery dilates. This adaptive enlargement is endothelial dependent and is mediated by endothelial nitric oxide (NO) release. In addition there is up-regulation of pro-inflammatory gene expression, endothelial and smooth muscle proliferation and restructuring of the elastin-collagen extracellular matrix. On the venous side, the increase in intraluminal blood pressure and flow velocity induces up-regulation of monocyte chemoattractant protein-1, plasminogen activator inhibitor-1, endothelin-1 and transforming growth factor-B1. Intimal and smooth muscle proliferation results in thickening of the wall of the vein and neointimal hyperplasia.

Large, high-flow arteriovenous fistulae can induce increased cardiac output with systemic effects which may lead to cardiac failure. This clinical situation is associated with increased activity of vasoconstrictor neurohormonal systems such as the renin-angiotensin system, the sympathetic nervous system, the endothelin system and arginine vasopressin. At the same time there is compensatory activation of systemic vasodilating systems such as atrial natriuretic peptide and nitric oxide. In decompensated patients enhanced sodium-retaining systems overwhelm the effects of vasodilating, sodium excretion systems with net reduction in sodium and water excretion and congestive heart failure.

## Diagnostic Principles

Superficial AV fistulas can be identified by the presence of distended and bulging veins, discoloration and swelling and increased warmth in the region of the fistula. High velocity blood flow in an AVF can be heard with a stethoscope as a continuous pulsating flow signal (bruit or machinery murmur). The turbulence of flow in the AVF induces vibrations in the vein which can be palpated as a thrill over the fistula. Increased pressure in veins close to the fistula can result in pulsatility in the veins, swelling of an extremity, venous varicosities and venous insufficiency. Alternatively, decreased pressure in arteries distal to an AVF can result in ulcerations and distal tissue ischemia. Increased cardiac output and stroke volume due to large AV fistulas can lead to tachycardia, left ventricular dilation and heart failure. Compression and temporary occlusion of an AV fistula may lead to reflex slowing of the heart. A number of imaging modalities can identify and localize both superficial and deep arteriovenous fistulas, including Duplex ultrasound, magnetic resonance imaging, CT scanning with contrast and catheter based angiography.

## Therapeutic Principles

Congential AVMs usually involve smaller arteries and veins and are most often managed conservatively. Small congenital AVMs can be excised or eliminated with laser coagulation therapy, however, they are often more extensive than they appear on the surface. If there are significant clinical symptoms or complications, treatment usually involves endovascular coiling or embolization. Acquired fistulas usually involve a single large connection which can be effectively treated surgically by repairing the defect in the artery and repairing or ligating the associated vein or veins. Traumatic or catheter induced AV fistulas require direct surgical repair. AV fistulas in the brain, eye or other major structures can be especially difficult to treat. Endovascular treatment strategies with angiographic image guidance to embolize, coil, glue and occlude the arterial and venous branches feeding the fistula have been effective. These procedures are performed using catheters and x-ray imaging and do not require open surgery.

## Synonyms

Suppurative, pyogenic, or septic arthritis are applicable terms for bacterial arthritis

## Definition and Characteristics

Infectious arthritis may involve single or multiple joints, and may be caused by an extensive number of microorganisms: bacteria, and less frequently viruses, fungi, mycobacteria, and other microorganisms [1,2]. Bacterial arthritis is the most common and relevant, due to its potential for rapid joint destruction and functional loss. Viral arthritis is usually part of a systemic disease and may involve multiple joints, but is not burdened by a comparatively severe outcome. Infectious arthritis caused by mycobacteria (Mycobacterium tuberculosis and multiple atypical mycobacteria), and more infrequently fungi, parasites, and some bacterial organisms (Borrelia burgdorferi, Treponema pallidum, Mycoplasma pneuoniae, and Nocardia spp.), usually appears as chronic, slowly progressive monoarticular disease [3]. Moreover, a reactive or sterile arthritis is occasionally linked to systemic or local infections at a remote localization. Infectious disorders involving articular prosthetic devices are usually caused by gram-positive cocci, and may lead to the frequent need to prosthetic surgical curettage and substitution.

## Prevalence

The reported incidence of native joint bacterial arthritis is 2–10 cases per 100,000 subjects per year, in the general population. It is slowly increasing, due to the increasing number of at-risk patients and invasive and surgical procedures. Estimates of incidence in patients suffering from rheumatoid arthritis may reach 28–38 cases per 100,000 patients per year [1,2]. The crude

mortality of bacterial-septic arthritis in adults ranges from 10 to 30%, but remnants of infectious may be responsible for some sequelae in up to 50% of affected patients.

## Molecular and Systemic Pathophysiology

Infectious arthritis is usually acquired by an occult or a clinically apparent bacteremia. The well-vascularized synovial membrane lacks a limiting basement membrane, and it is therefore highly susceptible to bacterial deposition. The rich synovial supply and the presence of membrane receptors for bacterial structures and products may allow negligible traumatic events to cause septic arthritis. In infants in their first 2 years of life, there is a communication between the arterial supply of the metaphysis and the epiphysis by transepiphyseal vessels, so that there is no anatomic barrier to extension of infection from the metaphysis to the epiphysis, and this localization may represent the origin of secondary involvement of the adjacent joint [1,2]. In both children and adults, the articular capillaries lack a basement membrane, and microorganisms in the bloodstream may gain access to the articular space by passing through the capillary walls. When reaching the joint space, all microorganisms encounter an environment rich in nutrients. The subsequent bacterial replication elicits a brisk host inflammatory response involving a rapid polymorphonuclear involvement, the release of lytic enzymes, and the subsequent increase in synovial fluid protein concentration associated with a concomitant decrease of pH and glucose concentration. As a whole, the inflammatory process leads to synovial thinning, leukocyte infiltration, cytokine secretion, and local fibrin deposition. Without rapid therapeutic intervention, irreversible changes may be induced in joint anatomy and function, leading to severe remnants. Besides, the most frequent bacteremic invasion, direct inoculation of microorganisms or contiguous spread from adjacent tissues (i.e. skin-soft tissues or bone), is also possible [1–3].

The clinical manifestation, severity, treatment, and outcome of infectious arthritis directly depend on the identity and virulence of the infectious causative microorganisms, source of joint infection, and eventually, underlying host factors (including immune defense, comorbidity, trauma, and altered joint architecture) [3]. From over 2,300 cases of bacterial septic arthritis [4], the major isolates were Staphylococcus aureus (46% of cases) and streptococci as a whole (22%, with Streptococcus pyogenes and Streptococcus pneumoniae 7%), whereas gram-negative organisms are less frequent (21% as a whole, with Haemophilus influenzae and Escherichia coli as the leading organisms) [4]. The pathogenesis of gonococcal arthritis (although representing no more than 3% of cases) involve several microbial virulence factors, mostly cell-surface proteins (especially protein A1), while complement deficiencies (especially C5 and C8), and circulating immunocomplexes may enhance dissemination of gonococci toward joint invasion.

The association of infection with early arthritis and the possible role of such infections with respect to the development of chronic rheumatic complications is also under investigation [1–3]. The role of preceding infection prompting the process of rheumatoid arthritis and other chronic collagen vascular diseases is still an option. In addition, the bacterial Campylobacter infection seems to deserve increasing attention and a causative agent of indirect, reactive arthritis. Viral infections (alpha viruses belonging to mosquito-borne viruses and HIV) are frequently associated with arthritis, but the pathogenetic mechanisms are still debated.

## Diagnostic Principles

Prompt recognition and treatment are major determinants in the final outcome of infectious arthritis, and are mandatory in order to prevent potential long-term sequelae. Radiographic and ultrasonographic findings are extremely simple but sensitive imaging techniques. Nevertheless, in selected cases, scintigraphic and computerized tomography scans, as well as resonance magnetic imaging are adequate to detect complication and monitor the follow-up [5]. Due to the extremely variable range of possible organisms and the need of prolonged courses of specific antimicrobials, a definitive ethological diagnosis should be always attempted, possibly with invasive approaches (i.e., arthrocenthesis), whenever possible.

The differential diagnosis of infectious arthritis includes several inflammatory joint diseases of noninfectious origin (i.e., gout and pseudogout, and a broad range of collagen vascular disorders).

## Therapeutic Principles

First-line antimicrobial therapy of native joint infection is prompted by synovial fluid gram stain, while definitive treatment should be based on the identification and in vitro antimicrobial susceptibility studies of infected pathogens [1,3]. The penetration of inflamed joints is adequate for a large number of parentheral and oral antimicrobial agents, whereas it is not the same when bone involvement is of concern [1,3]. When gram-positive cocci are isolated, oxacillin-nafcillin or cefazolin are adequate when methicillin resistance is absent, whereas vancomycin is the first-choice agent for resistant gram-positive cocci, and clindamycin or vancomycin should be preferred when patients suffer from allergy to beta-lactam antibiotics. Gram-negative

cocci require a ceftriaxone approach, whereas gram-negative rods are better treated with ceftazime or cefepime or piperacillin-tazobactam or a carbapenem derivative; fluoroquinolones are highly active and have an elevated joint tissue penetration, so that they may represent a first choice when beta-lactam allergy is a problem.

# Arthro-Ophtalmopathy, Hereditary

Jeno Sebes
Saravanan Kasthury University of Tennessee Medical Center, Memphis, TN, USA

## Synonyms

Wagner-Stickler syndrome; Stickler syndrome

## Definition and Characteristics

Autosomal dominant connective tissue dysplasia with variable expressivity and virtually complete penetrance leading to multiple ocular, cardiac, articular, and bony abnormalities.

## Prevalence

A rare syndrome with a frequency of 0.1–0.3 per million. With increasing recognition of the syndrome, it is now considered the most common autosomal dominant connective tissue disorder.

## Molecular and Systemic Pathophysiology

Recent studies indicate that mutation in the type II procollagen gene COL2A on chromosome 12 along with abnormal amino acid substitution in COLIIA2 responsible for coding the alpha chain of type XI collagen is responsible for the syndrome. Type II collagen is a major contributor to collagen of the vitreous, cartilage and the nucleus pulposus of the intervertebral disc. The ocular abnormalities include myopia (35%) usually occurring before the age of 10 years, retinal detachment (5%) usually occurring by the age of 30 years and in severe cases leading to blindness. Associated abnormalities include maxillary or mandibular hyperplasia cleft palate, and sensory neural deafness. Mitral valve prolapse is reported in 45% of the patients. Osteoarticular abnormalities are common; premature osteoarthritis is found in 16% of patients by the second decade and 50% by the third. Osteoporosis is found by the fourth decade. In the neonatal period, the epiphyses and metaphyses of long bones are enlarged and the joints are hyperextensible. In childhood, there is platyspondyly and anterior wedging of the vertebral bodies. Kyphoscoliosis, coxa and genu valgum, and premature degenerative changes occur. Occasionally, there is an accessory ossification center in the wrist between the capitate and the third metacarpal bones bilaterally. When present, this finding is diagnostic of this syndrome.

## Diagnostic Principles

This disorder should be considered as the diagnosis in cases of unexplained juvenile arthropathy, early degenerative joint disease in a young adult, with severe myopia or retinal detachment. Radiological findings are helpful in distinguishing from other syndromes including spondyloepiphyseal dysplasia, otospondylomegaepiphyseal dysplasia, and Marshall Syndrome. Other conditions including acromegaly, hemochromatosis, alcaptonuria, Wilson disease, and rarely Kashin-Beck syndrome are included in the differential diagnosis; however, none of these syndromes have retinal and maxillofacial abnormalities seen in Stickler's syndrome.

## Therapeutic Principles

Treatment of the ophthalmic manifestations involves surgical repair of the retinal tear, orthopedic management of kyphosis, and total hip arthroplasty for hip dysplasia. Additionally, medical treatment may be required for osteoporosis usually with bisphosphanates and drug treatment of the symptoms of degenerative arthritis.

## Asbestosis

Yun Zhao, Darryl C. Zeldin
Laboratory of Respiratory Biology, NIH/NIEHS, Research Triangle Park, NC, USA

### Definition and Characteristics

Asbestosis is defined as chronic, progressive inflammation and scarring of the lungs caused by exposure to asbestos fibers. It is characterized by diffuse, bilateral interstitial involvement of the lung that often leads to respiratory insufficiency and secondary cardiac complications.

### Prevalence

Asbestosis is most common in men over the age of 40 years who have worked in asbestos-related occupations. Smokers have increased risk of developing the disease. In the United States, more than 10,000 individuals over the age of 15 years died between 1968 and 1992 as a result of asbestosis. It has been estimated that the cumulative number of asbestos-associated deaths in the United States may exceed 200,000 by the year 2030.

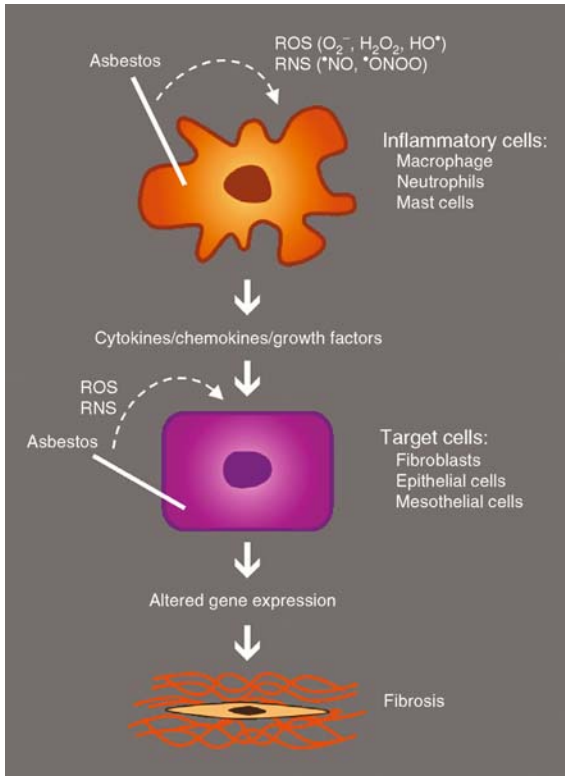
### Genes

No known genetic pattern exists. A deficiency of glutathione-S-transferase is a known risk factor for pulmonary asbestosis.

### Molecular and Systemic Pathophysiology

Asbestosis is caused by inhalation of asbestos, a group of naturally occurring fibrous silicates with crystalline structure, once widely used in the construction, insulation, and manufacturing industries. Asbestos fibers that are long and thin have the greatest fibrogenic potential since they are retained in the lung for extended periods of time. Short fibers are cleared more rapidly and hence are less fibrogenic. The fibers trigger a persistent inflammatory response after being engulfed by alveolar macrophages. The response involves the generation of reactive oxygen and nitrogen species, and the expression of cytokines, growth factors, and chemokines, which together lead to activation of lung fibroblasts and overproduction of extracellular matrix. The precise molecular mechanisms regulating asbestos-induced lung damage are not fully understood; however, it has been found that multiple signaling events are involved in the pathogenesis of this disease. Asbestos exposure induces increased expression of platelet-derived growth factor (PDGF) isoforms, tumor necrosis factor (TNF)-α, transforming growth factor (TGF)-β, TGF-α, interleukin (IL)-1, IL-6, IL-8, macrophage inflammatory proteins (MIP), epidermal growth factor (EGF) and insulin-like growth factor (IGF) (Fig. 1). Activation of mitogen activated protein kinase (MAPK) signaling cascades has been implicated in the development of asbestos-associated lung disease through regulation of cell proliferation or apoptosis. In addition, genetic susceptibility may play a role in the development of asbestos-induced disease. In a mouse model of disease, the 129/J strain has been shown to be resistant, whereas the C57BL/6 strain has been shown to be susceptible to asbestos-induced fibrosis. In humans, individuals with a genetic deficiency in glutathione-S-transferase (GST)-mu have a significantly higher risk of non-malignant asbestos-related disease than those who are not deficient.

Symptoms of the disease may first appear years after the initial exposure to asbestos. The early symptoms of asbestosis typically include exertional dyspnea, dry nonproductive cough, and chest pain. Auscultation commonly reveals dry inspiratory crackles (rales). As the disease progresses and lung damage increases, shortness of breath occurs even when the patient is at rest. Recurrent respiratory infections, hemoptysis and clubbing are common occurrences. In advanced asbestosis, the lungs shrink and stiffen, and severe restrictive lung disease occurs. Several serious conditions are associated with asbestosis including



**Asbestosis. Figure 1** The pathogenesis of asbestos-related pulmonary fibrosis.

mesothelioma, bronchogenic carcinoma and congestive heart failure.

## Diagnostic Principles

An evaluation for asbestosis should begin with a detailed medical, occupational and environmental history. Typical findings on chest radiographs and computerized tomography scans, together with a history of asbestos exposure, is the basis for the diagnosis. The gross pathologic picture of asbestosis is that of diffuse interstitial fibrosis, most marked in the lower lung zones. The most severe involvement is generally seen closest to the pleura with relative sparing of the central portions of the lung. Honeycombing is common in advanced cases. The disease is almost always bilateral. Benign asbestos-induced pleural disease may also be present, but it is not synonymous with asbestosis. High-resolution computerized tomography scans will often show parenchymal fibrous bands, thickened intra- and interlobular lines, and curvilinear subpleural lines. The microscopic diagnosis of asbestosis requires two findings: diffuse interstitial fibrosis, which in advanced cases is identical to that seen in usual interstitial pneumonia, and the presence of asbestos (ferruginous) bodies in microscopic sections. Classic pulmonary physiological changes include restrictive lung disease with reduced lung volumes, impaired gas exchange with hypoxemia and reduced diffusing capacity, and reduced lung compliance.

## Therapeutic Principles

There is currently no effective therapy to reverse the course of asbestosis. Treatment is directed at exposure prevention, amelioration of symptoms, and reduction of risk for related conditions. Coughing can be treated with humidifiers and/or antitussive agents. Regular exercise helps maintain and improve lung capacity. Antibiotics may be prescribed to combat infection. Oxygen should be used to treat hypoxemia. Asbestosis patients should receive vaccines for the influenza and pnuemococcus. People with asbestosis who smoke, particularly those who smoke more than one pack of cigarettes per day, are at increased risk for developing bronchogenic carcinoma and should be strongly advised to quit.

# Ascites

Pere Ginès, Mónica Guevara
Liver Unit, Hospital Clinic and University of Barcelona, IDIBAPS, CIBERHED, Barcelona, Spain

## Definition and Characteristics

Ascites is defined as the accumulation of fluid in the peritoneal cavity. A number of primary disorders of the peritoneum and intraabdominal organs may produce ascites. However, liver cirrhosis is the most common cause of ascites in Europe and North America [1].

## Prevalence

Approximately 50% of patients with compensated cirrhosis (without complications) develop ascites after a mean follow-up of 10 years. Moreover, almost 50% of patients with ascites die within 2 years, leading to inclusion of ascites as one of the indications for evaluation for liver transplantation.

## Molecular and Systemic Pathophysiology

Several theories have been postulated to explain ascites formation in cirrhosis. The accumulation of fluid within the abdominal cavity secondary to portal hypertension and hypoalbuminemia was believed to lead to a reduction of the intravascular volume, which in turn would stimulate renal sodium and water retention. This is known as the classic underfilling theory. The most important argument against this theory was the demonstration that plasma volume is increased in cirrhotic patients with ascites. In view of these findings, an alternative theory of renal dysfunction and ascites formation in cirrhosis was proposed. This theory, the overflow theory, suggested that advanced cirrhosis triggers a sodium-retaining signal in the renal tubules. The renal retention of sodium and water would result in expansion of plasma volume and adaptative circulatory changes to accommodate the excess of intravascular volume. The presence of portal hypertension and circulating hypervolemia would lead to ascites formation. This theory did not satisfy many investigators because it did not offer a clear explanation of the main clinical features of cirrhotic patients with ascites. Finally, in 1988 a new theory to explain the pathogenensis of ascites formation and renal dysfunction in cirrhosis was proposed [2]. The peripheral arterial vasodilation theory is probably the best explanation as to why the hemodynamic changes that occur in cirrhosis are directly related to the major clinical consequences, which include the development of ascites and renal failure. According to this theory, portal hypertension is the initial event, with resultant splanchnic arteriolar vasodilation that induces a decreased arterial blood volume. This effective hypovolemia increases the activity of vasoconstrictor systems leading to water and sodium retention. In the early stages of cirrhosis, the arterial circulation is maintained by transient periods of sodium and water retention. In advanced cirrhosis, the arterial vasodilation increases and effective arterial blood volume decreases. In this setting, the activity of vasoconstrictor systems further increases leading to intense sodium and water retention, which results ascites formation.

## Diagnostic Principles

The diagnosis of ascites is simple when a large amount of fluid is accumulated in the peritoneal cavity. On physical examination the abdomen is distended, the flanks bulge, and a fluid wave may be demonstrable. The diagnosis is more difficult when ascitic volume fluid is small. In this case, ultrasonography is very useful. It can detect as little as 100 ml of abdominal fluid and may also provide information on the etiology of ascites. The diagnosis is confirmed by fluid aspiration by paracentesis. The procedure should be performed by inserting a needle into the left lower abdominal quadrant under strict sterile conditions.

The biochemical and cytological analysis of ascitic fluid provides important information for the differential diagnosis. Traditionally, ascites in cirrhotic patients was considered to have the characteristics of a transudate, with a total protein concentration of less than 2.5 g/dl and with relatively few cells. However, in up to 30% of these patients, total protein concentration is greater than 3 g/dl. It is useful to subtract the ascites fluid albumin concentration from the serum albumin, a serum-ascites albumin gradient of more than 1.1g/l predicts portal hypertension with great accuracy. The ascitic fluid in cirrhosis usually has fewer than 300–500 white blood cells/$mm^3$. Nevertheless 10–15% may have more than 500 cells/$mm^3$. Most of these cells (>70%) are mononuclear leukocytes. If the ascitic fluid contains more than 250 neutrophils/$mm^3$ the diagnosis of spontaneous bacterial peritonitis (SBP) is made, and antibiotic treatment should be initiated.

## Therapeutic Principles

The aim of medical treatment of ascites in patients with cirrhosis is to mobilize the intraabdominal fluid by inducing a negative sodium balance. Treatment strategy is shown in Table 1. In ~10–20% of cirrhotic patients with ascites, this goal can be obtained simply by means of reducing dietary sodium intake and treatment with diuretics such as spironolactone, and loop diuretics. Patients who do not respond or who develop diuretic-induced complications should be considered to have refractory ascites and should be treated with other therapeutics maneuvers.

Therapeutic paracentesis is currently considered in many centers as the treatment of choice for cirrhotic patients with large ascites. An intravenous infusion of albumin (8 g/l of ascitic fluid removed) should always be given after paracentesis to prevent so-called post-paracentesis circulatory dysfunction (PICD).

Transjugular intrahepatic portosystemic shunt (TIPS) is a non-surgical method of portal decompression. Data on the impact of this treatment as compared to paracentesis and albumin on patient survival are, however, conflicting, due to increased incidence of hepatic encephalopathy.

Peritoneovenous shunt is more effective than therapeutic paracentesis in the control of refractory ascites.

**Ascites. Table 1** Treatment of ascites

| **Uncomplicated ascites** |
|---|
| *Grade 1 ascites* is ascites only detectable by ultrasound examination. It does not require specific treatment. |
| *Grade 2 ascites* is ascites that causes abdominal distension and moderate discomfort and is easily detectable by physical examination. It should be treated with sodium restriction and diuretics. |
| *Grade 3 ascites* is large ascites. The treatment of choice is large volume therapeutic paracentesis plus intravenous albumin followed by sodium restriction and diuretics. |
| **Refractory ascites** |
| *Diuretic-resistant ascites*: Ascites that cannot be mobilized or the recurrence of which after large-volume paracentesis cannot be prevented because lack of response to low sodium diet and intensive diuretic treatment (e.g. 400 mg of spironolactone plus up to 160 mg of furosemide) |
| *Diuretic-intractable ascites*: Ascites that cannot be mobilized or the early recurrence of which cannot be prevented due to the development of diuretic-induced complications.<br>The first line treatment of refractory ascites is repeated total paracentesis plus intravenous albumin. In patients who require frequent paracentesis or in those in whom paracentesis is not effective because of the existence of peritoneal adhesions the use of TIPS should be considered.<br>Patients with refractory ascites should be evaluated for liver transplantation |

However, it has many complications and currently, its use is not recommended.

Liver transplantation is a frequent intervention for patients with advanced cirrhosis.

# Aspergillosis

Zhirong Yao
Medical Mycology Laboratory, Xinhua Hospital, School of Medicine, Shanghai Jiaotong University, Shanghai, China

## Definition and Characteristics

Aspergillosis, caused by members of the genus Aspergillus, is a spectrum of diseases, ranging from allergic responses to Aspergillus molecules/antigens without fungal growth (asthma, hypersensitivity pneumonitis) to colonization with or without allergic responses (allergic bronchopulmonary aspergillosis, aspergilloma, saprophytic growth on devitalized tissue), or to invasion and destruction of lung parenchyma (invasive aspergillosis, chronic necrotizing pulmonary aspergillosis) [1]. The forms and severity of the disease depend on the immunologic state of the patient and sites to be affected. Although almost all sites of humans, such as the skin, peritoneum, kidneys, bones, eyes, and gastrointestinal tract can be affected by Aspergillus spp., the respiratory tract is the most commonly affected. Three forms of aspergillosis are most important: (i) allergic bronchopulmonary aspergillosis (ABPA) is a severe allergic pulmonary complication caused by Aspergillus spp. in patients with atopic asthma or/and cystic fibrosisis. Aspergillus fumigatus is usually the causative organism and Aspergillus niger is occasionally implicated, (ii) aspergilloma (fungus ball) is overgrowth of Aspergillus spp. in preexisting cavity lesions produced by previous lung diseases, such as tuberculosis and sarcoidosis, and (iii) invasive aspergillosis is a serious Aspergillus infection that usually occurs in severely immunodeficient patients.

## Prevalence

The exact prevalence of aspergillosis is not clearly known and is different in various study cohorts of patients. The prevalence of ABPA ranges from 2 to 25% in patients with cystic fibrosis and from 1 to 8% in patients with asthma. Aspergilloma occurs in 10–15% of patients with cavitating lung diseases. The incidence of invasive aspergillosis ranges from 7.3 to 10.5% in patients undergoing bone marrow transplantation and from 10 to 25% in patients with leukemia [2,3].

## Molecular and Systemic Pathophysiology

*Aspergillus fumigatus* is one of the most ubiquitous of the airborne saprophytic fungi. The conidia of Aspergillus species are usually inhaled to the lungs through the respiratory tract. Normally, the inhaled conidia are efficiently eliminated in the immunocompetent hosts by innate immune mechanisms. However, in some individuals with high-risk genetic types for ABPA, such as HLA-DR2+ and HLA-DR5+, the inhaled conidia may incite ABPA [4]. Recent studies suggest that genetic factors may play a key role in ABPA. These ABPA patients usually have gene polymorphisms of IL-4Ra and promoter region of the IL-10 gene. It is hypothesized that in these hosts predisposing for suffering from ABPA, the inhaled conidia germinate in the airways and release antigenic molecules, resulting in increased synthesis of $I_gE$ by B cells and the attraction of eosinophils into the airway tissue. Additionally, the expression of cytokines, such as IL-10 and IL-4, attracts Th2 lymphocytes into airways. All these factors incite clinical pictures of ABPA: increased mucus secretion into the airway, episodic eosinophilic-rich pulmonary infiltrations, and remodeling of the airway [3].

In patients with preexisting pulmonary cavities produced by tuberculosis and sarcoidosis, Aspergillus species may colonize in the cavities and overgrow to form fungal ball (aspergilloma). Aspergilloma are usually confined to a limited area. Slight or mass bleeding usually develops due to disruption of blood vessels in the wall of the cavity or in the bronchial artery supply.

In severely immunosuppressed patients, such as hematopoietic stem cell transplants or solid organ transplant recipients receiving neutropenia inducing chemotherapy, Aspergillus species may cause fatal invasive infections of central nervous system, heart, liver, kidney, and especially lung. Production of invasive aspergillosis depends on the defense of hosts and the virulence of Aspergillus spp. The virulence of Aspergillus spp. is multifactorial, including adhesions, pigments, toxic molecules, and enzymes [2]. To invade the hosts, conidia bind to various epithelial cells through nonspecific physicochemical interactions and/or specific receptor-mediated recognition. Then, Aspergillus fumigatus produces toxic molecules (i.e., gliotoxin) to inhibit macrophage phagocytosis and induce apoptosis in macrophages, and proteases (i.e., oxidative enzymes) to counteract the killing effect of reactive oxygen species. In comparison to the role of virulence of the organism, defense factors of hosts undoubtedly play a key role in the invasive Aspergillus infection. Animal experimental studies show that, although high doses of conidia are challenged, the majority of inoculums can be eliminated in immunocompetent hosts within hours. In contrast, fatal invasive infection usually occurs in severely immunosuppressed subjects. The host defense against Aspergillus may include the following: anatomical barriers, humoral factors (i.e., complement), and phagocytic cells (i.e., macrophages, neutrophils) and their related antimicrobials [2].

The role of acquired immunity in protection against Aspergillus and the mechanism of immunosuppressive agents in the development of invasive aspergillosis are less clearly known.

## Diagnostic Principles

Clinical findings, patient history, physical examination, radiographic features, and laboratory tests are important in the diagnosis of ABPA. Transient or permanent pulmonary infiltrates and central bronchostasis are usually seen by chest radiographs and computed tomography scan in ABPA. Laboratory tests show that ABPA is usually associated with an increased serum $I_gE$ level, peripheral blood eosinophilia, as well as positive reaction of antibody against Aspergillus antigen [3].

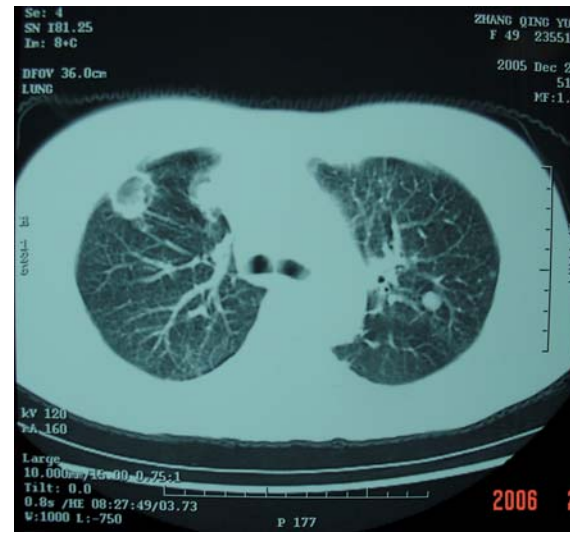
Aspergilloma (fungus ball) in the lungs may cause no symptoms or hemoptysis and may be merely discovered with a chest X-ray. Although the radiographic feature (spherical masses surrounded by a radiolucent crescent) is usually characteristic for diagnosis of aspergilloma, occasionally, other fungi may produce similar lesions.

For diagnosis of invasive aspergillosis, nonspecific Aspergillus-positive culture from the upper/lower respiratory tract specimens bears limited significance. Galactomannan enzyme immunoassay (GM EIA) has an acceptable sensitivity and a high specificity. The radiographic features (Figs. 1 and 2) revealed by computed tomography (CT), especially high-resolution CT, have significant suggestive role in diagnosis of invasive pulmonary aspergillosis.

Invasive examination, such as fiberoptic bronchoscopy (FOB) with bronchoalveolar lavage (BAL), transbronchial biopsies (TBB), CT-guided percutaneous transthoracic lung biopsies, and surgical lung biopsy for histopathological examination and culture are undoubtedly the most reliable methods (Fig. 3) [5].

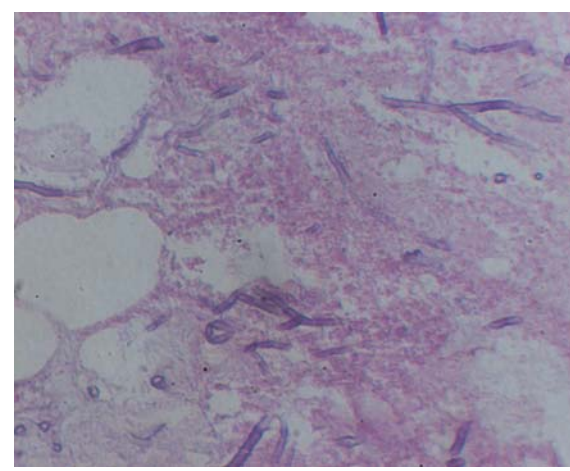
## Therapeutic Principles

Corticosteroids are the primary treatment of ABPA. Antifungal therapy using intraconazole or other agents is adjunct [3]. More recently, recombinant anti-$I_gE$ antibody has been used to successfully treat ABPA.



**Aspergillosis. Figure 2** Computed tomography scan of histopathologically proven invasive pulmonary aspergillosis due to *A. fumigatus* in a patient with acute lymphoblastic leukemia.

**Aspergillosis. Figure 1** Chest radiographs of histopathologically proven invasive pulmonary aspergillosis due to *A. fumigatus* in a patient with acute lymphoblastic leukemia.



**Aspergillosis. Figure 3** Septal hypha with 45° branch in affected tissue.

Aspergilloma does not require treatment unless repeat bleeding or mass bleeding is associated with the disease; then, surgery is required. Surgical treatment for both simple and complex aspergilloma can achieve satisfactory long-term outcomes [5].

Intravenous voriconazole or/and amphotericin B (deoxycholate and lipid preparations) is the primary choice for treating invasive aspergillosis. Itraconazole, posaconazole, and caspofungin are also active against Aspergillus spp. However, they are usually used as alternative treatment of voriconazole and amphotericin B. Considering the high mortality associated with invasive aspergillosis despite introduction of new antifungal agents, lung resection may be a choice for invasive pulmonary aspergillosis [5].

# Asphyxiating Thoracic Dystrophy

Colin A. Johnson
Section of Ophthalmology and Neurosciences,
Leeds Institute of Molecular Medicine,
St. James University Hospital, Leeds, UK

## Synonyms

Jeune syndrome; Thoracic-pelvic-phalangeal dystrophy

## Definition and Characteristics

A rare autosomal recessive chondrodysplasia, with variable renal, hepatic, pancreatic and retinal abnormalities. ATD is characterised by abnormal skeletal development, with typical radiographical findings.

## Prevalence

Estimated at 1 per 100,000 live births.

## Genes

A genetic locus, ATD1, has been mapped to chromosome 15q13 [1], and there is a report of a single affected case with a de novo deletion of chromosome 12p11–p12 [2]. Mutations in the IFT80 gene, encoding the human intraflagellar transport 80 protein, are causative in a subset of ATD patients with a milder form of the condition that lack extraskeletal features [3]. Further genetic heterogeneity in ATD may be caused by mutations in other IFT-associated genes. A similar phenotype occurs in Ellis-van Creveld syndrome (EVC).

## Molecular and Systemic Pathophysiology

The intraflagellar transport 80 (IFT80) protein is a component of pirmary cilia, a ubiquitous organelle of many cell types, including epithelial cells. Almost all epithelial cells are ciliated, and they commonly exist as a sheet of polarised cells forming a tube or tubule with the primary cilia projecting into the lumen. The cilia are then exposed to the extracellular environment of the lumen where it can provide a mechano- or chemosensory role that can mediate specific signalling cues. For example, a failure of mechanosensation in the primary cilia of renal tubular cells is a cause of polycystic kidney disease (PKD). A class of human disorders that arise from defects in the structure or function of primary cilia are now known as “ciliopathies” [4]. These comprise a broad range of phenotypes encompassing a number of different autosomal recessive and dominant syndromes of previously unknown aetiology, with cystic dysplasia of the kidneys as a common feature for most conditions. ATD is the only known human ciliopathy that is associated with mutations in an intraflagellar transport (IFT) protein. IFT is the process by which protein complexes, called IFT particles that contain cargo proteins, are transported bi-directionally along the axoneme of cilia and flagella by the coordinated action of IFT motors. The axoneme is essentially the cilia “backbone” which consists of a polarized array of microtubules which guide the movement of large vesicular complexes or IFT particles. IFT may also have an important role in vertebrate Sonic Hedgehog (Shh) signalling. During zebrafish embryonic development, the orthologue ift80 may act downstream of ptc 1 (the zebrafish Hedgehog receptor, Patched 1) in the Shh pathway [3]. Most cases die in infancy because of a severely constricted thoracic cage and respiratory insufficiency. For those patients who survive infancy, the thorax tends to revert to normal with improving respiratory function. The main visceral abnormality is renal in this condition, and approximately one-fifth of children with ATD survive beyond the neonatal period, only to develop significant renal impairment, with cystic changes and peri-glomerular fibrosis leading to chronic renal failure. Polydactyly is an inconstant feature of ATD and, when present, usually also affects the feet. Nail dysplasia is absent in this condition. Liver

involvement may be severe and biliary cirrhosis can cause early morbidity. Ophthalmological involvement is not a presenting symptom, but retinal dystrophy is an occasional feature.

## Diagnostic Principles

Characteristic findings of prenatal ultrasonography at the second- and third-trimester include a narrow thorax, short hypoplastic ribs, and short tubular bones. Newborn and infant radiography reveals typical findings that include a long, narrow "bell shaped" thorax with short, abnormal ribs, metaphyseal irregularities and short long bones (involving predominately ulnae, radii, fibulae and tibiae) [4,5]. Clavicles can be abnormal ("bicycle handlebar-shaped") and cone-shaped epiphyses of the hands and abnormalities of the pelvis are considered to be diagnostic [4]. Features of the latter, in the neonatal period, comprise small ilia and irregularity of the acetabulum ("trident shaped"), from which a medial and lateral bony projection is visible. Severe restrictive lung disease is supported by pulmonary function testing and arterial blood gas analysis, which reveals hypoxia and hypercarbia in room air. Urinalysis may reveal haematuria and proteinuria. Renal biopsy may reveal cystic tubular dysplasia.

## Therapeutic Principles

Mechanical ventilation is indicated for severe cases when respiratory distress develops in neonates. Multiple recurrent pulmonary infections should be treated with antibiotics, endotracheal suctioning, and postural drainage. Surgical procedures, to enlarge the thoracic cage and reconstruct the chest by sternotomy or lateral thoracic expansion, may be considered for severe cases. Dialysis and renal transplantation are indicated for renal failure.

# Asplenia

Damian C. Melles[1], S. De Marie[1,2]
[1]Department of Medical Microbiology and Infectious Diseases, Erasmus University Medical Centre, Rotterdam, The Netherlands
[2]Department of Internal Medicine, Section of Infectious Diseases, Erasmus University Medical Centre, Rotterdam, The Netherlands

## Synonyms

Absence of the spleen; Splenic agenesis; Ivemark syndrome; Right atrial isomerism; Asplenia syndrome; Congenital asplenia

## Definition and Characteristics

Asplenia refers to the absence of the spleen, while functional asplenia (or hyposplenia) refers to the absence (or impairment) of the normal splenic function. Both conditions are associated with a significantly increased risk of overwhelming infection (postsplenectomy sepsis), particularly involving the encapsulated bacteria Streptococcus pneumoniae and Haemophilus influenzae. In 1919, Morris and Bullock recognized the importance of the spleen in resistance to infection in studying splenectomized rats. The first reported case of postsplenectomy infection was by O'Donnel in 1929. It was not until 1952 that attention focused on the subject, when King and Shumacker reported five cases of severe infection in infants who had undergone splenectomy for spherocytosis.

Asplenia may be congenital, or acquired through surgery (splenectomy). In infants, asplenia usually is linked to serious organ malformations (Ivemark syndrome), but isolated congenital asplenia diagnosed in adults can occur. Surgical removal of the spleen is performed for several reasons, including trauma, immunologic diseases, hypersplenism and malignancy. Functional hypo- or asplenia is associated with a wide variety of diseases, including several immunologic and hematologic diseases. Among the mechanisms responsible for splenic dysfunction are repeated infarction, infiltration, intrasplenic blood flow redistribution, and antigen-antibody complex blockade.

## Prevalence

The true prevalence of functional hypo- or asplenia is unknown. However, the frequency of splenectomies has decreased during the last decades. Growing awareness of possible long-term complications has led to greater efforts to preserve splenic tissue.

In Hodgkin's disease splenectomy is no longer a routine procedure. However, it remains important in the management of hereditary hemolytic anemias, spherocytosis in particular.

## Molecular and Systemic Pathophysiology

The spleen is the largest lymphoid organ and has several immunologic functions (next to removal of old and damaged red blood cells from the circulation). These include the production of opsonizing antibodies and the efficient clearance of encapsulated bacteria. In asplenic patients the immunologic defects include decreased production of serum type-specific IgM and decreased levels of tuftsin (phagocytosis-stimulating tetrapeptide) and properdin, which both promote phagocytosis and initiate the alternate pathway of complement activation. Importantly, well-opsonized bacteria are largely cleared by the Kupffer cells of the liver, while encapsulated bacteria such as Streptococcus pneumoniae resists antibody binding, presenting a unique challenge to the immune system and are primarily removed by the spleen. Exposure of the asplenic patient to such encapsulated organisms as S. pneumoniae and Hemophilus influenzae, could lead to uninhibited bacterial overgrowth and subsequent invasive disease.

## Diagnostic Principles

The presence of Howell-Jolly bodies in the erythrocytes on a peripheral blood film is an important clue to the diagnosis of asplenia, representing a risk for postsplenectomy sepsis. Howell-Jolly bodies are nuclear remnants normally removed by the spleen and may not occur with mild hyposplenism. The "pocked erythrocyte count" (or "pit count") is a more sensitive indicator of splenic clearance and can be visualized by interference phase microscopy. Pocks (or pits) are membrane vesicles removed only by the spleen. Counts seen in normal persons, persons with functional hyposplenia and with asplenia, are less than 2%, more than 3.5%, and more than 12%, respectively. The absence of the spleen is best confirmed with a technetium-99m radionuclide scan.

## Therapeutic Principles

The risk of overwhelming infection is highest in infants and young children, but adults are also at risk. Preventive strategies are very important and fall into three major categories: (i) immunoprophylaxis (most important the pneumococcal polysaccharide vaccine (PPV23)); pneumococcal conjugate vaccine (PCV7) in children under 5 years of age); (ii) antibiotic prophylaxis (including daily antibiotic prophylaxis for the first 2 years after splenectomy in children and "stand-by" antibiotics for all individuals at risk); and (iii) patient education (patients should be aware of their increased risk for serious infection and the appropriate health precautions that should be undertaken).

## Synonyms

Bronchial asthma

## Definition and Characteristics

A chronic inflammatory disease of the bronchi, manifested as episodic airway narrowing – reversible spontaneously or with medication – accompanied by chest tightness and wheezing. Non-specific hyperresponsiveness to bronchoconstrictor stimuli is a cardinal feature. The disease may progress to a stage where a component of airflow obstruction becomes irreversible.

## Prevalence

Asthma was reported in 1997 to affect 14–15 million people in the USA (~6.4%), including an estimated 4.8 million children. More than 5,000 people die annually in the USA from asthma [1].

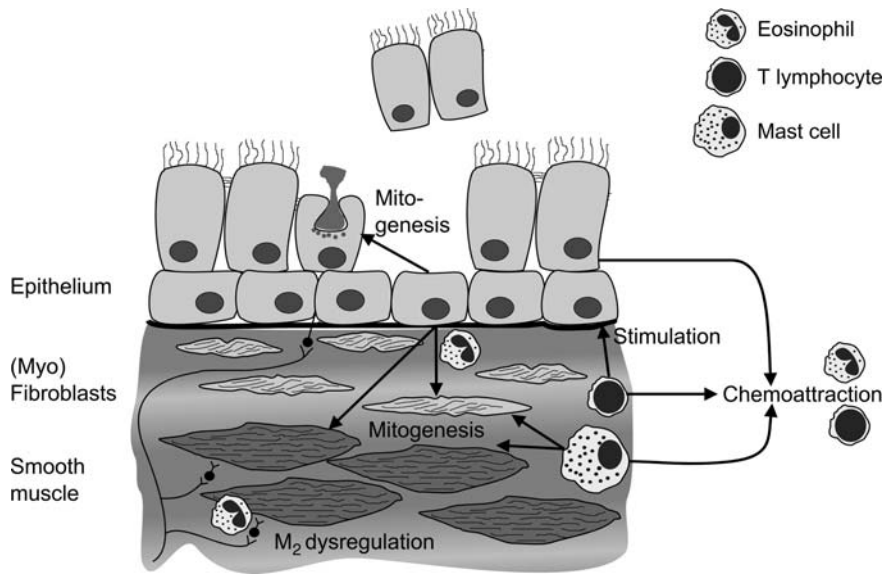
## Genes

The clustering of asthma in families indicates that hereditable factors are involved in this disease. However, the rapid increase in the incidence of asthma over recent decades cannot be explained by genetic changes alone, but rather point to an important role for environmental factors. Therefore, it is likely that the development of asthma requires the involvement of environmental stimuli acting on genetically susceptible individuals. In the search for markers of genetic susceptibility to asthma, the ADAM-33 (a disintegrin and a metalloproteinase-33) gene has been found to be associated with asthma, and in particular, bronchial hyperresponsiveness [2].

## Molecular and Systemic Pathophysiology

Damage to the bronchial epithelium is observed, with focal shedding of columnar cells (Fig. 1).

This epithelial damage leads to the release of mitogenic cytokines that produce tissue remodeling, manifested as sub-epithelial fibrosis, increases in smooth muscle mass and goblet cell hyperplasia. The bronchial smooth muscle becomes populated by increased numbers of chymase-containing mast cells and the lamina reticularis is thickened. This last feature is pathognomonic for asthma and has been observed in children with asthma, suggesting that changes in airway structure occur at an early stage in the disease, perhaps even before the appearance of symptoms [3]. The airways of asthma patients contain an infiltrate of inflammatory leukocytes, particularly eosinophils and Th2 helper T cells, and in severe cases may be plugged by an excess of mucus. The recruitment of eosinophils



**Asthma. Figure 1** Cellular interactions in asthmatic bronchi.

and Th2 cells results from allergen-induced activation of airway-resident T-cells and mast cells, which also stimulate signaling in the epithelium and fibroblasts [2,3]. Activated eosinophils contribute to epithelial damage through the liberation of reactive oxygen species and cytotoxic proteins. An apparent dysfunction of autoinhibitory $M_2$ muscarinic receptors in parasympathetic nerves, possibly also caused by eosinophil proteins, leads to increased acetylcholine release with consequently increased smooth muscle contraction, augmented by the increase in smooth muscle mass [2,4]. In allergic forms of the disease, elevated serum IgE levels correlate with the degree of bronchial hyperresponsiveness; this appears to reflect both increased IgE-dependent mast-cell activation and as yet uncharacterized effects on smooth muscle contractility [5].

### Diagnostic Principles

Episodes of wheezing, coughing, tightness of the chest or shortness of breath may occur. Bronchial provocation tests will reveal hyperresponsiveness to inhaled direct (histamine, methacholine) or indirect bronchoconstrictors (adenosine monophosphate). Untreated asthma patients are likely to show appreciable diurnal variability in lung function as determined by measurement of the forced expiratory volume in one second ($FEV_1$) or peak expiratory flow rate (PEFR). The lung function of patients with asthma should improve following inhalation of bronchodilators or on completion of a short course of corticosteroids.

### Therapeutic Principles

Bronchoconstriction in an asthma attack can be relieved by short-term relaxation of bronchial smooth muscle *via* activation of $\beta_2$-adrenoceptors, and can be prevented by long-term activation of $\beta_2$-receptors or, to a lesser extent, by antagonism of specific receptors for endogenous bronchoconstrictors (e.g., acetylcholine, cysteinyl leukotrienes). Nocturnal asthma attacks are particularly susceptible to inhibition by long-acting $\beta_2$-agonists. Chronic airway inflammation can be suppressed by the use of inhaled – or, during periods of severe disease, oral – corticosteroids, leading to reduced frequency and severity of attacks. Methylxanthines are weak bronchodilators but may provide some benefit given prophylactically. Cromones exert some anti-inflammatory actions that can give effective prophylaxis of mild asthma in children.

## Ataxia due to Vitamin E Deficiency

Alfried Kohlschütter
Department of Pediatrics, University Medical Center Hamburg-Eppendorf, Hamburg, Germany

### Synonyms

AVED; Familial isolated deficiency of vitamin E; Tocopherol transfer protein deficiency

### Definition and Characteristics

Familial ataxia due to vitamin E deficiency (AVED), (MIM 277460) is an autosomal recessively inherited disorder characterized by the absence of a plasma protein specific for the transport of alpha-tocopherol (vitamin E). The condition is associated with a progressive neurological disorder (mainly presenting as spinocerebellar ataxia and neuromyopathy, closely resembling ►Friedreich ataxia) which is caused by the degeneration of tissues that are highly dependent on an adequate tocopherol supply.

### Prevalence

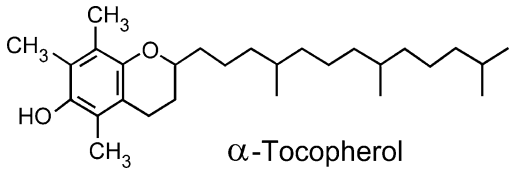
A rare or insufficiently recognized disorder. Most reported cases were from Germany, North Africa, and Italy [1–3].

### Genes

The disease is caused by mutations in the tocopherol transfer protein (TTP) gene on chromosome 8q13.1–q13.3 [2,3]. The exclusion of a TTP gene mutation in one case suggests the existence of a second gene defect causing AVED.

### Molecular and Systemic Pathophysiology

Patients with TTP deficiency do not have intestinal disease and have normal plasma lipoproteins. They



**Ataxia due to Vitamin E Deficiency.**
**Figure 1** Chemical structure of vitamin E.

are, however, unable to transport vitamin E, the major lipid-soluble antioxidant in vivo (Fig. 1) to their tissues and develop a neurological disease due to the degeneration of membranes within the nervous system that are specifically dependent on vitamin E.

The resulting condition [4] is similar to that seen in cases of abetalipoproteinemia and nutritional vitamin E deficiency and is caused by a "dying-back" axonal neuropathy, which predominantly involves the centrally directed fibers of sensory neurons, with the large-caliber myelinated fibers being particularly affected. It is assumed that the primary abnormality is a degeneration of the axons, which then results in a secondary demyelination and that lipid peroxidation of neuronal membranes, as a consequence of a deficient anti-oxidant protection, is part of the mechanisms involved. The primary clinical manifestations include spinocerebellar ataxia, skeletal myopathy, and retinopathy. Other common symptoms are diminished proprioception, loss of vibratory sensation, and ophthalmoplegia.

## Diagnostic Principles

The diagnosis is based on a neurological picture suggestive of Friedreich ataxia and the demonstration of very low plasma levels of vitamin E in the absence of a significant nutritional disorder and the presence of normal plasma lipoproteins.

## Therapeutic Principles

Although the patients lack the specific transport protein for vitamin E in their blood, neurological progression can be halted by large amounts of vitamin E supplements. Under these conditions vitamin E is transported non-specifically within plasma lipoproteins. Plasma vitamin E levels should be brought into the normal range and monitored, as the right dosage has to be titrated and even a short discontinuation of supplements leads to rapid loss of vitamin E from the circulation. The first AVED patient discovered [1] and treated by the author for over 20 years has not shown any further neurological progression while under massive vitamin E supplements. Several studies have documented the efficacy of such supplements to prevent disease progression [5].

# Ataxia, Episodic

►Episodic Ataxia Type 1 and Type 2

# Ataxia Friedreich

►Friedreich's Ataxia

# Ataxia Telangiectasia

THOMAS KLOCKGETHER
Department of Neurology, University Hospital Bonn, Bonn, Germany

## Synonyms

Louis-Bar syndrome

## Definition and Characteristics

Ataxia telangiectasia (AT) usually begins in early childhood. It is clinically characterized by a combination of neurological and non-neurological symptoms. Cerebellar ataxia is the clinical hallmark of AT. In addition, many patients have choreoathetosis and

dystonia. Muscle reflexes are usually weak or absent. AT patients have a peculiar difficulty in initiating saccades (oculomotor apraxia). Telangiectasias are the second hallmark of AT. They develop after the onset of ataxia and are most frequently found in the lateral angles of the conjunctivae and the external earlobes. Approximately 60% of AT patients have immunodeficiency. The most frequent clinical manifestations are recurrent sinopulmonary infections. AT patients have a considerably increased risk of malignancies. Overall, one third of AT patients develop a malignant disease during their lives. Before the age of 20 years, malignancies are mainly lymphoid. In older patients, solid tumors are more frequent. Increased radiosensitivity is a typical feature of AT.

## Prevalence

According to an Italian epidemiological study the prevalence is 1.2:100,000.

## Genes

AT is an autosomal recessively inherited disorder caused by mutations in the ATM gene. More than 200 distinct mutations distributed over the entire gene have been reported.

## Molecular and Systemic Pathophysiology

ATM acts specifically in the cellular response to ionizing radiation and DNA damage. The ATM protein is a kinase phosphorylating more than eight different substrates and thereby setting in motion several different signal transduction pathways that result in at least three distinct cell cycle checkpoints. As a consequence of reduced ATM activity, DNA repair is severely impaired. While these abnormalities provide clues for the understanding of the abnormal radiosensitivity and malignancies, the cellular mechanisms underlying neurodegeneration are not well understood.

## Diagnostic Principles

A diagnosis of AT is probable in patients with a typical clinical phenotype and elevated serum levels of α-fetoprotein. In vitro demonstration of radiosensitivity of lymphocytes is used as a laboratory test to confirm the diagnosis. Genetic testing is not routinely offered due to the diversity of mutations causing AT.

## Therapeutic Principles

There is no effective treatment for the neurological disturbances of AT. Treatment of infections should be initiated early and maintained over prolonged time. Administration of immunoglobulins can be considered in patients with repeated infections. Treatment of malignant neoplasias is a particular problem because AT patients have increased sensitivity to radiation and chemotherapy. Therefore, conventional radiotherapy should be avoided and chemotherapy should be administered only on an individual basis.

# Ataxias, Spinocerebellar

Thomas Klockgether
Department of Neurology, University Hospital Bonn, Bonn, Germany

## Synonyms

Autosomal dominant cerebellar ataxia; ADCA; Dominant ataxia; Dominant olivo-ponto-cerebellar atrophy; dOPCA; Menzel's ataxia; Marie's ataxia; SCA

## Definition and Characteristics

The spinocerebellar ataxias (SCA) comprise a group of dominantly inherited progressive ataxia disorders. Up to now, more than 25 different gene loci (SCA1-28) have been found in association with SCA. Neurodegeneration is mainly found in the cerebellum, brainstem and spinal cord, but other parts of the central and peripheral nervous system may be involved. The most common SCA disorders, SCA1-3, usually present with progressive ataxia accompanied by a variety of additional neurological symptoms with an onset of ataxia between 30 and 40 years. This group of disorders was previously named autosomal dominant cerebellar ataxia type I (ADCA-I). Only a few disorders, formerly named ADCA-III, are characterized by an almost purely cerebellar syndrome and isolated degeneration of the cerebellar cortex. The most frequent disorder of this group is SCA6. Age of onset in SCA6 is later than in SCA1-3 and varies between 30 and 75 years. SCA7 (or ADCA-II) has the unique feature of cerebellar ataxia combined with retinal degeneration [1].

## Prevalence

In a recent epidemiological study, the prevalence of SCA in the Dutch population was estimated to be 3.0:100,000. The prevalence may vary considerably from region to region due to founder effects.

## Molecular and Systemic Pathophysiology

In 13 SCA disorders (SCA1-3,5–8,10,12–14,17,27), the causative mutations have been identified. In six of them (SCA1-3, 6,7,17), the mutation is a translated CAG repeat expansion coding for an elongated polyglutamine tract within the respective proteins. These disorders belong to a larger group of polyglutamine disorders that also includes Huntington's disease and spinobulbar muscular atrophy. It is assumed that the polyglutamine disorders share important pathogenetic features including intracellular aggregation of polyglutamine-containing proteins resulting in dysregulation of essential cellular functions such as transcription [2,3].

In other SCA disorders, repeat expansions are found in the 5′ untranslated region (SCA12), in an intron (SCA10) and in the 3′ untranslated region (SCA8). SCA5 is due to mutations of the gene encoding beta-III spectrin [4], SCA14 is due to a missense mutation in the gene coding for protein kinase C γ and SCA27 is caused by a point mutation in the FGF14 gene encoding a fibroblast growth factor.

## Diagnostic Principles

A diagnosis of SCA is suspected in patients with otherwise unexplained progressive ataxia and a family history compatible with autosomal dominant inheritance. A definite diagnosis can be made by genetic tests in those disorders, in which the causative mutation is known. Genetic tests for the most common SCA disorders, SCA1-3,6 are widely available.

## Therapeutic Principles

To date, there are no rational treatment approaches for SCA. Patients should receive physiotherapy and speech therapy.

# Ataxias, Sporadic

Thomas Klockgether
Department of Neurology, University Hospital Bonn, Bonn, Germany

## Synonyms

Idiopathic cerebellar ataxia; IDCA

## Definition and Characteristics

The sporadic ataxias are a heterogeneous group of adult-onset ataxia disorders that have a defined acquired cause (acquired or symptomatic sporadic ataxias) or occur without a discernible cause (sporadic ataxia of unknown etiology, SAOA) [1]. The latter category has been recently defined and distinguished from multiple system atrophy (MSA). The major categories of acquired ataxias are alcoholic cerebellar degeneration (ACD) [2] and paraneoplastic cerebellar degeneration (PCD) [3]. Sporadic ataxias are characterized by progressive cerebellar ataxia without major accompanying symptoms. Disease severity and progression rate are variable and partly depend on the underlying cause. In contrast to SAOA, which usually starts insidiously, ACD and PCD may have a subacute onset.

## Prevalence

A recent population-based study of SAOA found a prevalence rate of 9.4:100,000. Prevalence rates of ACD and PCD are unknown.

## Molecular and Systemic Pathophysiology

The etiology and pathogenesis of SAOA are unknown.

ADC is due to the toxic action of alcohol and its degradation product acetaldehyde on cerebellar Purkinje neurons. In addition, a nutritional deficiency in vitamin B1 (thiamine) strongly contributes to the development of this disorder.

PCD degeneration is an immune-mediated disorder occurring in patients with malignant tumors, mainly small cell lung and breast cancer as well as malignant lymphomas. Many PCD patients have circulating anti-neuronal antibodies. However, these antibodies do not cause PCD. Instead, PCD is caused by a T-cell-mediated immune attack directed against cerebellar Purkinje neurons.

## Diagnostic Principles

SAOA is diagnosed by exclusion of MSA and acquired as well as genetic causes of ataxia.

ACD is diagnosed by history and the typical clinical presentation of alcoholic patients.

A definite diagnosis of PCD can only be made by demonstration of an underlying malignant tumor. Screening for antineuronal antibodies alone is not sufficient, since PCD may occur in the absence of antineuronal antibodies.

## Therapeutic Principles

SAOA is an untreatable condition. As in other ataxias, physiotherapy and speech therapy may be helpful.

A diagnosis of ACD should prompt immediate administration of vitamin B1 (thiamine). Alcohol intake should be completely and lastingly stopped.

In PCD, the underlying tumor should be treated. In most cases, this does not improve ataxia.

# Atelectasis

Eleanor M. Summerhill[1,2],
F. Dennis McCool[1,2]
[1]Warren Alpert Medical School at Brown University, Providence, RI, USA
[2]Pulmonary Critical Care Medicine, Memorial Hospital of Rhode Island, Pawtucket, RI, USA

## Synonyms

Collapsed lung

## Definition and Characteristics

Atelectasis is a condition in which the volume of the lung is diminished. Causes of atelectasis can be categorized as either obstructive or non-obstructive. Obstructive atelectasis results from airway occlusion of either large or small airways. Over time, gas distal to the obstruction is resorbed, causing alveolar collapse. Obstruction may be due to tumor, foreign body aspiration, inflammatory processes, or mucous impaction. By contrast, non-obstructive atelectasis refers to a loss of lung volume caused by (i) external compression of the lung by space-occupying lesions, (ii) infiltrative lung disease, or (iii) surfactant dysfunction. Adhesive atelectasis is caused by loss or dysfunction of surfactant [1]. The disease results primarily from surfactant deficiencies in respiratory distress syndrome of the preterm infant (RDS) and from acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) in the adult.

## Prevalence

There are ~150,000 cases of (ARDS) per year in the United States according to the NHLBI ARDS Act study. RDS affected ~24,000 infants in the United States in 2003 according to the National Vital Statistics Reports. Atelectasis is a characteristic feature of both of these disorders.

## Genes

There are currently three recognized genetic forms of surfactant deficiency, caused by mutations in the SP-B, SP-C, and ABCA3 genes. SP-B deficiency, with an autosomal recessive inheritance pattern, is most commonly caused by a frameshift mutation in codon 121 of SP-B gene (SFTPB), located on chromosome 2. SP-B deficiency results in rapidly progressive respiratory failure that is ultimately fatal. Exogenous surfactant does not alter the course of disease, with lung transplantation being the only effective treatment option. The clinical severity of SP-C deficiency is more variable. SP-C deficiency is caused by mutations in the SP-C gene (SFTPC) on chromosome 8 which result in a misfolded protein. The inheritance pattern is autosomal dominant, with incomplete penetrance. SP-C deficiency has been associated with familial forms of ILD, with age of onset in the neonatal period to the sixth decade of life. ABCA3 is a transmembrane protein located on lamellar bodies within the type II cell. The ABCA3 gene is located on chromosome 16. Infants with ABCA3 deficiency are severely surfactant deficient, with a clinical course similar to SP-B deficiency. It is thought that ABCA3 is most likely involved in the transport of surfactant lipids into the lamellar bodies [2].

## Molecular and Systemic Pathophysiology

Elasticity is a property of the lung that causes it to return to its resting shape after deformation by an external force during inspiration. Elastic tensions in the lung are borne mainly by two components, (i) the fibrous network of collagen and elastin that supports the alveolar septa, airways, and pleura, and (ii) the

air-liquid interface within the alveolus. The normal alveolus is lined with a thin layer of liquid. Surface tension is created by the interaction of molecules at the interface between this thin layer of liquid and alveolar air. The two forces are additive.

Due to the presence of surface active agents, or surfactants, the surface tension of the alveolar fluid is less than that of water alone. By lowering surface tension in the alveoli, lung elastance is decreased and the work of breathing reduced. Surfactant is especially important at low lung volumes where the decrease in surface tension prevents alveolar collapse thereby maintaining alveolar and small airway stability. It also prevents fluid from being drawn into the airspaces from the interstitium [3]. The absence of surfactant contributes to alveolar instability and subsequent atelectasis.

Pulmonary surfactant consists of ~90% phospholipids and 10% surfactant-associated proteins. Phosphatidylcholine (PC), is the predominant phospholipid, of which dipalmitoylphosphatidylcholine (DPPC) forms the largest component. This molecule has been shown to be primarily responsible for the surface tension lowering properties of surfactant. The hydrophobic components of the phospholipid adhere to the alveolar wall and the hydrophilic components disrupt water molecules in the lining fluid; thereby reducing the interactions among water molecules and decreasing surface tension. The other lipids in surfactant include unsaturated phospholipids and cholesterol. These facilitate spreading of the surface film as the lung expands during inspiration. There are four surfactant-associated proteins, SP-A, SP-B, SP-C and SP-D. Two hydrophobic proteins, SP-B and SP-C, work in concert with phospholipids to modify surface tension. Hydrophilic SP-A and SP-D play an important role in the host defense and immune functions of the lung.

Surfactant is synthesized by type II alveolar cells, stored intracellularly within lamellar bodies, and excreted via exocytosis. The hydrophobic SP-B and SP-C are assembled and secreted along with the phospolipid components of surfactant. Synthesis of the hydrophilic proteins occurs via separate pathways. Tubular myelin is a cross-hatched complex of lipid and protein formed following exocytosis of the lamellar bodies into the alveolar lining fluid. Individual lipids then separate from the tubular myelin to form the functional surfactant film [3]. The regulation of surfactant synthesis in the developing lung is complex and is affected by a number of hormones, growth factors, and cytokines [4]. The study of a number of these substances, including glucocorticoids, retinoic acid, keratinocyte growth factor, Vitamin D (1α, 25-dihydroxyvitamin $D_3$), triodothyronine, thyrotropin releasing hormone, prolactin, catecholamine agonists, ATP, and prostaglandins, has produced some insight into the regulation of surfactant associated protein gene expression.

## Diagnostic Principles

The incidence of RDS is inversely proportional to gestational age. Over 75% of infants born at less than 30 weeks gestation will develop RDS [4]. RDS is diagnosed in the appropriate setting based upon oxygen requirement, physical examination, and chest radiograph. An inheritable form of surfactant deficiency should be suspected when a full-term infant presents with the clinical and radiologic findings of RDS. A positive family history is helpful as well. The diagnosis of ALI/ARDS is made based upon physical examination, chest radiograph showing bilateral airspace filling disease, and the presence of severe hypoxemia, with $PaO_2/FiO_2$ ratios of ≤300 for ALI and ≤ for ARDS.

## Therapeutic Principles

Glucocorticoid therapy given prior to birth may enhance surfactant activity and be helpful in preventing RDS when premature delivery is known to be imminent. Prophylactic surfactant treatment is also given to the high-risk premature neonate. Treatment of RDS consists of the instillation of surfactant preparations containing both phospholipids and surfactant proteins SP-B and SP-C into the trachea of premature infants. Treatment has been shown to significantly reduce the rate of mortality and severity of respiratory complications [3,4]. Inherited SP-B deficiency is rapidly fatal, and mortality is not improved by exogenous surfactant therapy. The only known effective treatment is lung transplantation. ABCA3 deficiency appears to be largely fatal as well [2]. Exogenous surfactant therapy in ALI/ARDS has thus far met with disappointing results in clinical trials [3]. The mainstay of care remains supportive with low tidal volume ventilation. The use of positive end-expiratory pressure (PEEP) may be useful in alveolar recruitment and prevention of atelectasis in the setting of both RDS and ARDS.

# Atheroembolism

Rita L. McGill, Mayumi Endo
Department of Medicine, Teine Keijinkai Hospital, Teine, Sapporo, Japan

## Synonyms

Cholesterol crystal embolism; Shaggy aorta syndrome; Cholesterol embolism

## Definition and Characteristics

Atheroembolism is a complication of systemic atherosclerosis with renal impairment, skin manifestations, and diffuse microinfarctions in the head and abdomen. Recurrent salvos of cholesterol crystal microemboli originate from ulcerated atheromatous plaque, usually in the aorta. Bombardment of small arterioles with crystal emboli causes characteristic lesions, which may manifest as catastrophic events, slow deterioration, or chronic asymptomatic impairment. Embolic events often occur after plaques are destabilized by mechanical means, such as surgery and catheter-based endovascular treatments, or medical therapies such as anticoagulation or thrombolysis [1–3].

## Prevalence

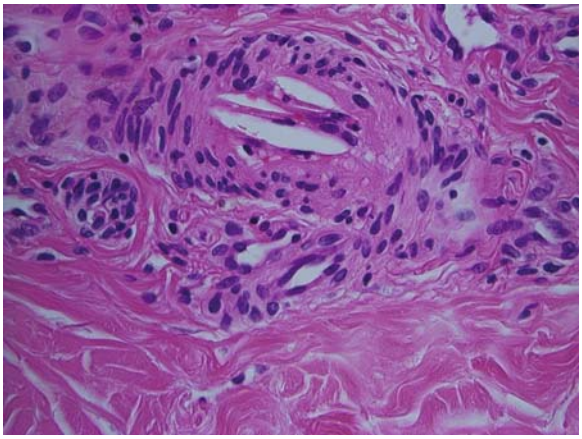
The true prevalence of atheroembolism is difficult to assess, as embolization may be asymptomatic and undetected despite substantial renal impairment. Patients with clinical symptoms represent only a small subset of patients with the most catastrophic forms of the disease. The variable time course of atheroembolization also complicates diagnosis. Patients may present with acute embolic crises, sub-acute deterioration, or asymptomatic chronic kidney disease.

Atheroemboli are found in <3% of unselected autopsies, but more frequently in autopsies of patients with severe aortic atherosclerosis. Renal atheroemboli have been found in ~ 5% of biopsies in elderly patients.

Risk factors for atheroembolic events mirror those of complex aortic atheromata, including age, male sex, tobacco, hyperlipidemia, and pre-existing atherosclerosis. The 'typical' patient is an elderly white hypertensive male smoker, who has vascular disease.

## Molecular and Systemic Pathophysiology

The sina qua non of atheroembolism is the exposure of friable material from an eroded atherosclerotic plaque. Resultant microemboli are distributed in proportion to blood flow, and lodge in small (150–200 μm) arterioles. The kidney, which receives 20–25% of aortic output, is targeted frequently and severely. Arterioles in the retinas, the central nervous system, and the gastrointestinal tract are also commonly affected, resulting in Hollenhorst plaques, cerebrovascular symptoms, and bowel ischemia.



**Atheroembolism. Figure 1** Skin biopsy showing cholesterol clefts surrounded by a giant cell reaction (Hematoxylin-eosin stain).

Impaction of cholesterol crystals is irreversible, as the body has no mechanism for phagocytizing or dissolving them. These intractable foreign bodies provoke secondary inflammation, attracting mononuclear infiltrates which transform into giant cell reactions and granulomata (Fig. 1). Local inflammatory processes lead to intimal proliferation and fibrosis which causes stenosis or occlusion of the arteriole. The symptoms of atheroembolic disease are due to ischemia in the territories served by the affected vessels.

Given this mechanism, inciting factors for atheroembolic events can be readily predicted. Mechanical manipulation of the aorta during surgical or catheter-based interventions exposes freshly traumatized atheroma to the circulation. The potential for anticoagulation or thrombolysis to disrupt a stabilizing thrombus atop an ulcerated plaque is also intuitively evident.

## Diagnostic Principles

This diagnosis is made primarily on clinical grounds, as there are no pathognomonic laboratory findings. Atheroembolism should be suspected in patients at risk for advanced atherosclerosis, who have the triad of: inciting event (anticoagulation, or manipulation of the aorta by scalpel or catheter), renal failure, and stigmata of peripheral embolization. Retinal emboli can be seen on ophthalmoscopic examination. Typical skin manifestations include toe lesions and livedo reticularis.

Hyperlipidemia suggests the risk of atheroembolism. Common findings include increased urea nitrogen, creatinine, LDH, ESR and CRP, none of which are specific for this condition. Mild transient hypocomplementemia often occurs. Eosinophilia and eosinophiluria have been reported, with variable frequencies. The urinary

sediment can be bland or non-diagnostic, though non-nephrotic proteinuria and microhematuria are common.

Histological evaluation of affected tissues may confirm the diagnosis. Biopsy of typical ischemic or purpuric skin lesions is simple, non-invasive, and diagnostic in > 90% of cases. Renal tissue is more difficult to obtain, and patchy involvement of small arterioles can lead to areas of misleadingly normal renal parenchyma. Atheroemboli have also been documented in biopsies of gastrointestinal tissue and lung. Affected arterioles have characteristic empty 'clefts' where the needle-shaped cholesterol crystals have been removed by tissue processing (Fig. 1). The birefringent crystals can be seen on frozen sections. Crystals are surrounded by occlusive inflammatory endothelial reactions, which can be distinguished from small-vessel vasculitis by negative testing for ANCA.

## Therapeutic Principles

No treatment modifies outcome after crystals have embolized, so therapy is directed at reducing the risk of further embolic showers. Procedural disruption of aortic plaque must be avoided, as well as anticoagulation and thrombolysis. These provocations may be difficult to avoid, if the initial atheroembolic insult requires dialysis support. Surgical approach of the aorta has potential for either prevention or provocation of recurrent embolization. Preliminary evidence suggests a protective effect of therapy with HMG-CoA-reductase inhibitors (statins), which may stabilize plaques by reduction of lipid levels or via the immunomodulatory properties of these drugs.

# Atherosclerosis

Rodolfo Paoletti, Andrea Cignarella
Department of Pharmacological Sciences, University of Milan, Milan, Italy

## Synonyms

Arteriosclerosis

## Definition and Characteristics

In most parts of the world, many people develop some degree of atherosclerosis or "hardening of the arteries" as they get older. Atherosclerosis is the result of an inflammatory response to oxidized apolipoprotein (Apo) B-containing lipoprotein, especially low-density lipoprotein cholesterol (LDL-C) [1]. However, only some of those affected with atherosclerosis develop the serious and often life-threatening complications of heart attack or stroke. In the arterial tree, these are the main cause of vascular occlusion with manifestations in different areas including coronary, cerebrovascular or peripheral vascular districts. Arterial thrombosis superimposed on atherosclerotic lesions is responsible for most fatal and nonfatal events worldwide.

## Prevalence

The prevalence of atherosclerosis is estimated to be approximately 1 in 58 or 1.7%. These estimates may have limited relevance to the actual prevalence of atherosclerosis in different countries.

## Genes

Atherosclerosis is a multifactorial disease involving circulating blood cells and the vessel wall. This makes it difficult to identify a single gene underlying the disease. A number of gene mutations and polymorphisms, however, are known to affect the risk for atherosclerotic cardiovascular disease. For instance, mutations in the LDL receptor (LDL-R) gene underlie a disease called familial hypercholesterolemia, whose prevalence in the heterozygous form is roughly one in 500 individuals. These patients have one-half the number of normal LDL-R and develop elevated plasma LDL-C levels because the liver removes cholesterol from the blood as LDL via LDL-R.

## Molecular and Systemic Pathophysiology

Atherosclerosis mainly affects large and medium-sized arteries, including the aorta, the carotid arteries, the coronary arteries and the arteries of the lower extremities. Atheroscerotic lesions or plaques develop within, rather than on, the arterial wall. The earliest lesion of atherosclerosis is called the fatty streak, which is common even in infants and young children. The fatty streak is a pure inflammatory lesion, consisting only of monocyte-derived macrophages and T lymphocytes [2]. In patients with hypercholesterolemia, this influx of cells is preceded by lipid deposition. Up to a few years ago, it was thought that the more severe the extent of vascular stenosis, the more was heart attack and stroke likely to occur. However, more recent research indicates that this is not always the case. Rather, heart attack and stroke are likely to happen to people who have patches of atherosclerosis of only

moderate extent. These unstable lesions are rich in cells, indicating a high level of metabolic activity, and contain a cholesterol-rich core that is separated from the blood stream only by a thin fibrous cap. Recent research indicates that minor injuries and tears in the lining of the arteries occur all the time but most of them do not cause serious problems. If a complete tear of the thin fibrous cap occurs, however, the contents of the culprit lesion are spilled into the bloodstream and the underlying tissue is exposed to the circulating blood. Like any wound, this exposure of tissue activates the clotting system so that a clot or thrombus forms at the site of the lesion. This clot blocks off the affected blood vessel, most commonly an artery in the heart or the brain, so that the tissue supplied by that blood vessel is deprived of oxygen and dies. This death of tissue is what we call heart attack or stroke.

### Diagnostic Principles

In people who do not have any symptoms and have not been diagnosed with cardiovascular disease, it is not easy to foresee if arteries are developing atherosclerotic lesions or plaques. However, in those people who have high blood cholesterol, are overweight and get little exercise, smoke, or have other risk factors, the odds increase of having atherosclerosis.

There are a number of tests used in diagnosing cardiovascular diseases, including blood tests, electrocardiograms, stress testing, coronary angiography, ultrasound, and computer tomography. These tests are advisable in people at high risk for cardiovascular disease.

### Therapeutic Principles

Global risk assessment is essential to identify the patients who will most benefit from risk-factor modification. The primary target of therapy is control of plasma LDL-C levels via lifestyle changes and drug treatment. Therapeutic lifestyle changes include a multifaceted nonpharmacologic approach to reduce the risk for atherosclerotic cardiovascular disease essentially comprising reduced dietary intake of saturated fat and cholesterol, weight reduction and increased physical activity. The primary drugs for the treatment of dyslipidemia are statins, which have been shown to reduce atherosclerotic cardiovascular events in patients at moderate to high risk [3]. Statins may be of particular benefit because they have anti-inflammatory properties in addition to their cholesterol-lowering action. Other drugs include fibrates, niacin, bile acid sequestrants and ezetimibe. These drugs work with different mechanisms of action but ultimately all of them reduce plasma lipid levels. Combination therapy with low doses of individual agents has the potential to reduce adverse effects and may be of use in selected groups of patients. Emerging protein biopharmaceuticals provide vascular benefits beyond those of hypolipidemic drugs [4].

## ATLL

►T-Cell Leukemia/Lymphoma, Adult

## Atopic Dermatitis

Randolf Brehler
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Atopic eczema; Endogenous eczema

### Definition and Characteristics

Chronic, highly pruritic, recurring inflammatory skin disease with various stages and different types of skin lesions. Acute AD is characterized by intensely pruritic, erythematous papules over erythematous skin with extensive excoriations, erosions, and serous exudates. Subacute dermatitis is associated with erythematous, excoriated, scaling papules and chronic dermatitis with thickened skin, lichenification, and fibrotic papules. Lesions predominantly occur in the flexural folds of the extremities.

At least two types of AD have been postulated: an extrinsic type that is associated with elevated serum IgE

levels, IgE-mediated sensitization to aeroallergens, and a history of atopic diseases accounting for ~70% of the patients, and an intrinsic type without these characteristics accounting for ~30% of patients.

### Prevalence

The prevalence of AD varies for different countries and was raised during the last decades. The live time incidence in children is estimated to be 10–20%; the prevalence in adults is in the range between 1 and 3%.

### Genes

AD is a genetically complex, familially transmitted disease. Several genes responsible for skin barrier function and the expression of various cytokines, chemokines and their receptors are discussed to be involved in the development of atopic dermatitis. Of special interest is chromosome 5q31–33 since it contains a clustered family of Th2 cytokine genes.

### Molecular and Systemic Pathophysiology

A lipid deficiency with a decreased ceramide production and a disruption of the skin barrier function, increasing the permeability to environmental irritants and allergens and increasing the transepidermal water loss are important factors in the pathogenesis of AD.

The pattern of immune effector cells and the cytokine expression is biphasic in AD. In the acute phase of AD, significantly more inflammatory cells express mRNA of the interleukins 4, 5, and 13; however, acute AD does not contain significant numbers of expressing mRNA of IFN-γ or interleukin 12. In chronic skin lesions, significantly fewer cells express mRNA of IL-4 and IL-13, but increased numbers of cells express mRNA of IL-5, GM-CSF, IL-12, and IFN-γ than do those of acute atopic dermatitis.

In this concept of extrinsic AD, the initiation of the skin inflammation is driven by allergen-induced activation of TH2 cells and switches in the chronic phase to a TH1-type response driven by the infiltration with IL-12 expressing eosinophils and macrophages, which accompanies the initial TH2 response. The cause initiating the skin inflammation of intrinsic AD is still under investigation, here autoimmune phenomena are discussed.

ASD

A

## Definition and Characteristics

Atrial septal defect (ASD) is a congenital heart defect (CHD) characterized by left-to-right shunting through the atrial septum and increased right ventricular overload.

Defects of the atrial septum include various anatomic types and different embryological origin:

1. "Ostium secundum type" is the most common defect (80%). It is localized at the central part of atrial septum and involves the foramen ovalis. It may be singular or can consist of multiple fenestrations. In agreement with the pathogenetic classification by Clark, this type of ASD is listed among the abnormal intracardiac blood flow defects. In 10% of the cases ASD is associated with other CHDs.
2. "Patent foramen ovale" is the result of a failure of fusion between atrial septum primum and septum secundum. This is not a true defect, since the higher pressure inside the left atrium closing the valve of the foramen ovale avoids the left-to-right shunt.
3. The "sinus venosus type" ASD can occur either high up in the atrial septum (superior sinus venosus defects), or, less commonly, low down in the atrial septum astride the entry of the inferior caval vein into the right atrium. Superior sinus venosus defect is frequently associated with anomalous drainage of the right superior pulmonary vein into the right atrium. It is pathogenetically included in the group of abnormal targeted growth defects.
4. "Ostium primum" ASD consists in a communication in the lower part of the septum often involving mitral valve anomalies (cleft). This anatomic variant is characteristic of the partial form of atrioventricular canal defect (or atrioventricular septal defect), and can be considered in the pathogenetic group of the extracellular matrix abnormalities.
5. The absence of the entire atrial septum is known as "common atrium," and can be associated with cardiac abnormalities of the situs and looping.

## Prevalence

The prevalence of ASD is about 1 in 1,000 livebirths and 8% of all CHDs. Females are more frequently affected than males (M:F 1: 2). ASD is associated with extracardiac malformations in 25% of the cases.

## Genes

Genes implicated in ASD include

*NKX2.5*: Heterozygous mutations in NKX2.5 (5q34) encoding a homeobox transcription factor [1].

*GATA4*: Heterozygous mutations in GATA4 (8p23.1) encoding a zinc finger transcription factor [1,2].

*MYH6*: Heterozygous mutations in MYH6 (14q12) encoding a structural protein [3].

*TBX5*: Heterozygous mutations in TBX5 (12q24.1) encoding a T-box transcription factor [4].

*PTPN11*: Heterozygous mutations in PTPN11 (12q22) encoding the protein tyrosine phosphatase SHP-2 [5].

*SOS1*: Heterozygous mutations in SOS1 (2p21) encoding a RAS-specific guanine nucleotide exchange factor.

## Molecular and Systemic Pathophysiology

Familial nonsyndromic ASD: Genetic factors play a role in causing nonsyndromic ASD, particularly in families segregating concordant CHD with autosomal dominant inheritance. Heterozygous mutations in three genes, NKX2.5 [1], GATA4 [1,2], and MYH6 [3] have been identified in a subset of familial ostium secundum ASD. NKX2.5 is known to cause ASD with atrioventricular conduction abnormalities, while GATA4 mutations are associated with ASD and pulmonary stenosis (Table 1). MYH6 mutation has been detected in a large family segregating autosomal dominant ASD ostium secundum type.

The NKX2.5 gene is important for regulation of septation during cardiac morphogenesis and plays a central role in the determination of myocardial cell fate. Additionally, it is involved in the maturation and maintenance of atrioventricular node function throughout life.

The GATA4 gene is expressed during cardiogenesis in the atrial and ventricular myocardia, endocardium, endocardial cushions, and outflow tract.

The MYH6 gene is highly expressed in the developing atria, and its expression is regulated by TBX5, the gene causing Holt–Oram syndrome. TBX5 mutations not only reduce MYH6 expression, but also disrupt the interactions with GATA4 and NKX2.5. In addition, GATA4 mutants causing ASD decrease MYH6 transactivation. On the whole, it seems that all these genes form a transcriptional complex necessary for atrial septation.

A multifactorial mechanism of inheritance, due to genetic-environmental interaction, could be involved in cases without identifiable mutations in known genes.

Syndromic ASD: Genetic syndromes associated with ASD include Holt–Oram syndrome due to TBX5 mutations [4], Noonan syndrome due to PTPN11 and SOS1 mutations [5], and Down syndrome (Table 1).

TBX5 is a member of the large T-box transcription factor family, and may contribute to cardiogenesis by regulating cell proliferation in specific cardiac domains. It interacts with NKX2.5, GATA4, and MYH6 genes.

PTPN11 and SOS1 genes cause Noonan syndrome, dysregulating the RAS-MAPK pathway.

## Diagnostic Principles

Patients with nonsyndromic ostium secundum ASD with conduction defects may be screened for mutations in the NKX2.5 gene, while the GATA4 gene is a candidate in patients with nonsyndromic ostium secundum ASD with pulmonary stenosis.

**Atrial Septal Defect. Table 1** Genetic conditions associated with atrial septal defect (ASD) ostium secundum type

| Condition | Cardiac characteristics | Genetic defect | Chromosome location | References |
|---|---|---|---|---|
| Isolated/Familial | | | | |
| Familial ASD | ASD ostium secundum ± atrioventricular conduction abnormalities | NKX2.5 gene mutations | 5q34 | [1] |
| | ASD ostium secundum ±– pulmonary stenosis | GATA4 gene mutations | 8p23.1 | [1,2] |
| | ASD ostium secundum | *MYH6* gene mutations | 14q12 | [3] |
| Syndromic ASD | | | | |
| Holt-Oram syndrome | ASD ostium secundum | TBX5 gene mutations | 12q24.1 | [4] |
| Noonan syndrome | ASD ostium secundum ± pulmonary stenosis | PTPN11 gene mutations | 12q22 | [5] |
| | | SOS1 gene mutations | 2p21 | |
| Down syndrome | ASD ostium secundum | Trisomy 21 | chromosome 21 | |

Mutations in the TBX5 gene may be searched in patients with ostium secundum ASD and skeletal anomalies in Holt-Oram syndrome.

Ostium secundum ASD associated with phenotypical features of Noonan syndrome can be screened for PTPN11 and SOS1 gene mutations.

## Therapeutic Principles

Management of ASD include surgery by primary or patch closure or, when the anatomy is permissive, percutaneous device closure.

►Intra-cardiac Shunts

# Atrial Tachycardia

Kurt C. Roberts-Thomson,
Jonathan M. Kalman
Department of Cardiology, Royal Melbourne Hospital, University of Melbourne, Melbourne, VIC, Australia

## Synonyms

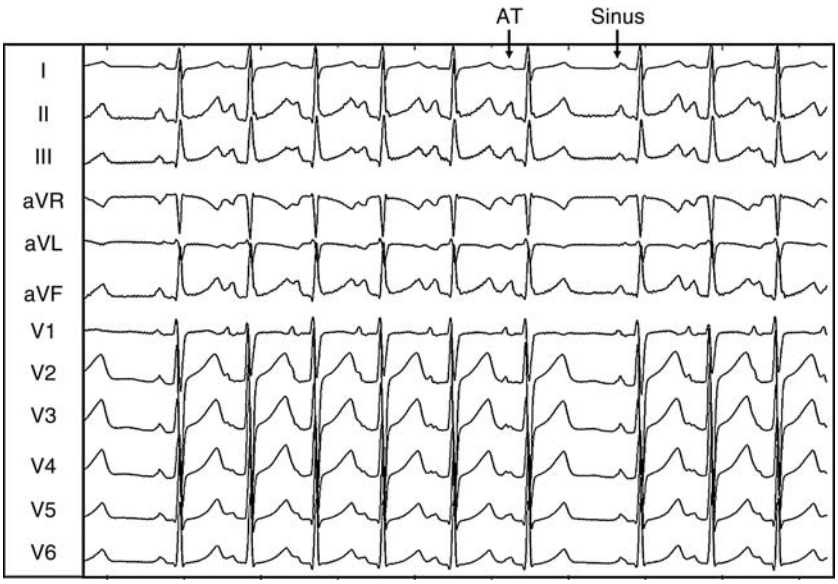
Focal atrial tachycardia

## Definition and Characteristics

Focal atrial tachycardia is an abnormal heart rhythm arising from a point source (focus) in the atria. It is usually manifest by atrial rates between 130 and 250 beats per minute. The P wave morphology is generally different to sinus rhythm but foci arising from the posterior right atrium, near the sinus node, may have morphology similar consistent with a sinus origin. The most common sites of origin include the crista terminalis, tricuspid annulus, coronary sinus ostium, and septum in the right atrium and the pulmonary veins and mitral annulus in the left atrium. Patients experience a variety of symptoms including palpitations, dizziness, chest pain, dyspnea, fatigue and syncope. Occasionally rapid atrial rates may cause a deterioration in left ventricular function.

## Prevalence

In asymptomatic young individuals the prevalence is 0.34%. In symptomatic individuals the prevalence is



**Atrial Tachycardia. Figure 1** Burst of atrial tachycardia arising from the crista terminalis in the posterior right atrium. Note the similarity to the sinus P wave and the variability in the QRS to P interval which is diagnostic of atrial tachycardia.

0.46% [1]. Atrial tachycardia accounts for 5–15% of adults undergoing electrophysiological studies for supraventricular tachycardia.

## Molecular and Systemic Pathophysiology

The three putative mechanisms of atrial tachycardia are abnormal automaticity, triggered activity, and microreentry. Abnormal automaticity occurs when myocardial fibers are depolarized to low membrane potentials. Triggered activity is due to early (EADs) or delayed (DADs) after depolarizations. DADs occur at high intracellular calcium levels and are due to spontaneous release of calcium from the sarcoplasmic reticulum. EADs usually occur in the setting of prolonged depolarization due to alterations in potassium or sodium currents. The mechanism of microreentry has not been fully elucidated however appears to be related to slow conduction around a small central obstacle [2]. Generally, atrial tachycardia arises from normal atrial myocardium but may also originate from regions of fibrosis, fatty infiltration and myopathic areas (Fig. 1).

## Diagnostic Principles

In the majority of cases, atrial tachycardia can be diagnosed from the electrocardiogram. A discrete P wave with an intervening isoelectric interval and a variable interval from R wave to P wave suggests atrial tachycardia. Automatic atrial tachycardias may manifest with recurrent self-limiting bursts of tachycardia. However, in some cases differentiation from other forms of supraventricular tachycardia may be difficult. The presence of upright P waves in the inferior leads excludes atrioventricular nodal reentant tachycardia but not atrioventricular reentry tachycardia. Ultimately, an electrophysiological study is required for a definitive diagnosis of focal atrial tachycardia.

## Therapeutic Principles

The efficacy of medical therapy is limited. Calcium channel blockers and beta-blockers are first line due to their low side effect profile. Flecainide, sotalol and amiodarone may be used subsequently. For patients with significant symptoms radiofrequency ablation is the treatment of choice.

## Definition and Characteristics

Atrioventricular (AV) block is a disturbance in conduction of sinus or atrial impulse through the specialized conducting system (AV node and bundle of His); it may be complete or incomplete. Incomplete AV block includes first-degree AV block (FAVB), second-degree AV block Mobitz Type I (MT1), and second-degree AV block Mobitz Type II (MTII). FVAB is characterized by prolongation of PR interval beyond 0.20 s in an adult, and beyond 0.18 s in children. MTI is characterized by progressive lengthening of successive PR interval till one sinus P is blocked, the PR interval immediately postblock returns to baseline interval, and the Wenckebach sequence begins again. As the PR intervals get longer, the RR intervals get shorter. There is a pause including the nonconducted P wave that is less than the sum of any two consecutively conducted beats. Group beating occurs when the RR intervals are irregular due to drop beats causing the QRS complexes to appear in clusters. MTII is characterized by constant PR intervals followed by sudden failure of a P wave to be conducted to the ventricles. The PP intervals remain constant and the pause including the blocked P wave equals two PP intervals. Third-degree AV block or complete AV block (CAVB) is characterized by complete or permanent obstruction to the conduction between the atria and the ventricles. Usually a faster supraventricular rhythm is completely dissociated from a slower ventricular rhythm, which may be either a slow idionodal, <45 b/m, or idioventricular, <35 b/m, escape rhythm. Individuals with FAVB are usually asymptomatic. Symptoms of dizziness or syncope, Stokes-Adams attack, fatigue, congestive heart failure, dyspnoea on exertion, angina, mental status change, and epilepsy can occur with acquired high grade or CAVB. MTI is generally benign and transient in acute inferior myocardial infarction and healthy athletes. On the other hand, MTII is usually seen with bundle branch block or associated with acute anterior myocardial infarction and carries a high risk of progression to advanced or complete heart block. The prognosis for patients with symptomatic CAVB is poor without pacemaker. Patients with congenital CAVB are generally asymptomatic and have a more favorable prognosis than patients with the acquired form when not associated with underlying heart disease. However, with time it congenital CAVB does carry a significant risk of syncope and sudden death especially when associated with concomitant structural heart disease [1].

## Prevalence

FAVB (pilots 0.52%, adults over 20 years of age 2%, adults > 60 years 5%, athletes 8.7%, adults > 60 years with heart disease 10%), second-degree AV block (SAVB) (young adults 0.003%, athletes 2.4%, patients with heart disease 2.7%), CAVB (congenital 0.007–0.004%, USA 0.02%, international 0.04%) [2].

## Molecular and Systemic Pathophysiology

The blood supply to the AV node is via the AV nodal artery, which is a branch of the right coronary artery in 90% of hearts with the remaining 10% arising from the circumflex artery. The His bundle has a dual blood supply from the branches of the anterior and posterior descending coronary arteries. Approximately 87% of FAVB is caused by delay within the AV node when the QRS complex is narrowed. When FAVB is associated with a bundle branch block, infraonodal conduction delay is present in 45% of these cases. MTI is almost always within the AV node when a narrow QRS complex is present. When MTI is associated with a bundle branch block, the block is still more likely to be in the AV node, but it can also be localized below the bundle of His when MTI is associated with bundle branch block or bifascicular block; the majority of the site of block is within or below the bundle of His. For FAVB, the level of the block may be at the AV node or the His-Purkinje system. FAVB with narrow conducted beats is

usually caused by block in the AV node. Features pointing toward block in the His-Purkinje system are conducted beats with bundle branch block and no improvement in block with atropine. Congenital CAVB within the AV node is characterized by narrow QRS complexes and with an escape rate between 40 and 60 b/m, which would increase with exercise or atropine. Acquired CAVB is usually associated with a block in the His-Purkinje system resulting in a wide complex with an escape rate between 20 and 40 b/m.

### Diagnostic Principles

ECG is the most important diagnostic tool. Carotid sinus massage increases vagal tone and worsens AV nodal block. Exercise or atropine improves AV nodal conduction because of sympathetic stimulation. In contrast, carotid sinus massage improves infranodal block whereas exercise and atropine worsen infranodal block because of the change in the rate of the impulses being conducted through the AV node. The electrophysiology study allows analysis of the His bundle electrogram and is the best definitive test to locate the site of the AV block.

### Therapeutic Principles

Pacing is the mainstay of treatment for symptomatic heart block [3]. Permanent pacing is usually recommended for asymptomatic patients with documented pause of greater than 3 s or a ventricular escape rhythm of less than 40 b/m [3]. Other situations where asymptomatic individuals are recommended to be paced include infranodal MTII and asymptomatic children with congenital heart block in association with a wide complex escape rhythm, complex congenital heart disease, ventricular dysfunction, or a long QT interval.

### Synonyms

Atrioventricular block; Heart block; Mobitz AV block; Wenckebach's AV block; Lev's disease; Lenegre disease; Lenegre-Lev syndrome; Wolff-Parkinson-White (WPW) syndrome; Preexcitation syndrome; Accessory atrioventricular pathways; (note: these synonyms do not necessarily describe the identical condition)

### Definition and Characteristics

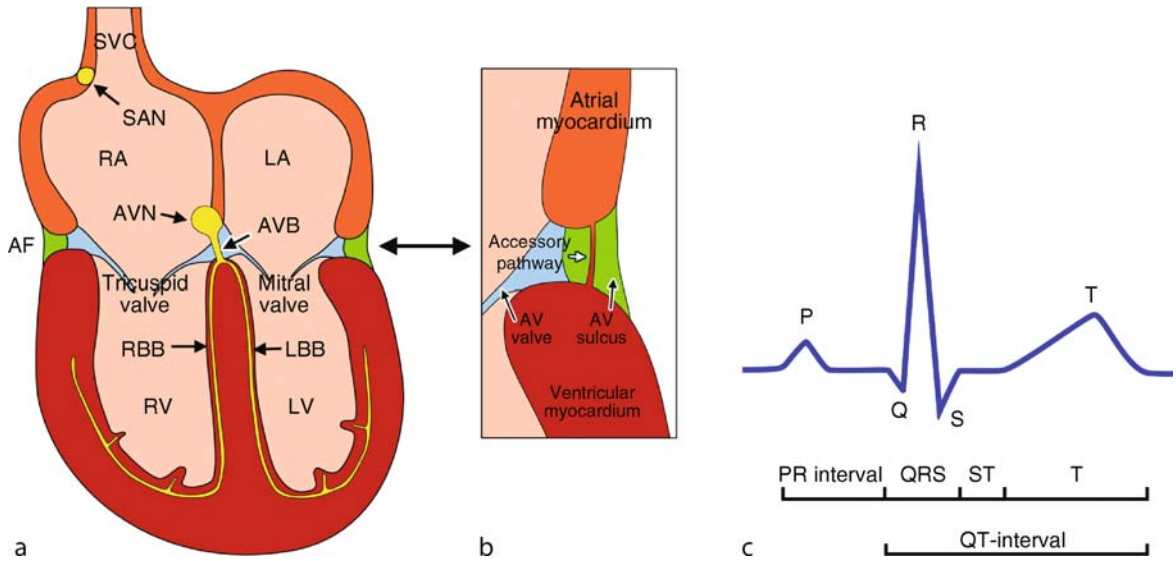
Atrioventricular (AV) conduction disturbances result from aberrant propagation of the cardiac conduction impulse through components of the AV junctional tissues and/or abnormal conduction through parts of the AV conduction system (Fig. 1a).

These disturbances lead to perturbation of the normal heart rate (tachycardias and bradycardias) and/or irregular heart beat (cardiac arrhythmias).

### Prevalence

First degree AV block is defined as prolongation of the interval between the onset of the P-wave and the onset of the QRS. It is usually asymptomatic and affects approximately 1% of young adults (>20 years), the prevalence increasing with advancing age. A significantly higher prevalence (~9%) is, however, seen in trained athletes. Second degree AV block is intermittent failure of atrial impulses to reach the ventricle and occurs in two forms, Mobitz Type I (also known as Wenckebach conduction) and Mobitz Type II. Mobitz type II is associated with risk of progression to complete heart block while Mobitz type I is generally benign. Complete heart block is defined as complete failure of atrioventricular conduction and is found in approximately 0.04% of adults [1], and while it can be temporary, it is potentially life-threatening and often requires implantation of a pacemaker.

Abnormal electrical connections may exist between the atria and ventricles and can form the anatomic substrate for arrhythmias. If abnormal ventricular



**Atrioventricular Conduction Disturbances. Figure 1** (a) This panel is a cartoon depicting the respective components of the cardiac conduction system in relation to other structures in the normal heart. Note that the atrial myocardium (*orange*) is separated from the ventricular myocardium (*red*) by the annulus fibrosus, formed by the fusion of (epicardial) AV sulcus tissue (*green*) and valvular tissue (*blue*). The only myocardial connection between atrial and ventricular myocardium occurs via the proximal component of the AVCS (i.e. the AVN and AVB). (b) This is a simplified representation of an accessory atrioventricular pathway as found in cases with WPW syndrome (note: the actual localization of the pathway may vary). (c) A schematic diagram of a typical electrocardiogram (ECG) as derived from an individual with normal electric heart activity. Abbreviations: AF = annulus fibrosus, AVB = atrioventricular bundle (or His bundle), AVN = atrioventricular node, LA = left atrium, LBB = left bundle branch, LV = left ventricle, RA = right atrium, RBB = right bundle branch, RV = right ventricle, SAN = sinoatrial node; SVC = superior vena cava.

depolarization is created by an aberrant conduction pathway the ECG diagnosis of Wolff-Parkinson-White syndrome (WPW, or ventricular preexcitation syndrome) can be made (Fig. 1b).

WPW is found in 1.5–3.1 per 1,000 persons in western countries. However, this percentage is higher (0.55%) in the group of first-degree relatives of patients with WPW.

## Genes

A number of different genes have been associated with AV conduction disturbances. Mutations in the gene encoding the homeobox transcription factor NKX2.5 were found to be associated with congenital heart malformations including atrial septal defects and AV block [2]. The AV block phenotype observed in patients with NKX2.5 mutations appears to be associated with progressive degeneration of the AVCS. Interestingly a similar phenomenon was also observed in the postnatal hearts of mice that are haploinsufficient for Nkx2.5. AV conduction defects are also seen in Holt-Oram Syndrome (HOS), an autosomal dominant heart-hand syndrome caused by mutations in the TBX5 gene. Humans with TBX5 mutations (HOS) are characterized by structural congenital heart malformations, including atrial septal defects, and associated progressive AV and bundle-branch block [3]. Some HOS patients have electrophysiological defects in the absence of structural defects. Studies on mice that are haploinsufficient for the Tbx5 gene demonstrate that Tbx5 is required for normal development and patterning of the AV conduction system. Thus, heterozygous Tbx5 mice showed severe AVCS patterning defects, including absence or severe abnormalities of the RBB [4]. Familial WPW has also been linked to mutations in PRKAG2, a gene that encodes for the gamma-2 regulatory subunit of AMP-activated protein kinases [5]. Additionally, some mutations in the SCN5a gene result in familial progressive atrioventricular conduction defects; other mutations in SCN5a are causative of Long QT syndrome and Brugada syndrome. Other genes that are associated with Long-QT Syndrome, a cardiac arrhythmia characterized by ventricular repolarization, but not necessarily involving AV tissues, include KVLQT1 (KCNQ1), HERG, ANKB, MinK (KCNE1), MirP1, and KCNJ2.

## Molecular and Systemic Pathophysiology

The molecular pathophysiology of AV conduction disturbances is poorly understood; so, too with aberrant conduction pathways. AV block can be either congenital or acquired; acquired causes include fibrosis secondary to ischemia and surgical trauma. In the congenital setting, it is most often seen in pregnancies complicated by lupus erythematosus and caused by transplacental transport of maternal SSA/Ro and SSB/La antibodies. Fibrosis and degeneration of the conductive tissues is a frequent finding.

## Diagnostic Principles

AV conduction disturbances can be diagnosed using electrocardiography. The atrioventricular conduction system (AVCS) includes the sinoatrial node (SAN), the atrioventricular node (AVN), the atrioventricular bundle (AVB), and the left and right bundle branches (LBB and RBB). In first degree AV block, every impulse generated in the SAN reaches the ventricles through the AVN and AVB. However, the length of the PR interval exceeds 0.2 s (upper limit of normal in an adult) indicating decreased conduction through the AV conduction axis. Individuals with first degree block are usually asymptomatic. In second degree AV block not all atrial impulses reach the ventricles. As a result, in the ECG not every P wave is followed by a QRS complex. There are two types of second degree AV blocks. Type I second degree block (or "Wenckebach" block) is characterized by progressive prolongation of the PR interval and a resulting shortening of the R-R interval. This ultimately results in failure of an atrial impulse to reach the ventricles, when the cycle begins again. After such a block, the cycle begins again. In type II second degree block, the PR and R-R intervals between conducted impulse are constant prior to failure of atrioventricular conduction. Patients that have second degree AV block often have an irregular heart beat and may suffer from bradycardia. In third degree AV block, there is no conduction of the atrial impulse through the AVN and AVB to the ventricular myocardium. Survival in such cases is dependent upon the ventricles developing an "escape rhythm." There is no correlation between the atrial P wave and the QRS complex generated through the escape mechanism. Patients with third degree AV block generally suffer from bradycardia, which can be quite severe.

In WPW syndrome, an accessory AV pathway bypasses the normal AV conduction axis (Fig. 1c). This results in early activation (or preexcitation) of ventricular myocardium before the normal conduction pathways activate that portion of the myocardium. The appearance of the resulting QRS reflects the relative amount of myocardium activated through the accessory pathway and the normal conduction tissues, as well as the relative location of the pathway in the heart. The PR interval on the ECG will be abnormally shortened, and the QRS complex, however, is generally abnormally-shaped and wide.

## Therapeutic Principles

At present the only effective treatment for absent or unreliable AV node conduction is a pacemaker. Postnatally acquired complete heart block, whether from genetic mechanisms or not, carries a high risk of Stokes-Adams attacks and sudden death and is an absolute indication for pacing. In contrast, congenital complete heart block carries a low risk of sudden death and pacing decisions are typically based on symptoms. Congenital complete heart block is usually well tolerated in infants if there are no co-existing cardiac structural abnormalities, but the combination of congenital complete heart block and cardiac malformation is very poorly tolerated and is a well documented cause of fetal demise.

Aberrant conduction pathways that result in symptomatic arrhythmias are generally treated by catheterization and ablation, although pharmacologic therapy can also be effective.

## Synonyms

AVD

## Definition and Characteristics

Atrioventricular dissociation (AVD) is a condition in which the atria and ventricles are activated independently of each other, so that the P waves and the QRS complexes do not have any relationship with each other. In AVD, the ventricular rate (VR) is either the same or faster than the atrial rate (AR), whereas in complete heart block the AR is faster than the VR [1]. In AVD, the atrial pacemaker is usually in the sinus node and produces any atrial sinus rhythms. The ventricular pacemaker may originate from the AV node, bundle of His, bundle branches or peripheral Purkinje tissue. No retrograde ventriculoatrial conduction occurs in AVD. When the AR and VR are similar, but the P wave is not conducting, the rhythm disturbance is known as isorhythmic AVD [2]. When the AR and VR are similar, but occasionally the atria conduct to the ventricles, the rhythm is known as interference AVD. During interference AVD, the atria are driven by a slowed down sinus pacemaker and the ventricles by an accelerated junctional or nodal pacemaker. The impulses from these two independent pacemakers meet or collide, usually in the AV node and interfere with each other's conduction. Incomplete AVD occurs when some of the P waves conduct and capture the ventricles as in interference AVD. AVD is regarded as complete when the atrial rhythm does not conduct and capture the ventricles. Complete AVD can mimic AV block, but the fact that none of the P waves conduct has more to do with the timing of the P waves in relationship to the QRS complexes rather than the presence of AV nodal disease that occurs in AV block. Clinically, most patients with AVD are asymptomatic. Symptoms of AVD are related to bradycardia, tachycardia, AV dyssynchrony, or the loss of "atrial kick" (diastolic filling of the ventricles secondary to atrial contraction). Symptoms of AVD may include exertional dyspnea, light-headedness, throbbing sensation in the neck, palpitations, fatigue or malaise. On physical examination, a patient may have variable pulse volume or blood pressure, intermittent cannon a waves, variable intensity of first heart sound and beat-to-beat variation in systolic murmurs.

## Prevalence

The exact prevalence is not known but deemed to be rare.

## Molecular and Systemic Pathophysiology

A normal cardiac impulse arises from the sinus node and is conducted through the AV junction, the bundle of His, and the bundle braches to the ventricles. The sinus node is the dominant pacemaker because its intrinsic rate (60–100 bpm) is faster than subsidiary pacemakers in the AV junction (40–60 bpm) or the ventricles (30–40 bpm). AVD results from (i) slowing of the dominant pacemaker (sinus node), which allows an escape junctional or ventricular rhythm, or (ii) acceleration of a normally slower (subsidiary) pacemaker, such as a junctional or a ventricular site that activates the ventricles without retrograde atrial capture. In AVD, as P-P intervals are longer (slow atrial rate) than R-R intervals (rapid ventricular rate), the P waves will overtake QRS complexes, and P-R intervals become progressively shorter. The P wave first becomes superimposed on the QRS complexes and then eventually moves progressively away from the QRS complexes. When the P wave falls sufficiently behind the QRS complex, it may find an opportunity to get conducted to the ventricles resulting in an earlier QRS complex known as a ventricular capture beat. Ventricular capture beats commonly occur due to AVD with interference within the AV node [3]. The ventricular or AV nodal impulse cannot be conducted antegradely to the atria, as a result sinus impulses cannot be conducted antegradely to the ventricles. However, as the two pacemakers discharge asynchronously (ventricle pacemaker is faster than atrial), the slower sinus discharge occurs later in relation to nodal or ventricular discharge. Therefore, the sinus P wave falls further and further away from the QRS until the stage is reached when a sinus impulse may eventually reach the AV node when it is no longer refractory. When the above occurs, the sinus wave gets conducted to the ventricle. This momentary activation of the ventricles by sinus impulse during AVD produces capture beats. The captured beat is an early beat that is related to the previous sinus P wave. Conditions that initiate AVD include surgical and anesthesia interventions, cardiac surgery, catecholamine surges, catecholamine blocking drugs, sinus node disease, digoxin toxicity, myocardial infarction,

hyperkalaemia, vagal activation, ventricular tachycardia, ventricular pacing, radiofrequency ablation, sinus bradycardia with escape junctional rhythm and cardiac surgery. Whatever the cause, AVD is usually secondary to some other rhythm disturbances or conditions.

### Diagnostic Principles

The electrocardiogram (ECG) is the most commonly used modality to diagnose AVD. The ECG criteria of AVD are as follows: (i) VR faster than AR; (ii) regular P-P and R-R intervals; (iii) no relationship between P wave and QRS complex; (iv) progressively shorter P-R intervals; (v) ventricular capture beats; (vi) P-R interval of the capture complex often longer than expected; and (vii) ventricular fusion complexes [4].

### Therapeutic Principles

The treatment of AVD depends on the underlying condition and its severity. The hemodynamic status of the patient as well as the underlying pathology are the chief determinants of medical care. For patients who are hemodynamically unstable (e.g., patients with ventricular tachycardia), the usual treatment of choice is direct current cardioversion or intravenous drug therapy.

### Synonyms

AVNRT; Atrioventricular nodal reentry; Atrioventricular nodal reciprocating tachycardia; Atrioventricular junctional reentrant tachycardia

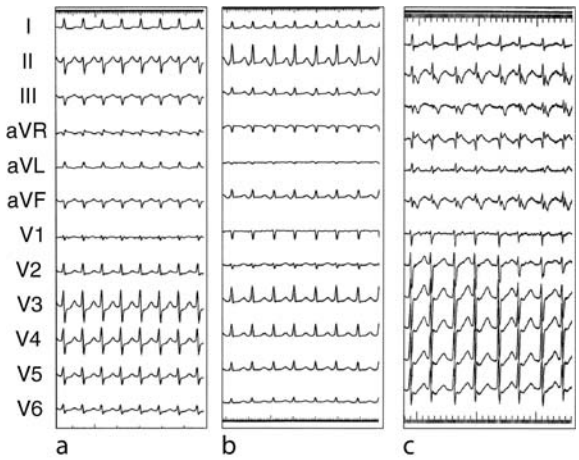
### Definition and Characteristics

Atrioventricular nodal reentrant tachycardia is the most common form of *paroxysmal* supraventricular tachycardia. AVNRT is more common in women than men (ratio 3:1). Symptoms (palpitations, polyuria, dizziness, presyncope or even syncope) may occur at any age but AVNRT is rare in children (mean age at symptoms onset: 30–43 years; range 5–90 years). Most patients with AVNRT have no structural heart disease. Tachycardia cycle length is extremely variable (600–220 ms) with a mean of 340 ms in the absence of drugs. Predisposing factors are non-specific but stressful situations, exercise or changes in position are frequently reported. The 12-lead resting ECG is usually normal without ventricular preexcitation.

AVNRT is related to the presence of functionally determined dual AV nodal pathways (a slow-conducting one and a fast conducting one) which can be suspected on the 12-lead resting ECG by a short (<0.12 s) P-R interval (non-specific), the occasional presence of two P-R intervals during sinus rhythm or by the presence of double responses (one sinus beat giving two ventricular responses).

AV nodal reentry occurs in three forms [1]: the common, typical form of AVNRT (90%) is called "*slow-fast*" because the anterograde limb of the tachycardia uses the slow pathway and the retrograde limb the fast pathway. In this form, the retrograde P wave during tachycardia occurs simultaneously with the QRS and the ECG demonstrates no P wave or a P wave distorting the terminal part of the QRS complex (rSr' aspect in lead V1) (Fig. 1a).

The second form of AVNRT (5%) is called "*fast-slow*" or atypical because the anterograde limb of the tachycardia uses the fast pathway and the retrograde limb the slow pathway. Therefore, during tachycardia, the retrograde P wave appears negative in inferior leads and before the QRS (long R-P' tachycardia) (Fig. 1b).



**Atrioventricular Nodal Reentrant Tachycardia.**
**Figure 1** (a) 12-lead resting ECG recorded during *slow-fast AVNRT*: tachycardia is regular, with a ventricular rate of 190 bpm and narrow QRS complexes. P wave is not visible but slight deformation of the terminal part of the QRS complex in lead V1 (rSr' aspect) suggests that the P wave is hidden within the QRS complex. (b) 12-lead resting ECG recorded during *fast-slow AVNRT*: tachycardia is regular, with a ventricular rate of 155 bpm and narrow QRS complexes. P wave is visible before the QRS complex (long R-P tachycardia) and is negative in lead II, III, avF (retrograde P wave). (c) 12-lead resting ECG recorded during *slow-slow AVNRT*: tachycardia is regular with a ventricular rate of 190 bpm and narrow QRS complexes. P wave is visible after the QRS complex in lead II, III, aVF suggesting a relatively slow retrograde activation of the atrium (differential diagnosis between slow-slow AVNRT and orthodromic AVRT using a concealed accessory pathway).

The third form of AVNRT (5%) is called "*slow-slow*" because one slow pathway is used for anterograde conduction and another slow pathway is used for retrograde conduction (Fig. 1c).

AVNRT may be associated with other forms of tachycardia (orthodromic AVRT using a concealed accessory pathway; atrial flutter or fibrillation; atrial tachycardia; fascicular tachycardia or right ventricular outflow tract tachycardia). Finally, a fourth form of tachycardia may be encountered in association with dual AV nodal conduction: nonreentrant junctional tachycardia related to repetitive double responses. In this particular form of tachycardia two QRS complexes are observed for each P wave which has the morphology of a normal sinus P wave.

## Prevalence

Overall prevalence is unknown because there is no specific ECG marker for AVNRT. AVNRT accounts for 60–70% of all narrow QRS complex tachycardias referred for investigation or curative treatment with the exception of atrial flutter. Dual AV node conduction may be recorded in many individuals without AVNRT (35–70%) and appears to be non-specific and only related to normal anterior and posterior inputs to the AV node.

## Genes

No specific gene defect or mutation has been described in AVNRT and the vast majority of cases are sporadic. Only one report of familial occurrence of AV nodal duality and AVNRT has been published and this observation has suggested an autosomal dominant genetic defect (dual AV nodal pathways in multiple generation, male-to-male transmission in one family) [2]. Another isolated report has shown dual AV nodal physiology in a pair of identical twin sisters with documented left-sided accessory pathways [3].

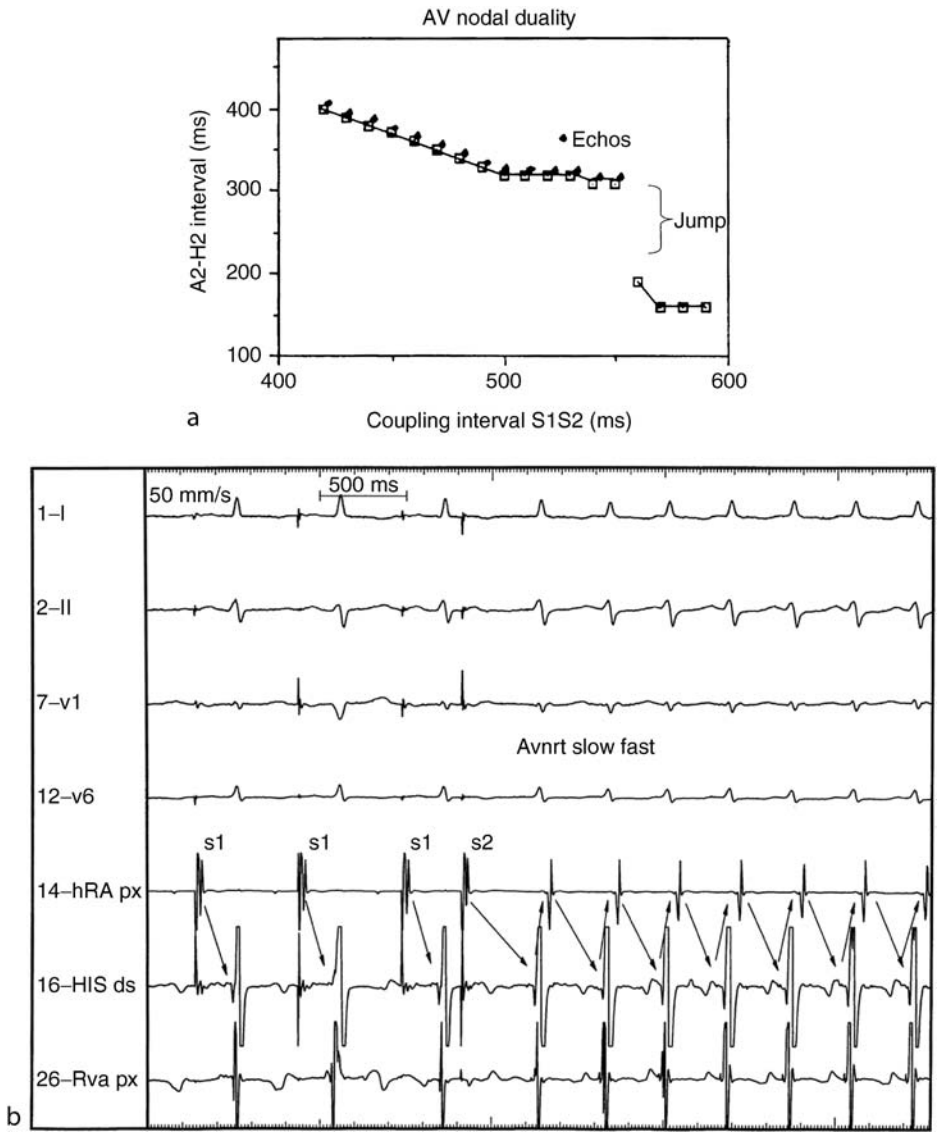
## Molecular and Systemic Pathophysiology

AV nodal reentry is based on dual (or multiple) AV nodal pathways which are essentially functional. The tachycardia circuit incorporates the compact AV node and the perinodal tissue extending from the apex of Koch's triangle to the coronary sinus os and there is still debate if pure atrial tissue is required for the tachycardia. A lower final common pathway also exists since AVNRT can persist despite 2:1 block in the AV node or in the His bundle. During the common slow-fast form of AVNRT retrograde atrial activation is complex reflecting nonuniform anisotropy but the earliest breakthrough usually occurs at the apex of Koch's triangle in the anterior septum close to the His bundle. In the fast-slow form of AVNRT earliest retrograde activation is seen in the posterior Koch's triangle and in the coronary sinus os region.

## Diagnostic Principles

Diagnosis may be suspected on the 12-lead ECG recorded during tachycardia but is confirmed by invasive electrophysiological techniques. In most patients with AVNRT (>85%), AV dual physiology can be demonstrated during atrial extrastimulus testing: when the coupling interval (A1-A2) of the atrial extrastimulus is progressively shortened, an abrupt increase in A2-H2 is observed in the presence of dual AV nodal conduction ("jump" of more than 50 ms in A2-H2 for a 10 ms decrement in A1-A2 which represents the shift of conduction from the fast to the slow pathway) (Fig. 2a).

The A-H "jump" is frequently associated with the appearance of an atrial echo beat (through the fast



**Atrioventricular Nodal Reentrant Tachycardia. Figure 2** (a) Demonstration of AV nodal duality by extrastimuli applied in the atrium. At 560 ms of coupling interval, a jump in A2-H2 interval is observed (from 190 to 310 ms) together with slow-fast echo beats. (b) Initiation of slow-fast AVNRT by a single atrial extrastimulus S2. A A2-H2 jump is observed after S2 and this critical increase in A-H interval initiates slow-fast AVNRT.

pathway used retrogradely) or with the initiation of a slow-fast AVNRT (Fig. 2b).

Therefore, AVNRT initiation depends on a critical A-H interval in most cases. During tachycardia atrial activation occurs simultaneously with ventricular activation (a mean of 50 ms after His bundle activation) and the earliest atrial depolarization is recorded at the apex of Koch's triangle just above the compact AV node. Differential diagnosis between AVNRT and orthodromic AVRT using a concealed septal accessory pathway may be difficult and is based on timing of retrograde atrial activation, on ventricular stimulus testing and on parahisian pacing techniques. Differentiation of AVNRT from atrial tachycardia is essentially made using ventricular extrastimuli (V-A-A-V response).

## Therapeutic Principles

1. *Acute Termination of AVNRT*: vagal manoeuvres can frequently terminate tachycardia and patients should be instructed on how to apply these techniques. Intravenous adenosine is highly effective for AVNRT termination and is considered the drug of first choice. Calcium channel blockers (verapamil, diltiazem) and betablockers can also be used. All these drugs affect reentry by slowing or blocking conduction over the slow pathway.

2. *Chronic Management*: betablockers, calcium channel antagonists, amiodarone, digitalis (acting mainly on the slow pathway) or class Ic antiarrhythmic drugs (acting mainly of the fast pathway) may all be effective for prevention of AVNRT but the pharmacologic approach is limited by partial inefficacy, numerous side effects and potential serious adverse reaction. Radiofrequency catheter ablation of the slow pathway is currently the method of first choice for symptomatic patients and should be proposed after the first recurrence [4]. Success rate of radiofrequency catheter ablation is 97–98%, recurrences are rare (2–3%) and the risk of AV block is <0.5%. Slow pathway ablation is conducted on anatomic and electrophysiologic basis and the optimal site is in the lower Koch's triangle just anteriorly to the os of the coronary sinus [5]. Junctional beats are observed during RF application at successful sites. Complete abolition of slow pathway conduction is not mandatory and a simple modification of conduction over the slow pathway is sufficient for clinical cure. Cryo-ablation techniques are currently under development in order to minimize the risk of AV block but recurrence rate is higher and AV block cannot be completely avoided.

## Synonyms

Atrioventricular canal defect; Endocardial cushion defect; Canalis atrioventricularis communis; Persistent atrioventricular ostium

## Definition and Characteristics

*Partial Atrioventricular Septal Defect*: Ostium Primum Defect and cleft in the anterior leaflet of Mitral valve.

*Complete Atrioventricular Septal Defect*: Ostium Primum Defect, Inlet Ventricular Septal Defect and Common Atrioventricular valve consisting of five leaflets [1].

*Classification on the Basis of the Anterior Bridging Leaflet (ABL)*: Rastelli Type A with ABL separated into two portions of approximately equal size and attached to the anterior papillary muscle of the respective ventricle; Rastelli Type B with unattached, but separated ABL; Rastelli Type C with unattached, undivided ABL floating above the interventricular septum.

## Prevalence

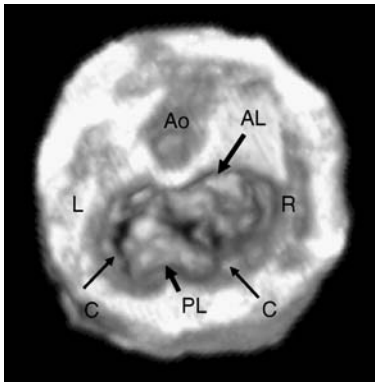
4.4 – 4.8% of congenital heart defects.

## Genes

23–60% of patients with AVSD are affected by Trisomy 21 (Down syndrome), where an alteration in the DSCR1 (Down Syndrome Critical Region 1) as a regulatory protein in the Calcium-NFAT-pathways is thought to be responsible for the insufficient fusion of endocardial cushions. In the remaining patients mutations in the AVSD1-locus (1p31-p21) or AVSD2-locus (3p25) can be found.

## Molecular and Systemic Pathophysiology

The septal defects of both partial and complete AVSD lead to increasing left-to-right shunt immediately after birth as pulmonary vascular resistance decreases. After 12 weeks of life, pulmonary (Qp) to systemic (Qs) blood flow ratio reaches its maximum. Frequently an additional volume load is caused by valve regurgitation. Children with partial AVSD may appear normal until adulthood, due to small shunt volume. Depending on the amount of the shunt, infants with complete AVSD

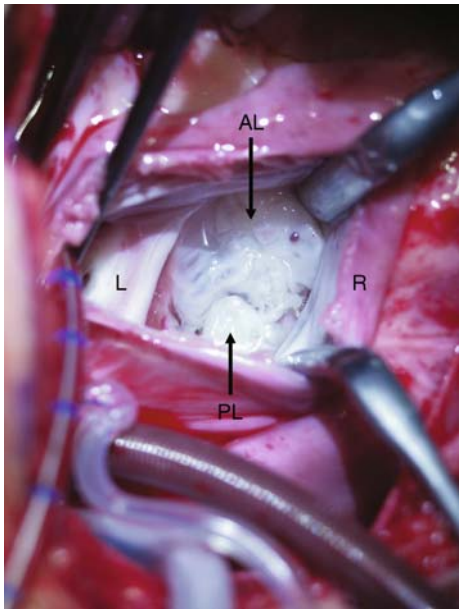


**Atrioventricular Septal Defects. Figure 1**
Three-dimensional echocardiographic view on the atrioventricular valves in atrioventricular septal defect from above: a prominent anterior bridging leaflet (AL), a small posterior bridging leaflet (PL) with the typical "cleft" in between is shown, R = right ventricular side, L = left ventricular side, A = aortic root.

present with signs of congestive heart failure such as dyspnea, growth retardation and tachycardia. Pulmonary vascular disease usually develops after the first year of life as a consequence of near systemic pulmonary pressure levels.

## Diagnostic Principles

Auscultatory findings depend on the nature of the underlying pathophysiology: in partial AVSD they are similar to fossa ovalis defects (pulmonic flow murmur in the second left intercostal space with wide, fixed splitting of the second heart sound) or – as atrioventricular valve regurgitation dominates – an apical holosystolic murmur. In complete AVSD the murmur of atrioventricular valve regurgitation is present, radiating toward the sternum rather than toward the axilla. In pulmonary hypertension the splitting of the second heart sound is narrow and associated with a loud pulmonic component. A loud holosystolic murmur indicating shunt flow across the Ventricular Septal Defect may be heard. ECG shows a prolonged PR interval, right ventricular hypertrophy and a deviation of the frontal plane QRS-axis between 90° and -120° in 95% of the patients. Echocardiography is diagnostic, revealing absent atrioventricular septum (Fig. 1). In partial AVSD the atrioventricular leaftlets appear to originate from the crest of the ventricular septum and usually at the same level. In complete AVSD the inlet-VSD is shown in addition. Colour-Doppler studies outline the regurgitation of the atrioventricular valves (Fig. 2) as well as the direction of atrial and ventricular shunting. Cardiac catheterization is necessary only when non-invasive diagnostic procedures leave significant



**Atrioventricular Septal Defects. Figure 2**
Intraoperative view on the atrioventricular valves: the right atrium is open and the small anterior bridging leaflet (AL) as well as the prominent posterior bridging leaflet (PL) and the cleft is seen.

questions unanswered or when there are concerns about pulmonary vascular disease with elevated resistance.

## Therapeutic Principles

In complete AVSD, corrective surgery is normally indicated in the fourth to sixth month of life. If the infant is developing congestive heart failure, a short term medical treatment with diuretics and fluid restriction can be discussed. Most centres prefer the surgical procedure in these circumstances, consisting of one- or two-patch repair of the septum and reconstruction of the atrioventricular valves. In partial AVSD the decision for corrective surgery is based on the amount of ventricular volume load and mitral regurgitation. Patch closure of the defect and reconstruction of the mitral valve are normally performed between the second and fourth year of life.

## Attention-Deficit/Hyperactivity Disorder

Klaus-Peter Lesch
Molecular and Clinical Psychobiology, Department of Psychiatry and Psychotherapy, University of Wuerzburg, Wuerzburg, Germany

### Synonyms

ADD; Attention-deficit disorder; HKS; Hyperkinetic syndrome; ADHD

### Definition and Characteristics

Attention-deficit/hyperactivity disorder (ADHD; MIM 143465) is defined as a clinically heterogeneous neurodevelopmental syndrome characterized by inattention, excessive motor activity, and impulsivity. It is the most common behavioral disorder in children with persistence into adulthood which profoundly compromises functioning in multiple areas throughout the life span and can significantly contribute to a variety of health, social, and economic problems. Affected individuals are at increased risk for poor educational and occupational achievement despite normal cognitive and intellectual abilities, low income, underemployment, impaired social skills and relationships, family dysfunction, legal difficulties, and delinquency. On the other hand, high IQ and a highly supportive, well-structured family environment are protective factors against ADHD-related behavioral limitations. While an age-dependent fading may render symptoms not prominent enough to justify diagnosis of ADHD in adulthood, they are frequently associated with clinically significant impairment of cognitive and executive functions as well as stress coping and emotion regulation. As a result, adult ADHD is characterized by high co-morbidity with depression, anxiety disorders, alcohol/drug dependence, and antisocial personality disorders.

### Prevalence

ADHD is a highly prevalent, worldwide disorder estimated to affect 5–10% of children and 3–6% of adults.

### Genes

Twin, adoption, and molecular genetic studies revealed that ADHD is a highly heritable disorder ($h^2$: 70–80%) with a multifactorial pattern of inheritance, likely due to several genes of small or moderate effect size [1]. Genom-wide linkage analyses identified several susceptibility loci with maximum LOD scores of 2.1–3.7, for example on chromosome 4q13.2, 5p13, 5q23.3,

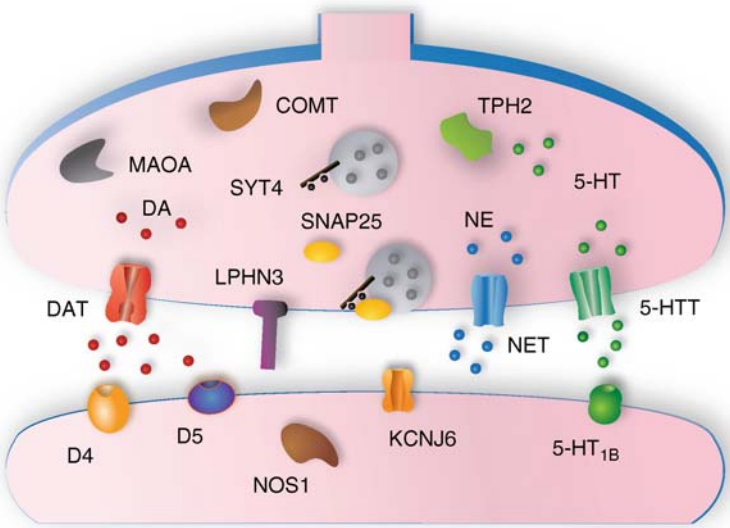
6q12, 7p13, 9q33, 11q22, 15q15, 16p13, and 17p11. Finemapping of the region on 4q13.2 identified a common haplotype within the latrophilin 3 (LPHN3) gene which confers susceptibility to ADHD with a relative risk (RR) of ~1.3 [2]. Frequency (~21%), extent of linkage disequilibrium (~300 kb), and ancestry of the LPHN3 susceptibility haplotype is consistent with the concept that traits associated with the ADHD phenotype have been subject to positive selection and that ADHD is the extreme of a normal variation exacerbated by adverse environmental circumstances.

With focus on relevance to pathophysiological and pharmacotherapeutic mechanisms, the candidate gene approach has also been utilized in case-control or family-based studies. Investigations concentrated on genes which modulate synaptic transmission and, on the basis of the pooled odds ratios of 1.19–1.45 across studies, association with ADHD was detected for genes encoding key modulators of the dopaminergic and serotonergic signalling pathways, such as the dopamine 4 receptor (DRD4), dopamine 5 receptor (DRD5), dopamine transporter (DAT, SLC6A4), serotonin 1B receptor (HTR1B), serotonin transporter (5-HTT, SLC6A4), tryptophan hydroxylase 2 (TPH2), and synaptosomal-associated protein 25 (SNAP25) (see Fig. 1) [3].

Moreover, gene targeting approaches, e.g. generation of a DAT knockout mouse, provide informative insight into pathophysiological mechanisms of locomotor hyperactivity and effects of psychostimulant drugs, such as methylphenidate or cocaine. Finally, complex interactions are to be expected between environmental factors and multiple genes each with a small to moderate influence on different traits. Perinatal complications, low socio-economic status, disruptive family environment and other psychosocial adversity have been identified as predisposing environmental risk factors. While prenatal and parental risk factors may be critical mediators of influences on the risk, the association between these variables and ADHD is generally indirect.

## Molecular and Systemic Pathophysiology

Converging evidence from animal and human studies including structural and functional neuroimaging implicates dysregulation of prefrontal–striatal–thalamic–cerebellar excitatory and inhibitory circuits with broadening to a multi-pathway framework in the



**Attention-Deficit/Hyperactivity Disorder. Figure 1** Proteins (*genes*) that are known or suspected to be altered in function or amounts in attention-deficit/hyperactivity disorder (ADHD). Dopamine 4 receptor (D4, *DRD4*), dopamine 5 receptor (D5, *DRD5*), dopamine transporter (DAT, *SLC6A4*), serotonin 1B receptor (5-$HT_{1B}$, *HTR1B*), serotonin transporter (5-HTT, *SLC6A4*), monoamine oxidase A (*MAOA*), catechol-O-methyltransferace (*COMT*), nitric oxide synthase 1 (*NOS1*), and tryptophan hydroxylase 2 (*TPH2*) are key modulators of dopaminergic and serotonergic signalling pathways. DAT, NET, and 5-HTT are targets for psychostimulant drugs, methylphenidate and d-amphetamine, the non-stimulant atomoxetine, and antidepressants. Synaptosomal-associated protein 25 (*SNAP25*), synaptotagmine 4 (*SYT4*), and latrophilin 3 (*LPHN3*) are critically important in the regulation of neurotransmitter release. DAT, SYT4, and potassium channel, inwardly rectifying, subfamily J, member 6 (*KCNJ6*) knockout mouse have provided insight into pathophysiological mechanisms of locomotor hyperactivity and effects of psychostimulant drugs.

pathophysiology of ADHD. It is widely accepted that ADHD is the common final behavioral consequence of an array of dysfunctions in each of several independent systems, such as cognitive, motivational, and executive pathways, as well as circuitries of stress adaptation and emotion regulation. Executive functions, which consist of a set of higher order thought processes required for adaptive and future-oriented behavior (e.g. deliberate suppression of a response to achieve a later, internally represented goal) and are controlled by frontal-subcortical circuits, include behavioral inhibition, working memory, attention set-shifting, interference control, planning, and sustained attention. Impairment of executive functions with failure of inhibitory control; dysregulation of brain systems mediating reward and response cost; and deficits in arousal, activation, and effortful control, are central to the pattern of neuropsychological deficits. Deficits in arousal and effort lead to state-dependent cognitive deficits and underscore the view of an impairment in regulating cognitive functions rather than core deficits in any single function. Inattention but not hyperactivity/impulsivity is associated with deficits in executive functioning and poor academic achievement, whereas hyperactivity/impulsivity appears to be more closely related to dysfunctions of reward mechanisms.

Functional neuroimaging studies have assessed the degree of brain activation associated with neuropsychological tasks of attention and disinhibition. The findings are consistent with the structural studies indicating delays in brain maturation processes and locating abnormalities of brain activation in patients with ADHD in fronto–subcortical–cerebellar circuits [4]. Since the spectrum of ADHD features is not explained by a single neuropsychological deficit, disorder-associated impairments are heterogeneous and this complexity corresponds with causal heterogeneity. Despite recognition of ADHD as a neurodevelopmental condition, only few causal explanations have considered the two-way interactions between pre-existing abnormal functioning and biological, cognitive, emotional, motor and social developmental processes, and their contribution to the expression of the clinical phenotype.

The notion that dysregulation of dopamine, norepinephrine, and serotonin signalling pathways underlies ADHD was initially suggested by the action of therapeutically effective compounds (e.g. methylphenidate, atomoxetine, citalopram), which increase the synaptic availability of these neurotransmitters, and by animals showing that lesions in or genetic modification of these pathways (as well as cholinergic, glutamatergic, and GABAergic signalling) create animal models of ADHD. Neuroimaging showed that methylphenidate exerts some of its therapeutic effects by binding to DAT located in subcortical structures abundant with dopaminergic terminals and synapses such as the striatum. Several but not all studies using radiolabelled ligands indicated an increase of DAT binding in adults with ADHD.

## Diagnostic Principles

Although classification systems such as DSM-IV and ICD-10 provide structured, criterion-based diagnoses for ADHD, they have several limitations. The diagnostic items, although well-described, largely fail to provide developmentally sensitive definitions and to assist differentiation of ADHD symptoms from developmentally healthy levels of inattention, hyperactivity, and impulsivity. During the diagnostic assessment, data from multiple informants (e.g. parent and teacher; parent and teenage child; adult with ADHD and spouse) are acquired but categorical classification systems provide no guidelines to integrate this information.

While basically descriptive and theoretical, three symptom-based subtypes of ADHD have been accepted: mainly inattentive, mainly hyperactive– impulsive, or both combined. Evidence for the validity and clinical use of these subtypes is mixed and the ongoing controversy about whether a purely inattentive disorder exists that could be causally different, is motivating the search for neurobiological construct-based and quantifiable intermediate traits, termed endophenotypes, that lie in the pathway from genes to behavior predicting an individual's disease risk [5]. Intermediate phenotypes may be neuromorphological, neurophysiological or neuropsychological in nature. Criteria whether or not an endophenotype relates to genetic causes of ADHD are that the endophenotype should itself be heritable, cosegregate with ADHD within families, and the endophenotype found in affected family members should also be found in non-affected family members at a higher rate than in the general population. Deconstructing ADHD into its underlying neurobiological component processes not only facilitates genetic analysis but also offers alternative ways of describing and classifying those with the disorder and reduce the heterogeneity associated with categorical classification.

## Therapeutic Principles

Pharmacological treatments of ADHD are psychostimulant drugs, methylphenidate (including long-acting formulations) and d-amphetamine, and the non-stimulant atomoxetine, which enhance neurotransmission of dopamine and norepinephrine [1]. Emotional dysregulation and comorbid depression is frequently treated with antidepressants, such as sertraline or venlafaxine. Psychosocial interventions are used for children and cognitive–behavior therapy is helpful against symptoms and associated features of ADHD particularly in adults. After pharmacological treatment has been initiated, assessment of residual dysfunctions

leads to subsequent implementation of psychosocial and behavioral treatment strategies.

## Synonyms

Pervasive development disorders; PDD; ASD

## Definition and Characteristics

Autism spectrum disorders (ASD) are diagnosed on the basis of a triad of behavioral impairments: impaired social interaction, impaired verbal and non verbal communication skills and restricted, repetitive and stereotyped patterns of behavior. Autism is not a single entity, but rather a constellation of conditions ranging from a severe form, called autistic disorder, to a milder form, Asperger syndrome. ASD also include pervasive developmental disorder not otherwise specified (PDD-NOS), and very severe disorders like Rett syndrome and childhood disintegrative disorder. ASD can be associated with other genetic disorders, chromosomal anomalies, but in the majority of the cases, the cause of ASD remains unknown (Fig. 1a).

## Prevalence

60–116:10,000 in ASD; 13–39:10,000 in autistic disorder; 3–10:10,000 in Asperger syndrome; 31:10,000 in PDD-NOS; 1:10,000 in Rett syndrome; 0.2:10,000 in childhood disintegrative disorders. For autistic disorder the male:female ratio is 4:1; For individuals with normal to high IQ, including those with Asperger syndrome, the male:female ratio may be closer to 10:1.

## Genes

Genes associated with ASD fall into three categories: genes causing syndromes associated with ASD, genes

altered by chromosomal abnormalities, and genes mutated in idiopathic ASD [1].

*Syndromes Associated with ASD (only the Most Frequent are Indicated)*: ►Fragile X syndrome: CGG triplet expansion in FMR1 (Xq28) encoding FMRP a protein regulating translation at the synapse.

►Rett syndrome: (mostly *de novo*) point mutations in *MECP2* (Xq28) encoding the methyl binding protein MECP2 regulating gene expression by remodelling chromatin.

►Tuberous sclerosis: point mutations in *TSC1* (9q34) or *TSC2* (16p13) encoding the tumour suppressor proteins TSC1 or TSC2.

►Neurofibromatosis: point mutations in *NF1* (17q11) encoding the tumour suppressor protein NF1.

►Cowden syndrome: (mostly *de novo*) point mutations in *PTEN* (10q23) encoding the tumour suppressor protein PTEN. *PTEN* mutations seem to be restricted to 3patients with macrocephaly.

*Chromosomal Rearrangements*: A large number of chromosomal rearrangements have been associated with ASD, but the most frequent anomalies are the 15q11–13 duplication and the 22q13 deletion.

Chromosome 15q11–13 duplication: The most frequent chromosomal rearrangement in ASD (≈1–2%) is a tandem duplication of a maternal 4–5 Mb region corresponding to 15q11–q13, or supernumerary pseudodicentric, inverted, and duplicated regions of chromosome 15. The ASD phenotype of 15q11–13 duplication is characterized by epilepsies, hypotonia and motor coordination problems combined with moderate to severe mental retardation and speech delay or absence of speech.

Chromosome 22q13 deletion: The de novo deletion can vary from 130 kb to 9 Mb, but always include SHANK3 (see below).

*Single Gene Associated with ASD*: NLGN3/NlGN4: point mutations or deletions of neuroligins NLGN3 (Xq13)/NLGN4 (Xp22) encoding the postsynaptic cell adhesion molecules NLGN3 and NLGN4.

SHANK3: deletions of chromosome 22q13 or point mutations in SHANK3 (22q13) encoding the synaptic scaffolding protein SHANK3. Mutations in SHANK3/22q13 seem to be restricted to patients presenting with neonatal hypotonia and absence or severely delayed speech.

NRXN1: a de novo deletion of neurexin NRXN1 (2p16) was identified in two sisters with ASD. NRXN1 encodes a presynaptic cell adhesion molecule, which binds to the postsynaptic neuroligins.

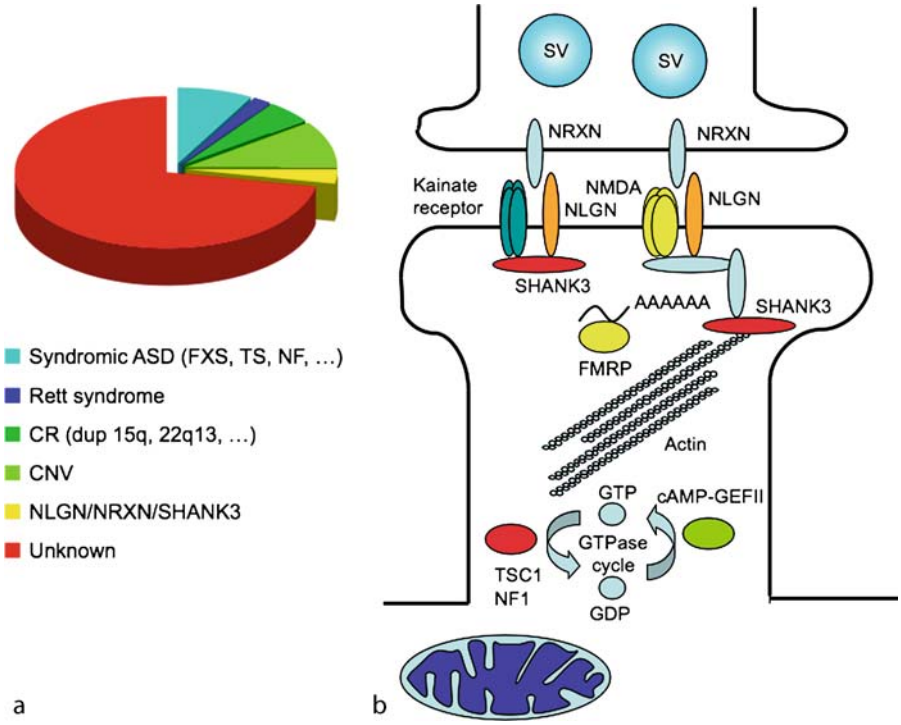
## Molecular and Systemic Pathophysiology

ASD can be associated with a broad range of anomalies affecting different physiological processes such as chromatin remodelling (MECP2), synaptic gene regulation (FMRP), actin skeleton dynamics (TSC1/TSC2, NF1), cell growth (PTEN) and calcium signaling (CACNA1C). Although the mutated genes are numerous and diverse, they might all affect the same downstream pathways at the origin of ASD. One such pathway may include the synaptic protein NLGN, NRXN and SHANK3 (Fig. 1b). NLGN and NRXN are synaptic cell adhesion proteins and crucial factors for the validation and maintenance of functional synapses. SHANK3 is the gene causing the neurological phenotype of the 22q13 deletion syndrome and encodes a postsynaptic scaffolding protein, which binds to the NLGN. Mutations in NLGN3, NLGN4, NRXN1 and SHANK3 were identified in apparent monogenic form of ASD [2–4]. The mutations of the NLGN and SHANK3 were found to cause abnormal synaptogenesis and SHANK3 clustering in neuronal cell cultures. Interestingly, at least in humans, this synaptic pathway is sensitive to gene dosage since mutations, or loss of one copy, of NRXN1 or SHANK3 are associated with autism, whereas the presence of an extra copy of SHANK3 might be associated to Asperger syndrome [3,4]. Although mutations within NLGN/NRXN/SHANK3 concern a limited number of patients, these results strongly suggest that this synaptic pathway – crucial for the appropriate functional validation of the synapse, as well as a correct balance between glutamatergic and GABAergic synapses – is a core component of ASD.

## Diagnostic Principles

Due to the genetic heterogeneity of ASD and the absence of biomarker, the diagnostic protocol should include a full clinical assessment, including neurologic and genetic assessment, along with cognitive and language testing. If present, syndromes associated with ASD should be carefully examined at the clinical and molecular level by genetic test of the causative genes. For research purpose, structured interviews are used such as the Autism Diagnosis Interview–Revised (ADI–R), the 3di (Developmental, Dimensional and Diagnostic Interview), and the DISCO (Diagnostic Interview for Social and Communication Disorders). Parental reports may be supplemented by standardized observational assessments such as the Autism Diagnostic Observation Schedule (ADOS) or the Childhood Autism Rating Scale (CARS).

At the genetics level, *de novo* copy number variants (CNVs) seem to be frequent (≈10%) in ASD and can be detected using DNA arrays [3, 5]. In addition, the synaptic genes NLGN3, NLGN4, SHANK3 and NRXN1 could also be screened for mutations. However, mutations in these genes affect a limited number



**Autism Spectrum Disorders. Figure 1** The heterogeneity of ASD and synaptic proteins associated with the disorder. a. A broad estimation of the cause of ASD. ASD includes ≈8% of known genetic syndromes (e.g. Fragile X Syndrome (FXS), Tuberous sclerosis (TS), Neurofibromatosis (NF)), ≈2% of Rett syndrome, ≈5% of chromosomal rearrangements (CR), ≈10% of copy number variants (CNVs), ≈3% of mutations in the NLGN/NRXN/SHANK3 pathway, and ≈72% of unknown causes. These numbers are only a broad estimation since epidemiological data concerning the causes of ASD are missing. In addition, the percentage may vary for sporadic or familial cases and if the affected individual has dysmorphic features. b. The synaptic genes associated with ASD. Synaptic vesicles (SV) and neurexins (NRXN) are present at the presynaptic side of a glutamate synapse. At the postsynaptic side, the NLGN and the glutamate receptors bind to scaffolding proteins of the postsynaptic density (PSD) such as SHANK3. The FMRP controls the translation of several synaptic proteins. TSC1 and NF1 are regulating the actin dynamics and the morphology of the neuron.

of individuals (≈3% of ASD) and their functional consequences are still difficult to interpret since they can be associated with a range of severities.

At the biochemical level, a high level of serotonin and a decrease of melatonin were repeatedly reported in ASD. The low level of melatonin was shown to be often the consequence of a primary enzyme deficiency of ASMT/HIOMT, the last enzyme of the melatonin synthesis pathway. When melatonin levels are low, individuals with ASD may benefit from melatonin treatment for reducing their sleep problems.

## Avascular Bone Necrosis

Nada Kanaan, Bruno Vande Berg, Eric Goffin
Departments of Nephrology and Radiology, Cliniques Universitaires Saint-Luc, Brussels, Belgium

### Synonyms

Osteonecrosis; Ischemic necrosis; Aseptic necrosis

### Definition and Characteristics

Pathological process characterized by deficient oxygen supply to the bone leading to bone tissue death, with possible epiphyseal fracture, and early osteoarthritis. Joint destruction eventually occurs within three to five years. The femoral head is most commonly clinically affected. Other sites include the knee, the humeral head, and less frequently the small bones of the wrist and the foot. Bilateral involvement is found in many patients at the time of diagnosis which is usually made between ages 30 and 60 years. Male to female ratio is 7:3 [1].

### Prevalence

300,000–600,000 cases of avascular necrosis (AVN) of the femoral head have been estimated in the USA. The incidence is approximately 15,000 new patients diagnosed per year.

### Genes

COL2A1 mutations in inherited familial osteonecrosis of the femoral head have been described in three Taiwanese families [2].

## Molecular and Systemic Pathophysiology

Avascular bone necrosis results from decreased blood flow within the bone as a result of traumatic or non-traumatic conditions. Traumatic causes include injury, fracture or dislocation leading to interruption of vascular supply to the bone. Non-traumatic conditions are associated with the administration of corticosteroids, excessive alcohol use, smoking, SLE, antiphospholipid antibodies, hemoglobinopathies (sickle-cell anemia, polycythaemia), acute leukaemias, storage disorders (Gaucher disease), hyperbaric events, radiation therapy, HIV infection, heritable thrombophilia (antiprothrombin or factor V Leiden genes mutations), hypofibrinolysis (variant plasminogen activator inhibitor-1 genotype) or it can be idiopathic. Although the pathogenesis of non-traumatic osteonecrosis is not well defined, it appears to involve vascular damage, occlusion of intra-osseous capillaries, increased local pressure, bone and cell death or defective bone repair [1]. Avascular necrosis generally develops in yellow marrow. In few conditions (hemoglobinopathies, storage disorders) it may develop in red marrow. There is a genetic predisposition for individuals exposed to the two leading etiologic associations for AVN: corticosteroids and alcohol [3]. In steroid-induced osteonecrosis, possible mechanisms involve alterations in circulating lipids resulting in fat embolism, intramedullary fat-cell hypertrophy with compression of local capillaries, or changes in venous endothelial cells, leading to stasis, increased intraosseous pressure (mainly in weight-bearing bones), and eventual necrosis. In alcohol-induced osteonecrosis, fat emboli, venous stasis and increased cortisol levels have been implicated as etiologic factors [1].

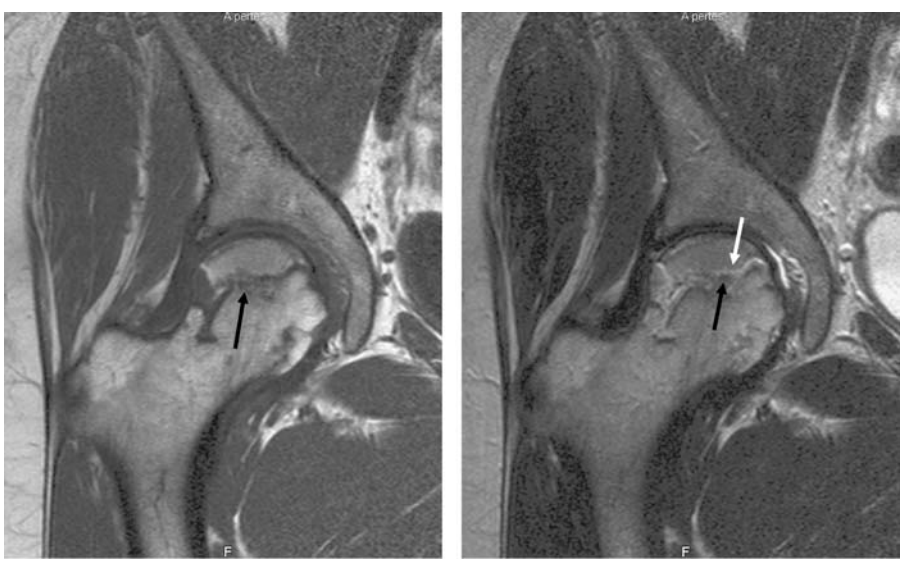
## Diagnostic Principles

Pain (often non-specific) is the most common presenting symptom. [1]. Magnetic resonance imaging (MRI) is the most accurate non invasive test for detecting AVN at early stages with sensitivities and specificities approaching 100%. The “double line sign” observed on T2- weighted images occurs at the interface between viable and non-viable tissue and is pathognomonic of AVN. This double line appears as a single low intensity band on T1- weighted images (Fig. 1) [4].

Plain radiography lacks sensitivity in the early stage of the disease and is generally diagnostic only after the development of the “crescent sign” at the ischemic interface. Bone scintigraphy can detect AVN before radiographic changes when there is increased vascularity [5].

## Therapeutic Principles

The choice of treatment depends on four factors: (i) the bone involved, (ii) the stage of disease, (iii) the size of the necrotic lesion, and (iv) the morbidity of the proposed treatment. Symptomatic joints should be put at rest. Joint-preserving procedures are indicated for the earlier stages of AVN and include core decompression with or without bone grafting (vascularized and non-vascularized) and osteotomy. Core decompression relieves pain by decreasing



**Avascular Bone Necrosis. Figure 1** Coronal T1- (left panel) and T2-weighted (right panel) Spin Echo Images of the right femoral head of an asymptomatic patient with previous hip dislocation show femoral head necrosis characterized by a rim of low signal intensity (black arrow) on T1-weighted and low (black arrow) and high signal intensity (white arrow) on T2-weighted images. The signal of the infarct is similar to that of fat because it contains mummified necrotic fatty marrow.

intra-osseous pressure and stimulating neovascularization and is used to treat early stages of AVN of the femoral head when the size of the lesion is small (less than 30% femoral head involvement). Osteotomy is an option for patients with discrete necrotic lesion that can be shifted away from the weight-bearing area of the joint. Arthroplasty procedures are indicated after loss of congruity or involvement of the acetabulum. Limited femoral head resurfacing is used to treat femoral head lesions before involvement of the acetabulum. Total hip arthroplasty must be left for late stages of the disease when the acetabulum is involved [5].

## Bardet-Biedl Syndrome

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

### Synonyms

BBS

### Definition and Characteristics

Bardet-Biedl syndrome (BBS) is characterized by obesity, retinal dystrophy, mental retardation, polydactyly (Fig. 1), hypogonadism, and renal abnormalities [1].

The expression and severity of the various clinical features show inter- and intrafamilial variability. Obesity is usually evident by 2–3 years of age and is localized to the trunk and proximal parts of the limbs. Retinal dystrophy affects both rods and cones and may result in night blindness, color blindness, decreased visual acuity, and constricted visual fields. Mental retardation is usually mild to moderate. Inappropriate mannerism and shallow affect are common. Postaxial polydactyly is more common on the feet than on the hands; the extra digit is usually toward the fifth toe or finger. Hypogonadism is usually primary but may also be secondary to hypothalamic dysfunction. Cryptorchidism occurs in ~20% of males. The majority of affected men have microorchidism and micropenis and are usually infertile. Affected women usually have irregular menses. Structural or functional renal abnormalities are extremely common. Most affected patients have impairment in urinary concentrating abilities. Other renal abnormalities include tubular acidosis, calyceal clubbing or blunting, calyceal cysts or diverticula, foetal lobulations, renal cortical loss, renal scarring, vesicoureteral reflux, and bladder instability. Other features of BBS include nystagmus, myopia, astigmatism, glaucoma, posterior capsular cataracts, retinitis pigmentosa, syndactyly, brachydactyly, clinodactyly, broad hands and feet (Fig. 1), brachycephaly, bitemporal narrowing, narrow, short, and down-slanting palpebral fissures, high arched palate, prominent mandible, oligodontia, congenital heart disease, hypertension, hepatic fibrosis, and diabetes mellitus.

### Prevalence

The prevalence of BBS in Europe and North America is 1:125,000–160,000 live births. In Newfoundland,

**Bardet-Biedl Syndrome. Figure 1** A 6-year-old girl with Bardet-Biedl syndrome. Note the short, broad feet with postaxial polydactyly.

Kuwait, and Saudi Arabia, the prevalence is 1:13,000–17,000 [2]. The sex ratio is equal.

### Genes

BBS is an autosomal recessively inherited disorder. At least 12 BBS genes have been cloned and mapped: BBS1 at 11q13; BBS2 at 16q21; BBS3 at 3p12-p13; BBS4 at 15q22.3-q23; BBS5 at 2q31; BBS6 at 20p12; BBS7 at 4q27; BBS8 at 14q32.1; BBS9 at 7p14; BBS 10 at 12q15-q21.2; BBS 11 at 9q33.1 and BBS 12 at 4q27 [2,3].

### Molecular and Systemic Pathophysiology

BBS genes are involved in intracellular and intraflagellar transport, microtubule organization, cell division, and maintenance of planar cell polarity which are key pathways in the pathogenesis of BBS [4].

### Diagnostic Principles

BBS and Laurence-Moon syndrome have a similar phenotype which includes obesity, retinal dystrophy, and hypogonadism. Laurence-Moon syndrome can be differentiated from BBS by the presence of spasticity and ataxia and the rarity of polydactyly. BBS should also be differentiated from McKusick-Kaufman syndrome, Cohen syndrome, Prader Willi syndrome, Alström syndrome, Carpenter syndrome, Rubinstein-Taybi syndrome, Usher syndrome, and Meckel syndrome which show some of the clinical features of BBS. The clinical diagnosis of BBS requires four of six primary symptoms or three primary symptoms and at least two secondary symptoms [4,5].

### Therapeutic Principles

Treatment is usually symptomatic and supportive.

## Barrett Esophagus

Marcus Schmitt
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

### Synonyms

Barrett's esophagus; Barrett's syndrome; CELLO; Columnar epithelium lined lower (o)esophagus; GERD

### Definition and Characteristics

Barrett esophagus [1] is the replacement of the stratified squamous epithelium that normally lines the distal esophagus by an intestinal-type epithelium called specialized intestinal metaplasia.

Characteristic symptoms are missing. Underlying condition is ►gastroesophageal reflux disease (GERD). Symptoms of GERD can occur: heartburn, retrosternal discomfort or pain. Dysphagia, odynophagia, and malnutrition are alarming symptoms suspicious for Barrett's adenocarcinoma.

### Prevalence

Ten percent of patients with gastroesophageal reflux disease will develop a Barrett esophagus. In a general population prevalence ranges from 0.9 to 4.5%. White males over 50 years are at highest risk. Barrett esophagus is associated with a 0.5–1% annual conversion rate to esophageal adenocarcinoma [2].

### Genes

So far affected single gene(s) as a cause for Barrett esophagus are unknown. In Barrett esophagus over 100 polymorphisms in genes involved in DNA repair, chemical detoxification and cytokine responses have been identified.

### Molecular and Systemic Pathophysiology

Barrett's esophagus is caused by chronic and severe acid reflux in patients with GERD. Esophageal mucosa reacts to the repeated injury from the acidic fluid by changing the type of cell from squamous to columnar

(intestinal-type cells). This transformation is believed to be a protective response because the specialized columnar epithelium in Barrett's esophagus is more resistant to injury from acid than is the squamous epithelium.

Metaplasia develops as a consequence of chronic gastroesophageal reflux disease (GERD), and predisposes to the development of adenocarcinoma of the esophagus.

The origin cell type may be due to transdifferentiation or, alternatively, the cell of origin may be an undifferentiated stem cell. Although intestinal type goblet cells are the characteristic feature for the diagnosis of Barrett esophagus, other cells resembling those of the stomach are also present as part of this metaplasia. Thus, there are several candidate genes for esophageal metaplasia (e.g. transcription factor p16, homeobox genes Cdx1/2, transforming growth factor beta).

Neoplastic progression in Barrett's metaplastic cells begins with genetic alterations that either activate protooncogenes (e.g. cyclin D1), disable tumor suppressor genes (e.g. p53, p16), or both. Aneuploid or tetraploid populations can be found by flow cytometery [3].

### Diagnostic Principles

Diagnosis is mainly based on endoscopy and biopsy-proven metaplasia. Moreover endoscopic tools like chromoendoscopy, confocal laser endomicroscopy and endoscopic imaging procedures (e.g. narrow band imaging) may detect suspicious areas. Microscopy of histologic samples shows the presence of intestinal-type goblet cells and establishes the diagnosis of Barrett's esophagus. The goblet cells of specialized intestinal metaplasia contain acidic mucins (sialomucins and sulfomucins) that can be demonstrated by staining with Alcian blue.

### Therapeutic Principles

Major goal of therapy is to avoid development of Barrett's adenocarcinoma. First choice is to treat the underlying gastroesophageal reflux disease "GERD" with proton pump inhibitors (PPI). For bile acid reflux induced esophagitis sucralfate is recommended.

Further treatment options depend on the histologic findings. Patients with atypia indefinite for dysplasia/neoplasia will be examined by repeated endoscopy every 8–12 weeks. For low-grade dysplasia/neoplasia (pre-cancerous change) antireflux therapy (medical or surgical) is recommended, followed by endoscopic surveillance at least every year. At high-grade dysplasia/neoplasia (severe precancerous change) antireflux therapy plus additional therapy is recommended. Therapy may include surveillance endoscopy every 3-6 months, photodynamic therapy, endoscopic mucosal resection, or surgery.

## Bartter Syndrome Type I–V

Christie P. Thomas
Division of Nephrology, Department of Internal Medicine, University of Iowa Hospitals and Clinics and VA Medical Center, Iowa City, IA, USA

### Synonyms

Type 1 and 2 – Hypokalemic alkalosis with hypercalciuria, antenatal; Hyperprostaglandin E syndrome; Type 3 – Hypokalemic alkalosis with hypercalciuria, classic; Type 4 – Hypokalemic alkalosis with hypercalciuria and deafness; Type 5 – Hypocalcemia, autosomal dominant with Bartter syndrome

### Definition and Characteristics

Bartter syndrome is an inherited disorder of renal tubular ion transport characterized by hypokalemia, salt wasting and metabolic alkalosis. The more severe forms are associated with maternal hydramnios and postnatal polyuria, hypercalciuria and nephrocalcinosis. The disorder is usually autosomal recessive and demonstrates genetic heterogeneity with mutations in five different genes accounting for the majority of cases.

### Prevalence

The majority of reported cases of Bartter syndrome type 1, 2 and 4 have occurred in consanguineous kindred and

the true prevalence of the disease in the general population is unknown. Most patients with Bartter syndrome type 3 appear to be the offspring of non-consanguineous unions. Of note, type 3 disease with homozygous deletion of ClC-Kb is the only form of Bartter syndrome identified thus far in African Americans.

## Genes

The genes involved are listed in Table 1 [1].

## Molecular and Systemic Pathophysiology

About 20–25% of the filtered load of $Na^+$ is reabsorbed in the thick ascending limb of the loop of Henle (TALH) mediated by the apical electroneutral furosemide-sensitive $Na^+$–$K^+$–$2Cl^-$ co-transporter, NKCC2. The driving force for $Na^+$ reabsorption is generated by the activity of the basolateral $Na^+$–$K^+$-ATPase which maintains intracellular $Na^+$ at a low level. $K^+$ and $Cl^-$ accompany $Na^+$ into the TALH cell via NKCC2 and $Cl^-$ leaves via a basolateral $Cl^-$ channel, ClC-Kb, which requires an accessory subunit, Barttin, to be functional. $K^+$ is recycled back into the tubular lumen via an apical $K^+$ channel, ROMK which creates the lumen positivity which provides the driving force for paracellular $Ca^+$ and $Mg^+$ reabsorption.

With loss of function mutations in NKCC2 or ROMK there is severe reduction or absence of $Na^+$ transport in the TALH leading to loss of the medullary osmotic gradient required for urinary concentrating ability resulting in polyuria. Increased fetal urine production manifests as maternal polyhydramnios. Postnatally, lack of $Na^+$ reabsorption in the TALH will simultaneously inhibit paracellular $Ca^+$ absorption leading to hypercalciuria and polyuria. With reduced NaCl entering the cells of the macula densa there is enhanced prostaglandin release leading to activation of the renin-angiotensin system. With absent TALH $Na^+$ reabsorption there is enhanced $Na^+$ delivery to the connecting tubule and collecting duct coupled with increased aldosterone levels resulting in increased distal $Na^+$ reabsorption with $K^+$ and $H^+$ secretion leading to hypokalemia and metabolic alkalosis. Despite enhanced distal $Na^+$ reabsorption there is increased NaCl loss in the urine leading to volume contraction with hypotension.

Mutations in Barttin, an accessory subunit for both ClC-Ka and ClC-Kb profoundly reduces basolateral $Cl^-$ exit in the TALH and distal convoluted tubule leading to the antenatal Bartter phenotype including polyhydramnios and hypokalemic alkalosis although hypercalciuria is absent. Deafness is a consequence of reduced function of ClC-Ka, a $Cl^-$ channel expressed in the inner ear. Reduced basolateral $Cl^-$ exit from mutations in ClC-Kb inhibits apical NaCl transport and also leads to the Bartter phenotype. However, polyuria and maternal hydramnios is not seen, perhaps reflecting the milder degree of TALH transport defect. Activating mutations of the calcium sensing receptor (CaSR) expressed on the basolateral membrane appears to inhibit apical ROMK function leading to a mild Bartter phenotype in some instances.

## Diagnostic Principles

The antenatal forms of Bartter present with maternal hydramnios reflecting fetal polyuria *in utero*. Polyhydramnios occurring between 24 and 30 weeks leads to preterm delivery and neonates manifest failure to thrive with profound metabolic disturbances. The typical manifestations include salt wasting, hypoesthenuria, polyuria, hyperprostaglandinuria, hypokalemic alkalosis and hypercalciuria. Inappropriate urinary NaCl loss leads to volume depletion and hypotension while hypercalciuria leads to nephrocalcinosis and osteopenia [2,3]. Amniotic fluid has a high $Cl^-$ and following birth, infants with the syndrome have high urinary $PGE_2$. Patients with Barttin mutations have sensorineural deafness and although they present with maternal hydramnios, hypercalciuria is absent. Some infants with antenatal Bartter type 2 have transient hyperkalemia within the first few weeks of life and may be mistaken for PHA type 1 [4].

In contrast to the antenatal forms, patients with ClC-Kb can present later in childhood and sometimes in adolescence and hypercalciuria and nephrocalcinosis

**Bartter Syndrome Type I–V. Table 1** Genetic basis of Bartter syndrome

[a]Leads to nephrocalcinosis.
[b]Associated with postnatal isosthenuria and polyuria.
[c]May be associated with transient neonatal hyperkalemia.
[d]Includes monogenic and digenic forms of disease.
[e]Disease typically manifests with hypocalcemia and only occasionally with Bartter features of hypokalemia and salt wasting.
[f]Included for comparison of clinical features; associated with hypocalciuria.

are uncommon [4]. Classically these patients have hypokalemic metabolic alkalosis sometimes associated with salt wasting and hypotension. Some may have hypocalciuria and hypomagnesemia: a phenotype that resembles Gitelman syndrome.

Type 5 Bartter is a clinically milder form of the disease seen in some patients with mutations in CaSR. Autosomal dominant hypocalcemia with mild relative hypercalciuria is the primary abnormality (see Table 2).

## Therapeutic Principles

The mainstay of therapy in the antenatal forms is the use of Indomethacin which can prevent progression of hydramnios and can reduce postnatal hypokalemia and polyuria. Oral or parenteral fluid and electrolyte replacements are required in all patients and in some cases spironolactone has been used.

# Basal Cell Carcinoma

Cord Sunderkötter, Meinhard Schiller
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Basalioma; BCC

## Definition and Characteristics

Basalioma is a locally destructive epidermal tumor, which does not usually metastasize. The originating cells may arise from interfollicular basal cells, hair follicles, or sebaceous glands.

## Prevalence

It is the most frequent form of cancer in the USA and Australia and one of the most frequent forms in Europe.

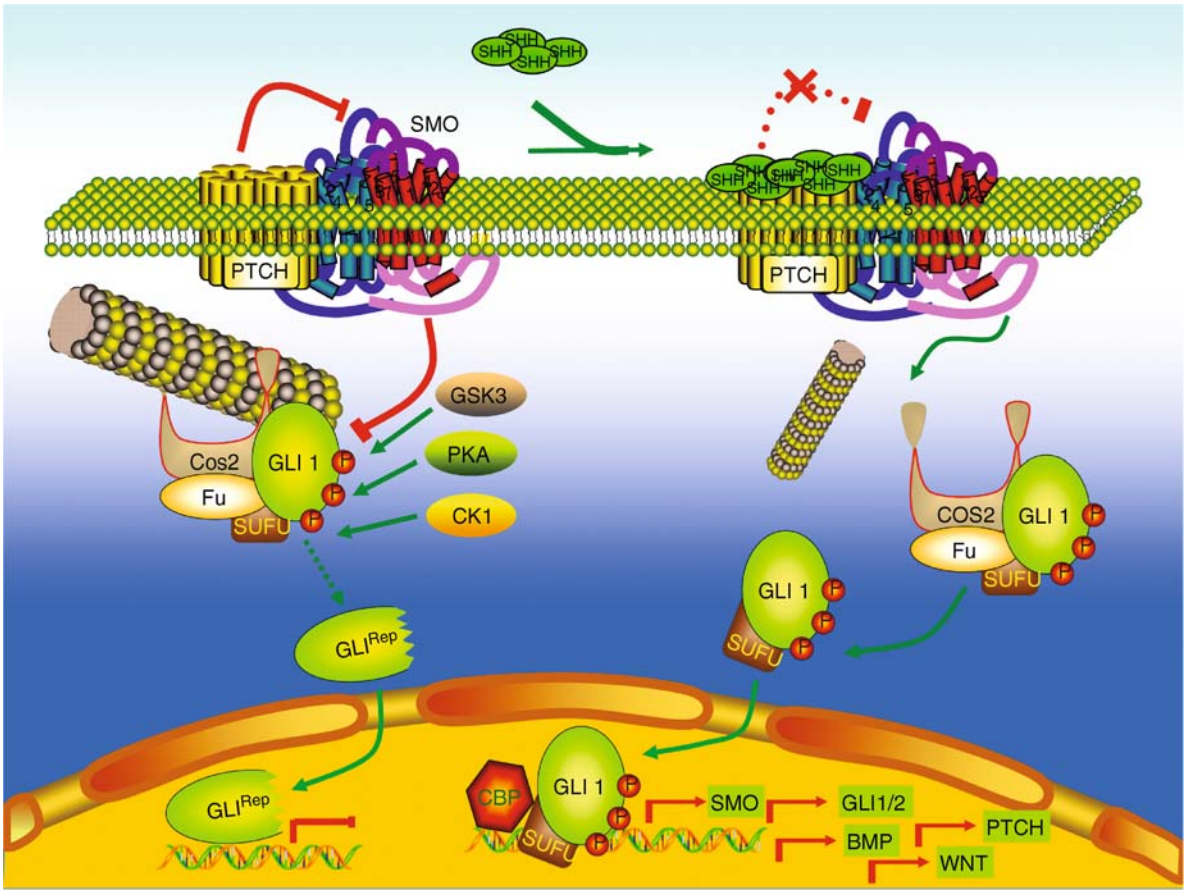
## Genes

Mutations of either PTCH or SMO (Fig. 1) are present in more than 70% of all BCC. Mutations in the tumor suppressor gene p53 may play an additional role in BCC development.

## Molecular and Systemic Pathophysiology

BCC are supposed to develop de novo, in contrast to squamous cell carcinoma (SCC) development, which is thought to be a multistep process. A key cellular signaling event presents mutation-mediated aberrant Sonic Hedgehog signaling.

Known risk factors that contribute to the development of BCC include ultraviolet (UV) exposure, race, age, gender, and DNA repair capacity. The most important trigger is chronic exposure to UV radiation



**Basal Cell Carcinoma. Figure 1** The Sonic Hedgehog (SHH) signaling pathway.

in sunlight which has two major tumor promoting effects: (i) it causes mutations in cellular DNA which, if not repaired, ultimately leads to unrestrained growth and tumor formation; and (ii) it causes relative immunosuppression in the cutaneous immune system (e.g. dendritic cells) thus impairing immunological tumor rejection. The latter is more relevant for SCC, but the combination of immunosuppressive drugs with UV radiation (e.g., in patients after organ transplantation) increases the risk for BCC.

UVB (especially from 290 to 320 nm) generates two major photoproducts in DNA: cyclobutane–pyrimidine dimers and 6–4 pyrimidine–pyrimidone (6–4PPs) [1]. In the absence of sufficient repair this results in characteristic C→T and CC→TT transition mutations. In BCC these mutations are often found in genes that code for p53 tumor suppressor gene and for PTCH.

The tumor suppressor PTCH gene, responsible for the autosomal dominant nevoid basal cell carcinoma (Gorlin-Goltz) syndrome (MIM 109400) [2], encodes for a transmembrane receptor in the Sonic Hedgehog (SHH) signaling pathway (Fig. 1).

It forms a receptor complex with smoothened (SMO), a G-protein-coupled-like receptor, by which secreted SHH signals are received and transduced. SHH signaling has been implicated in hair follicle growth and morphogenesis. In the absence of SHH, PTCH inhibits SMO, so that Costal2 (COS2), Fused (FU), and glioma transcription factor 1 (GLI1) are bound together in a high molecular weight protein complex that is attached to microtubules. GLI1 is cleaved into a smaller N-terminal fragment that moves to the nucleus to repress SHH target genes. When SHH signals are present, they bind to PTCH, upon which SMO is released and causes the FU/COS2/GLI complex to loosen its hold on microtubules. This leads to the stabilization of the full-length GLI1 that travels to the nucleus and functions as a transcriptional activator (Fig. 1). Mutation of either PTCH or SMO (present in >70% of BCC) results in elevated levels of GLI1 that can induce BCC and hair follicle tumors by opposing cell cycle arrest and differentiation [3].

Allelic instability and loss of heterozygosity (LOH) profiles appear to be the de novo global somatic events that may underlie such mutations in BCC tumorigenesis. As such, more than 60% of BCC with 9q LOH present de novo mutations in *PTCH*. Uniparental disomy, a result of somatic recombination leading to a loss of

heterozygosity at 9q21-q31, appears to be a key alternative genetic mechanism to allelic imbalances in BCC.

Another key step in cancer development is clonal expansion of mutant cells. This may be supported in the skin by mutations in the p53 gene. The latter prevents normal UVB-induced apoptosis, which usually deletes DNA-damaged cells in unmutated stem cell compartments. Mutations in p53 gene have been shown in 30–50% of BCC, and more than half of these mutations were UV-specific changes so that the pattern of hot spots in skin tumors differs from that of internal malignancies [4].

It is not completely clear why BCC do not metastasize. One reason may be that detached cells require a certain tissue stroma that is only present in already existing BCC. Also, high expression levels of collagen type IVα1, IVα2, and IVα5, the principal component of the basement membrane, by BCC may result in a physical barrier to metastasis [5].

### Diagnostic Principles

The diagnosis is usually made clinically, but needs histological confirmation. Characteristic clinical signs are a small smooth-surfaced nodule arising in actinically damaged skin. It often presents with a translucent pearly border and is covered by thin epidermis that shows few dilated superficial vessels. The surface can sometimes be rough, hyperkeratotic, or crusted.

When the nodules are pigmented, the use of a dermatoscope is helpful to exclude patterns characteristic for tumors of pigment-forming nevus cells or melanomas.

A histological confirmation of the diagnosis is mandatory, either from a biopsy or from a complete excision. When there is suspicion of destruction of deeper tissue layers, imaging diagnostics is necessary.

### Therapeutic Principles

Standard procedure is surgical excision with histological control. Other procedures may be chosen, depending on the patient's general health and the location: radiation therapy, as well locally destructive procedures such as cryosurgery, curettage, laser therapy, and photodynamic therapy or topical drugs such as imiquimod or 5-fluorouracil.

## Basal Cell Nevus Syndrome

Thomas Schwarz[1], Mark Berneburg[2]
[1]Department of Dermatology, University Hospital of Schleswig-Holstein, Campus Kiel, Kiel, Germany
[2]Department of Dermatology, Eberhard Karls University, Tuebingen, Germany

### Synonyms

Gorlin syndrome; BCNS

### Definition and Characteristics

BCNS is a genetically determined disease characterized by the occurrence of multiple basal cell carcinomas, medulloblastomas, ovarian fibromas and less frequently fibrosarcomas, meningiomas, rhabdomyosarcomas and cardiac fibromas. In addition, malformations are a typical component of BCNS, these include pits of the palms and soles, cysts of the jaw, other dental malformations, cleft palate, hypertelorism, strabism, calcification of the falx, spine anomalies, bifid ribs, polydactyly, ectopic calcification and generalized overgrowth with acromegalic appearance [1].

### Prevalence

Approximately. 1:50,000.

### Molecular and Systemic Pathophysiology

Autosomal dominant disease with chromosomal location at 9q22–31. BCNS is caused by mutations in the Patched (Ptch) gene [2–4]. The Ptch protein, a receptor for the Sonic hedgehog (Shh) protein, represses hedgehog target gene expression through its interaction with Smoothened (Smoh). This repression is relieved when Shh binds to Ptch, or after mutational inactivation of Ptch. Relieved Smoh activates the transcription factor Gli which causes cell proliferation. Mutational inactivation of Ptch and consequent loss of Ptch protein function result in

increased Ptch expression and the accumulation of high levels of Ptch and Gli transcripts. PTCH mutations have also been detected in sporadic basal cell carcinomas, trichoepitheliomas and medulloblastomas, suggesting a common genetic basis for the sporadic and syndrome-associated tumors [5].

### Diagnostic Principles

The clinical picture of patients with the typical facial appearance and the stature as well as the high incidence of basal cell carcinomas occurring already early in life indicate the diagnosis. Since the clinical picture is so typical, no confirmatory diagnostic procedure is necessary, although sequencing of the Patched gene will confirm the diagnosis.

### Therapeutic Principles

Adequate treatment of the basal cell carcinomas is required. Regular medical examinations are warranted for early detection of other internal tumors. Protection from ultraviolet radiation is necessary.

### Synonyms

Acanthocytosis; Abetalipoprotinemia; Apolipoprotein B deficiency; Microsomal triglyceride transfer protein deficiency

### Definition and Characteristics

Abetalipoproteinemia (MIM 20100) is an autosomal recessively inherited disorder of lipoprotein metabolism characterized by the virtual absence of VLDL and LDL from plasma and associated with clinical manifestations of fat malabsorption and a variety of progressive neurological symptoms including ataxia and retinitis pigmentosa. Biochemical abnormalities in the patient's plasma lead to a "thorny" deformation of erythrocytes (acanthocytosis).

The neurological symptoms are directly related to a deficiency of alpha-tocopherol (vitamin E).

### Prevalence

The disorder seems to be very rare. Most earlier reported patients were Jewish, but the disease was also reported in patients from African origin and from Japan.

### Genes

Abetalipoproteinemia is caused by mutations (most of them private family mutations) in a gene on chromosome 4q22–24 coding for a subunit of the microsomal triglyceride transfer protein (MTP). Hypobetalipoproteinemia, a biochemically closely related disorder of lipoprotein metabolism without neurological symptoms, is caused by truncations in the gene coding for apolipoprotein B (APOB) [1,2].

### Molecular and Systemic Pathophysiology

The microsomal triglyceride transfer protein is physiologically expressed in intestinal and in liver cells and is needed for the transfer of lipids to lipoproteins

that contain apoprotein B. The protein is absent in abetalipoproteinemia patients who are unable to secrete stable apoprotein B-containing lipoproteins in their liver. Their blood is therefore virtually free of chylomicrons, very low density lipoproteins, low density lipoproteins (beta-lipoproteins) and lipoprotein (a). Because of these deficiencies, patients are unable to absorb fat from their intestine and to transport fat-soluble vitamins in their circulation, thus resulting in the clinical syndrome of fat malabsorption and in neurological sequelae, which are related to the degeneration of structures depending on an adequate supply of vitamin E (see the article on ►Ataxia due to vitamin E deficiency) [1–3]. The retinopathy may also be partially related to vitamin A deficiency.

### Diagnostic Principles

The diagnosis depends on the examination of serum lipids. Total cholesterol is low (<70 mg/dL), triglycerides are almost undetectable. A lipoprotein profile shows virtually absent low density and very low density lipoprotein cholesterol.

### Therapeutic Principles

The severe neurodegenerative complications of abetalipoproteinemia belong to the potentially treatable or preventable conditions associated with vitamin E deficiency, provided that the disorder is recognized early and that great care is used with the theoretically simple treatment. Therapy consists in a dietary regimen and vitamin supplements, but requires sophisticated studies and long-term attention by a specialized metabolic team [4].

## B-Cell Lymphoma, Cutaneous

Lorenzo Cerroni
Department of Dermatology, Medical University of Graz, Graz, Austria

### Synonyms

Extranodal marginal zone lymphoma of MALT; Cutaneous MALT-type B-cell lymphoma; CBCL; SALT-type B-cell lymphoma; Cutaneous follicle center lymphoma; FCL; Cutaneous marginal zone B-cell lymphoma; MZL; Cutaneous diffuse large B-cell lymphoma, leg-type; LBCLLT; Intravascular diffuse large B-cell lymphoma

### Definition and Characteristics

Malignant proliferation of B-lymphocytes with particular tropism for the skin.
*Classification*:

- Cutaneous marginal zone lymphoma
- Cutaneous follicle center lymphoma
- Cutaneous diffuse large B-cell lymphoma, leg-type
- Cutaneous diffuse large B-cell lymphoma, others
- Intravascular large B-cell lymphoma

### Prevalence

CBCLs represent about 20–30% of all malignant lymphomas arising primarily in the skin [1,2]. The exact prevalence is not known.

### Genes

A chromosomal translocation involving the IgH gene on ch.14 with the MALT1 gene on ch.18 has been identified in a proportion of cases of cutaneous MZL [3]. The t(14;18) involving the IgH and Bcl-2 genes, common in nodal follicular lymphoma, is very rare in cutaneous FCL [4].

### Molecular and Systemic Pathophysiology

The three main entities of CBCL listed in the classification of cutaneous lymphomas proposed in 2005 by the European Organization for Research and Treatment of Cancer (EORTC) and the World Health

Organization (WHO) [1], namely, cutaneous MZL, cutaneous FCL, and cutaneous LBCLLT, have different etiologic and pathogenetic features. A small percentage of primary CBCLs was demonstrated to harbour Borrelia burgdorferi DNA sequences within specific skin lesions in studies carried out in different countries, but negative results have also been reported [5]. This association may be important in particular for cases of MZL arising in European Countries with endemic Borrelia infection. The presence of Borrelia burgdorferi within skin lesions of cutaneous lymphoma underlines the analogies between CBCLs and B-cell lymphomas of the gastric mucosa, where, at least in some cases, infection by Helicobacter pylori is considered to be a causative agent. Infectious agents have been implicated in the etiology of MALT-lymphomas arising at other body sites as well. The observation of Borrelia burgdorferi-specific DNA within skin lesions of CBCL provides also the rationale for antibiotic treatment of these patients.

In spite of progresses in molecular understanding of CBCLs, the exact mechanism of growth of neoplastic B lymphocytes within the skin is not known, as these cells are not part of the skin-associated lymphoid tissue, and are not present in the skin under normal circumstances. Persistent antigenic stimulation may play a role: besides the described association with infection by Borrelia burgdorferi, CBCL has been observed in association with other infections and at the site of vaccination.

## Diagnostic Principles

Exact classification of CBCLs rests upon morphologic and phenotypic identification of the neoplastic population of B lymphocytes (marginal zone cells, lymphoplasmacytoid cells, and plasma cells = marginal zone B-cell lymphoma; germinal center cells = follicle center lymphoma; large B lymphocytes = large B-cell lymphoma, leg-type). Detection of monoclonality by either immunohistology, molecular analysis of the IgH gene rearrangement, or both confirms the diagnosis. Negative complete staging investigations are mandatory for a diagnosis of primary CBCL.

## Therapeutic Principles

Low-grade malignant CBCLs (FCL, MZL) can be treated by surgical excision (solitary tumors), local radiotherapy, or a combination of both [5]. Antibiotic treatment and locally or systemically applied interferon α2a and anti-CD20 monoclonal antibody have been successfully administered in some patients. Systemic chemotherapy should be restricted to patients with LBCLLT, or to those with generalized lesions of low-grade CBCL, who do not respond to conventional treatment modalities. Radiotherapy is also available.

# Behçet's Disease

Haner Direskeneli[1], Kenneth Calamia[2]
[1]Marmara University Medical School, Istanbul, Turkey
[2]Department of Rheumatology, Mayo Clinic, Jacksonville, FL, USA

## Definition and Characteristics

A systemic vasculitis of unknown etiology with mucocutaneous, ocular, arthritic, neurological, gastrointestinal, and vascular involvements.

## Prevalence

In Turkey 8–32/10,000 and in Caucasian populations 1/300,000. Most common along the ancient "silk route" with greatest prevalences in Turkey, Iran, and Japan. M/F ratio is close to 1 with a disease onset usually between 20 and 35 [1].

## Genes

Main genetic association is shown with HLA class I antigens B51*01 and B51*08 with a relative risk of 4–16. Although not confirmed in every study, associations with procoagulant mutations factor V Leiden, protrombin G/A 20210A are observed. MHC class I chain-related gene-A (MICA), inducible nitric oxide synthase, familial Mediterranean fever-associated MEFV, and tumor necrosis factor-α (TNF-α) mutations are also found with a higher presence.

## Molecular and Systemic Pathophysiology

The main pathologic feature is a vasculitis with neutrophil and mononuclear cell infiltrations. Infections such as streptococci and herpes simplex virus are implicated with an impaired oral health and increased tonsillitis. Nonspecific hyperreactivity such as pathergy test (skin reaction to simple trauma) is possibly associated with a proinflammatory cytokine mileu. Immune cross-reactivity due to molecular mimicry between bacterial and human molecules such as heat-shock proteins are suggested to drive T and B cell responses with a proinflammatory and Th1 type cytokine profile (TNF-α and IL-12). Increased γδ T cells secreting TNFα and IFNγ in peripheral blood and tissue infiltrates are also a consistent finding suggesting a role of innate immunity [2,3].

## Diagnostic Principles

Mainly a clinical diagnosis with the presence of recurrent oral ulcers and at least two of genital ulcers, erythema nodosum-like lesions, folliculitis, uveitis (anterior or pan-uveitis), and pathergy test. Arthritis/arthralgias, venous vascular thrombosis, arterial aneurysms, central nervous system (CNS), and gastrointestinal involvements are also observed. Male sex and young age is associated with a more severe disease course and mortality. There is no characteristic investigation. The erythrocyte sedimentation rate and C-reactive protein is usually mildly elevated, mainly in cases with arthritis or EN-like lesions. Autoantibodies such as rheumatoid factor and antinuclear antibodies are generally absent [1].

## Therapeutic Principles

There is no cure for Behçet's disease. However, the disease has a remitting–relapsing course with a decreasing disease activity with the passage of time. Mucocutaneous and arthritic manifestations are treated with topical antiinflammatory agents, colchicine, nonsteroidal antiinflammatory drugs, and low-dose corticosteroids. Major organ involvements such as pan-uveitis, CNS, and vascular thrombosis require high-dose corticosteroids (1 mg/kg/day prednisolone) and immunosuppressives such as azathioprine, cyclophosphamide, and cyclosporin-A, with the aim to prevent irreversible organ damage. Interferon-α and TNF-α antagonist infliximab are also successfully used in refractory uveitis. Ruptured pulmonary and peripheral aneurysms, parenchymal neurological disease and severe gastrointestinal complications are the major causes of mortality [1].

# Berylliosis

Gloria L. David, Darryl C. Zeldin
Laboratory of Respiratory Biology, NIH/NIEHS, Research Triangle Park, NC, USA

## Synonyms

Chronic beryllium disease; CBD

## Definition and Characteristics

Chronic granulomatous disease primarily affecting the lungs and characterized by delayed hypersensitivity to beryllium.

## Prevalence

CBD occurs following exposure to beryllium in the form of the metal, metal oxide, or metal alloy [1]. Exposure usually occurs in the workplace with those in the aerospace, ceramics, electronics, and defense industries at highest risk. CBD is estimated to develop in 2–16% of exposed workers, depending on type of exposure and genetic susceptibility. Approximately one million individuals in the United States are potentially exposed to beryllium in the workplace.

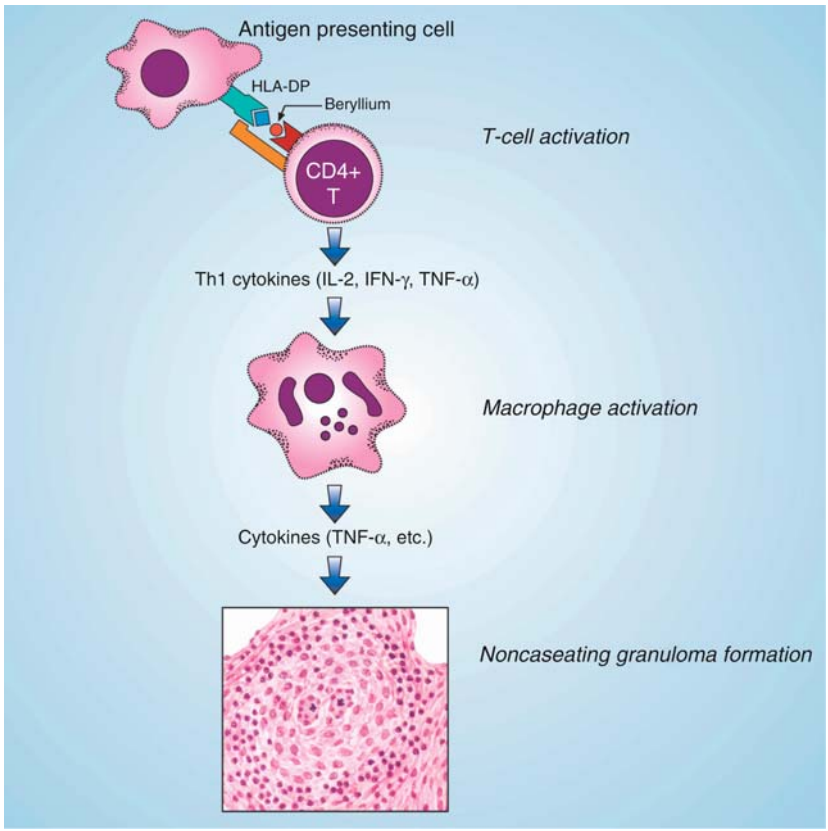
## Genes

Human leukocyte antigen-DP (HLA-DP), localized on chromosome 6p21.3, has been shown to influence the risk of CBD [2,3,4].

## Molecular and Systemic Pathophysiology

Acute respiratory reaction to beryllium, which is inhaled as a dust or a fume, is characterized by tracheitis, bronchitis and chemical pneumonia which can sometimes lead to acute respiratory insufficiency. About 90% of patients recover from the acute reaction without long-term sequelae, but some develop CBD. CBD is caused by a specific immunological response directed against beryllium (Fig. 1).

$CD4^+$ T-cells are thought to mediate the immunopathogenesis of CBD. The development of granulomatous



**Berylliosis. Figure 1** Mechanism for the development of granulomatous inflammation in CBD. Upon presentation of beryllium to $CD4^+$ T-cells, Th1 cytokines are released which trigger accumulation and activation of macrophages and subsequent development of noncaseating granulomas.

inflammation is associated with the accumulation of $CD4^+$ T-cells in the bronchoalveolar lavage fluid, and $CD4^+$ T-cells from patients with CBD proliferate in response to $BeSO_4$ exposure *in vitro*. Upon T-cell activation, Th1 cytokines (including interleukin-2, interferon-γ, and tumor necrosis factor (TNF)-α) are released, and lead to accumulation and activation of macrophages and the subsequent development of granulomatous inflammation. HLA-DP is the primary HLA class II molecule involved in beryllium presentation. In epidemiologic studies of exposed workers, berylliosis risk has been consistently associated with HLA-DPB1 alleles containing glutamic acid at position 69 (Glu69). The HLA-DPB1 Glu69 marker is expressed in 73–97% of disease cases and only 30–48% of controls. Recent studies have suggested that polymorphisms in HLA-DRB1, HLA-DQB1, and TNF-α may also be associated with genetic susceptibility to CBD [5].

Animal models of CBD have been developed in rats, mice, dogs, and nonhuman primates; however, none of the models duplicate the chronic and progressive nature of CBD present in humans.

## Diagnostic Principles

Symptoms of CBD usually appear within 5 years but may be delayed as long as 20 years after the initial exposure. It is possible for CBD to develop without a symptomatic acute phase. Patients with CBD often complain of progressive exertional dyspnea, dry cough, chest pain, weight loss, and fatigue. Clubbing of the fingers occasionally occurs. Auscultation of the chest reveals rales and rhonchi. The chest radiograph, which shows diffuse infiltrates with bilateral hilar adenopathy, is often difficult to distinguish from sarcoidosis. Pulmonary function studies reveal restrictive lung disease with reduced compliance and diffusing capacity. CBD often results in progressive loss of respiratory function with hypoxemia, pulmonary hypertension, right-sided heart failure, and death from cor pulmonale. Extrapulmonary manifestations of CBD include hypercalcemia, hypercalciuria, hyperuricemia, hypopituitarism, skin reactions, and conjunctivitis. Diagnosis depends on the following: (i) a history of beryllium exposure; (ii) histologic evidence of noncaseating granulomas on transbronchial or open lung biopsies; and (iii) beryllium-stimulated blood or bronchoalveolar lavage lymphocyte proliferation. If exposure is suspected but cannot be confirmed by the patient's history, beryllium can be measured in lung or lymph node tissue or in urine; however, the utility of such analyses is questionable.

## Therapeutic Principles

Patients with CBD should be removed from further beryllium exposure. There is no specific treatment for this disorder; however, treatment with corticosteroids may induce remission.

## Bilateral Absence of Vas Deference, Congenital

Bärbel Schütte
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

CBAVD

### Definition and Characteristics

Congenital bilateral absence of vas deference (CBAVD) is a severe reproductive disorder characterized by

bilateral absence or atrophy of the vas deferens, often associated with hypo- or aplastic epididymal corpus or cauda, and deficiency of the seminal vesicles leading to obstructive azoospermia and infertility. Men with CBAVD suffer from unilateral renal malformations such as renal aplasia or ectopy in ~10% [1]. Patients exhibiting CBAVD have generally normal or only slightly reduced spermatogenesis and normal values of testosterone, FSH and LH. Most men with CBAVD are carriers of mutations in the cystic fibrosis (CF) transmembrane conductance regulator (CFTR) gene. Thus, CBAVD is regarded as a mild form of CF without clinical signs of pulmonary or digestive symptoms, respectively, with subclinical symptoms of CF such as mild elevation of sweat chloride concentrations and mild respiratory infections [1]. CBAVD with chronic sinopulmonary infections but without mutations of the CFTR gene is called Young syndrome.

## Prevalence

CBAVD affects one in 10,000 men and is responsible for up to 1–2% of male infertility and 6% of all obstructive azoospermia cases. In CF, the most frequent autosomal recessive disorder with a prevalence of 1/2,500 life births and a carrier frequency of 1:25, patients are infertile due to CBAVD in ~98%. Conversely, ~75% of patients with CBAVD have mutations of the CFTR gene [2].

## Genes

In CBAVD and CF mutations have been detected in the CFTR gene, localized on the long arm of chromosome 7, subregion q31.2. The CFTR gene is a chloride channel protein found in concentrated levels in the apex membranes of epithelial cells that line the passageways of the lungs, pancreas, colon and genitourinary tract. The most common mutations in CBAVD phenotypes are delta F508, R117H and the T5 allele (IVS8-T5) [2,3]. The latter is the most frequent CFTR gene alteration in CBAVD and has been demonstrated to cause a high level of exon 9 skipping, leading to a non functional CFTR protein and is considered to be a mild mutation with an incomplete penetrance [2].

## Molecular and Systemic Pathophysiology

CBAVD, not associated with mutations of the CFTR gene, is caused by abnormal development of the Wolffian duct during embryogenesis including epididymis, vas deferens, seminal vesicles and ejaculatory ducts. Defective versions of the CFTR protein due to gene mutations cause cystic fibrosis and CBAVD. CFTR contains 27 exons and encodes a protein of 1,480 amino acids that functions as a cAMP-activated chloride channel. Furthermore, it is a regulator of water and sodium transport. In the epididymis the CFTR protein and aquaporin (AQP), a water channel protein, play an important role in the generation of epididymal fluid and controlling water permeability. AQP-9 in rats causes an increase of water permeability which is further potentiated by the CFTR protein [4]. In men with CBAVD due to mutations in CFTR genes, it is suggested that the epididymal fluid becomes viscous and thickened secondary to the effects of the CFTR protein mutations on the function of the chloride channel. Thus, water and sodium reabsorption from the epididymal lumen outweighs the limited chloride secretion leading to a high protein concentration and a low flow rate with thick mucus secretions in the epididymal lumen. The thick abnormal mucus may lead to a progressive obstruction and atrophy of the ductal system.

## Diagnostic Principles

CBAVD is a clinical diagnosis based on scrotal palpation, transrectal ultrasound and semen analysis. Furthermore, diagnosis of CBAVD requires genetic screening of the patients to detect cystic fibrosis mutations [5].

## Therapeutic Principles

Microepididymal spermatozoa aspiration (MESA) or percutaneous epididymal spermatozoa aspiration (PESA) combined with intracytoplasmatic spermatozoa injection (ICSI) is the treatment of choice for patients with CBAVD. However, the couples should have genetic counseling about the risk of CF and CF mutations before proceeding with assisted reproduction.

## Biliary Atresia

Lee A. Denson
Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

### Synonyms

Extra-hepatic biliary atresia

### Definition and Characteristics

Idiopathic progressive necro-inflammatory obliteration of the biliary tree occurring in the neonatal period leading to obstructive biliary cirrhosis [1].

### Prevalence

This occurs in 1 of 8,000 Asian to 1 of 14,000 European live births. It is more common in females than males, and in some countries has seasonal peaks.

### Genes

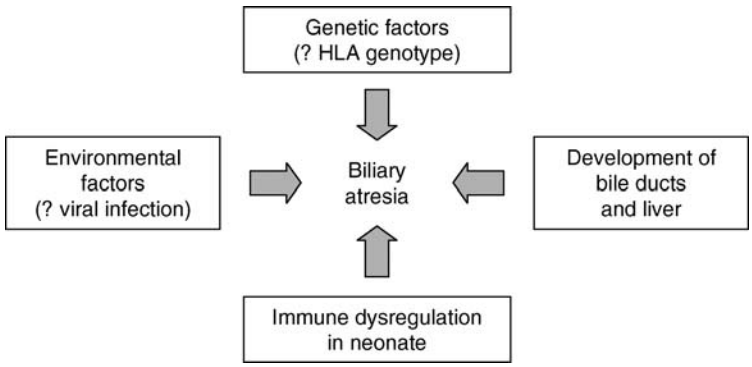
Twenty percent have an embryonic form which may be associated with other birth defects, however no causative gene has been identified. Coincident mutations in JAG1 have been associated with a more severe phenotype.

### Molecular and Systemic Pathophysiology

Biliary atresia (BA) is characterized by a progressive necro-inflammatory obliteration of the biliary tree occurring in the neonatal period leading to obstructive biliary cirrhosis. Without surgical treatment, this will lead to complete fibrous obliteration of the extra-hepatic biliary tree within 3 months of birth; children will then progress to biliary cirrhosis and liver failure between 12 and 36 months of age. In these infants, it has been proposed that a combination of (i) genetic susceptibility, (ii) postnatal environmental insult(s), (iii) neonatal immune dysregulation, and/or (iv) intra-uterine abnormalities in hepatobiliary development lead to the progressive cholestatic phenotype (see Fig. 1).

Eighty percent of affected infants have the postnatal or acquired form, in which an initial jaundice free period is followed by the development of jaundice and acholic stools in the second to fourth week of life. For these infants, it has been proposed that the combined effects of a genetic susceptibility and perinatal viral infection may cause a viral-induced autoreactivity leading to cellular destruction of the biliary epithelium [2]. While several viruses including reovirus and rotavirus have been implicated in individual cases series, none have been conclusively demonstrated to play a causative role. Recently, Bezerra et al. have demonstrated a pattern of gene expression consistent with a $T_H1$ immune response in infants with BA relative to cholestatic controls [3]. This has supported a role for auto-reactive T cells in mediating the progressive biliary destruction in the majority of cases.

Twenty percent of infants present with the embryonic form, characterized by jaundice and acholic stools within the first 3 weeks of life without a jaundice free period, in association with other congenitial abnormalities. For most, this includes some or all of the components of the polysplenia syndrome, which include polysplenia, a midline liver, interrupted vena cava, situs inversus, preduodenal portal vein, and malrotation of the intestine.



**Biliary Atresia. Figure 1** Proposed pathogenesis of biliary atresia. Adapted with permission from [1].

Congenital heart defects may be present in up to 30%. It is presumed that an abnormality in bile duct development may play a role in these cases, although a causative gene has not been identified. While a mutation in the inv gene leads to abnormal hepatobiliary development and biliary obstruction in the mouse, sequencing of the human INV gene has not implicated this in cases of BA. Heterozygous mutations of the CFC1 gene have been identified in two unrelated patients with the syndromic form of BA, raising the possibility that these may combine with other genetic or environmental insults to yield the BA phenotype in some patients. Finally, several patients with a more severe form of BA have recently been shown to have mutations in the JAG1 gene, implicating this as a potential disease modifier in BA.

## Diagnostic Principles

The diagnosis of BA should be suspected in all infants presenting with neonatal cholestasis, particularly when hepatomegaly and acholic stools are present. Stool color cards alerting parents to the presence of acholic stools at 4 weeks of age have proven to be quite useful in terms of reducing the age at diagnosis in Japan. A timely diagnosis is critical, as this will influence the success of the surgical intervention, the Kasai portoenterostomy. A fractionated bilirubin will demonstrate conjugated hyperbilirubinemia. The differential diagnosis for neonatal conjugated hyperbilirubinemia is beyond the scope of this review; the reader is referred to the section in this text covering intrahepatic and obstructive cholestasis. However, BA, together with specific infectious, metabolic, and obstructive entities should be amongst the first conditions which are evaluated and ruled out. Affected infants will present with progressive jaundice, hepatosplenomegaly, and acholic stools in the first 8 weeks of life. Weight gain is typically normal. A liver biopsy is the most sensitive and specific test for identifying the presence of extrahepatic biliary obstruction consistent with BA. This is combined with appropriate serum and urine tests to rule out other treatable infectious or metabolic causes of neonatal cholestasis, as well as an abdominal ultrasound to rule out choledochal cyst. Recently, the "triangular cord" sign has been characterized as a potentially sensitive and specific finding on abdominal ultrasound, with a diagnostic accuracy which may approach 95% [4]. Hepatobiliary scintigraphy may be used to determine whether there is excretion of bile into the small intestine. However, this test may be abnormal in more severe forms of intra-hepatic cholestasis, including neonatal hepatitis, and so is only 50–75% specific for BA. Conversely, though, the sensitivity for BA is on the order of 95%. An intraoperative cholangiogram will then confirm obliteration of the lumen of the extrahepatic biliary tree.

## Therapeutic Principles

For most infants diagnosed before 12 weeks of age, the Kasai portoenterostomy will afford sufficient restoration of bile flow to allow resolution of jaundice, and a significant period of relatively normal growth and development. The older the infant at the time of surgery, the less likely it is that bile flow will be restored, and the more likely it is that they will progress to biliary cirrhosis and liver failure. Postoperative management of these patients varies widely, in terms of the use of prophylactic antibiotics or corticosteroids to maintain patency of the biliary tree [5]. Suspected episodes of ascending cholangitis should be managed aggressively with antibiotics and in some cases, corticosteroids, as these will ultimately accelerate the development of cirrhosis. Nutritional management includes providing a formula enriched in medium chain triglycerides and adequate fat soluble vitamin supplementation. Ursodeoxycholic acid (UDCA) is widely used to promote bile flow and reduce toxicity of the endogenous bile. Ultimately, repeated bouts of ascending cholangitis and ongoing destruction of initially patent intrahepatic ducts will lead to biliary cirrhosis and liver failure in 70–80% of patients during the first two decades of life. These patients then receive orthotopic liver

transplantation, which is currently associated with an 80–90% long-term survival.

# Biliary Calculi

►Cholecystolithiasis

# Biliary Cirrhosis, Primary

Andreas Erhardt
Department of Gastroenterology, Hepatology and Infectious Diseases, Heinrich-Heine University of Duesseldorf, Duesseldorf, Germany

## Synonyms

PBC

## Definition and Characteristics

Chronic cholestatic liver disease in adults with autoimmune features characterized by destruction of biliary epithelial cells resulting in progressive fibrosis and eventual cirrhosis.

## Prevalence

The prevalence of PBC is reported to range between 19 and 240 cases per million affecting females to males at a ratio of 9/1.

## Genes

Genetic predisposition to autoimmunity has been associated in certain subgroups with alleles from MHC loci including DR3, DR8, DQA1*0102, DQ/β1*0402.

## Molecular and Systemic Pathophysiology

PBC is morphologically characterized by portal inflammation, biliary cell necrosis and focal destruction of bile ducts. There is evidence for an immune mediated disease mechanism in PBC [1]. The finding of antimitochondrial auto-antibodies (AMA) is a major hallmark in humoral immunity in PBC [2]. The most frequent target antigen of AMAs is a nine amino acid sequence (159–167) in the E2 subunit, a lipoamide acetyltransferase, of the mitochondrial pyruvate dehydrogenase complex (PDC), which is aberrantly found in the apical region of bile duct epithelia in PBC. The AMA-M2 subtype is specific for PBC. Despite a close association between autoantibody and disease, the pathogenic role of AMAs is unresolved. Molecular mimicry by microbial or pharmacological antigens, like Escherichia coli, Helicobacter sp, Chlamydia pneumoniae or antibiotics, as well as enhanced expression of the PDC-E2 subunit in cholangiocytes triggered by retrovirus infection have been proposed as a possible pathogenic mechanisms. Further disease mechanisms regard impaired T cell function, disequilibrium in the Th1–Th2 lymphocyte subsets, and their interplay with cytokines like TNF-α, interleukin-8 and interleukin-12.

## Diagnostic Principles

Fatigue and pruritus are early clinical signs present in the majority of patients. Rises in serum alkaline phosphatase, hyperlipidaemia, increased levels of IgM and bile acids point to the disease. Osteoporosis, steatorrhoea and fat soluble vitamin deficiency might be present. For diagnosis of PBC two of the three following criteria are needed: (i) serum alkaline phosphatase levels at least two times the upper limit of normal values (ii) presence of AMA, which are found in 90–95% of patients (iii) liver biopsy showing florid bile duct lesions. The Mayo Clinic model can be used for prediction of long-term survival [3]. Patient's age, serum bilirubin, albumin, prothrombin time and presence of edema and ascites are independent predictor variables. Screening for fat-soluble vitamins is recommended.

## Therapeutic Principles

Ursodeoxycholic acid at daily doses between 13 and 20 mg/kg has been shown to reduce liver transaminase activity, the risk of death and liver transplantation, but there are nonresponders to this treatment [4]. Liver transplantation is a therapeutic option in advanced disease. Cholestyramine (8 g daily) and rifampicin (150–600 mg) can relief pruritus. Replacement therapy for fat-soluble vitamins has to be considered in case of deficiency.

# Biliary Ectasia, Congenital

Ralf Kubitz, Dieter Häussinger
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

Congenital biliary (tract) ectasia; Caroli's syndrome

## Definition and Characteristics

Congenital biliary ectasia is characterized by segmental and multifocal dilatation of large intrahepatic bile ducts [1]. Dilatation of bile ducts in congenital biliary ectasia goes along with congenital hepatic fibrosis (Caroli's syndrome/combined form), but in some patients there is no other apparent hepatic abnormality (Caroli's disease/pure form). Congenital biliary ectasia may become symptomatic in early infancy with rapid progression or may be first diagnosed in patients 50 years and older.

## Prevalence

Several hundred cases of congenital biliary ectasia are reported in the literature, however, no exact statistics of this condition exist. Congenital hepatic fibrosis and autosomal *recessive* polycystic kidney disease (ARPKD), the most frequent associates to congenital biliary ectasia, are estimated to affect 1:20.000 persons in the general population.

## Genes

Congenital biliary ectasia is transmitted in an autosomal recessive mode. There is an association with ARPKD but occasionally it also develops in patients with autosomal *dominant* polycystic kidney disease (ADPKD).

The gene underlying congenital biliary ectasia in the context of ARPKD has been mapped to the long arm of chromosome 6 (6p21-p12). It is termed polycystic kidney and hepatic disease 1 (PKHD1). PKHD1 is a large gene (~470 kb) with 86 exons [2]. It encodes for a protein as large as 4074 amino acids (fibrocystin polyductin). Shorter splice variants exist (tigmin). The gene product of PKHD1 is expressed in kidneys and livers and to a lesser extent in pancreas and lungs. Its function has not been fully elucidated, however, due to structural similarities with the hepatocyte growth factor receptor and plexins, is has been speculated that it may be involved in the regulation of cell proliferation and/or cell adhesion.

The less common variant of congenital biliary ectasia emerges in the context of dominant polycystic kidney disease (ADPKD) [3]. ADPKD has been linked to mutations of PKD1 or PKD2, which encode for their gene products polycystin-1 and -2 [4]. These proteins interact to form heterodimers. They are probably part of a membrane spanning complex, which signals toward β-catenin and AP-1 transcription factor involving G proteins, protein kinase C, and MAP kinases [5]. Polycystin-1 is expressed in kidney, liver, and the biliary system during embryogenesis that may explain the association between liver and kidney disease.

## Molecular and Systemic Pathophysiology

A major pathophysiological consequence of congenital biliary ectasia is stasis of bile within dilated bile ducts. Cessation of bile flow promotes the formation of biliary sludge and intraductal bile stones. It may favor cholangitis due to bacterial infections, which may result in septicemia and hepatic abscess formation. Pruritus due to cholestasis is common.

Because in most cases congenital biliary ectasia is associated with congenital hepatic fibrosis, symptoms of portal hypertension may arise (ascites, splenomegaly, or esophageal varices).

## Diagnostic Principles

Clinical signs are nonspecific and include an enlarged liver. Furthermore, kidneys and spleen may be palpable,

if polycystic kidney disease or portal hypertension coexists. Laboratory findings show cholestasis with elevation of alkaline phosphatase and direct bilirubin.

Diagnosis of congenital biliary ectasia is based on imaging techniques. Abdominal ultrasound shows irregular dilatation of intrahepatic bile ducts, while the common bile duct is not affected, unless congenital biliary ectasia is combined with a choledochal cyst. These features may also be seen by endoscopic retrograde cholangiography (ERC) or, with high sensitivity, by magnetic resonance cholangiography (MRC), a favorable technique for the diagnosis of biliary ectasia in children. Renal involvement can be diagnosed by ultrasound and MRI along with hepatic assessment.

Histological findings include an increase in fibrous tissue (typical for congenital hepatic fibrosis) surrounding the dilated and deformed bile ducts. Inflammatory cells can be present and are indicative for cholangitis. Branches of portal veins may appear hypoplastic.

### Therapeutic Principles

Causative treatment for congenital biliary ectasia is not available. The aim is to limit complications arising from chronic cholestasis, recurrent cholangitis, biliary stone formation, and portal hypertension. Chronic cholestasis may necessitate the supplementation of fat soluble vitamins. Cholangitis should consequently be treated by antibiotics, which may be necessary for prolonged periods, if cholangitis recurs frequently. Biliary stone formation and cholangitis may support each other; therefore endoscopic stone extraction is often required. Stone formation within intrahepatic ducts may limit the success rate of endoscopy. In these cases, therapy with ursodeoxycholate in order to increase solubility of bile is a medical treatment option (10–20 mg/kg body weight per day); however, bile stones in congenital biliary ectasia are pigment stones that are more resis tant to ursodeoxycholate than cholesterol gall stones. Portal hypertension is treated according the general principles. Ultimately, liver transplantation may be necessary in end stage liver disease.

## Billowing Mitral Leaflet Syndrome

►Mitral Valve Prolapse

## Biotin Deficiency

Wendy M. Sealey, Donald M. Mock
Department of Biochemistry and Molecular Biology, University of Arkansas for Medical Sciences, Little Rock, AR, USA

### Synonyms

Vitamin H deficiency; Egg-white syndrome; Egg-white injury

### Definition and Characteristics

A nutritional disorder that results due to a deficiency of the water-soluble, B vitamin biotin.

### Prevalence

Overt biotin deficiency has never been reported in healthy individuals consuming a regular diet but has been demonstrated in three situations: prolonged intravenous feeding without biotin supplementation, prolonged consumption of raw egg white, and in one infant on a rice-based formula without biotin [1]. Biotin deficiency also occurs in patients with three hereditary disorders: ►biotinidase deficiency, holocarboxylase synthetase deficiency, and biotin transporter deficiency [2,3]. Other conditions that predispose patients to marginal degrees of biotin deficiency include anticonvulsant medications, liver disease, inflammatory bowel disease and pregnancy.

## Genes

Biotin deficiency can result from mutations in holocarboxylase synthetase or in biotinidase, and possibly a putative biotin transporter [2,3].

## Molecular and Systemic Pathophysiology

Available evidence suggests that the pathological effects of deficiency are due to the reduced activities of the five biotin-dependent enzymes [1]; acetyl-Co A carboxylase isoenzymes I and II, pyruvate carboxylase, methylcrotonyl-CoA carboxylase, and propionyl-Co A carboxylase. Depletion of biotin results in decreased activities of these carboxylases. Specifically, reduced acetyl-Co A carboxylase activity decreases formation of malonyl-Co A and subsequently reduces fatty acid elongation. Decreased pyruvate carboxylase reduces the formation of glucose from amino acids under conditions of gluconeogenesis. Decreased methylcrotonyl-Co A carboxylase activity blocks the metabolism of leucine. Decreased propionyl-Co A carboxylase activity alters the metabolism of several amino acids, cholesterol, and odd-chain fatty acids and results in the increased accumulation of odd chain fatty acids in plasma lipids and red cell membranes.

## Diagnostic Principles

Symptoms of overt biotin deficiency include hair loss and a scaly red rash around the eyes, nose, mouth and genital area. Neurological symptoms include depression, lethargy and hallucination as well as numbness and tingling of extremities. Definitive indicators of biotin status include increased urinary excretion of 3-hydroxyisovaleric acid, decreased urinary excretion of biotin, and decreased propionyl-Co A carboxylase activity in peripheral blood leukocytes [4].

## Therapeutic Principles

Biotin toxicity has not been demonstrated with daily oral doses of up to 200 mg/day [1]; metabolic acidosis will likely result from ingestion of gram quantities of biotin per day. Children with either holocarboxylase synthetase or biotinidase deficiency respond well, respectively, to 40–100 and 5–20 mg of oral biotin daily.

# Biotinidase Deficiency

Barry Wolf
Department of Pediatrics, University of Connecticut School of Medicine, Hartford, CT, USA

## Synonyms

Late-onset multiple carboxylase deficiency; Juvenile-onset multiple carboxylase deficiency

## Definition and Characteristics

Autosomal recessively inherited metabolic disease due to a defect in the recycling of the vitamin biotin and if not treated with biotin can lead to neurological and cutaneous abnormalities.

## Prevalence

Based on newborn screening for the disorder, the incidence is about 1 in 60,000 births worldwide [1].

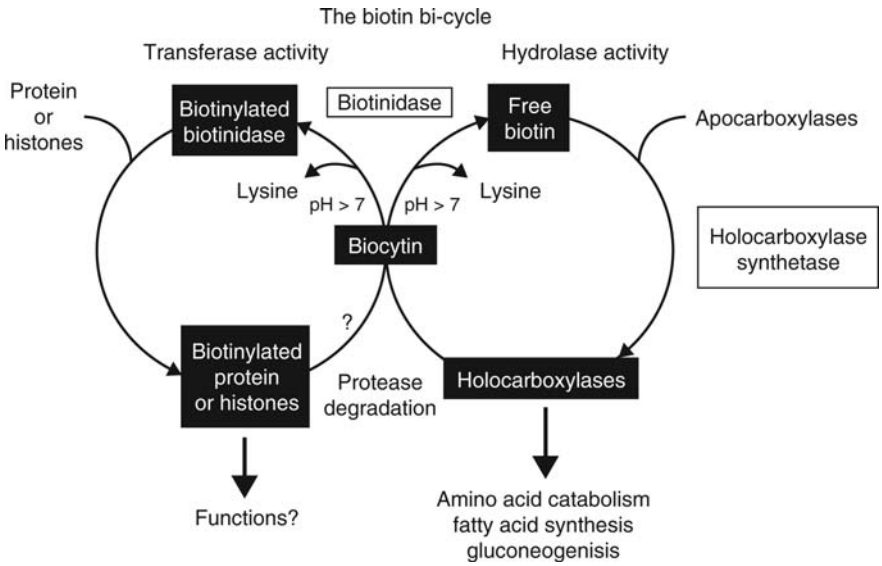
## Genes

The biotinidase (BTD) gene is located on chromosome 3p25 [1].

## Molecular and Systemic Pathophysiology

Biotin is a water-soluble vitamin that as a coenzyme is covalently attached to four carboxylases in humans (Fig. 1) [1].

These carboxylases are involved in glucogenesis, fatty acid synthesis, and the catabolism of several branched-chain amino acids. The enzyme biotin holocarboxylase synthetase covalently attaches biotin to the various apocarboxylases. The carboxyl group of biotin is linked by an amide bond to an ε-amino group of specific lysine residues of the apocarboxylases forming holocarboxylases. When the carboxylases are degraded proteolytically to biocytin (biotinyl-ε-lysine) or biotinyl-peptides, the enzyme biotinidase (EC 3.5.1.12) cleaves the amide bond thereby releasing lysine or lysyl-peptides and free biotin, which is then recycled [2]. Biotinidase apparently also plays a role in the processing of protein-bound biotin, making the vitamin available to the pool of free biotin. In addition, biotinidase has biotinyl-transferase activity resulting in the transfer of biotin from biocytin to



**Biotinidase Deficiency. Figure 1** Biotinidase bi-cycle pathway.

nucleophilic acceptors, such as histones (Fig. 1) [3]. Because biotinyl-transferase activity occurs at physiological pH and at physiological concentrations of biocytin, this may be a major function of the enzyme in serum and other tissues. Finally, there is some evidence to suggest that biotinidase functions as a carrier of biotin in plasma [4]. There are over 80 known mutations of the BTD gene that cause biotinidase deficiency [5].

## Diagnostic Principles

More than 70% of the children ascertained clinically suffer from seizures, hypotonia, skin rash, or alopecia at some time prior to diagnosis and treatment with biotin [1]. About half of the symptomatic children have ataxia, developmental delay, conjunctivitis, and visual problems, including optic atrophy. Three quarters of symptomatic children develop hearing loss. Symptomatic children usually have metabolic ketoacidosis or organic aciduria. Although most symptoms resolve after biotin therapy is begun, hearing loss, visual abnormalities and some degree of developmental delay may be irreversible. Symptoms usually occur at several months of age, but may not occur until several years of age. The initial clinical presentation and ultimate expression of the disorder are variable, even within the same family. Clinical features can range from multiple mild episodes of seizures and ataxia to severe metabolic compromise, that can result in coma or death. Some individuals with biotinidase deficiency manifested only one or two features, whereas others exhibit a full spectrum of findings. A group of children with profound biotinidase deficiency first develop symptoms during late childhood or adolescence. These individuals exhibit motor limb weakness, spastic paresis, and eye problems, such as loss of visual acuity and scotomata, rather than the more characteristic symptoms observed in younger untreated children with the disorder.

Biotinidase deficiency is determined by demonstrating low biotinidase activity in serum or plasma using a variety of assays [1]. A colorimetric assay that measures the liberation of para-aminobenzoate from the enzyme's artificial substrate, biotinyl-para-aminobenzoate, is the most commonly used. Newborn screening for biotinidase deficiency is performed in over 25 states in the United States and in over 25 other countries. Children identified by newborn screening and treated with biotin soon after birth remain asymptomatic [1].

## Therapeutic Principles

Biotinidase deficiency is effectively treated by administering 10–20 mg of oral biotin for life [1]. There are no dietary restrictions or other pharmacological therapies required in the treatment of this disorder.

# Bipolar Affective Disorder

►Bipolar Disorder

# Bipolar Disorder

Johannes Schumacher, Peter Propping
Institute of Human Genetics, University of Bonn, Bonn, Germany

## Synonyms

Bipolar affective disorder; BPAD; Manic depressive illness; Manic depression

## Definition and Characteristics

The core feature of BPAD is a pathological disturbance in mood ranging from extreme elation or mania to severe depression. Typically, BPAD is an episodic illness, usually with full recovery between episodes. The social burden resulting from BPAD is significant, as evidenced in the WHO report which cites BPAD as being the sixth leading cause of disability worldwide [1].

## Prevalence

BPAD is a common psychiatric disorder and has a lifetime prevalence of approximately 1%.

## Genes

Family, twin and adoption studies provide strong evidence of the importance of genes in predisposing to BPAD [2]. Although in occasional families a single gene may play a major role, most family studies support the view that the majority of cases of BPAD have a complex genetic basis. However, the number of susceptibility genes, the disease risk conferred by each gene, the extent of genetic heterogeneity and the degree of interaction between risk genes, all remain unknown.

So far, several genomic regions have been implicated repeatedly in linkage studies of BPAD. The best evidence for BPAD susceptibility genes presently exists for the Disrupted-in-schizophrenia-1 gene (DISC1) on chromosome 1q42 and the G72 gene (G72) on chromosome 13q33.

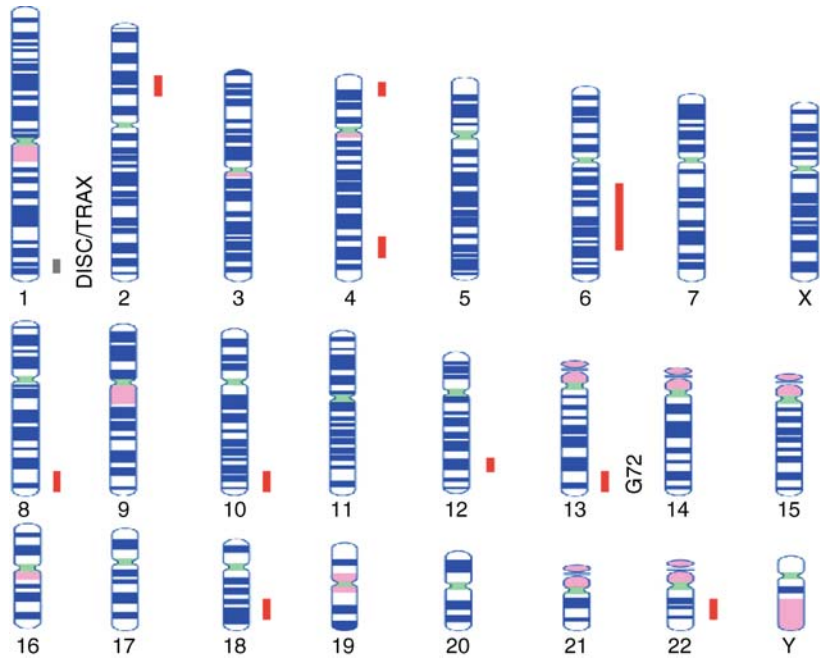
*Results of Genome-Wide Linkage Studies in BPAD*: The pattern of linkage findings in BPAD is typical for a complex disorder: Levels of statistical significance and estimated effect sizes in individual studies are modest, chromosomal regions of interest are typically broad, and no findings are replicated in all data sets. Despite these obstacles, several promising loci have been identified in BPAD by genome-wide linkage studies. These include regions on chromosomes 2p13–p16, 4p16, 4q32, 6q15–q25, 8q24, 10q25–q26, and 12q23–q24 (Fig. 1) [3].

Three additional regions, on chromosome 13q32–q34, 18q21–q23, and 22q11–q12, have repeatedly shown linkage to BPAD and overlap with linkage findings implicated in schizophrenia (Fig. 1) [3]. These chromosomal regions might harbor genes that contribute to the development of psychotic disorders in general.

*Susceptibility Genes in BPAD*: G72 is located in the chromosomal linkage region 13q33 and was initially implicated in schizophrenia by systematic association studies. Until now ten studies were published, which report positive association between schizophrenia and SNPs at the G72 locus [4]. Furthermore, different groups assessed whether G72 also contributes to BPAD, since linkage to chromosome 13q33 has also been reported for BPAD. Applying single marker and haplotype analysis a total of five groups found association between SNPs at the G72 locus and BPAD [4]. Therefore, G72 seems to be rather unspecific at the phenotypic level, contributing to both, schizophrenia and BPAD. At the functional level, there is evidence that G72 contributes to the different psychiatric phenotypes through modulation of the NMDA signaling pathway.

DISC1 was cloned in a multi-generation Scottish family with a translocation t(1;11) (q42;q14.3) [5]. DISC1, which is located on chromosomal region 1q42, is interrupted through the translocation breakpoint. Most of the family members in whom the translocation was detected demonstrated severe affective (bipolar, unipolar, and schizoaffective) or psychotic disorders. In order to determine whether DISC1 is of significance for affected cases outside of this family, several association studies using genetic markers at the DISC1 locus have been performed. In schizophrenia, positive association was found in 6 independent samples. In addition, significant association to markers at the DISC1 locus was also found in two samples with BPAD [5]. Similar to G72, DISC1 seems to increase risk across the traditional classification systems that dichotomized schizophrenia and BPAD. However, the disease causing DISC1 variant(s) have not been identified so far and therefore association studies in the future have to determine the exact genotype–phenotype relationship. At the functional level, DISC1 binds a number of proteins known to be involved in essential processes of neuronal function, including neuronal migration, neurite outgrowth, cytoskeletal modulation, and signal transduction.

Identifying susceptibility genes for BPAD will facilitate the understanding of underlying biochemical



**Bipolar Disorder. Figure 1** Chromosome ideogram showing locations of genome-wide linkage findings in BPAD (*given in red*) and promising genes implicated in the pathogenesis of BPAD.

pathways and the development of more specific therapies. In addition, it will provide insights into the interaction of the various etiological factors (gene–gene and gene-environment relation) and will have an impact on disease classification (genotype–phenotype correlation).

## Molecular and Systemic Pathophysiology

The pathophysiology of BPAD has not been determined, and no objective biological marker exists so far that corresponds with the disease state. However, a number of neurotransmitters have been linked to BPAD, largely based on patients' responses to psychoactive agents.

## Diagnostic Principles

The diagnosis of BPAD can only be made clinically, on the basis of existing symptoms and on the history of any previous episodes. However, a physical examination as well as some laboratory tests (thyroid and drug screen) may be performed to rule out other causes of the symptoms.

## Therapeutic Principles

The treatment of BPAD is related to the phase of the episode and its severity. Depressive episodes are treated with antidepressant medication and episodes of mania are usually treated with antipsychotic medication. Often, during acute episodes of illness, mood-stabilizing medicines are used. These are also used for longer-term preventive therapy, the aim of which is to prevent relapses. The most widely used example is lithium. Others include sodium valproate, carbamazepine and olanzapine.

# Birth Asphyxia

►Perinatal Asphyxia

# Birt-Hogg-Dube Syndrome

Dieter Metze
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

Fibrofolliculomas with trichodiscomas and acrochordons

## Definition and Characteristics

Birt-Hogg-Dube syndrome is an inherited genodermatosis characterized by hair follicle hamartomas, kidney tumors and spontaneous pneumothorax with autosomal inheritance [1]. The hair follicle hamartomas present with multiple skin-colored papules, usually on the face. Associated diseases are renal carcinomas, lung cysts, or pneumothorax, and/or colonic polyps, the latter has been disputed [2].

## Prevalence

Birt-Hogg-Dube syndrome is a rare disorder.

## Genes

The Birt-Hogg-Dube syndrome locus lies within the chromosomal band 17p11.2, a genomic region that is unstable and is associated with a number of diseases where protein-truncating mutations could be identified [3]. By positional cloning in the critical region, Nickerson et al. identified mutations in a novel gene (BHD) encoding a protein designated folliculin.

## Molecular and Systemic Pathophysiology

The transcript of folliculin is expressed in most normal adult tissues, including skin, kidney, and lung [4]. The BHD gene is a tumor suppressor gene associated with an increased risk for kidney cancer. Folliculin may interact with the energy- and nutrient-sensing 5′-AMP-activated protein kinase-mammalian target of rapamycin (AMPK-mTOR) signaling pathways.

## Diagnostic Principles

Skin biopsies reveal abnormal hair follicles with epithelial strands extending from the infundibulum of the hair follicle embedded in a perifollicular mesenchyme. According to the proportion of the epithelial and mesenchymal component the morphologic spectrum of this hamartoma ranges from fibrofolliculoma, trichodiscomas to acrochordons [5].

## Therapeutic Principles

Neoplasms are treated according to location and type.

## Definition and Characteristics

In classic bladder exstrophy, the urinary bladder protrudes from the abdominal wall and the mucosa is exposed (Fig. 1).

The mucosa is initially soft and friable [1]. Within 48 h of exposure to the air, the bladder mucosa becomes hyperemic and polypoid [1]. The ureteric orifices are often visible as elevated openings. The bladder is usually smaller than normal. The umbilicus is displaced downward and lies just above the bladder plate. The rectus muscles are separated. In boys, the penis is short and epispadic, with a dorsal chordee. In girls, the labia and mons pubis are separated anteriorly, and the clitoris is bifid. The vaginal introitus is displaced anteriorly. In both sexes, the anus is displaced anteriorly. Diastasis of the pubic symphysis is caused by outward rotation of the innominate bones, outward rotation or eversion of the pubic rami, and a posterolateral direction of the acetabula. Affected children often walk with a waddling gait. Associated anomalies include inguinal hernia, cryptorchidism, vesicoureteral reflex, horseshoe kidney, pelvic kidney, unilateral renal agenesis, and spinal anomalies. Complications include urinary tract infection, urinary incontinence, hydronephrosis, fecal incontinence, rectal prolapse, uterine prolapse, subfertility, and carcinoma of the bladder [2].

## Prevalence

The incidence has been estimated to be 3.3 per 100,000 live births [1]. Boys are affected 2–3 times more frequently than girls [2].

## Molecular and Systemic Pathophysiology

The defect likely develops within 8 weeks of fetal development after the urorectal septum has partitioned the cloaca into a posterior rectum and an anterior primitive urogenital sinus [1]. The most popular theory is that abnormal overdevelopment of the cloacal membrane produces a wedge effect that prevents medial migration of the mesenchymal tissue and proper development of the lower abdominal wall [3]. Another theory postulates that abnormal persistence of the caudal position of the insertion of the body stalk on the embryo makes normal ingrowth of mesenchymal tissue to the midline impossible. A further theory is that early rupture of the cloacal membrane interferes with mesodermal ingrowth.

**Bladder Exstrophy. Figure 1** Bladder exstrophy. Note bladder mucosa protruding through a triangular fascial defect in the abdominal wall.

## Diagnostic Principles

The diagnosis is mainly clinical. Prenatal diagnosis is possible with ultrasonography which may show absence of cyclical bladder filling, a low-set insertion of the umbilicus, widening of the pubic rami and iliac crests, a small penis with a anteriorly displaced scrotum, difficulty in ascertaining the sex of the fetus, and a lower abdominal bulge that represents the exstrophied bladder [3].

### Therapeutic Principles

At birth, the umbilical cord should be ligated with a suture and the umbilical clamp removed to avoid trauma to the exposed bladder mucosa [2]. The bladder should be covered with a sterile non-adherent plastic wrap dressing to prevent adherence of the bladder mucosa to clothing or diapers. Broad-spectrum antibiotic therapy should be administered prophylactically. The traditional surgical approach involves a series of staged reconstructive procedures. Primary closure of the bladder is usually performed within 48–72 h of birth; epispadias repair, between 6 and 12 months of age; and bladder neck reconstruction, between 4 and 5 years of age, or when there is a bladder capacity of at least 60 ml. Recently, a single-stage complete reconstruction of the epispadic penis with closure of the bladder has been reported with good preliminary results [4]. A renal ultrasonogram is necessary to identify hydronephrosis or other renal anomalies. A voiding cystourethrogram (VCUG) should be obtained after surgical correction of the exstrophy to look for vesicoureteral reflux.

Mark Berneburg[1], Thomas Schwarz[2]
[1]Department of Dermatology, Eberhard Karls University, Tuebingen, Germany
[2]Department of Dermatology, University Hospital of Schleswig-Holstein, Campus Kiel, Kiel, Germany

### Synonyms

Bloom-Torre-Machacek syndrome; Congenital telangiectatic erythema; BLM

### Definition and Characteristics

Clinical features include proportionate pre- and postnatal growth deficiency, diabetes mellitus, susceptibility to infections, infertility in men and reduced fertility in women, photosensitivity, lupoid aspect of the face with telangiectasia, hypo- and hyperpigmented skin and a long narrow face with prominent nose, malar hypoplasia and small mandible. Patients suffer from an increased risk to develop solid or hematopoietic tumors including lymphoma, adenocarcinoma of the sigmoid and carcinoma of the mouth and esophagus. This leads to a reduced lifespan with few patients reaching ages of 40 years or older.

### Prevalence

Approximately 150 cases reported.

### Molecular and Systemic Pathophysiology

Autosomal recessive disease with chromosomal location at 15q26.1. Mutations in DNA ligase I cause Bloom syndrome. DNA ligase I is a member of the RecQ gene family (see ►Werner syndrome) which is responsible for maintaining genomic stability.

DNA ligase I is involved in coordinating replication and DNA repair. Normally, upon ultraviolet radiation, x-ray or restriction enzyme digestion of cells transcriptional upregulation of the tumor suppressor gene *p53* gene can be found. This does not occur in cells from patients suffering from BLM showing a complete absence of p53 increase although the exact mechanism is unclear.

### Diagnostic Principles

The clinical features, in particular the facial appearance lead to the diagnosis of BLM. Chromosomal abnormalities called quadriradial figures are characteristic for BLM. The diagnosis is confirmed by sequencing of the DNA ligase I gene.

### Therapeutic Principles

Since the underlying defect cannot be cured the occurring complications need to be treated. Tumors have to be diagnosed as early as possible and treated according to the specific tumor entity although treatment modalities are restricted since cultivated cells of BLM patients show hypermutability after exposure to x-rays or chemotherapeutic agents. Consequent photoprotection and supportive skin care is recommended.

# Bourneville-Pringle Disease

Markus Hengstschläger
Medical Genetics, Obstetrics and Gynecology, Medical University of Vienna, Vienna, Austria

## Synonyms

Tuberous sclerosis complex; TSC; Tuberous sclerosis

## Definition and Characteristics

Tuberous sclerosis (TS) is an autosomal-dominant genetic disease characterized by the development of mostly non-malignant tumors, named hamartomas, in the kidney, heart, skin and brain. The last often cause seizures, mental retardation and a variety of developmental disorders, including autism.

## Prevalence

The severity ranges from mild skin abnormalities to severe phenotypes including renal failure and mental retardation. Mildly affected persons often go undiagnosed. Accordingly, it is hard to estimate the true prevalence. The incidence is estimated to be 1 in 6,000 newborns.

## Genes

Patients carry a mutant TSC1 or TSC2 gene in each of their somatic cells and loss of heterozygosity has been documented in a wide variety of hamartomas. One third of the mutations are inherited from a parent who is also affected; two thirds are sporadic. Inactivation of TSC1 and TSC2 cause similar, but probably not identical, phenotypes. The tumor suppressor gene TSC1 on chromosome 9q34 encodes hamartin and TSC2 on chromosome 16p13.3 encodes tuberin.

## Molecular and Systemic Pathophysiology

Hamartoma development is assumed to be the result of somatic second hit mutations according to Knudsen's tumor suppressor model. Accordingly, although the disease is transmitted in an autosomal dominant fashion, mutations in TSC1 or TSC2 are believed to be recessive at the level of the affected cell.

Hamartin and tuberin form a complex. They have been implicated in the regulation of different functions, such as transcription, neuronal differentiation, cell adhesion or apoptosis. A major function of the TSC1/TSC2 complex is its role as a GTPase activating protein against Rheb (a Ras-like small GTPase), which in turn regulates mTOR (mammalian target of rapamycin) signaling. The TSC1/TSC2 complex antagonizes the mTOR signaling network, which has a central role in the regulation of cell growth in response to growth factors, cellular energy and nutrient levels. In addition, tuberin and hamartin have been demonstrated to be potent regulators of the mammalian cell cycle by controlling the activity of the cyclin-dependent kinase inhibitor p27.

## Diagnostic Principles

A definite diagnosis includes either two major or one major and two minor features, a probable diagnosis includes one major and one minor feature, and a possible diagnosis includes either one major or two minor features:

If a familiar gene mutation in either TSC1 or TSC2 has been detected, prenatal genetic diagnosis is possible. In addition prenatal ultrasound diagnosis of e.g. a cardiac rhabdomyoma or a cortical tuber is possible (Table 1).

## Therapeutic Principles

Until now there has been no curative therapy available. Mildly affected patients may often not show symptoms until later in life. Most people with tuberous sclerosis

**Bourneville-Pringle Disease. Table 1** Diagnostic principles of tuberous sclerosis

| Major features | Minor features |
|---|---|
| Facial angiofibromas or forehead plaques | Multiple randomly distributed pits in dental enamel |
| Non-traumatic ungual or periungual fibroma | Hamartomatous rectal polyps |
| Hypomelanotic macules | Bone cysts |
| Shagreen patch | Cerebral white matter migration lines |
| Multiple retinal nodular hamartomas | Gingival fibromas |
| Cortical tuber | Non-renal hamartoma |
| Subependymal nodule | Retinal achromic patch |
| Subependymal giant cell astrocytoma | Confetti skin lesions |
| Cardiac rhabdomyoma | Multiple renal cysts |
| Lymphangiomyomatosis | |
| Renal angiomyolipoma | |

have a normal life span. In severely affected individuals, early interventions are recommended to overcome putative developmental delays. Although the hamartomas are non-cancerous they may still cause problems. Brain tumors can trigger a number of symptoms including seizures and mental disability. Mostly in women, tuberous sclerosis can be associated with lung involvement, including e.g. lymphangioleiomyomatosis or clear cell tumors, which may cause severe problems. Such involvement is treated with tamoxifen and progesterone. Surgery to remove hamartomas in the kidneys may be recommended to preserve the function of the organ; in the brain, surgery of epileptogenic tubers can be helpful. The finding that the TSC1/2 genes are involved in regulation of the mTOR-signaling network has already initiated clinical trials of treatment of renal tumors and lung cysts by rapamycin, a negative regulator of mTOR. It is the hope of investigators and patients alike that further understanding of the underlying molecular mechanisms will lead to new therapies.

# Bowen's Disease

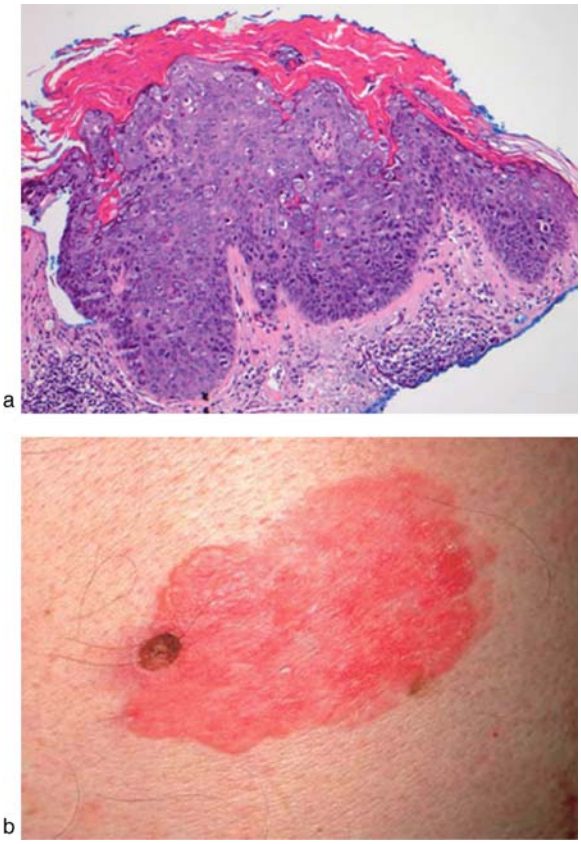
Whitney A. High, Kenneth R. Shroyer
Departments of Dermatology and Pathology, University of Colorado School of Medicine, Denver, CO, USA

## Synonyms

Squamous cell carcinoma in situ; SCCIS

## Definition and Characteristics

Bowen's disease (BD) is an eponym for SCCIS, first described by John Bowen in 1912. BD manifests as full-thickness atypia of epidermal keratinocytes, with architectural and maturational disorder, but without invasion (Fig. 1a).



**Bowen's Disease. Figure 1** Histologic sections of Bowen's disease demonstrates full-thickness atypia of the epidermis, marked disorganization and dysmaturation, innumerable atypical mitotic figures, and overlying parakeratotic debris (a). Clinical examination of this same lesion demonstrated a well-circumscribed scaling, erythematous plaque with a visible punch biopsy site at the lower left edge (b).

BD was once thought to be associated with internal malignancy, but larger epidemiological studies have now refuted this assertion.

BD presents as an asymptomatic, slowly-enlarging, erythematous, and scaling plaque (Fig. 1b). The head and neck are involved most often. Plaques may attain a diameter of several centimeters. A single lesion is present in two thirds of cases.

## Prevalence

Data regarding prevalence is unavailable. Incidence varies with the population under study. In Minnesota, an incidence of 14 cases per year per 100,000 Caucasians was reported; while a similar study from sun-exposed Hawaii reported a tenfold higher incidence. Studies from Canada documented gender variance as well, with 22.4 cases per year per 100,000 women, and 27.8 cases per year per 100,000 men [1]. In all studies, BD has proven more common in the elderly.

## Genes

Genes implicated in the pathophysiology of BD include p53 gene encoding for p53 tumor suppressor protein, INK4 gene encoding for p16 tumor suppressor protein that inhibits cyclin-dependent kinases, Rb gene encoding for pRb tumor suppressor protein (cylin-dependent kinases, themselves inhibited by p16, can dephosphorylate and inactivate pRb), hTERT gene encoding for the human telomerase protein catalytic subunit, survivin gene encoding for an anti-apoptotic protein which acts through phosphorylation-dependent interactions with caspase-9, as well as PKC-δ gene encoding for a pro-apoptotic protein kinase that is downregulated or inactivated in keratinocytes expressing the activated Ha-ras oncogene.

## Molecular and Systemic Pathophysiology

BD may be caused by ultraviolet radiation, human papilloma virus (HPV) infection, or exposure to carcinogens. Immunosuppression may contribute to the development or progression of lesions. The extent to which any single factor predominates depends upon location of the lesion and the patient's exposure history.

The occurrence of BD upon sun-exposed skin implicates ultraviolet radiation. Postproduction of pyrimidine dimers (CC → TT) leading to mutation of the p53 gene is well-recognized. Fifty to 100% of BD demonstrate evidence of p53 mutation. Increased expression of non-functional p53 is demonstrated as lesions progress from actinic keratoses ("pre-malignancy") to frank BD.

The prototypical association between HPV and carcinogenesis is demonstrated in epidermodysplasia verruciformis (EV), a rare autosomal recessive immunodeficiency leading to persistent infection with HPV types 5 and 8. Detection of HPV within BD in the general population, however, is more variable. PCR-based modalities have demonstrated high-risk HPV DNA in 0–83% of cases from the general population, including HPV types 16, 18, 31, 33, 34, 58, 59, and 82. Location has been an important factor in HPV detection, and while genital disease is more likely to demonstrate HPV DNA, infection has been detected in up to 31% of non-genital BD. In periungual and palmoplantar lesions, HPV type 16 has been detected in up to 60% of cases.

HPV-oncoproteins E6 and E7 promote degradation of tumor suppression proteins p53 and pRb, respectively, resulting in unregulated cell proliferation. E6 expression promotes the ubiquitin-mediated degradation of p53, inhibiting apoptosis. E7 binding to pRb results in abbreviation of the G1/S checkpoint. Dysregulation of the G1/S checkpoint is associated with telomerase re-expression, cellular immortalization, resulting in the proliferation of cytologically abnormal cells as a key step in the development of BD. Irrespective of HPV-status, a reciprocal pattern of p16 over-expression and pRb under-expression has been demonstrated in 70–88% of cases [2,3]. Because p16 is unable to arrest the cell cycle in the absence of functional pRb, the observed over expression of p16 in BD is likely a response to lack of functional pRb.

Other described biomarkers of BD include survivin, a member of the inhibitor of apoptosis (IAP) gene family (over-expressed in 80% of BD) [4]; and PKC-δ, a pro-apoptotic kinase (under-expressed in 40% of BD) [5].

## Diagnostic Principles

BD is diagnosed via biopsy of a clinically suspicious lesion using standard histological techniques. Criteria for diagnosis include: (i) full-thickness cytologic atypia of keratinocytes in the epidermis, (ii) disorder maturation, (iii) numerous and/or atypical mitoses above the basal layer. While immunohistochemical stains for the discussed biochemical abnormalities exist (p53, pRb, p16, hTERT, survivin, PKC-δ), such testing is not utilized in the clinical setting.

## Therapeutic Principles

Therapy for BD focuses upon early identification, prior to frank invasion beyond the epithelium, followed by extirpation or chemodestruction. Destructive modalities include: curettage and electrodessication, liquid nitrogen, topical chemotherapy (5-fluoruaracil) or topical immunomodulators (imiquimod 5% cream). Patients with BD are at a higher risk for development of other non-melanoma skin cancers and should be followed accordingly.

## Brachydactyly Type A

M. Elizabeth McCready, Dennis E. Bulman
Ottawa Health Research Institute, Ottawa, ON, Canada

### Synonyms

Brachydactyly type A1; Farabee type brachydactyly; Fitch type 9 BDA1, BDA1A; BDA1B; Brachydactyly type A2; Mohr-Wreidt type brachydactyly; Fitch type 2; Brachymesophalangy II; BDA2; Brachydactyly type A3; Fitch type 3; Brachydactyly-clinodactyly; Clinomicrodactyly; Brachymesophalangy V; BDA3; Brachydactyly type A4; Temtamy type brachydactyly; Brachymesophalangy II and V; BDA4; Brachydactyly type A5; Brachydactyly type A5 with nail dysplasia; BDA5; Brachydactyly type A6; Osebold-Remondini syndrome

### Definition and Characteristics

An autosomal dominant trait characterized by hypoplastic or absent middle phalanges. Brachydactyly type A can occur as an isolated malformation or part of a complex syndrome and is subdivided into five subtypes, types A1–A5, based on the digits involved. In brachydactyly type A1, bones of the hand and feet may be reduced in size, but shortness is most pronounced in the middle phalanges of digits 2–5, and the proximal phalanges of digit 1. Phenotypes may range in severity from a mild variant in which shortness is more prominent in the middle phalanges of digits 2 and 5 than the other digits, to a severe variant in which the middle phalanges are absent or fused to the terminal phalanges. Unlike brachydactyly type A1, which involves all of the digits, shortening of the middle phalanges is limited to digit 2 in brachydactyly type A2 and digit 5 in brachydactyly type A3. Clinodactyly is also common in types A2 and A3, due to a triangular phalanx in brachydactyly type A2 and a sloping of the distal articular surface in brachydactyly type A3. Brachydactyly type A4 is characterized by short middle phalanges in digits 2 and 5, while type A5 is characterized by absent middle phalanges in all of the digits, nail dysplasia and bifid thumbs. It has been suggested that brachydactyly type A4 and A5 may represent mild forms of brachydactyly types A1, and type B respectively [1].

### Prevalence

Brachydactyly types A1, A2, A4 and A5 are rare conditions, although the prevalence of each subtype has not been reported. Brachydactyly type A3 is more frequent, occurring in <1% in people of European and African ancestry, and up to 21% in isolated populations' worldwide.

### Genes

In a subset of individuals with brachydactyly type A1, the condition is caused by mutations in the Indian Hedgehog (IHH) gene, on chromosome 2q35 [2]. The identification of a second locus on chromosome 5p13.3–13.2 in a Canadian kindred with mild brachydactyly type A1, suggests that this condition is genetically heterogeneous [3]. Genetic heterogeneity has also been noted in individuals with brachydactyly type A2 [4]. While mutations in the bone morphogenetic protein receptor 1B (BMPR1B) gene were identified in two unrelated families with brachydactly type A2, linkage analysis of a third family was suggestive of a second locus [4]. More recently, mutations of the growth differentiation factor 5 (GDF5) gene were identified in patients with BDA2 [5]. To date the genes that cause brachydactyly types A3–A5 have not been identified.

### Molecular and Systemic Pathophysiology

Although a mutant gene has been identified in several families with brachydactyly type A1, it is unclear how these mutations contribute to the pathophysiology of this abnormality. IHH is a secreted protein that regulates differentiation of chondrocytes from the proliferative stage to the hypertrophic stage during endochondrial ossification and promotes chondrocyte proliferation and osteoblast differentiation. The IHH mutations identified thus far are in regions of the protein thought

necessary for binding to the Patched receptor. Attenuation of IHH signaling may thereby decrease the growth potential of developing bones by reducing the number of proliferating chondrocytes, and/or increasing the number of cells differentiating from the proliferative to hypertrophic stages. As the middle phalanges are the last phalanges to ossify they may be more affected by reduced chondrocytes than other phalanges [1]. Premature closure of the epiphyses and bone shaft may also contribute to the shortening of these bones [1].

In brachdactyly type A2, the disorder appears to result from abnormal epiphyses, rather than shortened cartilage anlagen. In this subtype of brachydactyly, the epiphysis of the abnormal middle phalanx run continuously from the proximal end of the bone to the distal end, along the short side. This allows for growth of the phalanx outward but not lengthwise. Mutations of the BMPR1B gene have been identified in two families with brachydactyly type A2, resulting in amino acid changes within the highly conserved GS and NANDOR regions of the receptor [4]. In vitro and in vivo studies using chicken Bmpr1b showed that, although the mutations affected normal protein function differently, they both inhibited chondrogenic differentiation through dominant negative mechanisms [4]. Additionally, a mutation of the GDF5 gene was identified in individuals with BDA2, which disrupts binding of GDF5 to BMPR1B [5]. This mutation further stresses the importance of BMPR1B in the molecular pathophysiology of BDA2.

## Diagnostic Principles

The use of metacarpophalangeal profiles can be useful during diagnosis, particularly if the middle phalanges are only mildly hypoplastic. In these profiles the length of each hand bone is measured and the standard deviation for age-matched, sex-matched controls is plotted on a graph. Measurements < 2.0 standard deviations for each middle phalanges in the respective digits, is indicative of brachydactyly type A. To distinguish between mild variances of brachydactyly type A1 and brachydactyly type C, it is also necessary to compare the third and fourth middle phalanges. In type A1 the third middle phalanx is usually longer than the fourth, and there is often a short proximal phalanx in digit one. In type C the fourth middle phalanx is usually longer than the third and the first metacarpal is frequently short [1]. Mutational analysis of the IHH gene can be useful to confirm a diagnosis in a subset of individuals with brachydactyly type A1, while analysis of the BMPR1B and GDF5 genes can be used to confirm a diagnosis of brachydactyly type A2.

## Therapeutic Principles

There are no therapies available for BDA at this time.

# Brachydactyly Type B

Ali R. Afzal
Cardiological Sciences Department, St George's Hospital Medical School, London, UK

## Synonyms

Brachydactyly type B1; BDB1

## Definition and Characteristics

Autosomal dominant absence or hypoplasia of terminal phalanges. Abnormalities are consistently symmetrical and can occur in combination with soft tissue syndactyly and carpal and tarsal fusions. It presents the severest deformity in the brachydactyly group of malformations.

## Prevalence

Brachydactyly type B is very rare. It can occur as an isolated trait or as part of a complex malformation syndrome (i.e., Robinow syndrome).

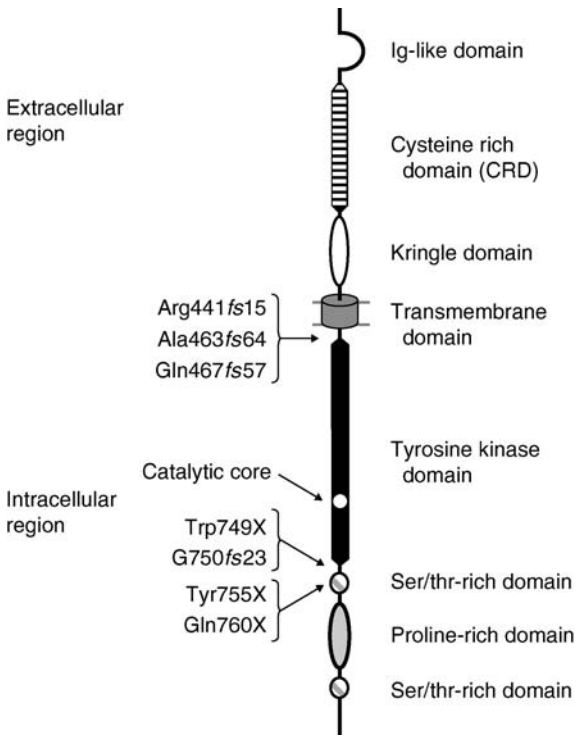
## Genes

Brachydactyly type B is caused by heterozygous mutations in the gene ROR2 coding for a receptor tyrosine kinase, localized on chromosome 9q22. The disease is allelic to recessive Robinow syndrome (see ►Robinow syndrome).

## Molecular and Systemic Pathophysiology

The ROR*2* gene codes for a cell surface orphan receptor tyrosine kinase, which consists of 943 amino acids and binds to an as yet unidentified ligand. It contains distinct motifs, including an immunoglobulin-like (Ig) domain, a Frizzled-like cysteine-rich domain (FRZ or CRD) and a kringle domain (KD) in the extracellular region; a transmembrane section; and an intracellular region with tyrosine kinase (TK), serine/threonine-rich and proline-rich structures. The extracellular domain(s) interact with either soluble ligands or cell membrane proteins i.e. other receptors. The intracellular portion contains the catalytic kinase domain that directly interacts with intracellular components of the relevant signaling pathways.

Heterozygous truncating mutations in the ROR2 gene were recently shown to cause brachydactyly type B. These mutations are located in different intracellular regions of the protein and are predicted to be associated with gain of function. The described sites of mutations in brachydactyly type B are shown in Fig. 1. It has been demonstrated that distal mutations with respect to the TK domain, invariably caused a severe, amputation-like phenotype, affecting three or more digits. However, proximal mutations gave rise to a generally less severe phenotype. ROR2 signaling cascade plays an important role in the control of most basic cellular processes including proliferation, differentiation, and precise migration of specially chondrocytes amongst the other tissues. This results in normal formation and ossification of all bones that undergo endochondral ossification, i.e. limbs, fingers and toes. These involvements explain the digital anomalies seen in brachydactyly type B. Receptor tyrosine kinases similar to ROR2 are monomers in the cell membrane. Ligand binding to the extracellular binding domain leads to dimerization of the receptor which in turn causes activation of the cytoplasmic kinase domain through autophosphorylation of tyrosine residues in the activation loop of the catalytic core and then on other target cellular proteins involved in signal transmission. Conserved tyrosine autophosphorylation sites function as binding sites for SH2 (src homology 2) or PTB (phosphotyrosine binding) domains of a variety of signaling proteins.



**Brachydactyly Type B. Figure 1** Shows location of mutations (see *arrows*) in Brachydactyly type B. fs, frameshift mutation; X, stop mutation.

## Diagnostic Principles

It is a familial disease and the hallmark of diagnosis is severe distal brachydactyly accompanied with nail dysplasia and short middle phalanges.

## Therapeutic Principles

Reconstructive plastic surgery may be needed in debilitating cases.

# Brachydactyly Type C

David B. Everman
Greenwood Genetic Center, Greenwood, SC, USA

## Synonyms

Brachydactyly, Haws type; BDC

## Definition and Characteristics

Brachydactyly type C (BDC) is an autosomal dominant condition characterized by underdeveloped or absent middle phalanges of the second, third, and fifth fingers and metacarpal bones of the thumbs [1,2]. Ulnar clinodactyly of the second and third fingers and radial clinodactyly of the fifth fingers are common findings. In addition to digital shortening, hypersegmentation of the proximal phalanges of the second and third fingers and/or abnormally shaped phalanges may be observed on hand x-rays. The fourth finger is less affected or unaffected and is often the longest finger. Foot changes are less frequently reported but may include shortened middle phalanges and talipes valgus or equinovarus. The condition is variable within and between families. The hand and foot findings are often isolated but may be accompanied by other skeletal abnormalities, including short stature, hip dysplasia, Madelung deformity, and vertebral abnormalities.

## Prevalence

The prevalence of BDC has not been well studied. It is considered to be a rare disorder, but its prevalence is probably underestimated since many cases may not come to medical attention.

## Genes

BDC is caused by mutations in the gene GDF5 (growth/differentiation factor 5), also known as CDMP1 (Cartilage-derived morphogenetic protein 1), on chromosome 20q11.2 [1,2].

## Molecular and Systemic Pathophysiology

GDF5 encodes a member of the transforming growth factor-β (TGF-β) superfamily of secreted signaling molecules that participates in skeletal morphogenesis. The GDF5 protein is involved in the formation of skeletal elements and joints within developing vertebrate limbs. This has been shown through analysis of endogenous GDF5 expression, studies of mice with Gdf5 mutations causing the brachypodism phenotype, and localized over expression of GDF5 protein during limb development in mouse and chick embryos [3]. Like other TGF-β molecules, GDF5 is comprised of a carboxy terminal active domain and an amino terminal prodomain [2,4]. The active domain contains seven conserved cysteine residues that participate in intra- and inter-chain bonding, and the prodomain facilitates dimerization of protein chains. Proteolytic cleavage at a specific site leads to release of the mature disulfide-linked dimeric signaling molecule. BDC typically results from heterozygous GDF5 mutations leading to functional haploinsufficiency [1,2]. The majority are frameshift or nonsense mutations in the prodomain, leading to production of a truncated protein [2]. Missense changes affecting the active domain also cause BDC and have been shown by in vitro expression analysis to prevent formation of the normal mature dimeric signaling molecule [2]. In contrast, homozygous mutations affecting the active domain or prodomain lead to chondrodysplasia, Grebe type and acromesomelic dysplasia, Hunter-Thompson type, which are characterized by severe digital and limb shortening [4]. GDF5 mutations also cause complex brachydactyly with fibular hypoplasia (DuPan syndrome). Recently, heterozygous missense mutations affecting the active domain of GDF5 in different ways have been associated with a variety of other skeletal disorders. These include brachydactyly type A2 (BDA2), which can also arise from mutations in the gene BMPR1B (encoding bone morphogenetic protein receptor 1B), as well as proximal symphalangism and multiple synostoses syndrome, which are also caused by mutations in NOG (encoding noggin, a GDF5 inhibitor). Moreover, in one family a heterozygous missense mutation in BMPR1B was shown to cause BDA2 in a child and overlapping features of BDC and proximal symphalangism in his mother, underscoring the interplay between different components of the bone morphogenetic protein pathway in this group of skeletal disorders (5).

## Diagnostic Principles

The characteristic pattern of digital shortening on clinical examination and hand and foot radiographs leads to the diagnosis of BDC and helps to differentiate it from other forms of brachydactyly. There is often a family history of the disorder. Detection of mutations in GDF5 confirms the diagnosis but is not usually necessary.

## Therapeutic Principles

The adverse effects of BDC are typically more cosmetic than functional, and hand surgery is not usually indicated. Physical therapy or treatment of associated skeletal abnormalities may be warranted.

# Brachydactyly: Oro-facio-digital Syndrome Type I

Claude Stoll
Laboratoire de Génétique Médicale, Faculté de Médecine, Strasbourg, France

## Synonyms

Papillon-Léage; Psaume

## Definition and Characteristics

An inherited syndrome in females comprising lobulated/bifid tongue with nodules, multiple and/or hyperplastic frenuli between the buccal mucosa membrane and alveolar ridge, pseudo cleft of upper lip, abnormal dentition, including absent lateral incisors, unusual facies: hypoplasia of the alae nasi, lateral placement of inner canthi and anomalies of the hand and feet: asymmetric shortening of digits (brachydactyly (Fig. 1) affecting the hands (50–70%) more often than the feet (25%) with clinodactyly, syndactyly and more rarely unilateral polydactyly of feet, variable mental deficiency in about 57 % with average IQ of 70, and polycystic kidney disease, adult type [1].

**Brachydactyly: Oro-facio-digital Syndrome Type I. Figure 1** Asymmetric brachydactyly in a patient with oro-facio-digital syndrome type I.

## Prevalence

The prevalence of the disease is low, estimated at one out of 50,000. About 250 cases are published.

## Genes

OFD1 (CXORF5) gene [2] is localised in Xp22.3–p22.2, acting via a protein - protein interaction mechanism. Most of the mutations identified so far lead to a premature truncation of the protein in its N-terminal region and are therefore predicted to act with loss of function mechanisms. However, due to interference with wild-type proteins in females a dominant – negative effect cannot be ruled out. OFD1 is the first gene for an X-linked dominant male lethal disorder found to escape X inactivation.

## Molecular and Systemic Pathophysiology

OFD1 is ubiquitously expressed in adult tissues. However, during development in mouse embryo a high to moderate level of expression was found in various craniofacial structures and in the nervous system, and lower levels of expression were detected in the integumentary system, the lung, the thymus, and the kidney, correlating well with the tissues affected in patients with OFD I [2].

The OFD1 gene encodes a protein containing coiled – coil α-helical domains. Mutations are spread along the 23 coding exons including missense, nonsense, abnormal splicing, and many frameshift mutations due to deletions and insertions [2].

In affected females, one normal copy of the X chromosome is not sufficient to protect from the disorder. Normal males, who carry only one normal copy of OFD1 may display a higher expression of the transcript on the single active X chromosome. An alternative hypothesis is that OFD1 undergoes X inactivation in the tissues affected in OFDI syndrome at developmental stages when its function is necessary. Therefore, some tissues of affected females during development may result in OFD1 functional nullisomy, by inactivation of the normal X [2]. Individual variation in the X inactivation pattern of this gene may also explain the clinical variability observed in OFD1 syndrome [2].

Thauvin-Robinet et al. [3] reported 25 females with OFD I from 16 French and Belgian families. Eleven novel mutations in the CXORF5 gene were identified in 16 patients from 11 families. The authors found a correlation between genotype and phenotype: renal cysts were associated with splice site mutations, mental retardation was associated with mutations in exons 3, 8, 9, 13, and 16, and tooth abnormalities were associated with mutations in coiled-coil domains. Seven (30%) of 23 patients showed nonrandom X inactivation.

### Diagnostic Principles

The coincidence of oral frenula and clefts, hypoplasia of alae nasi, and digital asymmetry points to the syndrome. The presence of the other features of the OFDI syndrome support the diagnosis. Family history of X-linked dominance with lethality in the vast majority of males is helpful for the diagnosis. However, about half of the cases are sporadic. Detection of mutations in the OFD1 gene confirms the diagnosis.

At least nine different types of oro-facio-digial syndromes were described [4], type II has some features common with type I, however inheritance is autosomal recessive. The other types of oro-facio-digital syndromes are less frequent and different from type I [4].

### Therapeutic Principles

Closure of clefts, removal of hypertrophic frenula, orthodontic and dental care are indicated as well as surgical correction of the hands. Special schooling may be provided for the patients with mental deficiency.

In polycystic kidney disease renal transplantation is able to cure the renal complications [5].

## Brachydactyly-Clinodactyly

►Brachydactyly Type A

## Brachymesophalangy

►Brachydactyly Type A

## Brachyolmia

Sukran Darcan
Department of Pediatric Endocrinology and Metabolism, Faculty of Medicine, Ege University, Bornova İzmir, Turkey

### Synonyms

Platyspondyly

### Definition and Characteristics

It is a skeletal dysplasia that is characterized clinically by short-trunk short stature and radiographically by generalized platyspondyly without significant long bone and skull abnormalities. There are four different types based on vertebral shape, associated features, and mode of inheritance.

### Genes

The basis defect of brachyolmia remains unknown. Clinical, radiological, and genetic differences suggest genetic heterogeneity in this group of platyspondylic disorders.

### Molecular and Systemic Pathophysiology

Qualitative abnormal excretion of glycosaminoglycans is described in some patients. As a likely etiology, a disturbance in chondroitin sulfate synthesis is suggested. Horton et al. found that the growth plate was shorter than normal, and the usual chondrocyte columns were replaced by a few rounded clusters of hypertrophic and degenerative chondrocytes separated by wide matrix septa on the growth plate of iliac crest biopsy.

### Diagnostic Principles

The disease is characterized clinically by short stature and radiographically by generalized platyspondyly. The normal upper/lower segment ratios in some affected patients suggest involvement of the lower limbs. There are four different types (i) Hobaek type is autosomal-recessively inherited, characterized by late childhood onset short-trunk short stature, generalized rectangular platyspondyly without significant long bone changes, in some patients brachydactyly and spinal stenosis are described (ii) Maroteaux type is autosomal-recessively

inherited – differs from the Hobaek type by the rounding of the anterior and posterior vertebral bodies (iii) dominant type – the vertebral bodies are similar to those seen in Maroteaux type but there may be more severe flattening of the vertebra as well as some involvement of the metaphyses; (iv) Toledo type – a qualitative abnormal excretion of glycosaminoglycans in four siblings with brachyolmia and peripheral corneal punctate opacities. Some patients may have borderline mental retardation, deafness, amelogenesis imperfecta associated with brachyolmia.

### Therapeutic Principles

There is no therapy available.

►Pure Autonomic Failure

## Bradypnea

Yu Ru Kou[1], You Shuei Lin[2]
[1]Department of Physiology, School of Medicine, National Yang-Ming University, Taipei, Taiwan
[2]Department of Physiology, Taipei Medical University, Taipei, Taiwan

### Synonyms

Slowing of breathing; Slowing of respiration; Respiratory slowing

### Definition and Characteristics

The normal respiratory rate depends on several factors including the patient's age. The term bradypnea is used to describe abnormally slow rates of breathing that are less than 8–10 breaths per minute in adults and below 16 breaths per minute in infants. This slowing of respiration is due to a prolongation of expiratory duration with or without alternation of the tidal volume. The degree and episodicity of the reduction in respiratory rate can vary from mild to severe depending on the etiology of the event and also the presence of concurrent diseases. A severe bradypnea may significantly reduce alveolar ventilation leading to hypoxemia, hypercapnea and respiratory acidosis. Exacerbation of bradypnea may progress to respiratory depression, a term that is preferentially used in the clinical setting [1].

### Prevalence

Bradypnea with a central origin is more prevalent than that with a peripheral origin because the etiologies that may slow the rhythm of central respiratory network are numerous.

### Molecular and Systemic Pathophysiology

Bradypnea is a clinical sign that reflects abnormality or dysfunction of the respiratory system. In general, the pathophysiological mechanisms for centrally-mediated bradypnea include desensitization of the medullary responses to $PCO_2$, reduction in respiratory neuronal activity, inhibition of neural transmission within the respiratory center and neuronal damage to the brain stem. Additionally, etiologies that disturb synthesis or release of neurotransmitters and their activity on specific pharmacological receptors are able to exert an inhibitory effect on the respiratory rhythm via their corresponding intracellular mechanisms [2]. Centrally-mediated bradypnea can be observed in neonates showing increased respiratory variability, in adults with sleep-related disorders and in patients with head injury or hypothermia; these are partly due to abnormalities of the neurotransmitters controlling the respiratory rhythm or a direct injurious impact on the brain stem. Centrally-mediated bradypnea is also frequently found in patients with neurotoxin poisoning, alcohol intoxication, narcotic abuse or undergoing therapeutic treatment with analgesics or sedative medicines. Alcohol-induced bradypnea is due to alcohol's ability to diffuse through the membranes of neuronal cells; this causes an inhibitory effect by GABA at the GABA receptors and decreases the excitatory effect of glutamate at the NMDA receptors. Opioids, via their action on μ-receptors, depress inspiratory interneurons in a region within the ventrolateral respiratory column that is critical for the generation of respiratory rhythm [3]. Opioids also cause membrane hyperpolarization and a suppression of the activity of

respiratory neurons through both presynaptic and postsynaptic inhibition resulting from a decrease in the intracellular concentration of cyclic adenosine monophosphate [4]. Experimental studies also suggested that activation of the adrenergic $\alpha_2$, cholinergic, purinergic and tachykininergic receptors in the brain stem may all have a capacity to participate in the pathogenesis of centrally-mediated bradypnea.

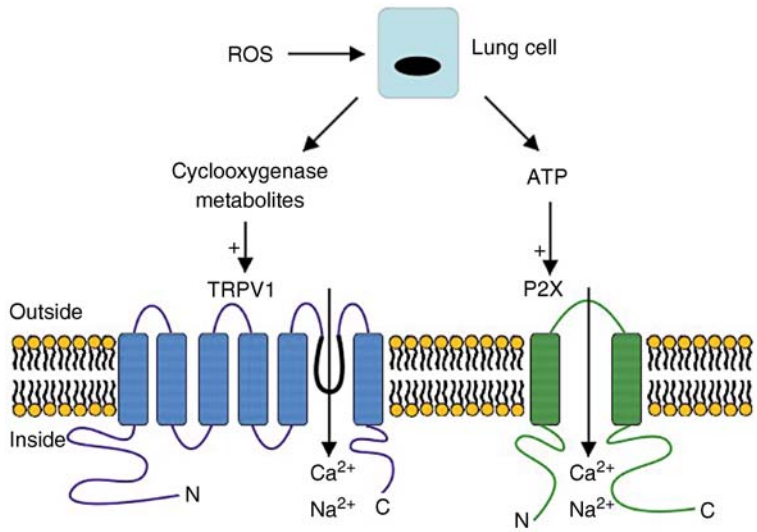
Peripherally-mediated bradypnea can result directly from dysfunction of the respiratory pump and the causes include severe diaphragmatic fatigue, respiratory muscle paralysis and extremely high resistive load for breathing, all of which induce difficulty in breathing. Peripherally-mediated bradypnea can also be trigged as a reflex consequence of stimulation of the vagal sensory receptors located in the upper and lower airways by stimuli such as airborne irritants, cold air, cigarette smoke, toxic smoke and inflammatory mediators. This type of bradypnea presumably is an airway protective reflex, but has been implicated in the pathogenesis of ►sudden infant death syndrome in neonates and ►sleep apnea in adults. Evidence suggests that capsaicin-sensitive vagal lung afferent fibers play a major role in triggering reflex bradypnea. This type of lung afferent fibers is nociceptive-like free nerve endings in the lungs and can be activated by stimuli including noxious heat, acidic pH as well as a variety of chemical irritants and inflammatory mediators. For example, reactive oxygen species (ROS), a major category of inflammatory mediators, can stimulate these lung afferent fibers and trigger reflex bradypnea. This sensory transduction of ROS appears to be mediated through activation of both the transient receptor potential vanilloid 1 (TRPV1) receptors and the P2X purinoceptors located at the terminals of these lung afferent fibers [5]. A hypothetic model for the sensory transduction of ROS is that pulmonary ROS induce the release of cyclooxygenase metabolites and ATP from neighboring cells, which in turn activate the TRPV1 and P2X purinoceptors, respectively, on the afferent nerve endings (Fig. 1).

## Diagnostic Principles

Approaches using devices, such as respiratory inductive plethysmography or pneumotachography, to continuously measure chest wall movement, respiratory flow or tidal volume over at least one minute, are suggested. The diagnosis should be cautious when the bradypnea is mixed with other types of changes in breathing pattern. The diagnosis also should encompass the causes of bradypnea.

## Therapeutic Principles

Elimination of the causes of bradypnea, if possible, is the major therapeutic strategy. Administration of respiratory stimulants has been suggested, although this is not evidence based. If oxygen saturation and blood gases are compromised, an antidote can be used to counteract the central effect of certain respiratory depressants; examples are naloxone for opioids and flumazenil for benzodiazepine. When necessary, the patient ought to be given respiratory support.



**Bradypnea. Figure 1** Schematic illustration showing the hypothetic model of sensory transduction of pulmonary reactive oxygen species by capsaicin-sensitive vagal lung afferent fibers. ROS, reactive oxygen species; TRPV1, transient receptor potential vanilloid 1 receptors; P2X, P2X purinoceptors. TRPV1 and P2X receptors are two types of ligand-gated cation channels. These lung afferent fibers are responsible for triggering reflex bradypnea when pulmonary ROS are increased.

# Brain Infarction

►Cerebral Artery Occlusion, Acute

# Brain-Thyroid-Lung-Syndrome

►Chorea, Benign Hereditary

# Branched Chain Ketoaciduria

Yoichi Suzuki, Keiya Tada
Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan

## Synonyms

Maple syrup urine disease; BCKA

## Definition and Characteristics

Branched-chain ketoaciduria (BCKA) is an autosomal recessive disorder caused by deficiency of branched-chain α-keto acid dehydrogenase (BCKD) complex. The deficiency of this enzyme complex results in the accumulation of the branched-chain amino acids (BCAAs) (leucine, isoleucine, and valine) and corresponding branched-chain α-keto acids. Based on clinical presentation and biochemical responses to thiamine administration, BCKA patients are divided into five clinical phenotypes – classic, intermediate, intermittent, thiamine-responsive, and dihydrolipoyl dehydrogenase (E3) deficiency. The classic type shows a neonatal onset, poor feeding, lethargy, muscle tone abnormality, ketoacidosis, and seizures. The intermediate type shows failure to thrive, often no ketoacidosis. The intermittent type shows normal early development, episodic ataxia/ketoacidosis, and usually normal intellect. Symptoms of the thiamine-responsive type are similar to the intermediate type and ameliorated by thiamine administration. E3 deficiency shows failure to thrive, hypotonia, lactic acidosis, and movement disorder.

## Prevalence

Pan-ethic distribution. One in 185,000 newborns is affected.

## Genes

The BCKD enzyme complex is composed of thiamine pyrophosphate-dependent (E1), with α2β2 subunit structure; a transacylase (E2); E3. E1α, E1β, E2, and E3 are coded by different genes located in 19q13.1–2, 6p21–22, 1p31, and 7q31–32, respectively. In addition, the BCKD complex contains two specific regulatory enzymes, BCKD kinase (16p11.2) and BCKD phosphatase.

## Molecular and Systemic Pathophysiology

Based on the subunits of the BCKD complexes that are shown to be affected, BCKA is classified into four molecular phenotypes: type IA (defects in E1α), IB (E1β), II (E2), and III (E3). Although not yet described, type IV and V are reserved for lesions in BCKD kinase and BCKD phosphatase, respectively. Molecular phenotypes IA and II cause classical, intermediate, or intermittent clinical phenotype. It is known that Type II also causes the thiamine-responsive type. Type IB causes classic phenotype in most of the patients.

## Diagnostic Principles

Clinical symptoms described above and elevated BCAAs in the blood and urine suggest BCKA. The presence of alloisoleucine is pathognomonic for BCKA. Gas chromatographic–mass spectroscopy analysis of urine and plasma organic acid gives characteristic profiles.

## Therapeutic Principles

Some patients are responsive to thiamine treatment (5 mg/kg/day). Limitation of intake of BCAAs while providing nutrition adequately to maintain normal growth and development.

For marked accumulation of BCAAs, blood exchange transfusion, hemodialysis, or hemofiltration is required. Glucose infusion combined with insulin is effective to stimulate anabolism.

# Branchial Cleft Cyst

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Branchial cleft anomalies may present as a cyst, sinus, fistula, or cartilaginous remnant [1]. Approximately 80% of branchial cleft anomalies present as a cyst and about 95% are formed from the region of the second branchial arch [2,3]. The remaining 5% arise from the regions of the first, third, or fourth arches [3]. A branchial cleft cyst typically presents as a painless, mobile, and fluctuant mass located along the anterior border of the sternocleidomastoid muscle, usually just above the clavicle (Fig. 1) [1,2].

Approximately 97–98% of the lesions are unilateral, and of these, 83–97% are on the left side presumably consequent to asymmetrical vascular development [4].

Although branchial cleft cysts are congenital and might be noted at birth, most are not detected until the first or second decade of life. Some are detected when they become more prominent in late childhood. Other cases become apparent during intercurrent upper respiratory tract infections or when the cyst becomes infected. Secondary bacterial infection is a possible complication. Squamous cell carcinoma is a rare complication reported in adulthood.

**Branchial Cleft Cyst. Figure 1** A 10-month-old girl with a branchial cleft cyst presenting as a cystic mass along the anterior border of the sternocleidomastoid muscle.

## Prevalence

A branchial cleft cyst is a rare condition. The prevalence is not known.

## Molecular and Systemic Pathophysiology

At approximately the second to eighth week of intrauterine life, six pairs of branchial arches develop, of which two pairs are rudimentary. The arches are mesodermal condensations on the lateral cervical area of the embryo. These arches are separated by five invaginations of ectoderm on the outside and endoderm on the inside, and are known as branchial clefts and pharyngeal pouches, respectively. The first arch forms the mandible, portions of the ossicles (head and neck of the malleus, incus body) and the muscles associated with these structures. The second arch forms the remaining portions of the ossicles (malleus handle, incus long process, stapes), styloid process, lesser cornus and upper part of the body of the hyoid bone, facial muscles, posterior belly of the digastric muscle, and the buccinator muscles. The third arch forms the greater cornus and lower part of the body of the hyoid bone, and the pharyngeal muscles. The fourth arch forms the superior and anterior portions of the larynx. The rudimentary fifth and sixth arches are transient structures. The first pouch develops into the Eustachian tube and the middle ear; the second into the palatine tonsil; the third into the thymus, inferior parathyroid glands, and pyriform fossa; the fourth into the superior parathyroid glands and the thyroid gland; and the fifth into the ultimobranchial body, which is incorporated into the thyroid gland. The second, third, and fourth clefts combine to form the cervical sinus of His. During the sixth embryonic week, the second branchial arch starts to grow caudally, and eventually overgrows the third and fourth branchial arches by merging with the epipericardial ridge of the lower neck. As the branchial arches coalesce, the cervical sinus of His is obliterated. Persistence of the cervical sinus of His accounts for the presence of a branchial cleft anomaly.

## Diagnostic Principles

The diagnosis is established by physical examination. Ultrasonography can help delineate the cystic nature of the lesion if the diagnosis is in doubt. The differential diagnosis includes cervical lymphadenopathy, fibrous dysplasia of the sternocleidomastoid

muscle (fibromatosis colli), dermoid cyst, and cystic hygroma. A thyroglossal duct cyst is a midline structure, and should be easily differentiated. Histologically, a branchial cleft cyst is lined by squamous or columnar epithelium. The cyst usually contains either a clear fluid or a toothpaste-like material, and may contain cholesterol crystals.

### Therapeutic Principles

Complete surgical excision with a careful attention to identifying deeper components is the treatment of choice. Aspiration, or incision and drainage, is associated with an increased risk of recurrence and of such complications as wound infection or hemorrhage.

## Branchio-oto-renal Syndrome

Susan Kupka
Department of General, Visceral and Transplant Surgery, University Hospital of Tuebingen, Tuebingen, Germany

### Synonyms

BOR syndrome

### Definition and Characteristics

Although phenotypically heterogenous, the most common clinical features of BOR syndrome encompass hearing impairment (93%), preauricular pits or tags (82%), renal anomalies (67%), branchial fistulae (49%), pinnae deformity (36%) as well as external auditory canal stenosis (29%) [1]. BOR syndrome represents an autosomal dominant disorder displaying an incomplete penetrance and variable expressivity.

### Prevalence

The estimated prevalence of BOR syndrome is 1:40,000 and it affects 2% of children displaying profound hearing impairment [2].

### Genes

The gene responsible for BOR syndrome was identified in 1997 by Abdelhak and coworkers [3]. The EYA1 gene encodes a transcription factor.

### Molecular and Systemic Pathophysiology

EYA1 plays possibly a role in genetic regulatory pathways controlling ear and kidney development by interacting with the GDNF cascade in kidney formation and with the PAX and SIX pathways in mammalian ear and kidney development [4].

### Diagnostic Principles

Due to phenotypic and genetic heterogeneity, diagnosis of BOR syndrome is difficult. Furthermore, mutations in EYA1 are responsible for ~20% of all BOR cases, whereas the genetic background of the remaining proportion is still unknown.

### Therapeutic Principles

Therapy includes hearing aids and treatment of renal insufficiency according to severity (transplantation, dialysis).

## BRCA1

►Breast and Ovarian Carcinoma, Hereditary

# Breast and Ovarian Carcinoma, Hereditary

Wolfgang Dietmaier[1], Arndt Hartmann[2]
[1]Institute of Pathology, University of Regensburg, Regensburg, Germany
[2]Department of Pathology, University Erlangen, Erlangen, Germany

## Synonyms

Breast cancer 1; Early-onset breast-ovarian cancer syndrome; BRCA1

## Definition and Characteristics

About 5–10% of all breast cancers and about 7–10% of all ovarian cancers arise on the basis of hereditary susceptibility caused by mutations in autosomal dominant genes. BRCA1- and BRCA2-mutations are considered to be responsible for the majority of these hereditary breast and ovarian cancers. BRCA1 was the first identified breast cancer susceptibility gene and was localized to 17q21 by positional cloning [1]. Germline mutations in BRCA1 occur in approximately 2.5–5% of all breast cancers, in 45% of inherited breast cancer families, and in up to 80% of breast/ovarian cancer families. Mutation carriers have a 82% risk of developing breast cancer and 54% risk of ovarian cancer by the age of 80 [2].

## Prevalence

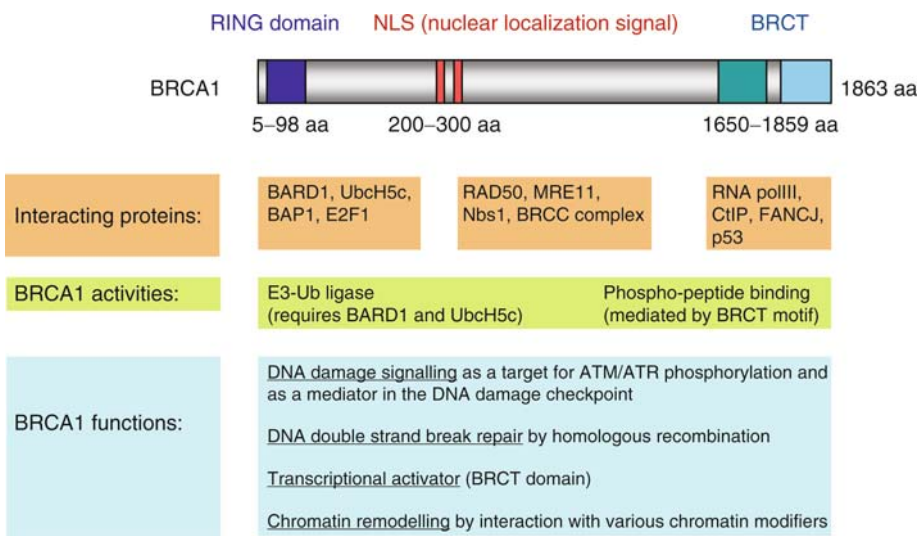
The prevalence of BRCA1 mutations in most Caucasian populations is estimated to be about 1:900.

## Genes

The BRCA1 gene is located on chromosome 17 (17q21) and contains 22 coding exons (exons 2–24) and two alternative exons (1a & 1b) in the 5'untranslated region (5'UTR). The 24 exons of BRCA1 span an 81-kb region that have an unusually high density of Alu repetitive DNA (41.5%), but a relatively low density (4.8%) of other repetitive sequences. BRCA1 intron lengths range in size from 403 bp to 9.2 kb and contain three intragenic microsatellite markers located in introns 12, 19, and 20. Exon 11 encodes 61% of the total protein which encodes for 1,863 amino acids. The aminoterminal RING finger domain and the carboxyterminal BRCT region (Fig. 1) are highly conserved regions among vertebrates while the remaining part of the gene shows only low homology to other known proteins.

BRCA1 germline mutations can occur throughout the entire gene. The majority of mutations lead to premature stop-codons and thus to truncated proteins. Loss of the remaining wild-type BRCA1 gene in tumors of mutation carriers is a typical event. Although there is no real BRCA1 hot-spot mutation founder effects have led to a higher prevalence of some mutations in certain populations as it described for e.g. a 185delAG mutation present in about 1% of all individuals of Ashkenazi Jewish ancestry [3]. Another relatively frequent mutation is 5382insC. Large interstitial deletions or insertions have been reported to comprise about 10–20% of the total mutation spectrum. Missense mutations of unknown clinical relevance may comprise up to 40% of all known BRCA1 sequence alterations.

Somatic mutations of BRCA1 are described in up to 10% of sporadic ovarian cancer but are extremely rare in sporadic breast cancer. However, there are reports of reduced BRCA1 protein expression in high



**Breast and Ovarian Carcinoma, Hereditary. Figure 1** Scheme of BRCA1 gene showing the functional domains.

grade sporadic breast and ovarian tumors, suggesting an epigenetic down-regulation of BRCA1.

## Molecular and Systemic Pathophysiology

BRCA1 protein is important in maintaining genomic stability through promoting repair of double strand DNA breaks. BRCA1 is colocalized with RAD51, which shows a recombinase function, BRCA2 and the BRCA1-binding protein BARD1. BRCA1 deficient cells show a high sensitivity to ionizing radiation and display chromosomal instability with both structural and numerical chromosomal alterations. Brca1 deficiency in mouse embryonic stem cells cause impaired repair of double-strand breaks (DBS) [4].

Several other factors involved in response to, or repair of, DNA damage has been described to be associated with BRCA1: BRCA2, RAD51 and BARD1 and other components together with BRCA1 form the BRCC complex (BRCA1-BRCA2-containing complex), which displays an E3 ubiquitin ligase activity implicated in the regulation of DNA repair factors. Another complex associated with BRCA1, BASC (BRCA1-associated genome surveillance complex), includes tumor suppressors, DNA damage sensors, signal transducers, including the MRN complex (MRE11-RAD50-NBS1), mismatch repair proteins MSH2, MSH6 and MLH1, the Bloom syndrome helicase BLM, the ATM kinase, DNA replication factor C (RFC) and PCNA. Most of them act as sensors of DNA damage, function directly in DNA replication or in DNA replication associated repair. Thus, BRCA1 is suggested to play a critical role in coordinating various functions of DNA replication important for maintaining genetical integrity. BRAC1 potentially influence the choice of repair pathway after double strand breaks. The association of BRCA1 and mismatch repair proteins suggests further an involvement of BRCA1 in the type of nucleotide excision repair that preferentially correct base lesions from the transcribed strand.

In response to DNA damage the protein kinases ATM and ATR phosphorylate and activate downstream proteins including BRCA1. As a consequence various cellular pathways are regulated including cell cycle regulation and DNA repair. The function of BRCA1 in responses to DNA damage is modulated by phosphorylation of specific phosphorylation sites through the checkpoint kinases ATM, ATR and CHEK2. Phosphorylation of Ser1423 residue appears to be important for a ionizing radiation-induced G2-M checkpoint, Ser1387 phosphorylation is required for ionizing radiation-induced S-phase arrest and phosphorylation of Ser988 leads to dispersion of CHEK2 and BRCA1 and the repair of double strand breaks by promoting error free homologous recombination.

The role of BRCA1 in checkpoint control is also well known. BRCA1 is reported to stimulate transcription of p21, a coactivator of p53, resulting in cell cycle arrest at the G1-S phase boundary. The ATM/ATR mediated phosphorylation of several proteins including CHK2 and p53 at Ser15, which is necessary for G1-S arrest, has been shown to require BRCA1.

BRCA1 can be copurified with RNA polymerase II and may be involved in the regulation of transcription. Furthermore, several studies have shown a chromatin remodeling role of BRCA1 by complexes with various chromatin modifiers.

## Diagnostic Principles

A definitive diagnosis of hereditary breast cancer syndrome is made by genetic testing. BRCA1 mutations are common in families with several early onset breast cancer cases. Another hint for the existence of a germline BRCA1 mutation are ovarian carcinomas at any age in combination with early onset breast cancer.

## Therapeutic Principles

With the exception of contralateral breast cancer, a BRCA1 mutation does not seem to supply additional prognostic information to the standard prognostic factors. Today, a breast conservation surgical therapy is reported to be a reasonable option for genetically predisposed breast cancer patients (reviewed in [5]). Prophylactic bilateral mastectomy lowers the risk of breast cancer in mutation carriers by more than 90%. Strategies to reduce the tumor risk like bilateral salpingooophorectomy, treatment with tamoxifen or other hormonal agents such as aromatase inhibitors and SERM's (selective estrogen receptor modulators) are not yet sufficiently evaluated in BRCA1 mutation patients. Although it has been reported that bilateral salpingo oophorectomy may reduce mortality [6] there is still a need for large prospective studies designed and stratified for risk reduction strategies.

## Synonyms

Rubinstein-Taybi syndrome

## Definition and Characteristics

Mental retardation - multiple congenital anomalies syndrome having as main symptoms cognitive and developmental delay, short stature, typical face (downward slanted palpebral fissures, beaked nose with low hanging columella, pouting lower lip), and broadening of thumbs and big toes [1]. There is an increased risk to develop malignancies.

## Prevalence

The prevalence at birth for the Dutch population is 1 in 100,000 to 125,000. The syndrome has been described in populations of different ancestries, but the number of reports in non-Caucasians is low [1].

## Genes

In about 10% of the patients, a microdeletion can be found at chromosome 16p13.3. An additional 40% has a de novo heterozygous constitutional mutation in the CBP (CREB-binding protein) gene, localized on chromosome 16p13.3 [2,3]. In another 1–2% a mutation can be found in the CBP-homolog P300, located on chromosome 22q13.2 [4].

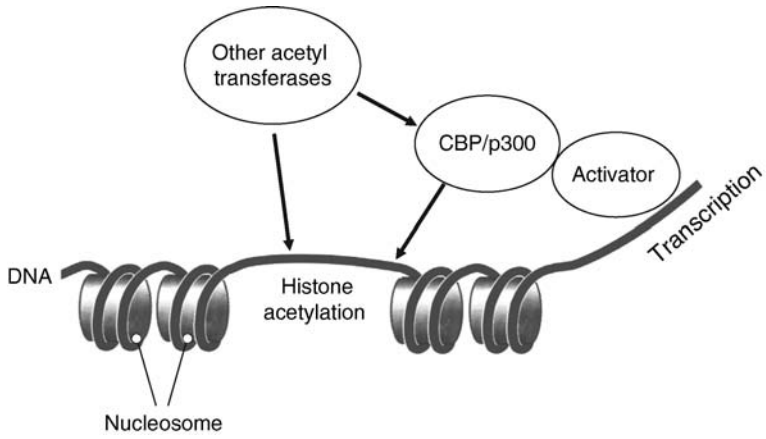
## Molecular and Systemic Pathophysiology

The CBP and P300 proteins have many different functions. Two important ones are as a transcriptional cofactor forming a physical bridge between the different components of the transcription machinery, and as a histone acetyltransferase (HAT) increasing the accessibility of the DNA for dozens other transcription factors (Fig. 1).

CBP resembles p300 to a very great extent. Together, CBP/p300 functions as a downstream effector in the hedgehog, decapentaplegic, wingless/WNT, and Toll signaling developmental pathways. Haploinsufficiency that reduces either the CBP or P300 protein level to 50% during one or more critical stages in fetal development is sufficient to cause the phenotype that is called Rubinstein-Taybi syndrome. At present, it seems likely that loss of the HAT activity of the CBP/P300 protein is sufficient to cause the syndrome, but its pathophysiology remains largely unknown [3,5].

## Diagnostic Principles

The diagnosis of the syndrome relies completely on recognition of the clinical symptoms. In only a limited percentage of the patients, the diagnosis can be confirmed by detection of a microdeletion or mutation of the CBP or P300 gene. Absence of each of these abnormalities does not exclude the diagnosis.



**Broad Thumbs - Broad Halluces Syndrome. Figure 1** Model of CBP and P300 functioning both as transcription cofactor and as histone acetyltransferase (HAT). Other acetyltransferases recruited by CBP/p330 are PCAF, SRC-1, and ACTR. CBP/p300 modifies mainly histone H3 and H4. The number of interacting proteins is large and include CREB, JUN, PCAF, TP53, and FOS.

### Therapeutic Principles

No specific therapy is available: there is no therapeutic regiment known that influences the functioning of CBP and it is at present uncertain whether exogeneous CBP can influence some of the complications (behaviour; keloid; malignancies). Specific guidelines to manage the increased frequency of upper airway infections, constipation, obesity, keloid formation, and tumor risk are available [5].

### Synonyms

Chronic lung allograft rejection; Obliterative bronchiolitis; BOS

### Definition and Characteristics

BOS is a chronic lung allograft rejection, characterized by a peri-vascular/bronchiolar mononuclear cell infiltration that extends into the interstium, and alveolar space causing parenchymal injury. Histopathologic features begin with a peri-bronchiolar leukocyte infiltration that invades/disrupts the basement membrane, submucosa, and luminal epithelium [1,2]. This is followed by fibroproliferation with increased numbers of mesenchymal cells, extracellular matrix deposition (ECM), and granulation tissue formation within/around the lumen of the allograft airway [1,2]. Ultimately, smooth muscle cells, myofibroblasts, inflammatory cells, and mature collagen obliterate the airway [1,2].

## Prevalence

BOS has been diagnosed as early as 3 months, with a mean onset that varies between 15 and 20 months. The incidence is anywhere from 35 to 65% at 5-years to up to 80% at 10 years [3,4]. Probable risk factors are the number and severity of acute lung allograft rejection episodes, lymphocytic bronchiolitis/bronchitis, CMV pneumonitis, medication non-compliance, and HLA mismatching. Other possible risk factors are CMV infection, organizing pneumonia, pulmonary infections, and older donor age.

## Molecular and Systemic Pathophysiology

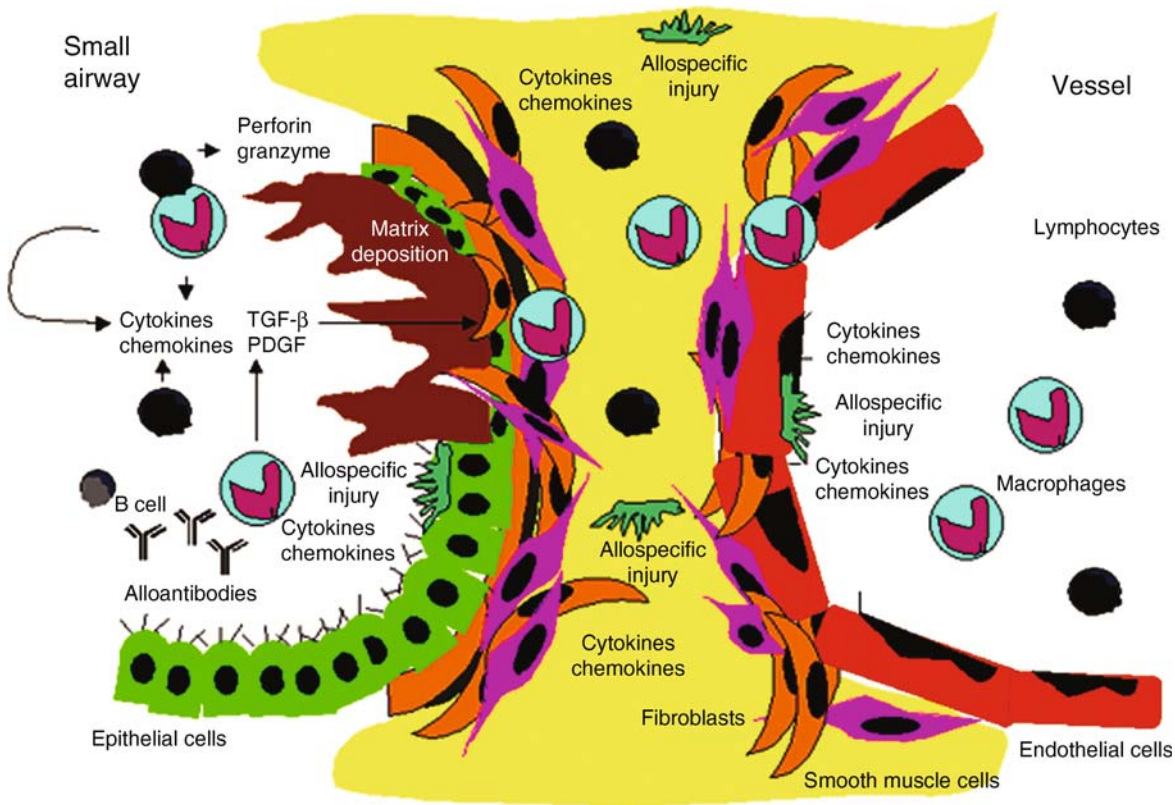
BOS occurs secondary to allorecognition of different MHC antigens between donor and recipients cells. This is followed by T cell activation via co-stimulatory molecules, which generate a vigorous cytokine/chemokine cascade. This cascade activates/recruits other effector cells (lymphocytes secrete more cytokines/chemokines/peforins/granzymes, B cells secrete toxic alloantibodies, and macrophages release cytokines/chemokines and growth factors inducing mesenchymal cells to lay down extracellular matrix) eventually obliterating the allograft airways (Fig. 1). Nonimmune injury to the airways via infections, gastroesophagus reflux, and ischemia-reperfusion injury also contribute the pathogenesis of BOS.

## Diagnostic Principles

BOS is a clinicopathologic syndrome in which there is a decline in the lung allograft function accompanied by obstructive airways disease (pulmonary physiology matching histopathology) with other causes (acute rejection, infection, airway compromise, increased body mass index, and native lung disease) being ruled out. BOS is presently classified based on percent $FEV_1$ as compared to peak post-transplantation $FEV_1$. Stage 0 (80% or more), stage I (66–79%), stage II (51–65%) and stage III (<50%) of peak $FEV_1$ [3]. A new classification has been proposed to determine, if $FEV_1$ and $FEF_{25–75}$ can diagnose the disease at an earliest state.

## Therapeutic Principles

Presently there is no effective prevention or treatment of chronic lung (BOS) allograft rejection including induction therapy. There is hope that newer immunosuppressive medications aimed at the specific mechanism involved in fibro-obliteration may prevent/treat BOS and induce allospecific tolerance.



**Bronchiolitis Obliterans Syndrome. Figure 1** Allorecognition and costimulatory T cell activation leads to allospecific injury with cytokine/chemokine activation of other cells thus the release of more cytokines/chemokines/growth factors/perforins/granzyme/alloantibodies ultimately causing fibro-obliteration.

# Bronchitis, Chronic

Nestor A. Molfino
Otsuka Maryland Research Institute, Rockville, MD, USA

## Synonyms

Chronic obstructive pulmonary disease; COPD; Emphysema

## Definition and Characteristics

COPD is a disease state characterized by airflow limitation that is not fully reversible, usually progressive and associated with abnormal inflammatory response of the lungs to noxious particles or gases. The most important risk factor for COPD is cigarette smoking (including passive exposure) but occupational exposure to dust and chemicals as well as air pollution are also documented causes [1].

Clear genetic predisposition seems to exist in a number of individuals with COPD [2].

## Prevalence

COPD is a major worldwide health burden in terms of morbidity, mortality and health care costs. As of 1990, COPD was the 12th leading cause of disease burden worldwide, but by 2020 it will represent the fifth. In the United States, COPD is currently the fourth leading cause of death. COPD is a common cause of hospital admissions and of chronic disability [3].

## Genes

Severe $\alpha_1$AT deficiency is the one proven genetic risk factor for COPD in otherwise healthy subjects. Although it is well-known that the homozygous deficiency of $\alpha_1$AT, phenotype PiZZ is associated with an increased risk of COPD, studies evaluating the association between the heterozygous forms of the $\alpha_1$AT phenotype PiMZ and rapid decline in lung function, both in patient and community populations, have yielded conflicting results. Furthermore, it is possible that in the general population the contributory genetic factors extend beyond $\alpha_1$AT deficiency, and it appears that COPD may be a multigenic disease [2]. Gene polymorphisms associated with COPD development and severity include: MMP1 and MMP12 genes, TNF-α-308–1 and TNF-α-308–2 alleles, IL-13 promoter, polymorphisms in the antioxidant genes GSTM1, GSTT1, GSTP1, HMOX-1, and mEPHX, and polymorphisms in TIMP-2. Gly16 ß$_2$-adrenoceptor polymorphism may increase susceptibility to the development of COPD, and the Gln27 ß$_2$-adrenoceptor polymorphism may be associated with the severity of COPD in the Chinese population. Heterozygosity at position 27 may be protective against an accelerated rate of decline in lung function, and polymorphism at position 16 does not contribute to the rate of decline in lung function in smokers of white origin [2].

## Molecular and Systemic Pathophysiology

COPD results in pathologic changes throughout the airways and lung parenchyma. These can be divided broadly into three: (i) Chronic bronchitis (mucus-hypersecretion) is associated with failure of the muco-ciliary system with hyper-production and -secretion of mucus, expectorated as sputum, and whose major source is the enlargement and inflammation of submucosal glands present in the large airways (i.e., roughly the first eight generations of airway branching with supportive cartilage in their walls); (ii) Chronic obstructive bronchiolitis (syn small airways disease) alters small airways (airways of about 2 mm in diameter and beyond the eighth generation of branching, most without supportive cartilage), considered to be the major anatomic site responsible for the airflow obstruction of COPD. The obstruction is the result of inflammation and structural changes (the latter referred to as remodeling [4]) that include mucous metaplasia and thickened, airway walls due to fibrosis and smooth muscle mass increase resulting in narrowed lumens; (iii) An increase of airspaces beyond the terminal bronchioli (the airway generation that immediately precedes the respiratory bronchioli, the first airway from which alveoli open) is the result of emphysematous destruction of the lung parenchyma that occurs in many but not all cases of COPD. Pulmonary vasculature is also affected with progressive thickening of pulmonary vessel walls [1].

## Diagnostic Principles

The symptoms of COPD include cough, sputum production and dyspnea. Diagnosis of COPD should be considered in subjects presenting with a history of exposure (s), with or without symptoms, and in whom the post-bronchodilator FEV1/FVC ratio is <70% of predicted and the post-bronchodilator FEV1 is <80%

of predicted [1]. A very small proportion (1–2%) of these patients have $\alpha_1$AT deficiency. Yet, this hereditary disorder should be considered, if a COPD patient, under 40 years of age, with or without smoking history presents with a predominant emphysematous phenotype.

Deficiency of $\alpha_1$AT is an autosomal, codominant genetic disorder. Low serum levels of $\alpha_1$AT, in conjunction with other genetically determined characteristics and environment influences, result in the development of a disease state (i.e., liver or pulmonary). The serum threshold level above which the lung appears to be protected lies at 11 μM, about 35% of the average normal level. Suspicion of $\alpha_1$AT deficiency can be confirmed quantitatively and qualitatively. Quantitative plasma $\alpha_1$AT levels are usually determined by rocket immunoelectrophoresis, radial immunodiffusion, or, more recently, nephelometry. Approximately 100 alleles of the $\alpha_1$AT gene have been identified and of these alleles, more than 30 genetic variants can lead to deficient levels of $\alpha_1$AT. The normal and deficient $\alpha_1$AT alleles can be identified by isoelectric focusing, the techniques currently used for definitive diagnosis, and are assigned a letter code (A to Z). The most common allele is referred to as M; most individuals have a protein phenotype PI*MM. The most frequent deficient $\alpha_1$AT allele is the Z variant, and individuals who are PI*ZZ homozygotes have plasma levels of $\alpha_1$AT that are about 15% of the normal plasma concentration and are at the greatest risk for developing $\alpha_1$AT deficiency-associated lung disease. The S variant is more frequent in the Mediterranean area and the homozygous form is associated with plasma levels about 60% of normal. The remaining frequent types of $\alpha_1$AT phenotypes include PI*SZ, PI*MS, and PI*MZ and these individuals are at increased risk of developing AAT deficiency-associated diseases [5]. The null alleles (homozygotes designated as PI QOQO) are associated with the most severe deficiency, producing no active $\alpha_1$AT, or less than 1% of the normal amount of plasma $\alpha_1$AT. Subjects with abnormal blood levels should be investigated further to provide a qualitative evaluation of their $\alpha_1$AT disorder. Even subjects with a borderline normal $\alpha_1$AT plasma level (12–35 μM or 90–140 mg/dL) should undergo qualitative testing, because these levels may correspond to an intermediate-level phenotype (SZ, SS, MZ, and MS). Also, a relative with asymptomatic or misdiagnosed $\alpha_1$AT deficiency may be uncovered within the family.

## Therapeutic Principles

Currently gene therapy is under development for $\alpha_1$AT deficiency.

Replacement therapy should be considered in selected $\alpha_1$AT deficient subjects (Prolastin ~60 mg/kg weekly).

Pharmaceutical therapy includes short and long-acting bronchodilators (albuterol, terbutaline, ipratropium salmeterol, tiotropium, formoterol), corticosteroids (oral: prednisolone or inhaled: budesonide, fluticasone, etc.), theophyllines. Many new entities are under development [6].

Malnutrition has poor prognosis. Thus, smaller, more frequent meals should be advised to alleviate dyspnea. The patients should be advised to stop smoking. Further measures may include long term oxygen therapy and pulmonary rehabilitation.

# Bronchopulmonary Dysplasia

Francesca Sciandra
CNR, Istituto di Chimica del Riconoscimento Molecolare c/o Istituto di Biochimica e Biochimica Clinica, Università Cattolica del Sacro Cuore, Rome, Italy

## Definition and Characteristics

Bronchopulmonary dysplasia is a chronic lung disease occurring in premature infants who underwent mechanical ventilation and oxygen therapy for acute respiratory distress [1]. It was originally described in a group of preterm infants who develop chronic respiratory failure and characteristic chest radiographic changes after prolonged mechanical ventilation. The lung damage was attributed primarily to the use of aggressive

mechanical ventilation and higher oxygen concentration. With advancements in perinatal care including surfactant administration and improved ventilator management, the clinical course of bronchopulmonary dysplasia has changed and infants nowadays suffer less severe acute respiratory disease.

## Prevalence

About 20% of ventilated premature newborns are affected. The risk of bronchopulmonary dysplasia rises with decreasing birth weight; in fact, the disease is uncommon in infants of more than 1,500 g birth weight or with gestational age exceeding 32 weeks.

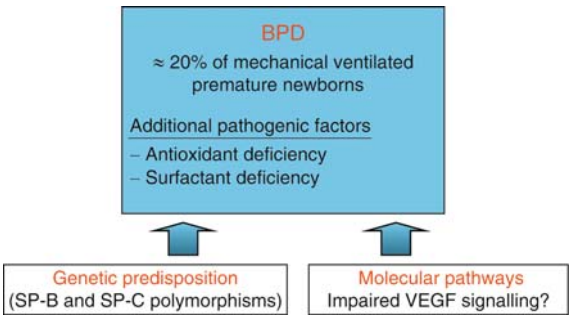
## Genes

Lung surfactant is a complex of phospholipids and proteins responsible for maintaining alveolar stability. Variability in the surfactant protein (SP) genes has been recently associated with bronchopulmonary dysplasia, in particular:

- SP-B gene (chromosome 2): polymorphism in exon 4 (Ile131Thr) and length variation of a microsatellite sequence $(CA)_n$ in intron 4 [2];
- SP-C gene (short arm of chromosome 8): three biallelic polymorphisms in exons 1, 4, and 5 encoding proSP-C [2].

## Molecular and Systemic Pathophysiology

Multiple factors contribute synergistically to bronchopulmonary dysplasia, but a detailed molecular pathway, leading to the development of the disease, has to be identified yet (Fig. 1). Bronchopulmonary dysplasia was originally ascribed to oxygen toxicity because of increased production of cytotoxic oxygen free radicals that can cause lung injury. Premature infants are also deficient in antioxidant enzyme systems and have low levels of antioxidants, such as vitamin C, increasing their vulnerability to oxygen toxicity. Many infants developing bronchopulmonary dysplasia demonstrate an early inflammatory response probably activated by oxygen free radicals. Proinflammatory cytokines (interleukins IL-1beta, IL-6, and soluble ICAM) are upregulated during bronchopulmonary dysplasia and trigger the release of additional inflammatory mediators. Neutrophils' activation leads to the inhibition of surfactant synthesis and the release of collagenase and elastase that may contribute to lung injury. During and after the inflammatory injury, the composition of the extracellular matrix surrounding the alveoli undergoes a deep alteration with an increasing deposition of the glycoproteins, fibronectin and tenescin-C. Further analysis at the molecular level will be needed to better characterize the possible involvement of other extracellular matrix components in bronchopulmonary dysplasia development. In premature infants, the lung is characterized by arrested development including alveolar simplification and dysmorphic vascular growth while during the normal lung development, alveolarization and vascular growth are closely synchronized. Vascular endothelial growth factor (VEGF) is a potent endothelial-specific mitogen and survival factor that stimulates angiogenesis. Recently, a potential role of impaired VEGF signalling in the pathogenesis of bronchopulmonary dysplasia was demonstrated, since the expression of VEGF and its receptors decreased in bronchopulmonary dysplasia affected infants [3].



**Bronchopulmonary Dysplasia. Figure 1** Schematic view depicting genetic and pathogenic factors influencing the susceptibility for bronchopulmonary dysplasia. The original clinical concepts associated bronchopulmonary dysplasia with ventilator-induced lung injury and high concentration of active oxygen species. Additional clinical studies suggested that other factors contribute to the disease, such as decreased VEGF expression and surfactant and antioxidant deficiency. In addition, data that support specific genetic susceptibility are emerging.

## Diagnostic Principles

The clinical diagnosis of bronchopulmonary dysplasia is mainly based on respiratory failure requiring oxygen therapy for ≥28 days and at 36-weeks postmenstrual age, and also include oxygen concentration (less than or greater than 30%) at 36-weeks postmenstrual age to further define the severity of lung injury.

## Therapeutic Principles

Improvements in mechanical ventilations associated with exogenous surfactant therapy have minimized lung injury. Appropriate nutritional support is critical to promote normal lung growth, maturation, and repair. In a recent clinical trial, vitamin A supplementation caused a significant reduction of bronchopulmonary dysplasia, and additional nutrients, such as sulfur-containing amino acids, may provide additional protection against the development of the disease [4]. A promising method for preventing bronchopulmonary dysplasia is prophylactic supplementation of human

recombinant antioxidant enzymes. For example, the negative effects of reactive oxygen species (ROS) can be alleviated by the administration of recombinant human superoxide dismutase (rhSOD) [5].

# Brooke-Fordyce Trichoepitheliomas

►Multiple Familial Trichoepithelioma

# Brugada Syndrome

Tom Rossenbacker[1,2], Silvia G. Priori[1,2]
[1]Molecular Cardiology, IRCCS Fondazione Maugeri, Pavia, Italy
[2]Department of Cardiology, University of Pavia, Pavia, Italy

## Synonyms

Sudden unexpected nocturnal death syndrome; Idiopathic ventricular fibrillation (obsolete)

## Definition and Characteristics

The Brugada syndrome is an inherited cardiac arrhythmogenic disorder that has been described as a clinical entity in 1992 [1]. In some patients, the electrical stability of the heart gets disturbed to the extent that ventricular arrhythmias develop, eventually resulting in syncope and/or sudden cardiac death (SCD). The syndrome is estimated to be responsible for ~20% of SCDs in patients with structurally normal hearts [2]. The age of onset of clinical manifestations is the third to fourth decade of life, although malignant forms with earlier, and even, neonatal onset have been reported [2].

## Prevalence

Unknown in general population; suggested prevalence ranges from 5 per 1,000 (Caucasians) to 14 per 1,000 (Japanese) inhabitants [2].

## Genes

The initial identification of mutations in the cardiac sodium channel, SCN5A, was published in 1998 [3] and, as of today, tens of different SCN5A mutations have been reported (http://www.fsm.it/cardmoc). However, SCN5A mutations account for not more than 20% of clinically diagnosed cases. Mutations in genes encoding the cardiac L-type $Ca^{2+}$ channel (CACNA1C, the α1 subunit, and CACNAB2, the β2b subunit) have been associated with a clinical entity, encompassing a Brugada phenotype together with short QT intervals [4]. Data are not available to allow defining which percentage of patients with the clinical diagnosis of Brugada syndrome carry mutations in the CACNA1C and CACNAB2 genes. Another gene, GPD1-L, encoding for the glycerol-3-phosphate-dehydrogenase 1-like protein, has been linked with the Brugada syndrome in one family [5]. A screening of GPD1-L in a large cohort of Brugada syndrome patients with negative SCN5A screening showed that GPD1-L mutations account for not more than 1% of Brugada syndrome cases (SG Priori and coworkers, unpublished data).

## Molecular and Systemic Pathophysiology

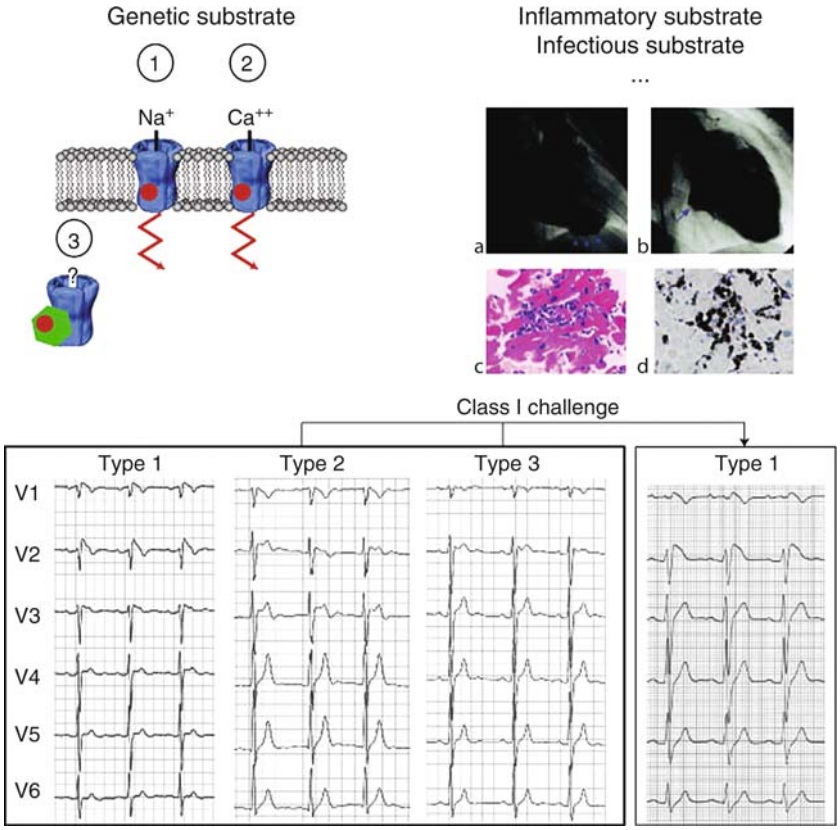
The overall consequence of SCN5A mutations, identified in the Brugada syndrome, is that of producing a loss of sodium current. This reduction in $I_{Na}$ has been shown to occur through the modification of several properties of the sodium channel including failure of the channel to express, a shift in the voltage-dependence of activation or inactivation, a reduction in the rate of recovery from inactivation and accelerated inactivation subsequent to channel opening. One SCN5A published mutation does not directly impair sodium current but causes a loss of binding of Nav1.5 with its intracellular target chaperone ankyrin G [6]. Consequently, the mutant Nav1.5 is not properly localized at the level of intercalated discs [6]. Defective sodium channels amplify the heterogeneity in electrical characteristics among different transmural cell types and result in voltage gradients between epicardium and endocardium that drive an electrotonic current causing ST segment elevations and arrhythmias based on transmural phase 2 reentry. One hypothesis ascribes the voltage gradients to premature repolarization of the right ventricular epicardial action potential due to prominent presence

of transient outward current, $I_{to}$, in this region and another hypothesis attributes the voltage gradients to a conduction delay in the right ventricular epicardial free wall. Likewise, a loss-of-function in calcium channel activity, secondary to mutations in CACNA1C and CACNAB2, is being thought of causing a preferential abbreviation of right ventricular epicardial action potential [4]. The function of GPD1-L mutations is poorly known at present, but preliminary in vitro data suggest that it controls the membrane expression of the sodium channels and that GPD1-L mutations may reduce the expression of the sodium channel [5].

The view that Brugada syndrome is a pure electrical disease has been countered by the histopathological detection of structural alterations in the right ventricular outflow tract of Brugada syndrome patients. These findings has inspired some to conclude that the aberrant ECG pattern should not be seen as a marker of a specific syndrome, but, rather, as a common electrical manifestation of structural abnormalities in the right ventricle that may have genetic, infective and/or inflammatory origins (Fig. 1).

## Diagnostic Principles

The documentation of a so-called type 1 ECG is needed to establish the diagnosis: it consists of an ST segment elevation ≥2 mm in at least two of the three right precordial leads (V1–V3), with a "coved morphology" associated with incomplete or complete right bundle branch block [2]. This pattern may be spontaneously evident or it may be induced by a provocative pharmacological test with intravenous application of a



**Brugada Syndrome. Figure 1** Upper panel. Left: Loss-of-functions mutations in *SCN5A*, encoding for the cardiac sodium channel (1), in *CACNA1C* and *CACNA2B*, encoding for subunits of the L-type calcium channel (2) and mutations in *GPD1-L* (green hexagon), encoding for the Glycerol-3-Phosphate-Dehydrogenase 1-like protein (3), have been linked with the Brugada syndrome. Red circles indicate mutations. Right: End-diastolic frames of right (a) and left (b) ventricular angiography from a Brugada syndrome patient showing multiple small aneurysms of the inferior-apical wall (arrowheads) and a localized microaneurysm of the posterobasal segment of the left ventricle (arrow). Right (c) and left (d) ventricular endomyocardial biopsy sample from the same patient showing active lymphocytic myocarditis. Lower panel: Three types of ST segment elevations in the right precordial leads; only presence of type 1 ECG, either spontaneous or induced by a class I drug challenge, is diagnostic for the Brugada syndrome.

class Ic sodium channel blocker. It is important to recognize that the sensitivity of these criteria in the identification of affected individuals is still undefined and it is certainly lower than 100%. Other known causes of ST segment elevation in the right precordial leads have to be excluded before a definite diagnosis of the Brugada syndrome can be made.

## Therapeutic Principles

The only effective treatment to abate mortality in Brugada syndrome is an implantable cardioverter defibrillator (ICD). Cardiac arrest survivors should be treated with an ICD (secondary prevention). Treatment in primary prevention is much less certain. Available evidence attributes the highest risk for SCD to patients with a spontaneously abnormal ECG and a history of syncope [7]. Consequently, an ICD can be recommended to this subpopulation of patients. The predictive role of programmed electrical stimulation (PES) is debated. Despite PES was proposed as a tool to identify high-risk patients in some studies [4], the newer meta-analysis [8] confirm the initial reports [7] suggesting that PES is not useful for prediction of cardiac events.

Quinidine, a nonspecific blocker of $I_{to}$, may be regarded as an adjunctive therapy for patients at higher risk and can be used to reduce the number of ICD shocks in patients with multiple recurrences [9].

# Buckley Syndrome

►Hyper IgE Syndrome

# Budd-Chiari Syndrome

Marco Senzolo[1], Christos Triantos[2], Dimitrios Samonakis[2], Evangelos Cholongitas[2], Andrew K. Burroughs[2]
[1]Gastroenterology, Department of Surgical and Gastroenterological Sciences, University-Hospital of Padua, Padua, Italy
[2]Department of Liver Transplantation and Hepatobiliary Surgery, Royal Free Hospital, Hampstead, London, UK

## Definition and Characteristics

The Budd-Chiari syndrome is defined as hepatic venous outflow obstruction due to any cause and at any level from the small hepatic veins (HV) to the junction of the inferior vena cava (IVC) and the right atrium.

## Prevalence

The Budd-Chiari syndrome is a rare disease estimated to affect 1/100,000 in the general population, first described in 1845 in London in three patients with abscess-induced phlebitis. Nowadays the typical patient affected is a 35 year old woman with an underlying thrombophilic state, and with or without oral contraception [1]. Primary membranous obstruction of the inferior vena cava without hepatic vein thrombosis accounts for 60% of cases in Asia and the Indian subcontinent.

## Molecular and Systemic Pathophysiology

Repeated venous thrombosis with secondary, but incomplete lysis within small or larger sections of

the hepatic venous tree. This accounts for the heterogeneity in clinical presentation and severity of the disease.

The hepatic consequences of venous obstruction depend on site, extent and rapidity of the prothrombotic/lysis process. Acute thrombosis of two or more HV is associated with an acute (20%)/fulminant (5%) presentation, whereas temporary thrombosis followed by lysis or partial thrombosis of the HV is associated with chronic (60%) or asymtpomatic presentation (<5%). In patients with primary IVC obstruction, leg and trunk edema are more common than ascites, compared to patients with hepatic vein thrombosis alone [2].

Obstruction of hepatic venous outflow causes congestion of the liver, which, if rapid, causes painful hepatomegaly because of stretching of Glisson's capsule. The engorgment with blood causes increased sinusoidal pressure, sinusoidal hemorrhage and hepatocyte necrosis, particularly in the centrilobular area, stimulating fibrosis, initially pericentrally. The consequent post sinusoidal portal hypertension leads to the development of ascites, often intractable from the presentation with a high protein content (>25 g/L).

Within a few months fibrous bridges connect between neighboring central zones of hepatic lobules giving rise to a histologic picture simulating cirrhosis in which the relationship between the central vein and the portal tract is reversed (reverse lobulation). In about 50% of patients this leads to the formation of large regenerative nodules, which can mimic hepatocellular carcinoma.

Clinically it is important to distinguish the primary forms, due to endoluminal venous lesions leading to thrombosis and secondary forms due to external compression of hepatic veins by tumor invasion, compression or echinococcal cysts.

In Western countries underlying thrombophilias are markedly increased in patients with primary BCS as compared with controls. At least one pro-coagulation disorder is found in 75%, principally myeloproliferative disorders in 25–50% [3]. Other causes of Budd-Chiari syndrome include paroxymal nocturnal hemoglobinuria, antiphospholipid syndrome, inherited deficiencies of protein C and S, and antithrombin III, 3′ UDT protrombin gene mutation and Factor V Leiden mutation. Use of oral contraceptives or pregnancy could be a co-factor for BCS in women with an underlying thrombophilic state.

Primary endophlebitis and congenital malformations have been proposed as causes of the short-length hepatic venous and IVC stenoses present in BCS, but current thinking is that they are a sequel of thrombosis as they have a similar incidence in adults as in children. Long standing chronic patients are at risk of developing hepatocellular carcinoma.

## Diagnostic Principles

BCS should be suspected when there is a rapid onset of hepatomegaly, refractory ascites and/or abdominal pain. A fulminant presentation is associated with abundant ascites and liver failure. Liver enzymes can be normal in the asymptomatic patient.

Ultrasound has a sensitivity of 80% or more to identify hepatic venous thromboses. All the splanchnic veins should be evaluated: portal vein thrombosis is found in 20–30% and is associated with a significantly higher mortality; IVC thrombosis can be due to the primary disease or frequently due to the compression by the hypertrophic caudate lobe.

CT scan or MRI is helpful in demostrating the parenchymal structure and nodules and the presence extra hepatic malignances. Echocardiography should be performed to exclude constrictive pericarditis which can mimic hepatic venous outflow obstruction. Hepatic venography should always be performed to determine the extent of venous thrombosis to outline the inferior vena cava to perform transjugular liver biopsy (21) and to outline the portal vein using retrograde $CO_2$ portography or radiographic dye. This helps plan dilatation of hepatic venous and/or inferior vena cava webs or stenting of hepatic veins or inferior vena cava as well as radiological or surgical shunting and as liver transplantation. It also allows access to disrupt a limited portal vein thrombus. However in some cases it is impossible to cannulate hepatic veins or portal vein. As the procedures may require large volumes of X-ray contrast, attention needs to be paid to preserving renal function.

Liver biopsy can help determine the grade of necrosis or fibrosis which are useful to plan either portosystemic shunting or liver transplantation.

## Therapeutic Principles

Standard medical therapy for managing ascites and variceal bleeding should be used. The fulminant presentation should be treated with hepatic transplantation if available as there is usually too much necrosis, even with immediate decompressive shunting for recovery to take place. In the absence of a liver donor, TIPS should be performed. Unless there are contraindications, all patients should be anticoagulated to prevent progression or new thrombosis whilst awaiting further therapy and even after transplantation. Early thrombolysis using streptokinase, urokinase or tissue type plasminogen activator may be an alternative to shunting in acute BCS. Systemic infusion of tPA using 5–10 mg of bolus followed by infusion of 0.5–2 mg/kg for a period of 24–96 h or local thrombolysis using Urokinase 240,000 U/h for 2 h, followed by 60.000 U/h or tissue plasminogen activator 0.5–1 mg/h infused directly into the thrombosed hepatic vein for about 24 h transfemorally or transjugularly. In patients with a less

acute presentation and in those without significant fibrosis, who also do not have significant inferior vena cava obstruction whose portal vein is patent, a side to side portal caval shunt or meso-caval shunt will decompress the liver, relieve the ascites and remove the threat of variceal bleeding [4]. This can result in a 90% 10 year survival with histological improvement. Focal thrombosis of the HV and IVC webs can be treated with angioplasty with stenting in 60 and 90% of cases respectively, but further reinterventions are needed in 40%. Transjugular porto systemic shunts should be considered the treatment of choice in patients in poor condition and in patients with IVC occlusion and compressive caudate lobe hypertrophy who can be considered for a trial of shunting with liver transplantation as rescue therapy. The HVPG, gradient after TIPS should be less than 6 mmHg. Long term survival is reported to be 90% for acute and 70% for chronic BCS but is influenced by the severity of the disease [5]. Shunt stenosis ranges from 36 to 72%. Indications for liver transplantation are fulminant presentation, chronic presentation with severe fibrosis or cirrhosis, rescue therapy following surgical and radiological shunt failure, late shunt dysfunction and curable thrombophilic defects. A 90% 5 year survival is reported but portal vein and hepatic artery thrombosis occurs in 13–21% of patients despite routine anticoagulation.

# Bulbospinal Muscular Atrophy

►Muscular Atrophy, Spinobulbar (Kennedy Syndrome)

# Bullous Emphysema

Marco Mura
Malattie Respiratorie, Policlinico Tor Vergata, Rome, Italy

## Synonyms

Bullous lung disease; Lung bullae

## Definition and Characteristics

Bullous emphysema (BE) is defined as a form of emphysema characterized by the presence of bullae, which are well-delimited air spaces with walls not more than 1-mm thick. In most cases, BE is a part of widespread diffuse (nonbullous) emphysema (DE).

## Prevalence

Lung bullae occur in a variety of disorders, most often in association with chronic obstructive pulmonary disease (COPD), especially DE. However, bullae may occur in lungs that are otherwise normal [1]. Consequently, patients with bullous lung disease can be subdivided into those with COPD-associated BE and those without airways obstruction (Primitive bullous disease, PBD). No prevalence studies on this specific form of emphysema are available.

Similar to DE, the main risk factors for the development of BE are tobacco smoke and α1-antitrypsin deficiency. In addition, marijuana and cocaine smoke have been associated with giant BE in young patients with no other risk factors [2].

## Genes

According to the present knowledge, given the lack of specific studies on BE, the genes involved in the molecular pathogenesis of BE are probably the same involved in the development of DE. However, a 4-bp deletion in the Birt-Hogg-Dube gene (FLCN) has recently been shown to be strongly associated with dominantly inherited spontaneous pneumothorax "(SP)" the main complication of subpleural bullae, in a large Finnish pedigree with a tendency to SP development [3].

A number of case reports showed an association between BE and lung cancer arising from scarred and contracted areas close to a bulla wall, although specific studies at the molecular level have not been conducted on this field.

## Molecular and Systemic Pathophysiology

Bullae develop after retraction and collapse of surrounding lung away from a region of weakness [1]. The mean pressure inside the lung bullae is negative and shows a

constant parallelism with the pleural pressure. The atelectasis of the surrounding areas, observed at times, is due to the elastic retraction of normal parenchyma and not to the compression by the bulla [1].

BE complicating DE substantially contributes to the functional deterioration and causes significant confounding effects on the functional assessment [4]. These findings can be explained by the contribution of lung bullae to the airways' obstruction, because of their complete loss of elastic recoil. The static elastic recoil pressure of the emphysematous lung is, therefore, further decreased. Even if the bullae remain in free communication with the airway, they do not significantly participate in the ventilation [1]. Furthermore, the chest wall mechanics is altered because of the loss of linkage with the nonbullous lung tissue, leading to increased chest wall work and worsening of hyperinflation and sensation of dyspnea [4]. The confounding functional effect of bullae depends on BE extent: relatively milder obstruction can be observed with severe BE, whereas moderate BE causes modest deterioration of diffusing capacity [4].

## Diagnostic Principles

Pulmonary function tests have remarkably practical value in distinguishing between localized bullae with otherwise normal lung PBD and bullae in conjunction with underlying COPD.

Computed tomography (CT) can locate the bullae with considerable accuracy, even when their presence was not suspected on the basis of clinical and radiographic data. Therefore, CT scan is the most useful single method of assessing the extent and localization of bullae and the possible association with DE. In CT scan, bullae are defined as confluent areas of low density, arranged on a single layer, with diameter of at least 1 cm, visible over two or more adjacent CT cuts, with a convex outline, thin walls, and absence of lung tissue within the bulla [4]. Bullae observed in inspiration and expiration do not change size to any appreciable degree. In the density histogram of CT, a specific sign has been associated with severe BE: the presence of a bimodal distribution of the lung density, in the range between –910 and –1024 HU, corresponding to the density of emphysema; this sign is associated with the presence of a single large bulla (occupying >50% of a lung) [4].

## Therapeutic Principles

The medical treatment of BE is the same adopted for DE.

Bullectomy and lung volume reduction surgery (LVRS) represent effective options to improve symptoms and exercise tolerance in selected patients with either BE or DE. To select those COPD patients who are more likely to benefit from LVRS, the preoperative assessment is essential. The presence of DE reduces the functional improvement after bullectomy when compared to a resection of large bullae in the absence of DE.

In giant bullous lung disease, operation is indicated for patients who have incapacitating dyspnea with large bullae that fill more than 30% of the hemithorax and for patients who have complications related to BE such as recurrent infections or pneumothorax [5]. Minimally invasive technique through video-assisted thoracoscopic surgery is associated with a quicker recovery and with less pain than is seen following thoracotomy [5].

# Bullous Ichthoyotic Erythroderma of Brocq

Markus Braun-Falco
Department of Dermatology, University of Freiburg, Freiburg, Germany

## Synonyms

Epidermolytic hyperkeratosis (MIM 113,800); Generalized acantholytic epidermal nevus; BIE

## Definition and Characteristics

Bullous ichthyotic erythroderma of Brocq (BIE) is an autosomal dominant genodermatosis with a high rate of sporadic mutations that starts congenital with erythema, scaling and blistering. Over time blisters become less frequent, but scaling more prominent with hyperkeratotic papules and plaques in a cobblestone- or ridge-like appearance in particular on the flexural areas. Palmoplantar keratoderma is a variable additional feature, usually associated with Keratin 1 mutations. Bacterial superinfections cause the characteristic odor of the patients and can lead to life-threatening complications, such as sepsis. Mild cases have to be

differentiated from ichthyosis bullosa of Siemens (MIM 146,800), which is caused by mutations in keratin 2e.

### Prevalence
1:200,000–1:300,000.

### Genes
Keratin (K) 1 and K10.

### Molecular and Systemic Pathophysiology
Keratin intermediate filaments belong to the cytoskeletal system within the cytoplasm of epithelial cells. They consist of type I and II proteins, which assembly into 10 nm intermediate filaments by heterodimerization. The central coiled-coil α-helical rod domain of each keratin contains highly conserved sequences at both ends, termed helix boundary motifs known to be involved in the filament assembly. The helix boundary motifs represent mutational high spots for keratin disorders. Any substitution or deletion within the rod domain is expected to cause distortion of the α-helix structure, and thus can lead to instability of the tonofilament aggregation, cytoskeletal instability, and cellular lysis of epidermal keratinocytes. K1 and K10 are pairing partners that are both expressed in suprabasal keratinocytes. So far, at least 20 different mutations in K1, and 19 in K10 have been found in BIE. Most of them are single heterozygous point mutations causing single aminoacid substitutions.

### Diagnostic Principles
If clinically suspicious for BIE, mutational analysis should be performed on K1 and K10.

### Therapeutic Principles
Treatment options are purely symptomatic and focus on the reduction of hyperkeratosis by using urea containing ointments, topical calcipotriol or mechanic keratolysis by careful rubbing with pumice stones. Oral retinoids may be beneficial to a certain degree. Antibiotic therapy, topical as well as systemic, is repeatedly necessary in case of superinfections. Gene therapy is not yet available.

## Bullous Lung Disease

►Bullous Emphysema

## Bullous Pemphigoid

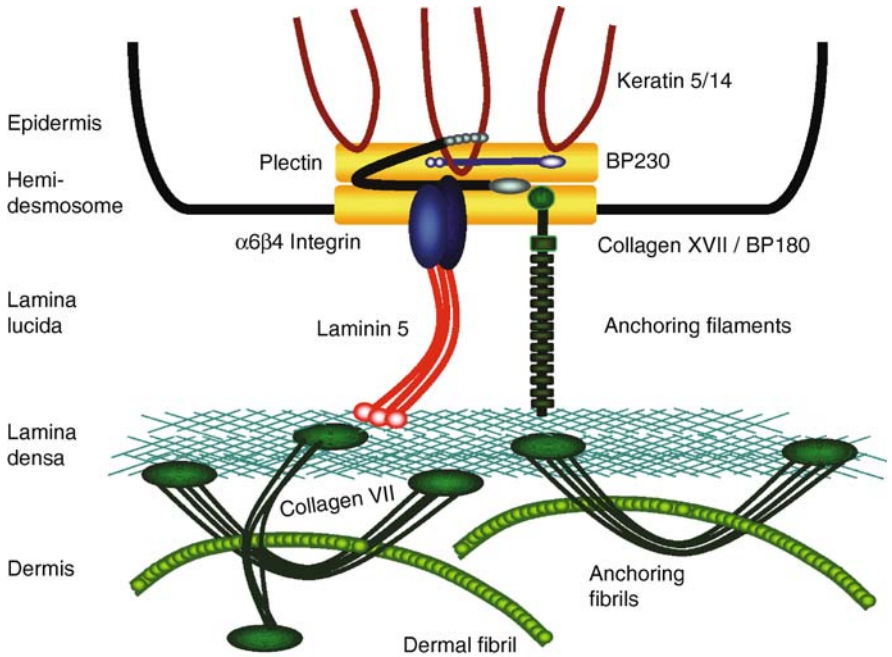
Silke Hofmann, Leena Bruckner-Tuderman
Department of Dermatology, University Medical Center, Freiburg, Germany

### Synonyms
Pemphigoid

### Definition and Characteristics
The most common autoimmune subepidermal blistering disease is associated with tissue-bound and circulating autoantibodies against distinct basement membrane proteins (collagen XVII/BP180 and BP230). Clinically, bullous pemphigoid (BP) presents as a generalized pruritic eruption with large, tense blisters on normal or erythematous skin and rare involvement of mucous membranes [1].

### Prevalence
Bullous pemphigoid affects predominantly the elderly (onset >60 years). The prevalence is not known; the annual incidence is estimated to be $7 \times 10^{-6}$.

### Genes
A prevalence of HLA class II alleles DQB1* 0301 in BP has been reported and epitope recognition of autoreactive T-cells appeared to be restricted by certain HLA class II alleles.



**Bullous Pemphigoid. Figure 1** Molecular structure of the basement membrane zone. Hemidesmosomes consist of two cytoplasmic proteins BP230 and plectin and two transmembrane proteins collagen XVII/BP180 and α6ß4-integrin. They provide stable cell-matrix-adhesion by connecting keratinfilaments of the basal keratinocyte with laminin-5. The anchoring filament protein laminin-5 may directly link the hemidesmosomal transmembrane proteins to the dermal anchoring fibrils. (Modified from [5]).

## Molecular and Systemic Pathophysiology

Autoantibodies in BP target two components of hemidesmosomes: the transmembrane protein BP180/collagen XVII and the intracellular BP230 [2]. Protein-protein interactions within hemidesmosomes play an essential role in maintaining the anchorage of basal keratinocytes to the basement membrane (Fig. 1). Recently, the pathogenicity of autoantibodies against collagen XVII was confirmed by genetically engineered model mice [3]. Binding of autoantibodies to the extracellular domain of collagen XVII, particularly to the membrane-adjacent NC16a-domain, induces a cascade of inflammatory events, including complement activation and recruitment of leukocytes with subsequent liberation of proinflammatory cytokines and proteolytic enzymes resulting in dermoepidermal separation. Autoantibodies against the cytoplasmic BP230 protein probably develop as a consequence of keratinocyte injury and play a role in enhancing inflammation. The etiology of autoantibody production in BP remains unclear. However, in some cases drugs (e.g. captopril, antibiotics) may trigger the disease.

## Diagnostic Principles

The diagnosis is based on subepidermal blister formation in histology and linear C3 and/or IgG deposits at the dermoepidermal junction in direct and indirect immunofluorescence. Circulating autoantibodies are detected by western blotting or ELISA using native or recombinant proteins. Antibody titers against the NC16a-domain correlate with disease activity [4].

## Therapeutic Principles

Treatment is based on superpotent topical corticosteroids. Severe cases require systemic therapy with oral prednisone alone or combined with immunosuppressive agents such as azathioprine, dapsone or mycophenolate mofetil. Alternatively, the combination of nicotinamide and tetracycline or high dose intravenous immunoglobulins may be useful.

## CADASIL

Nils Peters, Martin Dichgans
Department of Neurology, Ludwig-Maximilians-University Munich, Munich, Germany

### Synonyms

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (OMIM 125310); Hereditary multi-infarct dementia; Chronic familial vascular encephalopathy

### Definition and Characteristics

Autosomal dominantly inherited microangiopathy associated with migraine (with aura), recurrent ischemic strokes and progressive cognitive deficits, frequently leading to subcortical ischemic vascular dementia [1]. Additional, less frequent manifestations include psychiatric abnormalities and epileptic seizures. Magnetic resonance images (MRI) of the brain show characteristic subcortical ischemic white matter lesions and lacunar strokes. The lesion pattern is comparable to that seen in sporadic cerebral small vessel disease, with particular temporo-polar involvement (Fig. 1). MRI lesions are known to occur prior to the clinical manifestation and there is a high inter- and intrafamilial clinical variability of the disorder. Sporadic cases without a positive family history (caused by neomutations) have been reported.

### Prevalence

The exact prevalence of the disorder is not known, the estimated prevalence of mutation carriers in the German population is >1:150,000.

### Genes

Mutations within the NOTCH3 gene (located on chromosome 19p) are causative for CADASIL [2].

### Molecular and Systemic Pathophysiology

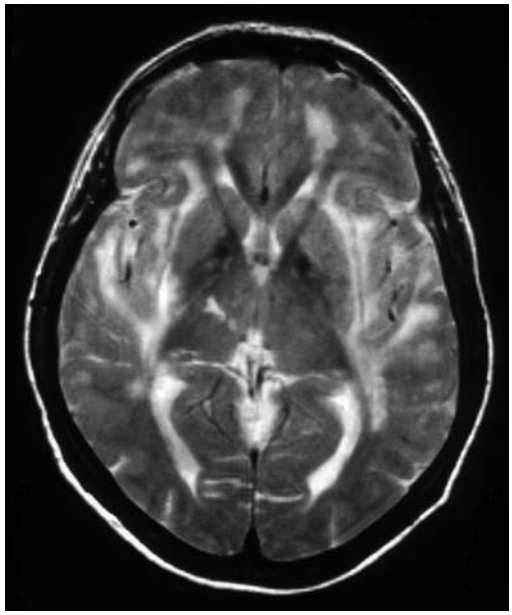
NOTCH3 encodes the Notch3 receptor, a large cell surface receptor of about 2,300 amino acids. The receptor is involved in cell fate decisions during embryonic development. In the adult human, expression of the Notch3 receptor is restricted to vascular smooth muscle cells (VSMC) and pericytes. Notch3 may promote the survival of VSMC.

CADASIL mutations are typically heterozygous missense-mutations (less frequent are in-frame deletions) leading to gain or loss of a cystein residue within an epidermal-growth-factor (EGF)-like repeat domain of the extracellular portion of the Notch3 receptor. This amino acid change results in an odd number (seven or five, respectively) of cysteine residues with the EGF-like repeat domain. The mutation pattern has been associated with an alteration of the Notch3 receptor conformation.

In CADASIL, there is an excessive accumulation of the ectodomain of the Notch3 receptor within small arterial vessels [3]. Upon ultrastructural, electron microscopic examination one can observe characteristic granular osmiophilic deposits, located within the vascular basal lamina and often seen in close contact with VSMC which degenerate. The pathophysiologic relevance of the protein accumulation as well as the factors eventually leading to VSMC degeneration are not fully understood. A loss of function mechanism with impairment of ligand-induced Notch3 receptor signalling does not seem to be of pathophysiologic relevance. More likely, mutations lead to alteration of Notch3 receptor processing and maturation [4] (Fig. 1).

### Diagnostic Principles

CADASIL may be suspected based on clinical information (a positive family history for recurrent strokes and dementia, possibly in the absence of vascular risk factors) as well as the characteristic MRI findings. The diagnosis may be confirmed by mutational screening or ultrastructural examination of skin biopsy material (characteristic ultrastructural



**CADASIL. Figure 1** T2-weighted axial MRI of 56 year old female CADASIL patient, illustrating subcortical ischemic lesions with temporo-polar involvement.

deposits within the vascular basal lamina). Mutational screening should initially be focused on NOTCH3 exons 2–6, since ~90% of mutations are located within these exons, with some variability among different populations [5]. In case of a negative result upon mutational screening and a high clinical suspicion, a diagnostic skin biopsy should be performed.

### Therapeutic Principles

To date, there is no causal treatment available. Although no specific evidence-based data is available for CADASIL, treatment should follow general recommendations for ischemic stroke. This may include antithrombotic treatment (e.g. aspirin), vasoprotective treatment with HMG-CoA reductase inhibitors (statins) and vascular risk factor control. Especially arterial hypertension could be identified as an important additional risk factor for clinical progression in CADASIL. Treatment of the other possible clinical manifestation (cognitive impairment, migraine, epileptic seizures) should also be performed according to the general recommendations.

## Canavan's Disease: Aspartoacylase Defect

Sankar Surendran
Internal Medicine, The University of Texas Medical Branch, Galveston, TX, USA

### Synonyms

Canavan-van Bogaert-Bertrand leukodystrophy

### Definition and Characteristics

Autosomal recessive disorder leading to spongiform degeneration of the brain with elevated levels of urinary N-acetyl aspartic acid (NAA).

### Prevalence

The disease is prevalent in Azhkenazi Jewish population.

### Genes

Human aspartoacylase (ASPA) gene is located on chromosome 17p13-ter.

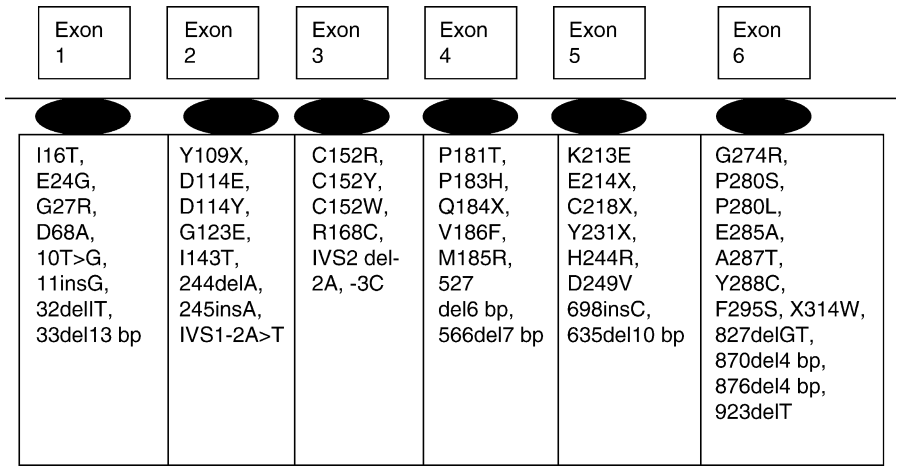
### Molecular and Systemic Pathophysiology

Aspartoacylase hydrolyzes NAA to aspartate and acetate. Aspartoacylase gene mutations result in abnormal levels of the enzyme leading to Canavan disease. Mutations of ASPA gene are shown in Fig. 1.

Homozygous mutation of the gene resulting in enzyme deficiency [1] leads to "classical" Canavan disease (CD). Abnormal hydrolysis of NAA leads to accumulation of NAA in the brain and elevated excretion of urinary NAA. Spongiform degeneration in the brain [2] and in the spinal cord are the consequence of CD. The mitochondria gets distorted and elongated in CD brain. When patients with CD become older, hypotonia gives way to spasticity. Feeding difficulties increase with age, and feeding by a nasogastric tube or permanent gastrostomy will be needed. The clinical features of the disease include psychomotor retardation, megalencephaly and hypotonia [2]. Heterozygosity of Y288C variant, resulting in reduced ASPA activity and slightly elevated urinary NAA lead to "mild" CD, which is reported in multiethnic population [3].

### Diagnostic Principles

The coincidence of megalencephaly, head lag and developmental delay points to the disease. Urinary NAA levels are high. Spongiform degeneration of the brain is an event in CD. Family history may reveal genetic origin. Expression analysis of ASPA gene mutation confirms the diagnosis of this rare disease.



**Canavan's Disease: Aspartoacylase Defect. Figure 1** Aspartoacylase gene mutations. Mutations E285A and Y231X are common in Jewish population. The Y288C variant during heterozygosity leads to mild clinical course of the disease.

### Therapeutic Principles

Aspartoacylase gene transfer improves ASPA activity and reduces the elevated NAA levels. Administration of lithium citrate decreases brain N-acetyl aspartate levels. The antiepileptic drug topiramate decreases the head growth velocity seen in CD [4]. Implantation of neural stem cells to the brain improves not only the lost enzyme but also the lost cells. Advanced glycation end products could induce ASPA gene expression [5] and this approach is important in the treatment of CD.

## Cancer Cachexia

Josep M. Argilés, Francisco J. López-Soriano, Sílvia Busquets
Departament de Bioquímica i Biologia Molecular, Universitat de Barcelona, Barcelona, Spain

### Synonyms

Cachexia-anorexia syndrome; Wasting disease; Malnutrition

### Definition and Characteristics

Cancer cachexia is a multiorganic syndrome associated with cancer, characterized by body weight loss (at least 5%), muscle and adipose tissue wasting and inflammation, often associated with anorexia.

The degree of cachexia is inversely correlated with the survival time of the patient and it always implies a poor prognosis. One of the most relevant characteristics of cachexia is asthenia (or lack of muscular strength), which reflects the severe muscle wasting that takes place in the cachectic cancer patient. Asthenia is also characterized by a general weakness as well as physical and mental fatigue. In addition, lean body mass depletion is one of the main trends of cachexia, and it involves not only skeletal muscle but it also affects cardiac proteins, resulting in important alterations in heart performance.

### Prevalence

Cancer cachexia is one of the most common manifestation of advanced malignant disease, occurring in the

majority of cancer patients (up to 80%) before death, being responsible for the deaths of at least 22% of patients [1].

## Genes

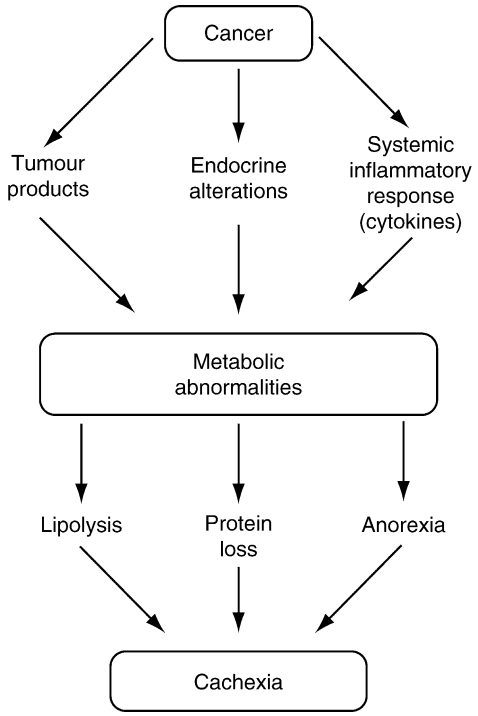
Related to both catabolic and anabolic cytokines (TNF-alpha, IL-6, IL-15). Proteolysis-inducing factor (PIF). Related to protein catabolism (i.e. ubiquitin-ligases).

## Molecular and Systemic Pathophysiology

Anorexia is not the only factor involved in cancer cachexia, metabolic abnormalities leading to a hypermetabolic state play a very important role (Fig. 1). Basically, the tumor-bearing host is energetically less efficient than in the normal non-tumor bearing state, and this leads to an increased energy expenditure that, together with the decreased food intake, has a key role in the development of cachexia. Different mechanisms can be involved in the increase in energy expenditure among their, uncoupling proteins (UCPs) may participate in generating energetic inefficiency. In particular both UCP2 and UCP3 mRNAs are elevated in skeletal muscle during tumor growth in experimental animals and cancer subjects [2].

Negative nitrogen balance in cancer patients is associated with an extensive skeletal muscle protein loss caused by an activation of intracellular proteolysis driven mainly by the ubiquitin-proteasome system [3]. In addition to the massive muscle protein loss, during cancer cachexia muscle DNA is also decreased, this leading to DNA fragmentation, and thus, apoptosis [4]. Cytokines (mainly produced by immune cells in response to the tumor) play a key role as the main humoral factors involved in cancer cachexia. Tumor necrosis factor-alpha, (TNF), interleukin-6 (IL-6) and interferon-gamma(IFN), leukemia inhibitory factor (LIF), ciliary neurotrophic factor (CNTF) or interleukin-1 (IL-1) have been suggested as mediators of cachexia (Fig. 1).

The final wasting status is determined by the balance between the mentioned pro-cachectic cytokines and the anti-cachectic cytokines, such as the interleukins-4 (IL-4), 10 (IL-10), and 13 (IL-13) and also by the soluble receptors for TNF (sTNFR) and IL-6 (sIL-6R). In addition to humoral factors, tumor-derived molecules (i.e. proteolysis-inducing factor (PIF), present in the urine of cachectic patients) have also been proposed as mediators of cancer cachexia [5].



**Cancer Cachexia. Figure 1** Cancer cachexia: factors involved. Cancer cachexia is a complex pathological condition characterized by many metabolic changes involving numerous organs. These changes are triggered by alterations in the hormonal milieu, release of different tumor factors and a systemic inflammatory reaction characterized by cytokine production and release.

## Diagnostic Principles

5% weight loss in less than 1 month or 10% weight loss in less than 6 months, changes in body composition (decrease in lean body mass), plasma elevation of C-reactive protein, and altered performance tests (grip force, treadmill resistance).

## Therapeutic Principles

Nutritional strategies are not sufficient to reverse cachectic syndrome. Indeed, patients on total parenteral nutrition are still subject to a significant waste, therefore emphasizing the role of the metabolic abnormalities in cancer-induced cachexia. It is perhaps for this reason that any therapeutic approach based on increasing food intake has to be combined with a pharmacological strategy to counteract metabolic changes. Another important problem associated with the design of the ideal therapeutic approach is that no definite mediators of cancer cachexia have yet been identified. Both tumoral and humoral (mainly cytokines) factors seem to be involved and, therefore, it is doubtful that a single drug may block the complex syndrome. The most used pharmacological strategies involve megestrol acetate (MEGACE, an appetite enhancer), glucocorticoids, ω3-fatty acids and anti-cytokine strategies which act on neutralizing metabolite alterations.

# Cancerogenesis

Klaus Dittmann, H. Peter Rodemann
Division of Radiobiology & Molecular Environmental Research, Department of Radiation Oncology, Eberhard-Karls University, Tuebingen, Germany

## Synonyms

Tumor growth

## Definition and Characteristics

Cancer is a genetic problem. Genes which regulate cell growth locally and temporally are altered and cells start dividing uncontrollably. According to the current concept cancer cells arise from stem cells, which exist in each normal tissue to ensure tissue homeostasis [1]. Typically, a series of several mutations are required before a normal stem cell transforms into a cancer cell. Furthermore, cancer cell populations can develop with latency periods that range from years and even to decades.

A variety of chemical as well as physical agents or viruses may induce cancer cell development. These occur either as part of our natural environment, such as aflatoxins, man-made compounds, like benz[a]pyrene or 2,3,7,8-tetrachlorodibenzo-p-dioxin or UV as well as ionizing radiation. In principle, many mutagens are also carcinogens, but some carcinogens do not act as mutagens. Examples of carcinogens that are not mutagens include alcohol and estrogen. Many carcinogens arise unwanted from inert precursors by metabolic activation during endogenous detoxification [2]. Several viruses that are known to cause cancer, such as HPV (cervical cancer), Hepatitis B (liver cancer) and EBV (lymphoma) belong to the group of DNA viruses. These viruses insert part of their DNA near the cell growth control genes and overtake control of gene expression of the host cell to ensure virus replication.

## Prevalence

Cancer is one of the leading causes of morbidity and death.

## Genes

Cancer cells transfer their property to daughter cells, which require genetic modification. A wide variety of gene variants have been identified, which favor the development of cancer cells, including variants of the genes encoding growth factors or signaling molecules (see below).

## Molecular and Systemic Pathophysiology

The main target of these oncogenic strategies is to acquire control over so-called proto-oncogenes. Proto-oncogenes promote cell growth in a variety of ways. Many of them can produce hormones, which stimulate mitosis. Some are responsible for the signal transduction system (e.g., N-RAS) and signal receptors (e.g., EGFR) in cells and tissues themselves. They often produce mitogens (e.g., c-sis, the platelet derived growth factor PDGF), or are transcription factors (e.g., c-myc) controlling gene expression to form proteins essential for the regulation of cellular processes, like proliferation and differentiation etc. Mutations in proto-oncogenes can alter their expression and function by increasing the amount or activity of the corresponding protein. Thus, proto-oncogenes become oncogenes resulting in a higher chance of the particular cell dividing excessively and uncontrollably.

The second possibility in promoting carcinogenesis is knock down of specific tumor suppressor genes (e.g., TP53). These genes code for anti-proliferation signals and proteins that suppress mitosis and cell growth. Generally, tumor suppressors are transcription factors that are activated by cellular stress or DNA damage. The function of such genes is to induce a cell cycle arrest, i.e., to inhibit progression through the cell cycle, in order to carry out DNA repair, which prevents the transfer of mutations to daughter cells.

In general, several mutations in both types of genes are required for cancer development. A mutation limited to one oncogene could be suppressed by tumor suppressor genes. On the other hand, mutation to only one tumor suppressor gene would not cause cancer due to the presence of many “backup” genes that duplicate its functions. Thus, the general principle is that a critical amount of mutations in both proto-oncogenes and tumor suppressor genes needs to accumulate in one cell to become a tumor cell. As this is a time consuming

process this may explain the observation that cancer is a disease of older people.

Due to loss of tumor suppressor genes, the tumor cell genome is not stable and will alter permanently to produce daughter cells adapted to new environmental conditions generated by increased tumor size, invasion or metastasis. The complex alterations in gene expression linked with late stages of tumor promotion are difficult to explain on the basis of a step by step mutation processes. Such global changes in gene expression are most likely due to the mutation of a genome organizer that tethers multiple genomic foci and recruits chromatin-remodeling enzymes to switch complex gene programs on or off. As a consequence the expression of more than 1,000 genes can be altered simultaneously. For example, the transcription factor SATB1 (i.e., Special AT-rich sequence Binding protein 1) mediates gene activation processes inducing the metastatic potential of breast cancer cells [3].

Finally, tumor promoting factors can promote cancer cell development by epigenetic silencing of genes responsible for differentiation processes in stem cells. For example epigenetically mediated dysfunction of the bone morphogenetic protein pathway can result in the initiation of neuronal stem cells to develop glioblastoma [4].

## Diagnostic Principles

Cancerogenesis is a multistep process of genetic alteration resulting in the conversion of proto-oncogenes to oncogenes which leads to a tumor specific gene expression profile. By use of microarray technology these alterations in gene expression can be determined. According to the expression profile staging procedure for individual tumors can be deducted.

## Therapeutic Principles

Based on gene expression profiling of tumors, specific response patterns to conventional therapeutic strategies applying chemo- as well as radiotherapy or a combination of both can be proposed. Moreover, the knowledge on tumor specific gene expression will provide therapeutic options by tailoring the treatment strategy to the individual tumor.

# Candidiasis, Mucous, Cutaneous and Systemic

Anca Sindrilaru, Cord Sunderkötter
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

C

## Synonyms

Thrush for oral candidiasis invasive, hematogenous or disseminated candidiasis for systemic candidiasis

## Definition and Characteristics

A variety of acute, subacute, or chronic infections caused by Candida spp., mainly Candida albicans, which range from superficial – mucosal or cutaneous candidiasis – to life-threatening disseminated candidiasis in immunocompromised hosts.

## Prevalence

The general prevalence of candida infection is 50/100,000. Systemic candidiasis occurs in 8/100,000 persons per year in the USA and it becomes more frequent because of the expansion of susceptible persons, i.e., in particular, of those with marked granulocytopenia such as transplant recipients or cancer patients under chemotherapy, or those with immunosuppression such as HIV-infected individuals and very low birth weight infants (≤1,500 g) and with the frequent use of invasive material (catheter, prothesis). Candida is the fourth commonest cause of bloodstream infection, with an increasing incidence of non-albicans strains: C. glabrata, C. tropicalis, and C. krusei.

Cutaneous and mucous candidiasis is mainly associated with diabetes mellitus, use of broad spectrum antibiotics, steroids, and immunosuppressive agents, and iron and vitamin deficiencies. Oral candidiasis is additionally favored by local factors such as salivary gland hypofunction or denture prostheses.

## Molecular and Systemic Pathophysiology

Candida spp. colonize human epithelia and most infections are endogenously acquired from this reservoir. Candida is normally a saprophyte for immunocompetent individuals with an intact skin and mucous barrier. For this balance an intact innate immune response is required. Phagocytosis by granulocytes is the first line of defense. It is mediated by complement receptor-type 3 (CR3)-, lectin-like receptor and Fc receptors. The lack of CR3 in the human leukocyte adhesion deficiency (LAD 1) results in spontaneous and severe mycotic infections. In diabetes mellitus, functional deficits of granulocytes in terms of chemotaxis,

phagocytosis, and killing are responsible for more frequent and more severe infections with candida, partly because the intracellular survival mechanisms of candida begin to dominate and ensure survival in the phagocytes. They encompass unique mechanisms, which include exploitation of ethanol for gluconeogenesis and synthesis of methionine and arginine in case of amino acid deprivation.

When alterations of the host's immune response occur, candida employs several pathogenic mechanisms to establish infection: (i) as a dimorphic fungus, it is able to switch from the saprophytic yeast form to pathogenic filaments, which are able to lyse phagocytes; (ii) in the yeast form, candida exhibit CR2- and CR3-like structures that scavenge complement fragments C3d and iC3b (molecular mimicry), but also mediates adhesion to ICAM-1 on endothelial cells which is important in case of invasion or dissemination; (iii) in the filamentous form, candida additionally expresses adhesions for binding to the surface of endothelial and epithelial cells. The best characterized are Hwp1, Ala1p/Als5p, and Als1p from the class of glycophosphatidylinositol-dependent cell wall proteins which adhere to β(1,6)-glucan as well as to the extracellular matrix proteins fibronectin, laminin, and collagen; (iv) candida is even able to penetrate the skin and mucosal barrier by secreting extracellular proteolytic enzymes, among them a family of 10 secreted aspartyl proteinases (Sap proteins) which digest and distort the host's cell membranes. This way, candida commonly causes infection of skin and mucosal surface. However, in case of severe immune deficiencies, especially in neutropenic states, it is able to invade the tissue and to enter the bloodstream so that it disseminates, causing life-threatening systemic infections.

### Diagnostic Principles

Clinical signs and symptoms, together with positive cultures or the presence of filamentous structures on swabs are the mainstay of mucous and cutaneous candidiasis. Clinical signs demarcated areas of erythema and maceration with satellite papules and pustules, accompanied by pruritus mainly in flexures (intertrigo).

Oralpharyngeal candidiasis is associated with burning, xerostomia, disgeusia, with erythema, atrophy, or whitish plaques. Vulvar pruritus, pain or burning and external dysuria, as well as vulvovaginal erythema, edema, and a thick, vaginal discharge are strongly suggestive of vulvovaginal candidiasis.

In case of invasive candidiasis the presence of fever in immunocompromised patients, which persists despite broad-spectrum antibiotics, must raise suspicion and the evidence of Candida spp. in blood confirms the diagnosis.

### Therapeutic Principles

There are several classes of antifungal drugs currently available, with different antifungal mechanisms: (i) irreversible binding of ergosterols at the fungal surface and alteration of the membrane function (polyens – nystatin, amphotericin B); (ii) inhibition of DNA or RNA synthesis (flucytosine); (iii) inhibition of ergosterol biosynthesis (azoles – fluconazole, itraconazole, voriconazole, posaconazole, and ravuconazole), and (iv) inhibition of glucan synthesis (echinocandins – capsofungin, micafungin, anidulafungin).

In uncomplicated mucous and cutaneous candidiasis topical therapy is effective. In chronic, recurrent mucous and cutaneous candidiasis, as well as in invasive candidiasis, general therapy is required.

## Synonyms

Sudden cardiac death; SCD

## Definition and Characteristics

SCD is unexpected death, defined as death occurring within a short time after symptom onset, usually less than 1 h, or without any prior symptoms. SCD accounts for 10–20% of all deaths in adults (300,000–350,000/year) in the United States. The commonest proximate etiology is cardiac arrhythmias, usually ventricular fibrillation (VF) or occasionally bradyarrhythmias, and underlying pathology causing the arrhythmia is typically identified. In those over 35 years old, coronary artery disease is usual; however, it is often subclinical and SCD is the presenting symptom in about half the cases. In younger victims, idiopathic cardiomyopathies are more common as SCD causes (Table 1). Occasionally (~5% of SCD), conventional autopsy does not determine an underlying pathology and molecular lesions associated with arrhythmias and no structural heart disease are invoked: these include the long QT syndromes (LQT), catecholaminergic polymorphic ventricular tachycardia (CPVT), the Brugada syndrome (BrS), and the short QT syndromes (SQT).

## Prevalence

2: 1,000/year in the general population and 20–30: 100/year in individuals with high-risk clinical features (depressed ejection fraction, heart failure, ventricular arrhythmias, etc).

## Genes

Mutations cause the congenital arrhythmia and cardiomyopathy syndromes, and are listed in specific chapters. Disease genes for those not listed include, CPVT: mutations in *RYR2* (1q42.1–q43) encoding ryanodine receptor 2 (cardiac isoform) or *CASQ2* (1p11–p13.3) encoding calsequestrin 2 (cardiac isoform) [1].

SQT: "Gain of function" mutations in KCNH2 (7q35–q36) encoding Kv11.1, the rapid component of delayed rectifier potassium channel ($I_{Kr}$); KCNQ1 (11p15) encoding Kv7.1, the slow component of delayed rectifier potassium channel ($I_{Ks}$); or KCNJ2 (17q23.1–24.2) encoding Kir2.1, the inwardly-rectifying potassium channel ($I_{K1}$). "Loss of function" mutations in CACNA1C (12p13.3) encoding Cav1.2, the L-type calcium channel (α1c subunit); or CACNB2 (10p12) encoding Cav1.2, the L-type calcium channel (β2 subunit) [1].

In addition, common variants have been associated with increased risk for arrhythmias: ADBR2 (5q31–q32) encoding the β2 adrenergic receptor [2]; SCN5A (3p21) encoding Nav1.5, the cardiac isoform of sodium channel [3].

## Molecular and Systemic Pathophysiology

The arrhythmogenic substrate resulting in SCD varies and depends on underlying structural heart disease and cardiac abnormality. In general, vulnerability to ventricular arrhythmia and SCD increases as the severity of the underlying pathology increases. In ischemic and idiopathic cardiomyopathies, disease-related remodeling including cardiomyocyte disarray and necrosis, scar formation, and geometric changes contribute to arrhythmia susceptibility. Drugs can also create a vulnerable substrate often by prolongation of repolarization due to potassium channel block [4].

A family history increases risk of primary SCD [5], strongly supporting the idea that risk of SCD includes a genetic component. In arrhythmia syndromes with no structural heart disease, inheritable abnormalities in ion channels, ankyrin-B, ryanodine receptor 2, and calsequestrin 2 create the arrhythmia-prone substrate. In addition, polymorphisms of ADBR2 (Gln27) and SCN5A (Ty,1103) have been associated with increased SCD risk.

It is notable that some underlying hereditary abnormalities become obvious in the presence of exogenous triggers. Modulation of autonomic tone can disrupt repolarization homogeneity or increase calcium leak from the sarcoplasmic reticulum to trigger SCD. Drugs can create the acquired LQT syndrome, and the BrS ECG phenotype can be unmasked by sodium channel blockers or fever. Myocardial ischemia is reported to convert a latent sodium channel abnormality into repetitive episodes of VF.

## Diagnostic Principles

Stratification of SCD risk depends on age and medical history. Evaluation of structural heart disease, preserved

*Including death from arrhythmia as well as unknown cause.
HCM denotes hypertrophic cardiomyopathy; DCM, dilated cardiomyopathy; ARVC, arrhythmogenic right ventricular cardiomyopathy.

cardiac function, and active ischemia are the key elements in older individuals. In patients with prior myocardial infarction, ECG techniques including signal averaged ECG, T-wave alternans, and heart rate variability may be useful. As initial screening for monogenic arrhythmic syndromes, family history and 12-lead ECG should be considered. Exercise stress test, drug challenge, and alternate positioning of the right precordial ECG leads can be used to unmask a subclinical channelopathy when there is a high index of suspicion (e.g. a strong family history). Genetic testing may be appropriate for relatives of patients with arrhythmic syndromes and SCD victims without any causative structural heart disease.

## Therapeutic Principles

Placement of an implantable cardioverter defibrillator (ICD) is standard therapy in victims resuscitated from aborted SCD unless a clear-cut precipitating and correctable cause (e.g., acute ischemia, electrolyte abnormality, drug) is identified. Antiarrhythmic drugs (e.g., beta-blockers, amiodarone) may be used if ICD therapy is not suitable or available, although their efficacy is incomplete. Catheter ablation of specific arrhythmia pathways may be indicated in specific situations, especially in the young.

ICD therapy is also increasingly used as primary prevention in patients at a high risk of SCD such as those with severely decreased cardiac function, hypertrophic cardiomyopathy with marked hypertrophy and/or nonsustained VT, and monogenic arrhythmia syndromes. However, risk is a continuum and so a quantitative "cut-off" is difficult to establish an indication for prophylactic ICD therapy. Incomplete penetrance of monogenic arrhythmic syndromes also makes the indication complicated. The recent development of automated external defibrillators has provided on opportunity to achieve chance of immediate defibrillation of out-of-hospital VF and successful resuscitation from SCD is established in certain crowded settings with at-risk people (airports, casinos, etc).

### Synonyms

Cardiogenic Shock

### Definition and Characteristics

Cardiogenic shock is a low-output state characterized by increased intracardiac filling pressure and peripheral hypo-perfusion. It most commonly results from a critical loss of cardiac muscle functional capabilities due to myocardial infarction (AMI). Non-AMI causes of cardiogenic shock include diverse but uncommon situations such as myocarditis, dilated cardiomyopathy, pericardial tamponade, and valvular dysfunction. Cardiogenic shock is manifested by low systolic pressure (<90 mmHg) resistant to fluid-resuscitation, pulmonary congestion, and tissue hypoperfusion (low urine output). Depressed mentation and cold extremities are frequent signs.

### Prevalence

The true incidence of cardiogenic shock is difficult to assess accurately. The range of cardiogenic shock is estimated between 2 and 20% with little change over the past three decades. Cardiogenic shock incurred high in hospital mortality estimated at 60–70% in the mid-1990s but contemporary trend suggest reduced mortality to about 50% due to aggressive intervention especially in the USA [1].

### Genes

No specific genetic causes to cardiogenic shock have been identified. Genetic predisposition to AMI include diverse risk factors such as dyslipidemias, homocystinemia, or hypertension.

### Molecular and Systemic Pathophysiology

Cardiac pump failure is usually associated with 40% or more loss of myocardial tissue. Following the loss of pump capacity, neural, humoral and mechanical derangements evolve, which degenerate to a vicious cycle of cardiac and systemic injuries. The perpetuation of cardiac injury in untreated patients is manifested by myocardial specific enzyme release. The systemic hypotension resulting from depressed cardiac performance activates the sympathetic nervous system, which increase heart rate and peripheral constriction resulting in compromised renal blood flow. The renal condition leads to activation of the renin-angiotensin-aldosterone system aiming to preserve vital organ function by increasing blood volume and maintain vascular flow. While such compensatory mechanism transiently improve cardiac and brain blood flow, they also increase afterload, cardiac strain and further compromise cardiac work capacity as well as coronary perfusion. Additional contributing pathophysiological factors may reside both within the ischemic zone-inflammation, as well as outside the ischemic zone where dilation, hypertrophy and hyperkinesis further reduce cardiac work efficiency and compromise the local coronary microcirculation.

### Diagnostic Principles

Meticulous assessments of vital signs focus on cardiac rhythm, venous pressure, breath sounds and blood pressure pulses. ECG identifies acute and old injuries while chest X-rays provide cardiac dimensions and pulmonary vasculature and lung congestion.

Identification of high risk patients (usually a composite of age, systolic blood pressure, Killip class and AMI location). Two-dimensional Doppler echocardiography provides information on left ventricle size as well as regional and global function and structure. Doppler echocardiography provide most valuable information in cardiogenic shock. Preparation for left and right cardiac catheterization to obtain definitive information on cardiac chambers pressures, oxygen and cardiac output are critical to optimize the treatment strategy.

### Therapeutic Principles

The key initial treatment strategy aims to optimize cardiac volume as well as pre-and after-loads pressures and preserve cardiac contractility. Efforts to alleviate increase in pulmonary pressures by vasodilators (nitroglycerine) are considered when high pulmonary pressures pose a threat for pulmonary congestion. Increase in cardiac contractility by pharmacological means – inotropic agents, is key to maintain cardiac output. Dopaminergic and beta-adrenergic agonists and indirect inotropic agents like milrinone and amrinone (phosphodiesterase inhibitors) with cardiotonic efficacy and relative preservation of renal function yet more aggressive vasopressor (norepinephrine) might be needed. Thrombolysis of clots is also a strategy that is still debated. Several interventions are important consideration in cardiogenic shock [2]. Intraaortic balloon pumping (IABP) can be highly effective for temporary mechanical support that increases cardiac output. Coronary angioplasty (with or without stent implantation) aimed at re-vascularization and coronary by-pass graft surgery (CABG) are more invasive and robust interventions yet of proven life saving efficacy [3].

## Cardiomyopathies

Ralph Knöll
Cardiovascular Molecular Genetics, Georg-August-University Goettingen, Goettingen, Germany

### Definition and Characteristics

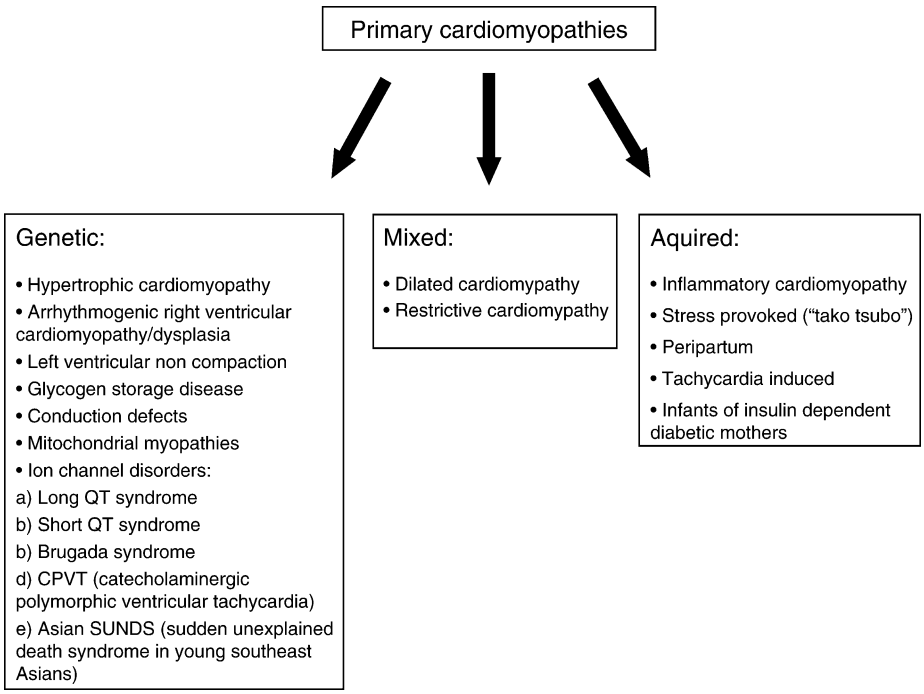
Cardiomyopathies (CM) are a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilatation and are due to a variety of causes that frequently are genetic (Fig. 1). Cardiomyopathies are either confined to the heart or part of generalized systemic disorders, often leading to cardiovascular death or progressive heart failure-related disability [1].

### Prevalence

Different types of cardiomyopathies are associated with different prevalences – hypertrophic cardiomyopathy (HCM or FHCM), for example, occurs with the highest frequency (about 1:500), dilated cardiomyopathy (DCM) occurs with a frequency of about 1:2,500; arrhythmogenic right ventricular cardiomyopathy (ARVD or ARVC) occurs with a frequency of about 1:5,000. There is considerable uncertainty regarding the frequency of other cardiomyopathies.

### Genes

A variety of different genes are involved in the pathogenesis of different cardiomyopathies (please see for a more complete overview: [2]). Hypertrophic



**Cardiomyopathies. Figure 1** (modified according to [1]).

cardiomyopathies are caused by mutations in genes encoding sarcomeric genes (i.e., genes involved in force generation – to date about eleven different genes are known), whereas dilated cardiomyopathies are caused by a variety of different genes involved in mechanical stability, mechanonsensation and force transmission (to date about 27 different genes are known). Arrhythmogenic right ventricular cardiomyopathies are predominantly caused by mutations in genes encoding desmosomal proteins (about five different genes are known). Channel disorders (also known as channelopathies) such as long QT syndrome (LQT syndrome), short QT syndrome (SQT syndrome), Brugada syndrome and catecholaminergic polymorphic ventricular tachycardia (CPVT) are caused by mutations in a variety of different potassium and sodium channels as well as by mutations in the ryanodine receptor (RyR2) gene.

## Molecular and Systemic Pathophysiology

As heterogeneous as this group is, as heterogeneous are the pathophysiological mechanisms. These mechanisms include changes in force generation (HCM), changes in mechanical stability, mechanosensation, or force transmission (DCM), defects in desmosomal architecture (ARVD/C) or changes in electrophysiological properties (channelopathies). Moreover, acute or chronic infection of the myocardium (myocarditis) can be caused by a variety of inflammatory agents such as viruses (adenovirus, herpesvirus, picornavirus), bacteria or fungi. However, all mechanisms have in common that they either cause mechanical and/or electrical dysfunction.

## Diagnostic Principles

Analysis of medical history, physical examination, electrocardiography, echocardiography, radionuclide angiography, and heart catheterization are probably the most important principles. However, additional diagnostic measures might be desirable following a first analysis such as genetic and/or electrophysiological mapping.

## Therapeutic Principles

Therapeutic strategy depends on the underlying form of cardiomypathy.

*Dilated cardiomyopath*y is usually treated with standard therapy for heart failure, including cardiac transplantation (last option).

*Hypertrophic cardiomyopathy* is classically treated using beta-blockers or calcium antagonists. In addition, insertion of a dual-chamber DDD pacemaker may be useful in some patients. Implantation of a cardioverter-defibrillator (ICD) might also be beneficial in a subset of patients as is "alcohol septal ablation." It is also possible to remove surgically parts of the septum ("Myotomy-Myectomy"), or to perform a "mitral valve replacement." In a minority of patients, not responding to maximal standard medical and surgical therapy, cardiac transplantation might be considered.

*Arrhythmic right ventricular cardiomyopathy* can be treated with beta-receptor blockers, sotalol, or amiodarone. Cryo- or catheter-based radiofrequency ablation of the presumed arrhythmogenic focus has been successful in resolving the ventricular arrhythmia in some patients unresponsive to or intolerant of antiarrhythmic drug therapy. Insertion of an implantable cardioverter-defibrillator (ICD) or cardiac transplantation is reserved for patients with indications for these procedures.

## Synonyms

DCM

## Definition and Characteristics

Dilated cardiomyopathy (DCM) is a chronic heart muscle disease characterized by cavity enlargement and impaired systolic function of the left ventricle (LV) or both ventricles. The extent of myocardial dysfunction is not accounted for by abnormal loading conditions such as systemic hypertension or valve disease, previous infarction, ongoing ischemia, or sustained arrhythmia.

## Prevalence

The age-adjusted prevalence of 36 cases per 100,000 population is likely to be an underestimate as milder forms of the disease frequently remain undiagnosed [1].

## Genes

DCM is familial in at least 40–60% of cases and demonstrates exceptional genetic heterogeneity (Table 1).

Autosomal dominant inheritance predominates, although X-linked and recessive transmission are also recognized.

## Molecular and Systemic Pathophysiology

The sarcomere generates contractile force, which is transmitted via the cytoskeleton to the sarcolemma and thence to adjacent cardiac myocytes. The "final common pathway" in DCM is thought to be a defect at any point in the linkage of the sarcolemma, cytoskeleton, and sarcomere [2]. DCM-related mutations in the sarcomeric genes, for example, are thought to produce a deficit in force generation. In contrast, actin, α-tropomyosin, titin, dystrophin, and components of the dystrophin-glycoprotein complex may cause DCM by impairment of force transmission (Table 1) [3].

Despite the diversity of molecular mechanisms in DCM, the consequences at the cellular level are similar: neuroendocrine activation and local production of cytokines, maladaptive myocyte hypertrophy, apoptosis, fibrosis, and progressive ventricular dilation and impairment.

## Diagnostic Principles

Current diagnostic guidelines for DCM are shown in Table 2 [1].

**Cardiomyopathy, Dilated. Table 1** Genetic basis of dilated cardiomyopathy

| | |
|---|---|
| **Impaired transmission of force** | Dystrophin (X-linked): serves as bridge between actin and dystrophin- glycoprotein complex |
| | Actin: bridge between the sarcomere and anchoring proteins dystrophin and α-actinin |
| | α-Tropomyosin |
| | ? Titin |
| | Desmin (intermediate filament) |
| | Components of dystrophin-glycoprotein complex (δ- and β-sarcoglycan) |
| | Cypher-Zasp (bridge between sarcomere and cytoskeleton) |
| | Metavinculin (connects actin filaments to intercalated disc) |
| **Impaired force generation** | DCM-related mutations in sarcomeric proteins (β-myosin heavy chain, troponins T, C, & I) |
| **Disruption of integrity of nuclear envelope** | Lamin A/C (autosomal dominant DCM + conduction system disease)<br>Emerin (X-linked DCM + conduction system disease) |

**Cardiomyopathy, Dilated. Table 2** Clinical Diagnosis of Dilated Cardiomypathy After [1]

| | |
|---|---|
| **Diagnostic criteria** | Ejection fraction of the left ventricle (LVEF) <0.45 (>2 SD) and/or fractional shortening <25% (>2 SD), as ascertained by echocardiography, radionuclide scanning, or angiography. |
| | Left ventricular end-diastolic diameter (LVEDD) >117% of the predicted value corrected for age and body surface area, which corresponds to 2 SD of the predicted normal limit +5%. |
| **Exclusion criteria** | Systemic arterial hypertension (>160/100 mmHg documented and confirmed at repeated measurements and/or evidence of target-organ disease) |
| | Coronary heart disease (obstruction >50% of the luminal diameter in a major branch) |
| | History of chronic excess of alcohol consumption, with remission of heart failure after 6 months of abstinence |
| | Clinical, sustained and rapid supraventricular arrhythmias |
| | Systemic diseases |
| | Pericardial diseases |
| | Congenital heart disease |
| | Cor pulmonale |

## Therapeutic Principles

Standard heart failure therapy with ACE inhibitors, angiotensin-2 receptor antagonists, and beta-blockers is indicated in DCM. Cardiac resynchronization therapy with biventricular pacing is beneficial in a select subgroup of patients. Prophylactic implantation of a cardioverter-defibrillator is recommended for patients with a left ventricular ejection fraction <35% and/or non-sustained ventricular tachycardia [4].

# Cardiomyopathy, Idiopathic Dilated

Jens Mogensen
Department of Cardiology, Aarhus University Hospital, Skejby, Denmark

## Synonyms

Dilated cardiomyopathy; DCM

## Definition and Characteristics

Dilated cardiomyopathy (DCM) is a leading cause of heart failure and characterized by unexplained left ventricle dilatation, impaired systolic function and non-specific histological abnormalities dominated by myocardial fibrosis. The etiology of the condition is heterogeneous (Fig. 1).

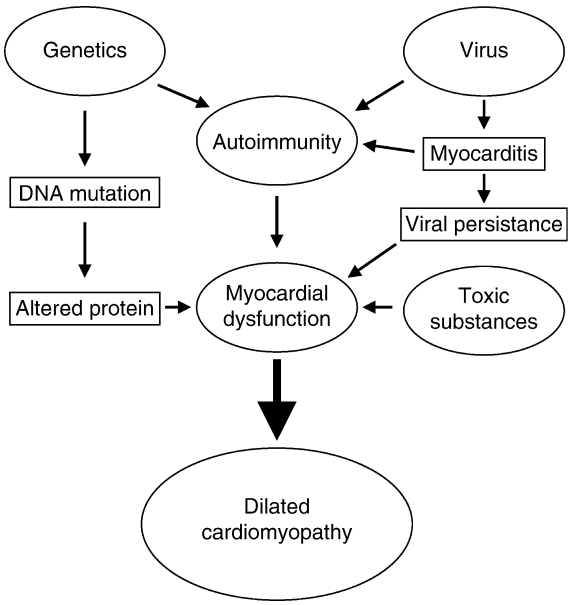
Viral infections, autoimmune diseases and toxic substances are believed to be causative in a proportion of DCM although definitive proof has been difficult to obtain. Recent studies suggest that hereditary components may account for 30–50% of cases and that penetrance is variable. The disease presentation is often heterogeneous even between related individuals. The condition is most frequently inherited by autosomal dominant transmission followed by recessive and X-linked transmission [1].

## Prevalence

DCM has an estimated prevalence of 36.5/100,000 in a US-population and is the commonest cause of heart failure and cardiac transplantation in the young. The prevalence varies between different racial groups [2,3].

## Genes

In common with other hereditary cardiac conditions, DCM is characterized by genetic heterogeneity. More than 25 different disease genes have been identified encoding proteins involved in a variety of cell functions. Theses include proteins of the sarcomere, nuclear envelope, Z-disc, cytoskeleton, sarcolemma, and various ion channels.



**Cardiomyopathy, Idiopathic Dilated.**
**Figure 1** Causes of dilated cardiomyopathy.

## Molecular and Systemic Pathophysiology

Most affected families present with a "pure" cardiac phenotype and recent genetic screening studies of large consecutive DCM cohorts have suggested that sarcomeric gene mutations may be quite common [4]. However, more genetic screening studies are needed to elucidate the prevalence of various disease genes and the clinical relevance of gene testing. In addition to impaired cardiac function variable degrees of skeletal muscle dystrophy and cardiac conduction disease has been reported with mutations in genes such as dystrophin, desmin, emerin and lamin A/C. Less frequent affected individuals present with involvement of other organ systems as in Barth syndrome which is characterized by DCM, neutropenia, abnormal mithochondrial function as well as skeletal myopathy. Disease responsible mutations for this condition have been identified in the gene G4.5 encoding the protein taffazin, in which mutations may also lead to "pure" DCM, endocardial fibrosis or left ventricle non compaction without any features of Barth syndrome. Mitochondrial mutations may be suspected in DCM patients with neurological deficits, skeletal muscle involvement in addition to symptoms from other organ systems.

## Diagnostic Principles

DCM is diagnosed by demonstration of unexplained left ventricle dilatation and impaired contractile performance by use of echocardiography. Recent studies have suggested that B-type natriuretic peptide (BNP) or aminoterminal pro-BNP are helpful biomarkers in diagnosing and management of heart failure patients [5]. Cardiac catheterization is often performed on a routine basis in individuals above 40 years of age to exclude ischemic heart disease as the cause of heart failure.

## Therapeutic Principles

The major clinical problems in DCM are heart failure, thrombo-embolic events and sudden death due to ventricular arrhythmia. Symptoms include shortness of breath, fatigue, palpitations, dizziness, and chest pain. Recent developments in medical treatment has diminished symptoms and improved prognosis considerably. This therapy includes angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, beta-blockers, nitric oxide, diuretics, and digoxin. In addition cardiac resynchronization therapy by use of bi-ventricular pacing modalities has improved symptoms and survival in severe heart failure patients with desynchronized contraction of the right and left ventricle. Furthermore prophylactic implantable cardiac defibrillator therapy is justifiable in patients with severe heart failure to prevent sudden cardiac death from ventricular arrhythmia [5].

## Synonyms

Dental caries; Carious lesion; Tooth decay

## Definition and Characteristics

Dental caries is a slowly progressive chronic disease that is seldom self-limiting. Without clinical intervention it results in infection of the dental pulp and surrounding periapical tissues leading to loss of the tooth.

## Prevalence

Dental caries is a unique process that constitutes one of the most prevalent diseases of mankind with life-long susceptibility. The presence of carious teeth does not confer protective immunity. Despite the implementation of effective public health measures, including water fluoridation in developed countries, the application of fissure sealants, and various awareness campaigns relating to diet and oral hygiene, dental caries continues to impose an enormous disease burden.

## Molecular and Systemic Pathophysiology

Streptococci are the primary bacterial colonizers of the oral cavity. These bacteria express multiple surface protein adhesins that have the capacity to bind to an extracellular matrix known as the acquired pellicle that includes salivary components, serum components and other microbial cells. The development of dental caries requires certain prerequisites including the presence of cariogenic microorganisms such as the mutans streptococci, lactobacilli and Actinomyces spp. and the ingestion of fermentable carbohydrates. By producing lactic and other organic acids, bacteria in dental plaque promote an acidic environment capable of demineralizing enamel and exposing the dentine tubules. The complex profile of organic acids produced by acidogenic bacteria and their subsequent modification by further metabolism by the Acidaminococcacae (including species of Veillonella, Dialister and Selenomonas) play a critical role in mediating decalcification of dentinal tubules leading to further invasion of bacteria and progression of the carious lesion into the dentine. As oxygen becomes depleted, obligate anaerobes, including fusobacteria, prevotellae and porphyromonads produce enzymes and toxic by-products that by diffusion through the network of dentinal tubules have the potential to induce progressive pathology in the pulp tissue. Further infection of the pulp tissue establishes the basis for dissemination of bacteria into adjacent bone and soft tissue. Despite the inherent capacity for regeneration, the inflammatory response of the pulp tissue to carious infection can also negatively impact on the generation of new odontoblast-like cells and the secretion of new mineralized dentine beneath the lesion [1–3].

## Diagnostic Principles

Many bacteria in polymicrobial oral communities have not been cultured. The application of 16S rRNA gene-based phylogenetic analysis has resulted in many recent and ongoing changes in the taxonomy of oral anaerobic bacteria and the realization that the oral cavity may contain as many as 700 different species. The use of "metagenomics" for the collective analysis of polymicrobial genomes by whole genome sequencing could overcome the current limitation of 16S rRNA gene-based PCR techniques that bias analysis by targeting dominant species and thus often mask the identity and role of minor species in infection. The nature of progressive caries is such that the hard matrix of dentine can preserve the spatial relationship between the bacteria and the diseased tissue. This allows the identification of the temporal and spatial juxtaposition of bacterial species within the lesion and the specific metabolic properties of the local microbial community at a given specific site. In recent years, a number of techniques have been developed to simultaneously correlate metabolic activity with phylogenetic identity. For example, fluorescence in situ hybridization (FISH) performed with rRNA-targeted oligonucleotide probes is used for phylogenetic identity, while micro-autoradiography is used for visualizing a bacterial cell's metabolic capabilities. By combining FISH and micro-autoradiography, cultivation-independent insight into the role of different bacteria within complex microbial communities should be feasible. A similar approach could indicate the interplay of bacteria with pulp cell response. Once identified, any polymicrobial oral consortium associated with disease could then be routinely detected by PCR, microarrays or in-situ hybridization. Future application of real-time PCR will also allow the rapid detection and quantification of bacterial DNA without the need for labor intensive post-PCR processing.

## Therapeutic Principles

Fluoride in water and dental products is widely used as a measure to control the early phase of dental caries. Disruption of metabolic interaction within dental plaque communities (oral biofilms) is considered to be another option for controlling disease. Strong association between the level of colonization of the mutans streptococci and the onset of disease has resulted in these bacteria being extensively studied as possible targets for a vaccine against dental caries. Surface adhesins, glucan-binding proteins and glucansucrases have been investigated as potential antigens for effective immunization. Another novel strategy currently under investigation is replacement therapy. In this approach, a harmless effector strain of mutans streptococci is permanently implanted in the host's microflora. Once established, the presence of the effector strain prevents the colonization or outgrowth of the indigenous, disease-causing Streptococcus by displacing it over time [4,5].

# Carious Lesion

►Caries

# Carney Complex

Markus Böhm, Thomas A. Luger
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

## Synonyms

CNC; LAMB; Lentigines, atrial myxomas and blue nevi; NAME; Nevi, atrial myxomas and ephelides

## Definition and Characteristics

Autosomal dominant multiple endocrine neoplasia (MEN) syndrome characterized by endocrine (thyroid, pituitary, adrenocortical and gonadal), non-endocrine (myxomas) and neural tumors (schwannomas) as well as cutaneous pigmented lesions (lentigines, nevi, café-au-lait spots) [1].

## Prevalence

One of the most common syndromes associated with lentiginosis. Approximately 400 patients with CNC are listed in the NIH-MC registry.

## Genes

CNC (MIM#160980): Two loci were identified: 17q22–24 coding for type I-α regulatory subunit (RIα) of protein kinase A (PKA), PRKA1A, and 2p16.

## Molecular and Systemic Pathophysiology

PRKAR1A encodes the regulatory subunit I-α of PKA, a key mediator of the cAMP signaling pathway. Half of the patients with CNC carry PRKAR1A mutations leading to a premature stop codon [2]. The most common PRKAR1A mutation is a deletion in exon 4B leading to a frameshift, 578delTG. Tumors from patients with CNC have loss of heterozygosity of 17q22–24 and the wild-type allele is lost in the associated tumors suggesting a functional role of PRKAR1A as a tumor suppressor gene [3]. Reversal of the PKA-mediated inhibition of the extracellular signal-regulated kinase pathway in CNC cells may contribute to tumorigenesis [4].

## Diagnostic Principles

To establish the diagnosis at least two of the classical criteria must be present: spotty skin pigmentation in typical distribution (lips, conjunctiva, inner and outer canthi, vagina, penile mucosa), cutaneous or mucosal myxoma, cardiac myxoma, breast myxoma, primary pigmented nodular adrenocortical disease (the most common endocrine tumor in CNC), growth-hormone-producing adenoma, large-cell calcifying Sertoli cell tumor, thyroid carcinoma, psammomatous melanotic schwannoma, multiple blue nevi, multiple breast ductal adenomas or osteochondromyxoma. The diagnosis can also be made if one the above signs is present plus an affected 1st-degree relative.

## Therapeutic Principles

Annual follow-ups including cardiac echocardiography, measurement of urinary free cortisol and serum insulin-like growth factor-I and ultrasonography of the

testicles, thyroid, abdomen and breasts are advised. Genetic counseling is essential and testing for PRKAR1A mutations is advised for detection of affected patients with known mutations of that gene.

# Carnitine Deficiency (without Transport and Uptake)

Tilman Grune
Institute of Biological Chemistry and Nutrition, Biofunctionality and Safety of Food, University Hohenheim, Stuttgart, Germany

## Synonyms

Primary systemic carnitine deficiency; Secondary systemic carnitine deficiency

## Definition and Characteristics

Carnitine (trimethylbetaine of 4-amino-3-hydroxybutyric acid) is involved in fatty acid utilization. Clinically, a carnitine deficiency manifests in unspecific symptoms with involvement of numerous organs. This includes muscle weakness, liver damage, and cardiomyopathy.

## Prevalence

Carnitine is either taken up with daily diet or is synthesized from amino acids. Major sources are meat, fish and dairy products. Therefore, some carnitine limitation might take place in vegans and persons with a predominantly cereal diet. These have lower levels of plasma carnitine. Furthermore, children with kwashiorkor also have a decreased plasma carnitine concentration.

## Genes

Mutations in several genes influence the carnitine metabolism:

- Carnitine-acylcarnitine translocase deficiency (CACT).
- Carnitine palmitoyl transferase 1 or 2 (CPT1 or CPT2) deficiency.
- Carnitine transporter (OCTN2).

## Molecular and Systemic Pathophysiology

The carnitine level is modulated by diet. 75% of body carnitine originates from food, whereas the remaining 25% is due to endogenous synthesis. The major food sources are animal products, whereas grains, fruit and vegetables contain a low level of carnitine. It should be mentioned that the determination of carnitine in food is not always reliable, since big differences in measurement due to technical methods exist. The normal intake should be between 2 and 12 μmol carnitine per kg of body weight per day. People with a high fat and low carbohydrate intake have high carnitine plasma levels. The absorption of carnitine from the diet depends on oral intake. No compounds interfering with the absorption are described. A high intake is associated with a low absorbed percentage. The remaining carnitine that is not absorbed is degraded by bacterial metabolism.

The endogenous synthesis is a multistep process using the amino acids lysine and methionine. The synthesis is mainly catalyzed in the liver, kidney and brain. For the synthesis a number of micronutrients such as vitamin C, iron, pyridoxine and niacin are required. The rate of carnitine synthesis strongly depends on the availability of trimethyllysine in the mitochondria and, therefore, of the trimethyllysine hydroxylase activity. Ninety-eight to ninety-nine percent of carnitine is reabsorbed in the kidneys, so that a relative constant endogenous carnitine pool exists.

Carnitine is separated in several compartments in the body. There are differences in the turnover, whereas liver carnitine rapidly interacts with the plasma carnitine and has a half life of a few hours, in muscle, where the exchange with the plasma carnitine pool is strictly limited, the carnitine pool has a half life of several days. The muscle to plasma ratio is about 100:1.

The major function of carnitine is the transport of fatty acids through membranes, including the mitochondrial inner membrane and the peroxisomal membrane. In the mitochondria carnitine plays a major role in the uptake of fatty acids into the mitochondrial matrix, whereas in peroxisomes carnitine seems to be involved in the export of the end products of fatty acid metabolism, like acetyl-, propionyl- and medium-chain acyl-residues. Since fatty acids are a major source of energy in most of the tissues, transport changes of fatty acids are deeply disturbing to the

cellular metabolism. Some authors attribute a further function to carnitine, as a sink for acyl groups in several statuses of overproduction/underutilization of fatty acids, leaving the limited CoA free for further metabolic activities [1,2].

However, in persons with a restricted carnitine intake (due to diet) the body is able to maintain a normal plasma carnitine level. Carnitine deficiency therefore develops in humans with an accompanying factor, including recessive mutations in the carnitine transporters. One has to consider that lysine and methionine, the substrates for the endogenous synthesis, might also be limited in the diet, e.g. in vegans. A correlation of plasma free carnitine levels with lysine and methionine was described in vegans and lactoovovegetarians, but not in omnivores. However, the carnitine level is still in the normal range in vegans, and no pathophysiological consequences are visible in general. Another risk factor is the treatment with antibiotics conjugated with pivalate. Pivalic acid is a highly branched fatty acid, used by the pharmaceutical industry to conjugate drugs for better absorption. It is metabolized via a COA ester to pivaloylcarnitine, which is excreted via the urine. This excretion of carnitine (in form of pivaloylcarnitine) might exceed the carnitine uptake dramatically.

## Diagnostic Principles

The diagnostic of carnitine deficiency is difficult. Skeletal muscle carnitine, which does not readily interact with plasma carnitine, is not visible in plasma.

However, carnitine deficiency is often accompanied by a low serum carnitine. Due to the disturbance in fatty acid utilization this is accompanied by hypoglycemia, and patients often develop a hyperammonemia leading to hepatic encephalopathy (Reye-like syndrome). Cardiomyopathy and skeletal muscle weakness leads to an elevated creatine kinase and the liver damage is often manifests in elevated transaminases. Accompanying clinical manifestations are hypoketosis, steatosis, and dicarboxyclic aciduria.

Special diagnostics reveal elevated concentrations of long-chain fatty acids and acylcarnitine esters (in CACT deficiency) [3].

Carnitine deficiency is very often associated with subclinical manifestation. In children this is often accompanied by reduced stamina [4].

## Therapeutic Principles

The major choice of treating carnitine deficiency is the increase of carnitine intake due to diet or supplements. This is true for primary and secondary systemic carnitine deficiencies. Although, in some genetic disorders associated with carnitine transport, the effect of carnitine supplementation is unclear.

# Carnitine Deficiency, Primary

Nicola Longo[1], Cristina Amat Di San Filippo[1], Elisabeth L. Schwarz[2], Marzia Pasquali[2]
[1]Medical Genetics/Pediatrics, University of Utah, Salt Lake City, UT, USA
[2]Department of Pathology and ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT, USA

## Synonyms

Carnitine uptake defect; CUD; Carnitine deficiency (systemic); Carnitine transporter defect; OCTN2 transporter deficiency

## Definition and Characteristics

Primary carnitine deficiency (OMIM 212140) is an autosomal recessive disorder of fatty acid oxidation due to the lack of functional OCTN2 carnitine transporters. Carnitine is required for the transfer of long-chain fatty acids from the cytoplasm to the mitochondrial matrix for their oxidation [1]. During periods of fasting, fatty acids become the predominant substrate for energy production via oxidation in the liver, cardiac muscle and skeletal muscle [1]. Patients with carnitine deficiency develop hypoglycemia and the accumulation of fat within organs leads to hepatic steatosis, cardiomyopathy and muscle weakness.

## Prevalence

Primary carnitine deficiency has a frequency of about 1:40,000 newborns in Japan [2] and 1:37,000–1:100,000 newborns in Australia [3]. In the USA and Europe, the frequency of primary carnitine deficiency has not been defined, but from the reported cases, it seems similar to that in Japan.

## Genes

The OCTN2 carnitine transporter is encoded by the SLC22A5 gene which is composed of 10 exons and spans about 30 kb on 5q31.1–32. The mature mRNA encodes a protein of 557 amino acids with 12 predicted transmembrane spanning domains. The gene is ubiquitously

expressed with higher levels of expression in heart, kidney, skeletal muscle, pancreas and placenta.

Heterogeneous mutations in this gene have been detected in primary carnitine deficiency [1,4]. These can lead to a decreased RNA stability due to nonsense mediated RNA decay [5], impair maturation of the transporter to the plasma membrane [4] or impair activity of the transporter [1,4]. The net result of all mutations reported is loss of carnitine transporter function.

### Molecular and Systemic Pathophysiology

The lack of functional OCTN2 transporters results in defective renal tubular reabsorption and urinary carnitine wasting with secondary systemic carnitine deficiency. The lack of carnitine impairs the oxidation of fatty acids, with defective energy production. This results in decreased production of ketones by the liver and increased utilization of glucose with resultant hypoglycemia (hypoketotic hypoglycemia). Fatty acids not utilized accumulate inside organs causing their dysfunction. Free fatty acids can also alter the electrical activity of cardiac cells resulting in arrhythmia.

### Diagnostic Principles

Hypoketotic hypoglycemia, hypotonia or cardiomyopathy can point to defective fatty acid oxidation. Common laboratory testing at the time of acute attacks can show hypoglycemia, elevated liver function tests and CK and hyperammonemia. Urine analysis can show minimal or no ketones at the time of hypoglycemia. Measurement of plasma carnitine levels indicates low levels of free carnitine (usually <8 μM, normal 25–60 μM). Urine organic acids are usually normal, but can show dicarboxylic aciduria. The plasma acyl carnitine profile shows low free carnitine (C0), low acetyl carnitine (C2) and no abnormal acyl carnitine species. Low levels of free carnitine on the acyl carnitine profile allow the presymptomatic identification of this disease by newborn screening programs using tandem mass spectrometry [3]. Diagnosis is confirmed by measurement of carnitine transport in fibroblasts, which is usually reduced to less than 10% of controls. Mutational analysis of the SLC22A5 gene can also confirm the diagnosis.

### Therapeutic Principles

Primary carnitine deficiency responds well to oral carnitine supplementation. Therapy is started at 100 mg/kg per day divided into three doses. Supplements usually increase plasma carnitine levels in affected patients slowly and rarely lead to complete normalization of free carnitine levels. Therapy should be continued for life, since discontinuation can lead to other episodes of hypoglycemia or sudden death. Acute episodes should be treated with intravenous infusion of glucose until oral intake of food and carnitine is normalized.

## Carnitine Deficiency, Systemic

►Carnitine Deficiency, Primary

## Carnitine Palmitoyltransferase I Deficiency

Elardus Erasmus, Lodewyk J. Mienie
School of Biochemistry, North-West University, Potchefstroom, South Africa

### Synonyms

Carnitine o-palmitoyltransferase; CPT-I; CPT-A; Outer membrane carnitine palmitoyl transferase; Acylcarnitine transferase; Palmitoylcarnitine transferase

### Definition and Characteristics

CPT I (carnitine palmitoyltransferase I) (EC 2.3.1.21), which is loosely associated with the outer mitochondrial membrane, catalyzes the formation of fatty acylcarnitines from acyl-CoA and carnitine. The carnitine esters cross the inner mitochondrial membrane by a process of exchange diffusion catalyzed by carnitine–acylcarnitine translocase [1]. The mitochondrial carnitine palmitoyltransferase system is the rate-limiting step of the oxidation of long-chain fatty acids. Major control over the process is exerted at the level of CPT I, by virtue of the unique inhibition of this enzyme by malonyl-CoA [2]. Both the active site and the malonyl-CoA-binding (regulatory) site are exposed on the cytosolic face of the mitochondrial

outer membrane. Inherited defects at the CPT locus, some with serious consequences, are also being reported with increasing frequency [3].

### Prevalence

Rare, less than 50 known cases.

### Genes

The hepatic (CPT IA) and muscle form (CPT IB) and are encoded by different genes localized on chromosome 11q13.1–13.5 and 22q13.31–13.32, respectively.

### Molecular and Systemic Pathophysiology

The heart and liver isoforms of CPT I plays a very important role in the energy metabolism of the heart, liver and pancreatic cells. A defective CPT I would result in the first step in the transport of long-chain fatty acids from the cytoplasm to the mitochondrial matrix not taking place. As a result there is a shortage of long chain substrates for oxidative metabolism in the mitochondria. The accumulating long chain acyl-CoA substrates are subjected to alternative metabolism and the resulting medium chain intermediates are then further metabolized by the mitochondria [4]. The first described CPT I mutation was from a patient homozygous for a missense mutation (D454G). A number of novel mutations have now been discovered amongst which a P479L founder mutation in Inuit populations and a G710E founder mutation in a Hutterite community.

### Diagnostic Principles

Clinical presentation is normally triggered by fasting or illness. Symptoms may include lethargy, hyperammonemia, seizures, hypoketotic hypoglycemia, coma and death. Diagnosis is normally based on plasma carnitine analysis which shows a high level of free and total carnitine and the very characteristic hypoketotic hypoglycemia without dicarboxylic aciduria. Preliminary diagnosis based on these findings are confirmed with CPT-I activity tests [5].

### Therapeutic Principles

Treatment possibilities for patients with CPT IA deficiency are limited. These include prevention of fasting, frequent feeding and treatment with medium chain triglicerides. Patients with critical episodes of hypoglycemia responded well to glucose infusions.

## Carnitine Palmitoyltransferase II Deficiency

Marcus Deschauer, Stephan Zierz
Department of Neurology, University of Halle-Wittenberg, Halle/Saale, Germany

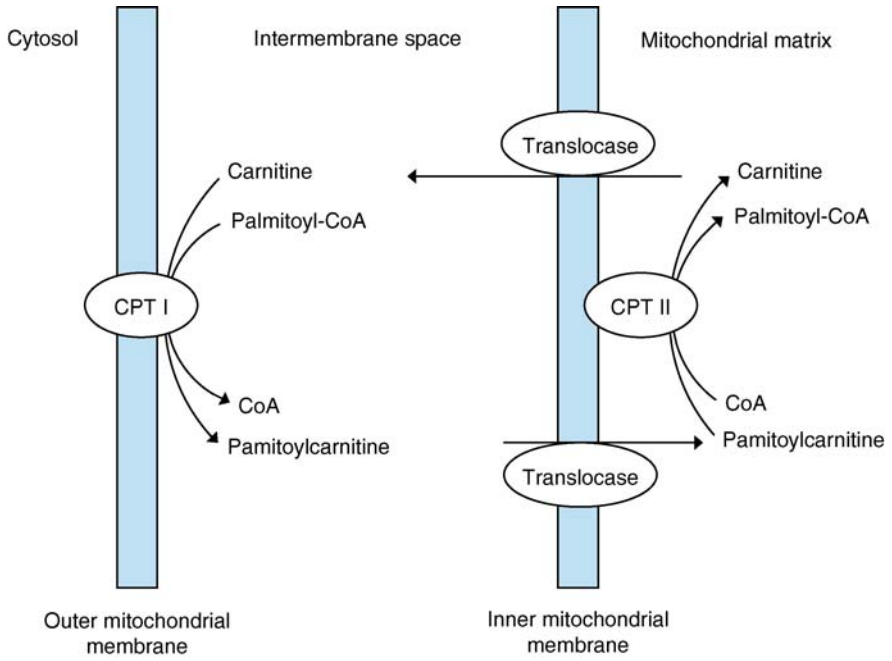
### Definition and Characteristics

Deficiencies of the enzymes carnitine palmitoyltransferase (CPT) I and II are autosomal recessive diseases due to impaired beta-oxidation of long-chain fatty-acids. Transport of long-chain fatty-acid into mitochondria depends on the carnitine shuttle consisting of CPT I and II and acylcarnitine translocase (Fig. 1).

There are three isoforms of CPT I (liver, muscle, brain). However, only patients with deficiency of liver CPT I (CPT I-A) are reported so far. This disease is characterized by attacks of hypoketotic hypoglycaemia with hepatomegaly and renal tubular acidosis in neonates or infants.

Although CPT II exists only in one isoform there are three different phenotypes of CPT II deficiency [1,2]:

1. Muscle form: Attacks of muscle pain with rhabdomyolysis after prolonged exercise, fasting, infections, cold, or drugs. First episode usually in childhood or adolescence.
2. Multisystemic infantile form: Attacks of acute liver failure with hypoketotic hypoglycemia, cardiac arrhythmias and hepatomegaly. Trigger factors: Fasting and febrile infections. Skeletal-muscle involvement restricted to mild increase of serum creatine kinase (CK).



**Carnitine Palmitoyltransferase II Deficiency. Figure 1** Scheme of the carnitine transporter system of long-chain fatty acids through the inner mitochondrial membrane.

3. Lethal neonatal form: Profound metabolic decompensation at birth characterized by hypoketotic hypoglycemia, hyperammonemia, metabolic acidosis, respiratory distress, hepatomegaly, and cardiomegaly. Developmental abnormalities possible.

## Prevalence

CPT I deficiency is a very rare disorder in general (no more than 30 patients have been reported so far) but is frequent in closed populations such as North American Hutterites. CPT II deficiency is more frequent. Most patients suffer from the muscle form (more than 300 patients reported). CPT II deficiency is the most frequent cause of hereditary myoglobinuria [1]. There are no accurate figures about prevalence.

## Genes

CPT I-A (liver isoforms) gene containing 19 exons on chromosome 11q13.

CPT II gene containing five exons on chromosome 1p32.

## Molecular and Systemic Pathophysiology

Hypoketotic hypoglycaemia during fasting, the main signs of CPT I-A deficiency, can be explained (i) by an increase in glucose utilization because of deficient production of ketone bodies and (ii) by a limitation of acetyl-coA synthesis, which stimulates gluconeogenesis. CPT I-A is expressed not only in liver but also in other internal organs explaining renal tubular acidosis.

Ubiquitous expression of CPT II can explain the multisystemic symptoms of infantile and neonatal CPT II deficiency but not the muscle form. An explanation for these distinct phenotypes are different levels of residual CPT II activity. Threshold activity could vary among tissues. When CPT is measured in muscle homogenate of patients with the muscle form under optimal assay conditions there are entirely normal total activities However, CPT II is abnormally inhibited in the presence of malonyl-CoA, palmitoylcarnitine, and detergents indicating that there is abnormal regulation when muscle is mostly dependent on beta-oxidation [3]. Situations in which fatty acids are the main energy source in muscle are prolonged exercise, fasting, and exposure to cold.

At least 24 mutations have been identified in the CPT I-A gene. Most of them are private mutations [1] resulting in reduced solubility due to improper folding [4]. At least 60 mutations have been identified in the CPT II gene distributed throughout the coding region and splice sites of the gene [4]. Important clues for genotype–phenotype correlations already exist, as some "mild" missense mutations are associated with the muscle form and some "severe" mutations with a multisystemic form if they are present in homozygous state. In patients with the muscle form, there is a common mutation (S113L) found in 60–70% of mutant alleles [1,2,4]. This mutation was never observed in multisystemic forms. In contrast to the muscle form, there is no common mutation in the multisystemic

forms. The lethal neonatal form was frequently associated with truncating mutations on both alleles. Crystal structure studies of rat CPT II, that is highly homologous to human CPT II, proposed that the identified human mutations do not affect active site residues but influence the active site indirectly; e.g. the S113L mutation changes the position of the catalytically important residues 116 and 498 [5]. Symptomatic heterozygous carriers are also reported due to possible dominant negative effects of CPT II mutations [4].

## Diagnostic Principles

Patients with CPT I-A deficiency and infantile CPT II deficiency show reduced blood glucose and keton bodies during an attack but also after a carefully monitored fasting test. Metabolic acidosis and hepatic insufficiency are often present. In CPT I-A deficiency there is elevated plasma carnitine.

In patients with muscle CPT II deficiency there are attacks of myoglobinuria and marked increase of CK. Usually CK levels return to normal by several weeks. Interictal muscle biopsies are often normal sometimes showing slight lipid accumulation.

Tandem mass spectrometry using serum samples or dried blood spots is a rapid screening test showing elevated long-chain acylcarnitines as an indirect evidence of CPT II deficiency. Long-chain fatty-acid oxidation is reduced in fibroblasts in CPT I and II deficiency. Diagnosis is ultimately made by demonstrating the enzyme defect in muscle or fibroblasts [1,4].

In patients with the muscle form of CPT II deficiency, rapid molecular genetic testing is possible since the common S113L mutation is found in more than 90% of the patients at least on one allele [2,4]. Genetic testing of patients with CPT I-A deficiency and multisystemic CPT II deficiency is more difficult since sequencing of the whole genes is necessary.

## Therapeutic Principles

Patients with acute episodes of myoglobinuria should be promptly hydrated accompanied by forced diuresis to prevent renal insufficiency. Prevention of attacks may be accomplished by high-carbohydrate (polysaccharides, not glucose), low-fat diet with frequent and regularly scheduled meals, by avoiding precipitating factors, and by increasing carbohydrate intake during infections or sustained exercise. Episodes of hypoglycemia require intravenous infusion of glucose [1,2].

# Carnitine Transport Defect

Du Toit Loots
School of Physical and Chemical Sciences, Division of Biochemistry and School of Physiology, Nutrition and Consumers Science, Department of Nutrition, North-West University, Potchefstroom, South Africa

## Synonyms

Systemic carnitine deficiency; Primary carnitine deficiency; Plasma membrane carnitine transport defect; Carnitine uptake deficiency

## Definition and Characteristics

An inherited defect in the plasma membrane carnitine transport protein, alternatively called the organic cation transporter 2 (OCTN2) [1–3].

## Prevalence

Poorly described internationally. In Japan it is estimated to occur in 1 per 40,000 births.

## Genes

The gene for OCTN2 is assigned to chromosome 5q31 [2].

## Molecular and Systemic Pathophysiology

A defective OCTN2 protein prevents effective carnitine uptake by the muscles, heart and kidneys [2,3], hence there is insufficient fatty acid oxidation in these tissues [3]. Insufficient carnitine reabsorption by the kidneys results in lowered plasma carnitine levels and subsequently less hepatic carnitine uptake by passive diffusion. Ketogenesis is consequently impaired. The accumulating acyl-CoA's become substrates for other cellular processes, such as peroxisomal β-oxidation and triglyceride synthesis. Peroxisomal β-oxidation produces medium chain fatty acids and dicarboxylic acids. These do not require carnitine for mitochondrial entry and are easily oxidized [3], hence only slight increases in these are occasionally detected [2].

## Diagnostic Principles

Clinically two forms exist: and early onset childhood cardiomyopathic form and a hepatic form with recurrent

crises of Reye-like syndrome [2]. Clinical symptoms include cardiomyopathy, hypotonia, coma, liver dysfunction, hepatomegaly, anemia and sudden death [2,4]. Routine laboratory analyses show decreased blood glucose, increased blood ammonia, decreased blood ketones, increased urinary myoglobin, increased creatine kinase activity and increased liver enzyme activity. Special laboratory analyses show normal to elevated dicarboxylic acids, normal acylglycine, decreased plasma free carnitine, and decreased long-chain acylcarnitines [2].

### Therapeutic Principles

Treatment of these patients during acute episodes entails glucose infusion in order to normalize blood sugar levels [2,4]. Carnitine supplementation is guided by plasma levels [2,3]. Patients should avoid periods of fasting by eating regularly [4].

## Caroli's Syndrome

Lee A. Denson
Division of Gastroenterology, Hepatology, and Nutrition, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA

### Synonyms

Type V choledochal cyst; Communicating cavernous ectasia of the intrahepatic bile ducts

### Definition and Characteristics

Autosomal recessive fibropolycystic disease characterized by intrahepatic bile duct dilatation (Caroli's disease) ± congenital hepatic fibrosis (Caroli's syndrome) [1]. Caroli's syndrome is associated with renal disorders including autosomal polycystic kidney disease, medullary sponge kidney, or medullary cystic kidney.

### Genes

Not known for most patients. However, mutations in PKHD1, the gene for autosomal recessive polycystic kidney disease (ARPKD), were recently reported in 32.1% of a series of adults with Caroli's syndrome [2]. These patients typically had minimal renal disease.

### Molecular and Systemic Pathophysiology

May be viewed as a type of ductal plate malformation. If the normal remodeling of the large intrahepatic ducts is affected, Caroli's disease may result, while if the small interlobular ducts are also affected leading to coincident congenital hepatic fibrosis, Caroli's syndrome will

result. The liver disease may be associated with kidney disease, most commonly ARPKD, in patients with Caroli's syndrome. In ARPKD, the PKHD1 gene product is fibrocystin, which may function as a receptor in collecting duct and biliary differentiation.

## Diagnostic Principles

Cholangiography, in most cases, MRCP, will define the bile duct abnormality [3,4]. This includes, by definition, intrahepatic saccular or fusiform ductal dilatation in all patients, with additional fusiform dilatation of the extrahepatic bile ducts in 21–53%. The extrahepatic dilatation is typically 3 cm or less in adults, in terms of distinguishing between this and choledochal cyst with intrahepatic ductal dilatation. Intrahepatic involvement is usually segmental. Liver biopsy will demonstrate the associated histopathology, with evidence of ductal plate malformation in all, with additional fibrous portal expansion in those with Caroli's syndrome. The pathological features include varying degrees of persistent embryonic bile duct structures, fibrosis, and ductal dilatation. Cirrhosis and evidence of cholangitis are commonly seen. Cholangiocarcinomas may be identified in 7–24%. Screening modalities for cholangiocarcinoma including imaging or serum markers (CA199) have not been sufficiently sensitive to allow early detection. Patients should be evaluated for coincident kidney disease.

## Therapeutic Principles

Patients may frequently present with complications, which include gallstones, cholangitis, biliary cirrhosis, and cholangiocarcinoma. Cholangiocarcinoma has been reported in 7–24%. In addition, patients with congenital hepatic fibrosis may develop complications related to portal hypertension, including variceal bleeding and ascites. Therapy is then guided by the presenting condition. Patients with segmental disease may benefit from partial hepatectomy [5]. Patients with diffuse disease complicated by recurrent cholangitis and/or cirrhosis will benefit from carefully selected liver transplantation, prior to the development of cholangiocarcinoma.

# Caspase-8 Deficiency State

Helen C. Su, Michael J. Lenardo
Molecular Development Section, Laboratory of Immunology, NIAID, NIH, Bethesda, MD, USA

## Synonyms

CEDS

## Definition and Characteristics

Caspase-8 is a member of a family of intracellular cysteine proteases called caspases that cleave target proteins after specific aspartic acid residues. The caspase-8 zymogen possesses a prodomain containing death effector domains (DED), a large enzyme subunit, and a small enzyme subunit.

Caspase-8 deficiency state (CEDS) is characterized by a prominent combined lymphocyte immunodeficiency superimposed upon a mild lymphoaccumulation with autoimmunity. Patients have impaired lymphocyte activation, resulting in hypogammaglobulinemia, recurrent sinopulmonary infections with bronchiectasis, and mucocutaneous herpesvirus infections. There is persistent but mild lymphadenopathy and splenomegaly, marginally elevated DNTs (double negative T cells, $CD4^-$ $CD8^-$ $TCR\alpha/\beta^+$), and autoantibodies. Although the lymphoaccumulation and autoimmunity are reminiscent of autoimmune lymphoproliferative syndrome (ALPS), the prominent feature of immunodeficiency distinguishes this as a separate clinical entity.

## Prevalence

Two full siblings, both affected and now young adults, have been identified [1]. Within the immediate and extended family, ten carriers, all unaffected, have also been reported.

## Genes

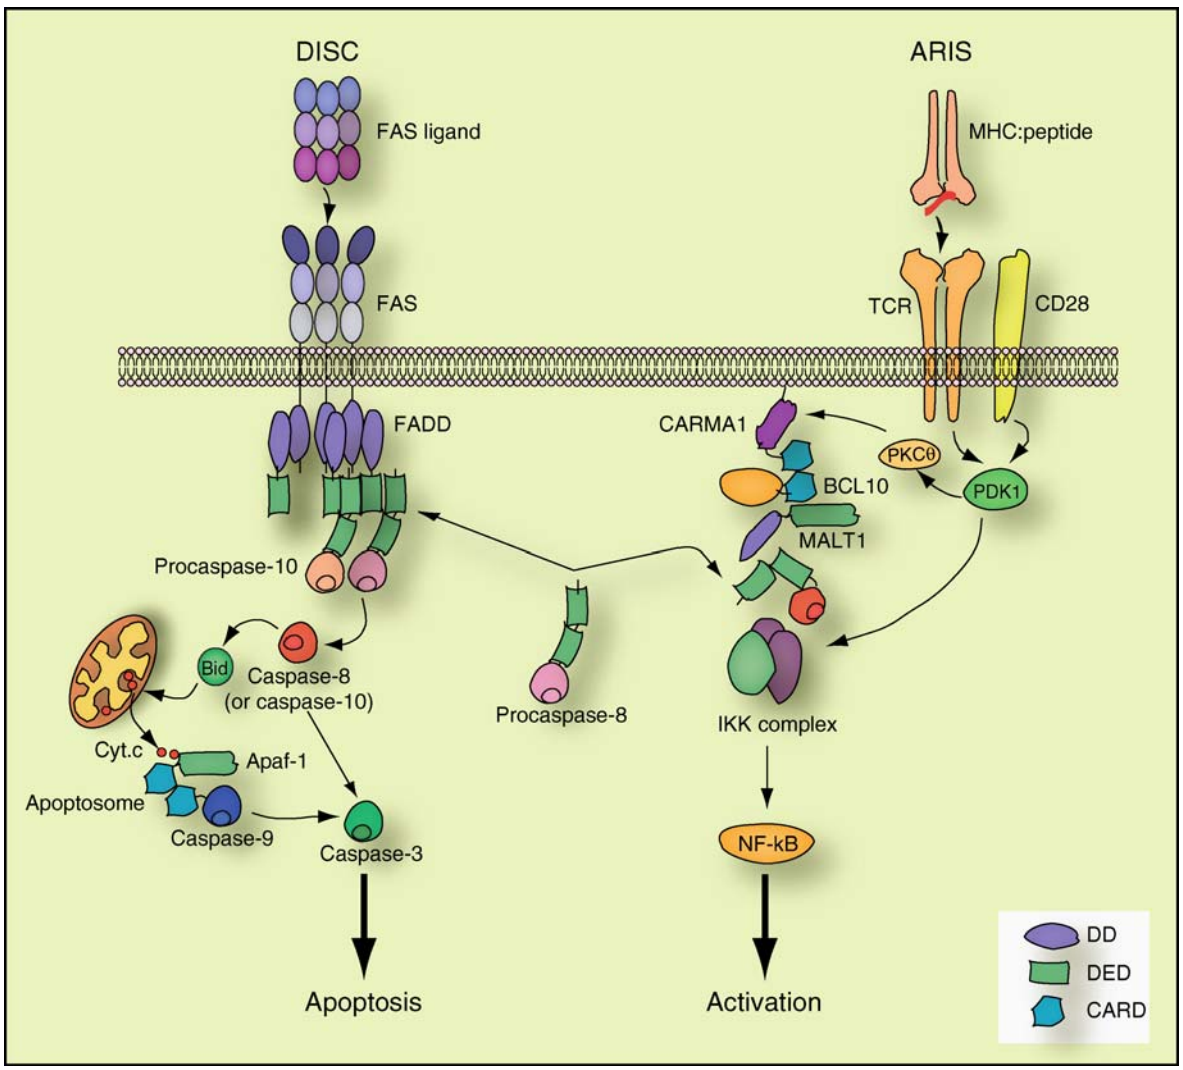
In this autosomal recessive disease, a homozygous C → T transition causes an R248W missense mutation

within the p18 large enzyme subunit of caspase-8 [1]. This mutation renders the protein product enzymatically inactive and unstable, resulting in caspase-8 deficiency.

## Molecular and Systemic Pathophysiology

The clinical features arise from caspase-8 participating in two different signaling complexes: (i) the activation-receptor induced signalosome (ARIS) necessary for Nuclear Factor kappa B (NF-κB) activation in lymphocytes; and (ii) the death-inducing signaling complex (DISC) for apoptosis induction see Fig. 1.

Lymphocyte activation requires the ARIS, which turns on the gene transcription factor Nuclear Factor κB (NF-κB). NF-κB is a transcription factor that activates a large number of genes important for the function of immune cells (see www.nf-kb.org). NF-κB is held in a repressed state in the cytosol by a protein called "inhibitor of κB" (IκB). Following antigen receptor stimulation in T cells, caspase-8 normally assembles and activates a complex containing CARMA1 (Card11), Bcl10, MALT1 (CBM), and IκB kinase (IKK) [3]. IKK then phosphorylates IκBα, which is then ubiquitinylated and degraded by proteosomes. This releases NF-κB to translocate from the cytosol to the nucleus, where it initiates gene transcription. Caspase-8 deficiency markedly impairs NF-κB activation by preventing formation of the CBM-IKK complex



**Caspase-8 Deficiency State. Figure 1** Caspase-8 participates in two signaling complexes: the activation receptor induced signalosome (ARIS) and the death inducing signaling complex (DISC). In the former, immunoreceptor stimulation leads to caspase-8-depending recruitment of the CBM-IKK complex and NF-κB activation. In the latter, death receptor stimulation results in the caspase-8 activation and cleavage of downstream caspases, leading to the cell's death. Adapted from [2].

necessary for optimal IKK activation. Biochemical experiments show that caspase-8 serves as a linker protein that physically mediates CBM association with IKK after receptor stimulation, and that caspase-8 enzymatic activity is also necessary for NF-κB activation. Impaired NF-κB activation occurs after stimulation through antigen receptor on T or B lymphocytes, toll like receptor (TLR) 4 on B lymphocytes, or CD16 (FcγRIII) or 2B4 receptors on NK cells, when caspase-8 is lacking. This accounts for the failure of T lymphocytes to produce IL-2 or express the IL-2 receptor p55 chain, B lymphocytes to secrete immunoglobulins, and NK cells to express the CD69 activation marker in CEDS patients.

Caspase-8 is also an initiator caspase that is part of the DISC, a different signaling complex that is necessary for apoptosis induction. Ligation of pre-assembled trimeric death receptors of the tumor necrosis factor receptor (TNFR) superfamily such as Fas (CD95/APO-1) induces the recruitment of the adaptor molecule FADD through homotypic death domain (DD) interactions. FADD in turn recruits and activates the initiator caspase-8 through homotypic DED interactions. By contrast to its full-length form in the ARIS, caspase-8 cleaves itself within the DISC, liberating its large and small subunits from the receptor complex. This forms highly active soluble caspase-8, which then cleaves and activates downstream effector caspases, leading to a proteolytic cascade that results in cell death. Caspase-8 deficiency cannot be entirely compensated for by caspase-10, another initiator caspase that can participate in the DISC. This accounts for the Fas-mediated apoptotic defect, and relatively mild lymphadenopathy and splenomegaly, seen in the patients.

Mice deficient in caspase-8 have been generated by homologous recombination, but unlike humans are embryonic lethal. Mice conditionally deficient for caspase-8 in T or B lymphocytes exhibit similar features as humans with CEDS, namely immunodeficiency, lymphadenopathy, splenomegaly, impaired NF-κB activation, and defective apoptosis [3–5].

## Diagnostic Principles

CEDS should be considered for patients who have combined immunodeficiency, along with lymphoaccumulation and autoimmunity. Defects in lymphocyte activation and apoptosis can be observed. Diagnosis is established by gene sequencing.

## Therapeutic Principles

No curative treatment exists. Intravenous immunoglobulin at replacement doses is used to decrease frequency of sinopulmonary infections. Acyclovir prophylaxis is used to decreased frequency of herpetic outbreaks.

## Acknowledgments

This manuscript was supported principally by the Intramural Research Program of the National Institute of Allergy and Infections Disease, NIH. H.C.S. is a recipient of a Burroughs Wellcome Fund Career Award in Biomedical Science.

# Cat Cry Syndrome

►Cri-du Chat Syndrome (Chromosome 5 Short Arm Deletion)

# Cat Eye Syndrome

Heather E. McDermid
Department of Biological Sciences, University of Alberta, Edmonton, AB, Canada

## Synonyms

Schmid-Fraccaro syndrome; Coloboma-anal atresia syndrome; Ocular coloboma-imperforate anus syndrome; Inv dup(22)(q11); Partial tetrasomy or trisomy (22pter–22q11); CES

## Definition and Characteristics

CES is a chromosomal disorder associated with multiple organ defects. CES is named for the eye abnormality coloboma, which is present in about half the cases. A supernumerary bisatellited dicentric chromosome of chromosome 22 origin (the CES chromosome) is present in most patients [1]. The karyotype is thus 47, XX or XY,+ inv dup(22)(q11), resulting in the presence of two extra copies of a region of 22q11. Three copies due to interstitial duplication have also been known to result in CES. Since the phenotype can be compatible with reproduction, CES can be familial and is dominantly inherited.

## Prevalence

The prevalence has been estimated at between 1:50,000 and 1:150,000, based on 20 years of clinical observations in Northeastern Switzerland (A. Schnizel, OMIM entry #115470).

## Genes

CES is presumably caused by the overexpression of a gene or genes in the triplicated critical region of 22q11, which contains 14 putative genes [2]. The specific gene(s) responsible for the CES phenotype have not yet been established. However, genes likely to be dosage sensitive and thus candidates for involvement in CES include CECR1, a putative growth factor predicted to affect extracellular adenosine levels and CECR2, a putative transcription factor.

## Molecular and Systemic Pathophysiology

The CES chromosome is thought to be formed by a U-type exchange between low-copy repeats (LCRs) in 22q11 [3]. Unequal exchange between the LCRs can also result in the deletion causing DiGeorge Syndrome/Velocardiofacial Syndrome (DGS/VCFS).

Multiple, discrete types of CES chromosomes exist. If both chromatids that form the CES chromosome exchange in the proximal LCR, then two copies of the CES critical region are present (Type I chromosome). If one or both exchanges occur in the more distal LCR, then one or two copies of the DGS/VCFS region are also duplicated (Type II chromosome). The presence of extra copies of the DGS/VCFS does not appear to cause a more severe syndrome, although the small sample size (ten cases) and the variability of the syndrome makes comparison difficult.

## Diagnostic Principles

The presence and severity of clinical features in CES are highly variable and can make diagnosis difficult. Major features include [4,5]: preauricular pits/tags (81–87%); anorectal malformations (73–81%); coloboma (55–61%); heart (50–63%), urogenital (71%), and skeletal defects (29–73%); and mental retardation (32–56%). Dysmorphic features include hypertelorism and downslanting palpebral fissures. Individuals with mild features may remain undiagnosed, leading to an overestimation of the incidence of malformations. Clinical diagnosis is confirmed cytogenetically by the presence of the CES chromosome. If amniocentesis reveals the presence of a bisatellited supernumerary chromosome, confirmation of the chromosome 22-origin can be done by fluorescence in situ hybridization (FISH) using a chromosome 22 paint probe. The commercial chromosome 22 centromeric probe cross-hybridizes with chromosome 14, and commercial probes for the CES region are not available. Smaller markers that presumably carry no dosage-sensitive genes and are associated with normal phenotype also exist.

## Therapeutic Principles

Individual symptoms are treated as appropriate.

## Synonyms

*Relevant conditions*: Pure autonomic failure; PAF; Idiopathic orthostatic hypotension or Bradbury-Eggleston syndrome; Multiple system atrophy; MSA or Shy-Drager syndrome; Familial dysautonomia or Riley-Day syndrome (FD); Atypical phenylketonuria (PKU) or dihydropteridine (BH4) reductase deficiency; Segawa disease or dopa-responsive dystonia; Tyrosine hydroxylase deficiency (TH); Aromatic L-amino acid decarboxylase (DDC) deficiency; Dopamine β-hydroxylase deficiency DBH; Menkes disease

## Definition and Characteristics

Most can be classified as dysautonomias; conditions in which altered function of the autonomic nervous system adversely affects health [1]. Dysautominias range from common transient episodes in otherwise healthy people (e.g., neurocardiogenic syncope), to more rare and severe conditions associated with deficiencies of catecholamines resulting from progressive neurodegenerative diseases (e.g., PAF) or rare genetic disorders involving loss of function of enzymes involved in catecholamine synthesis (e.g., DBH deficiency).

Abnormalities of blood pressure control represent the most common presenting clinical features of dysautonomias [1]. In those involving interruption of sympathetic outflow or deficiency of norepinephrine (NE), the presenting clinical feature is usually orthostatic hypotension. In other catecholamine deficiencies – e.g., atypical PKU, Menkes disease – abnormalities of autonomic function are obscured by more globally severe manifestations.

## Prevalence

MSA, 2–5 per 100,000; FD, restricted to Ashkenazi Jews, 3 per 10,000; Menkes, 3–4 per million live births. All other conditions are extremely rare with prevalences of <1 per million.

## Genes

*Catecholamine biosynthetic enzymes*: TH (11p15.5); DDC (7p11); DBH (9q34).
*Indirect causes of catecholamine deficiencies*: BH4 reductase, QDPR, (4p15.31) in atypical PKU; GTP cyclohydrolase 1, GCH1 (14q22.1–q22.2), in Segawa disease; IKBKAP (9q31) in FD; $Cu^{2+}$ transporting P-type ATPase, ATA7A, (Xq13.2–q13.3) in Menkes disease.

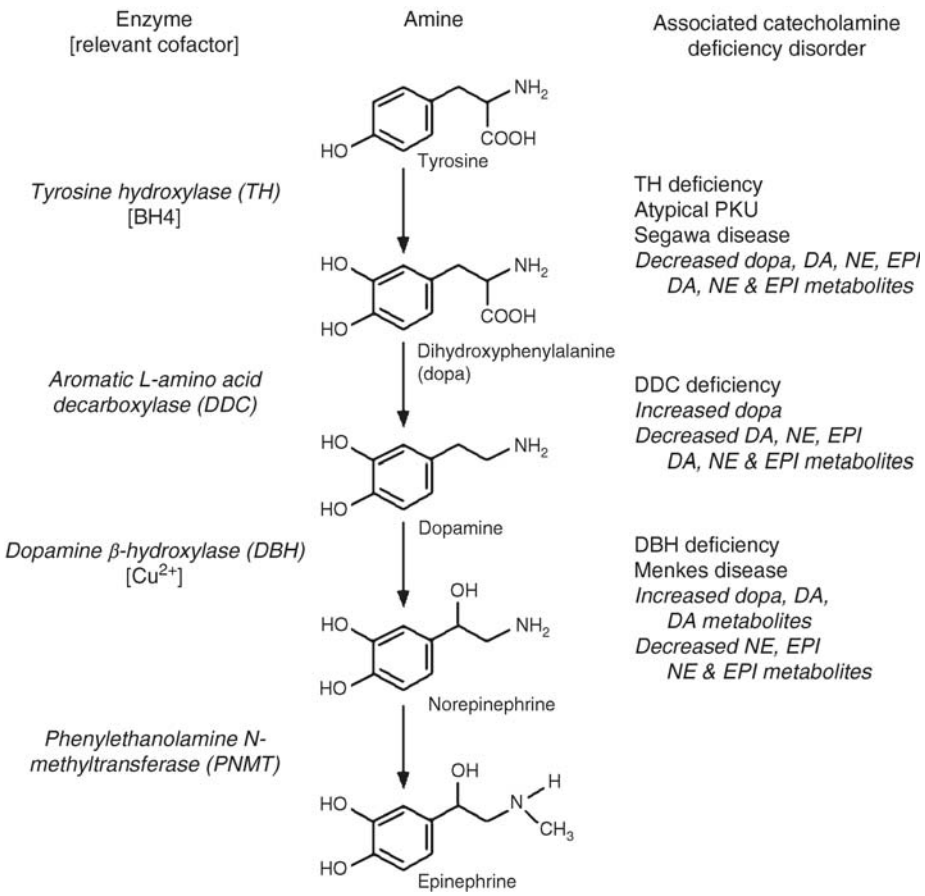
## Molecular and Systemic Pathophysiology

Blood pressure disturbances due to failure of neurogenic vasoconstrictor responses result either from sympathoneural degeneration or deficient synthesis of catecholamines. In PAF, the lesion is postganglionic, involving degeneration of sympathetic nerves and lack of NE release, whereas in MSA and FD, the lesion is preganglionic and sympathetic nerves are present but do not release NE appropriately [2]. In genetic disorders featuring deficient catecholamine synthesis the extent of systemic pathology depends on the relationship of the affected protein to the catecholamine biosynthetic cascade (Fig. 1).

Deficiency of DBH results in reduced levels of NE and epinephrine (EPI) without affecting synthesis of dopamine (DA) so that the clinical sequelae involve mainly postural hypotension [3]. In contrast, more extensive systemic pathology in Menkes disease results from a defect in the gene for a $Cu^{2+}$-transporting ATPase; impaired activity of many copper dependent enzymes, including DBH, makes the deficiency of NE and EPI a minor part of the pathophysiology [4]. Deficiency of TH leads to reduced levels of all three catecholamines with a severe clinical presentation involving neurological abnormalities in early childhood [5]. Similarly, in deficiencies of enzymes involved in production of BH4 – a cofactor important for TH, phenylalanine hydroxylase, and tryptophan hydroxylase – the pathogy severely affects all monoamine systems [5].

## Diagnostic Principles

Aside from clinical features, measurements of monoamines and metabolites are useful for pinpointing the molecular basis of catecholamine deficiency states and, when there is a genetic basis, the appropriate genes to test for a definitive diagnosis [4,5]. Low plasma and CSF levels of catecholamines and their metabolites, but normal levels of serotonin metabolites diagnose deficiencies of TH (Fig. 1). Patients with DDC deficiency also show decreases in catecholamine metabolites, but with additional decreases in serotonin metabolites and increases in dopa. Decreased levels



**Catecholamine Deficiency. Figure 1** Catecholamine biosynthetic cascade, including relevant enzymes, cofactors, and associated catecholamine deficiency disorders.

of NE and metabolites, but increased levels of dopa, DA, and metabolites best diagnose deficiency of DBH [2–4]. Similarly, diagnosis of Menkes' disease is best achieved from increased ratios of dopa and DA metabolites to NE metabolites [4]. In contrast to classical forms of BH4 deficiency, characterized by PKU (e.g., BH4 reductase deficiencies), deficiencies of GTP cyclohydrolase responsible for Segawa disease are not accompanied by hyperphenylalaninemia and require additional measurements of pterins for diagnosis [4]. Neurodegenerative-based deficiencies of catecholamines are usually indicated by absent or attenuated standing-induced increases in plasma NE [1]. In PAF, levels of NE and its metabolites are usually severely decreased, whereas in MSA or FD resting levels of NE may be normal or even increased, but fail to increase with upright posture.

## Therapeutic Principles

Therapies designed to replace the missing monoamines or improve function of affected enzymes represent key treatments for many catecholamine deficiency disorders [2–5]. L-dihydroxyphenylserine (L-DOPS) is a synthetic amino acid that is directly converted to NE by the actions of DDC. By restoring levels of NE, l-DOPS provides an effective treatment of othostatic hypotension in DBH deficiency, and shows promise in other NE deficiency disorders, such as PAF. As in Parkinson disease, therapy with l-dopa and carbiodopa can be useful in catecholamine deficiencies featuring defective TH catalyzed conversion of tyrosine to dopa, but additional supplementation with 5-hydroxytryptophan is required where the defect also influences tryptophan hydroxylase (e.g., BH4 deficiency).

## CD8 Deficiency

Oscar De La Calle-Martin,
Natalia Casamitjana
Servei d'Immunologia, Hospital de Sant Pau,
Barcelona, Spain

### Synonyms

Familial CD8 deficiency

### Definition and Characteristics

Autosomal recessive defect leading to absence of the CD8 glycoprotein on T lymphocytes and NK cells and causing immunodeficiency (Fig. 1).

### Prevalence

CD8 deficiency is presumably extremely rare. The disease was only recently first described in a single consanguineous family from Spain [1]. Since childhood, the patient has suffered otitis media and bronchitis, and presented with disseminated bronchiectasis. Two younger sisters also suffered from CD8 deficiency. Another family with the same mutation has recently been reported. The families were unrelated but both were Gypsies, suggesting a founder mutation [2].

### Genes

CD8A coding for the CD8α chain is localized on chromosome 2p12. In humans, CD8B1 is coding for the CD8β chain, whereas CD8B2 is a pseudogene, recently generated by a duplication event. Both genes are also located on chromosome 2. Patients with a CD8 deficiency carry the same missense mutation (Gly111-Ser). The change in the protein sequence generates a new N-glycosylation site in the CD8α chain.

### Molecular and Systemic Pathophysiology

CD8 T cells recognize processed peptides associated with class I molecules of the MHC. Recognition of such peptide–MHC complexes by T cell receptors (TCRs) leads to cytotoxic T lymphocyte (CTL) activation and lysis of the cell presenting the ligand. CD8 serves as a coreceptor for TCR recognition of MHC class I-associated peptides and supports CTL activation by binding to the MHC, while making no direct contact with the peptide. The ability of CD8 to act as a TCR coreceptor lies in its capacity to interact with MHC class I and β2-microglobulin (β2m). CD8 associates with β2m and the α2 and α3 domains of MHC class Ia. CD8 is a surface glycoprotein expressed as an αα homodimer or as an αβ heterodimer, but surface expression of CD8β is dependent on expression of CD8α.

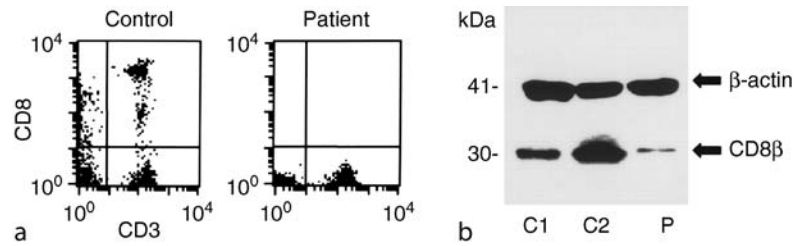
Familial CD8 deficiency has recently been included in a novel category of genetic diseases with inherited missense mutations creating novel N-glycosylation sites, and their pathogenic effects may be a consequence of the addition of N-linked carbohydrate [3]. Besides the described mutation, any other significant mutation in the CD8A gene, or even in the CD8B gene, could originate a similar phenotype.

### Diagnostic Principles

The absence of positive CD8 cells (either T cells or NK cells) together with normal levels of B lymphocytes, NK cells, and normal or elevated $CD4^+$ T cells in a young patient with multiple infections suggests this disease. Family history and lymphocyte population studies in relatives may reveal genetic origin, since heterozygotic individuals show altered levels of surface and soluble CD8. Detection of mutations in the CD8A gene confirms the diagnosis of this extremely rare disease.

### Therapeutic Principles

Therapy of CD8 deficiency is similar to that of other cellular immunodeficiencies: prevention and treatment of recurrent infections. Bone marrow transplantation could be a definitive cure for this disease.



**CD8 Deficiency. Figure 1** CD8 expression analysis. (a) Expression of CD8 on T lymphocytes and NK cells in the CD8-deficient patient and a healthy donor. (b) CD8β expression studied by Western blot analysis in two controls (C1 is a primary immunodeficient patient with low CD8 T cells, and C2 is a healthy adult) and the CD8-deficient patient. Weak intracellular expression of this molecule was detected in the patient; β-actin was the same as in controls.

# CD19 Deficiency

Cristina Woellner[1], Bodo Grimbacher[2]
[1]Division of Rheumatology and Clinical Immunology, University Hospital Freiburg, Freiburg, Germany
[2]Department of Immunology and Molecular Pathology, Royal Free Hospital and University College Medical School, London, UK

## Definition and Characteristics

The diagnosis "common variable immunodeficiency" (CVID) is given to a heterogeneous group of individuals with low serum immunoglobulin concentrations, defective antibody production and an increased susceptibility to bacterial infections of the respiratory and gastrointestinal tracts [1]. A small subgroup of CVID patients show mutations in the CD19 gene, resulting in a deficiency of the CD19 molecule on the B-cell surface.

## Prevalence

CD19 deficiency is very rare. To date four patients from two different families are published with CD19 deficiency [2]. Both families display an autosomal recessive trait; one family has been shown to be consanguineous.

## Genes

The human CD19 gene is located on chromosome 16p11.2, spans over 7.5 kb genomic DNA, has 15 exons and codes for a 556 amino acid protein including the signal peptide. In one patient, a homozygous insertion of one base pair in exon 6 has been detected, whereas the other three patients harbor a homozygous deletion of two base pairs in exon 11, both leading to a frameshift. All mutations described to date lead to an early stop codon prior to the two critical tyrosine residues, which are important for the CD19 mediated signaling into the B cell.

## Molecular and Systemic Pathophysiology

CD19 is expressed early in B-cell differentiation in the bone marrow and in the peripheral B-cell compartments and remains until plasma cell differentiation. On the surface of mature B-lymphocytes CD19 forms the "CD19 complex" together with CD21, CD81 (TAPA-1) and CD225 (Leu-13). This complex signals in conjunction with the B-cell antigen receptor (BCR) to decrease the threshold for BCR dependent signaling [3]. CD81 and CD225 are widely expressed on hematopoietic cells and their precursors, including precursor B-cells. In contrast, CD21 is only expressed on mature B-lymphocytes and to a lesser degree on follicular dendritic cells.

In mice, CD19 mutations lead to hypogammaglobulinemia, impaired B-cell memory, low $CD5^+$/B1 B-cells and decreased germinal center formation [4].

Depending on the mutation, CD19-deficient humans completely lack CD19 surface expression or show a severely reduced expression. The lack of CD19 leads to

a decreased expression of CD21, whereas CD81 and CD225 levels are normal.

In CD19-deficient humans, the composition of the precursor B-cell compartment in bone marrow and the total number of blood B-lymphocytes is normal, but the frequencies of $CD27^+$ memory lymphocytes and $CD5^+$B-lymphocytes are reduced. Secondary follicles in lymphoid tissue are small to normal in size and have normal cellular composition. However, after immunizations, CD19-deficient patients fail to mount significant IgG antibody levels.

In CD19 deficiency a few Ig switched B-cells containing VH-Cα and VH-Cγ transcripts with somatic hypermutation have been identified, indicating that in principle the process of hypermutation is intact. However, following stimulation with IgM, B-cells of CD19-deficient patients did not mobilize calcium as efficiently as normal controls, indication that the loss of CD19 on the B-cells' surface renders them more anergic.

### Diagnostic Principles

To diagnose CD19 deficiency, co-staining of whole peripheral blood with anti-CD19 and anti-CD20 antibodies is recommended.

### Therapeutic Principles

See entry on ►Immunodeficiency, Common Variable.

## Synonyms

Celiac disease

## Definition and Characteristics

Inflammatory small intestinal disorder that is triggered by the ingestion of gluten proteins from wheat, barley and rye [1]. Patients show small intestinal (duodenal) intraepithelial and subepithelial lymphocytic infiltration, villous atrophy and crypt hyperplasia. Classical celiac disease (Cd) presents with diarrhea and malabsorption, but most (>80%) screening-detected patients have minor or non-diarrheal clinical symptoms (silent, oligosymptomatic or atypical celiac disease). Atypical symptoms include neurological dysfunction, arthritis, infertility, or unexplained hypertransaminasemia. Up to 30% of adult patients with classical Cd have an associated autoimmune disease like type 1 diabetes, dermatitis herpetiformis, thyroiditis or hepatitis. Patients with longstanding untreated symptomatic Cd are at risk for developing diet-refractory Cd, enteropathy associated T cell lymphoma (EATL), and other cancers of the gastrointestinal tract. Treatment is by strict dietary exclusion of wheat, barley and rye. How far patients with silent Cd develop clinically manifest Cd, secondary autoimmune diseases or even malignancy, when continuing on a gluten containing diet, remains to be shown.

## Prevalence

Cd prevalence in the USA, most Western, middle Eastern and North African countries ranges from ~1:80 to 1:200 [1].

## Genes

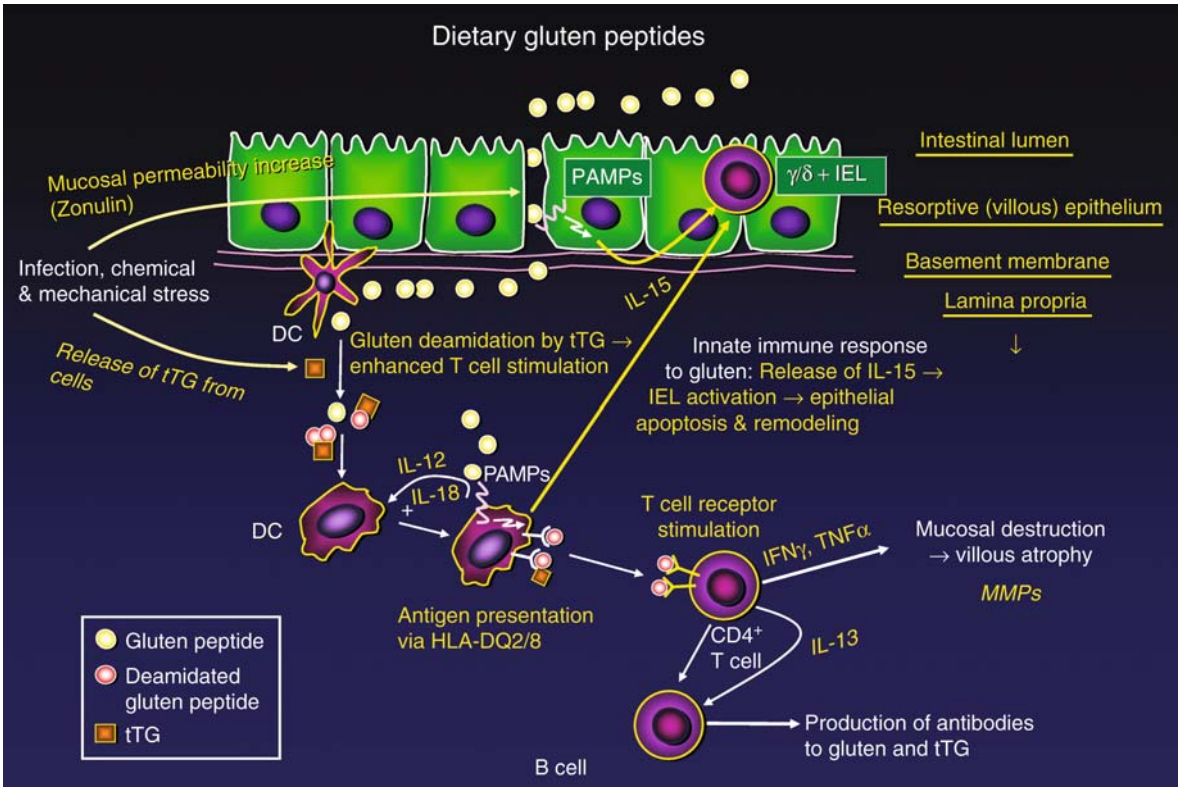
HLA-DQ2 or -DQ8 is the essential genetic predisposition, but only one out of ~30 carriers develops Cd. Cd prevalence is ~15% in first-degree relatives and concordance is an amazing 75% in monozygotic twins. The impact of other genes is much lower and varies with the population studied. These minor genes are MICA, MICB, Myo9B, and genes on chromosome 5q31–33 and chromosome 2q33, where clusters of cytokines and immune regulators like CTLA-4, ICOS-1 and CD28 are encoded [1].

## Molecular and Systemic Pathophysiology

Cd is the best defined HLA-linked disorder: (i) the trigger is well defined (certain peptides from dietary gluten, i.e., the storage protein of cereals which is composed of at least 50 different gliadins and several structurally more distant glutenins); (ii) HLA-DQ2 or -DQ8 is the essential genetic predisposition; and (iii) it is uniquely associated with an IgA (mucosal) autoimmune response to the autoantigen tissue transglutaminase (tTG, Tgase2) (15). The enzyme tTG can deamidate neutral glutamine to acidic glutamate residues in certain gluten peptides which are generally rich in glutamin. HLA-DQ2 or -DQ8 present these deamidated gluten peptides particularly well on the surface of antigen presenting cells, resulting in the activation of Th1 T cells in the subepithelial lamina propria of the intestine (adaptive immune response) [2]. Several immunodominant (e.g., gliadin α2 58–72) and numerous minor HLA-DQ2 or -DQ8 binding gluten peptides have been identified [3]. A different set of gluten peptides (e.g., gliadin α2 31–43) can fuel innate immunity, with subsequent activation of mainly intraepithelial cytotoxic T lymphocytes that play a central role in the development of refractory Cd and EATL [2]. The innate immune response also potentiates the adaptive immunity to gluten. Yet undefined gluten peptides can increase the permeability of intestinal epithelial cells by inducing the release of the protein zonulin that disassembles tight junctions, further increasing the influx of gluten into the subepithelial lamina propria (Fig. 1).

## Diagnostic Principles

Duodenal biopsy and histology (2–4 samples) have long been considered the gold standard for the diagnosis of Cd [1]. These usually reveal significant villous atrophy and crypt hyperplasia (lesions of Marsh stage III), but a mere increase of intraepithelial lymphocytes (Marsh I) or crypt hyperplasia (Marsh II) are also found. However, serum assays are highly predictive of Cd, serve as screening tools, and do at least in part replace histology. IgA autoantibodies to the autoantigen tTG are highly predictive of Cd, with a sensitivity and specificity exceeding 95 and 99%, respectively [1]. However, IgA deficiency which occurs in 2% of celiacs has to be excluded. A recent assay for IgG and IgA antibodies to a synthetic peptide that contains three immunodominant gliadin epitopes deamidated by tTG reaches comparable sensitivities and specificities, and a combination of both assays likely will be an even more powerful diagnostic tool. The conventional anti-gliadin antibody assays and the immunofluorescent test for endomysial autoantibodies (that detect tTG on tissue sections) are outdated. Patients on a longstanding gluten free diet often require



**Celiac Sprue. Figure 1** Mechanisms of mucosal injury in celiac disease. Gluten reaches the subepithelial lamina propria, especially when the permeability of the epithelial barrier is increased, such as during infections or mechanical stress. One specific mediator of increased permeability is zonulin. Cellular stress leads to enhanced intestinal expression, release and activation of the predominantly intracellular tTG. Deamidation of gluten peptides by tTG creates potent immunostimulatory epitopes that are presented via HLA-DQ2 or -DQ8 on antigen presenting cells, such as dendritic cells (DC), macrophages or B cells. Subsequently, $CD4^+$ T cells are activated (adaptive immune response), secreting mainly Th1-cytokines that via activation of macrophages and myofibroblasts cause the release and activation of matrix metalloproteinases (MMPs) that finally result in mucosal destruction. B cells are stimulated to produce autoantibodies to tTG, and antibodies to (deamidated) gluten peptides. Pathogen activated membrane proteins (PAMPs) can also be stimulated by certain gluten peptides, resulting in innate immune activation which acts in concert with the adaptive immune response. IL-15 that is upregulated after such activation drives activation and proliferation of cytotoxic intraepithelial lymphocytes (IELs) that play a central role in refractory Cd and EATL. Modified from [4].

a prior gluten challenge over several weeks before their histology and serology again become positive.

## Therapeutic Principles

An effective therapy of coeliac disease is adherence to a strictly gluten-free diet, a burden for most patients. Therefore, alternative treatments are being explored [4,5]. These include: (i) Degradation of immunodominant gliadin peptides that resist intestinal proteases by use of exogenous bacterial and fungal (prolyl-) endopeptidases; (ii) Decrease of intestinal permeability by blockade of the putative zonulin receptor on intestinal epithelia with the zonulin-derived octapeptide AT-1001; (iii) Inhibition of intestinal tTG activity by specific inhibitors; (iv) Inhibition of specific T-cell stimulation by peptides that only bind to HLA-DQ2 or -DQ8 but not to the gluten peptide specific T-cell receptors; (v) Induction of oral tolerance to gluten; and (vi) Modulation or inhibition of proinflammatory cytokines, e.g., inhibition of IL-15 in refractory Cd or intestinal T cell lymphoma. Clinical studies for (i) and (iii) are ongoing.

## Synonyms

CCDF

## Definition and Characteristics

CCDF is an autosomal dominantly inherited disorder characterized by posterior small and often polygonal patches of grayish opacities with a posterior mosaic or crocodile pattern. The CCDF changes are located in the central cornea. The youngest affected patient was 8 years old. In contrast, similar corneal opacification located at either the central or peripheral cornea in the deep stromal layer are known as "posterior crocodile shagreen" and are usually considered to be age related corneal degeneration.

## Prevalence

CCDF is a rare corneal disorder first described by François in 1956 [1]. Strachan reported about five cases in a British family [2].

## Genes

Not reported.

## Molecular and Systemic Pathophysiology

The histology of this condition has only been studied in non-inherited phenocopies of the disorder. Light microscopy revealed stromal staining for acid mucopolysaccharide [3]. Electron microscopy revealed extracellular vacuoles. Fibrillogranular material was present in and around some keratocytes. Numerous endothelial vacuoles contained light-staining fibrillogranular material and round electron-dense granules [3].

## Diagnostic Principles

The clinical diagnosis of CCDF is based on slit lamp examination in direct and indirect illumination, best seen with dilated pupil. The CCDF landmark is characterized by central crocodile shagreen in pre-Descemet's location. The differential diagnosis includes the degenerative form of Vogt's posterior crocodile shagreen and the degenerative anterior forms of central and peripheral crocodile shagreen.

## Therapeutic Principles

No therapy is required.

# Central Core and Multi-Minicore Disease

Tommie V. McCarthy
Department of Biochemistry, University College Cork, Cork, Ireland

## Synonyms

Central core disease; Minicore myopathy; Multicore myopathy; Multiminicore disease; CCD

## Definition and Characteristics

Central core disease (CCD) is a rare myopathy usually characterized by hypotonia ("floppiness" of muscles) and proximal muscle weakness at birth and/or in infancy. Delays in motor milestone development, such as walking are evident. Kyphoscoliosis, congenital hip dislocation, foot deformities and joint contractures are associated with CCD. The clinical course of the disorder is usually non progressive. The severity of symptoms may vary from apparently normal to severe with a wide variation in muscle involvement. Autosomal-dominant forms of the disorder have been described with recessive and sporadic forms appearing less frequently. Multi-minicore disease (MmD ) is a rarer autosomal recessive non progressive congenital myopathy and is not as well described as CCD.

## Prevalence

CCD and MMD are considered rare myopathies with an occurrence of <1 per 100,000. However, the incidence of the different subtypes in these disorders is difficult to determine since differential diagnostic criteria are still being established.

## Genes

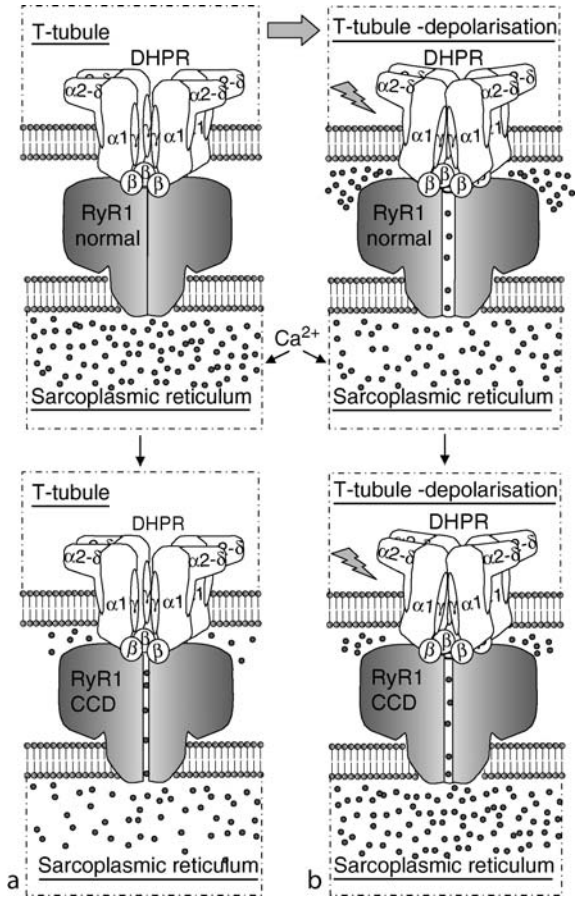
Almost all CCD cases arise from mutations in the skeletal muscle ryanodine receptor calcium release channel (RYR1) [1]. Most mutations in the 15,117 bp coding sequence occur at a low frequency and result in single amino acid substitutions in the RyR1 protein. A small number of in frame deletions have also been described. Three main clusters of RyR1 mutations are linked to CCD namely mutations in the N-terminal region (Cys35-Arg614), the central region (Asp2129-Arg2458) and the C-terminal region (Ile3916-Ala4942). C-terminal RYR1 mutations are strongly associated with more severe and penetrant forms of CCD. A subgroup of the C-terminal mutations are found within the putative pore-lining region of the RyR1 channel. It has been shown that mutations in the human selenoprotein gene SEPN1 are the cause of the "classical form" MmD, rigid spine muscular dystrophy (RSMD1), rare cases of desmin-related myopathy with mallory body-like inclusions (MB-DRM) and congenital fiber type disproportion (CFTD) [2]. These four muscular diseases, now collectively categorized as SEPN1-related myopathy, are characterized by an early onset of hypotonia and weakness, which predominantly affect axial muscles leading to neck weakness, scoliosis, respiratory insufficiency and a variable degree of spinal rigidity. Evidence suggests that SEPN1 plays a major role in muscle organization during early development. In the moderate and rarer form of MmD with hand involvement homozygous RYR1 mutations have been identified.

## Molecular and Systemic Pathophysiology

Skeletal muscle function is dependent on robust communication between depolarization events and calcium release from the SR in the excitation-contraction coupling process. In this process, the dihydropyridine receptor (DHPR) undergoes voltage driven conformational changes upon membrane depolarization and triggers activation and opening of interacting RyR1 calcium release channels in the SR leading to contraction. RYR1 mutations in the N-terminal and central regions linked to CCD promote an excessive or uncompensated SR calcium leak that results in a net depletion of SR calcium stores [3]. The reduced level of calcium available for release could explain the muscle weakness associated with CCD. Mutations in the pore region of RyR1 appear to cause an excitation-contraction coupling defect that reduces calcium release during coupling without affecting SR calcium content. These mutations appear to reduce the ability of membrane depolarization to induce calcium release from a full calcium store. The compromised communication between the depolarization events and calcium release from the SR caused by these mutations can also explain muscle weakness in CCD. It is likely that the abnormal muscle histology observed in CCD results from the effects of altered calcium homeostasis in the myofibers. The relationship between RYR1 mutations causing CCD vs. MmD arising from RYR1 mutaions is unclear. While both conditions share a number of characteristics, the differences between the conditions suggest that there are subtle differences between the pathophysiology of CCD and MmD arising from RYR1 mutations (Fig. 1).

## Diagnostic Principles

Diagnosis of CCD is by histological examination of skeletal muscle biopsy samples. Typical CCD samples show type 1 fiber predominance and amorphous central areas (cores) in these fibers when stained for oxidative enzyme activity (as they are devoid of mitochondria). Cores run the length of the myofiber. At the electron microscopic level, CCD exhibits sarcomeric filamentous disruptions and subtle pathological changes in the contractile apparatus, sarcoplasmic reticulum (SR) and t-tubules [4]. However, different patterns are seen even within families. There does not appear to be a correlation between cores and muscle weakness. Almost all CCD individuals tested are susceptible to malignant hyperthermia (a pharmacogenetic disorder whereby patients develop a strong hyper-metabolic and sometimes fatal reaction to commonly used volatile anesthetic agents). MmD is morphologically defined by the presence of multiple small zones of sarcomeric disorganization and lack of oxidative activity ("mini-cores") in muscle fibers and centrally located nuclei. Cores are seen in most fibers and are variable in size



**Central Core and Multi-Minicore Disease.**
**Figure 1** Schematic diagram of the effect of *RYR1* mutations on RyR1 calcium release channel activity in CCD. In normal excitation-contraction coupling, depolarization causes a conformational change in the DHPR that opens the RyR1 channel and releases calcium stored in the SR into the myoplasm. This results in muscle contraction. In CCD the levels of calcium released in excitation-contraction coupling are compromised leading to muscle weakness. Evidence suggests that in some forms of CCD (depicted in A), the mutated RyR1 channel is inherently leaky resulting in depleted SR calcium stores and lower levels of calcium available for release in excitation-contraction coupling. In other forms of CCD, SR calcium stores are unaffected but the mutated RyR1 channel is compromised with respect to induction of calcium release through the channel by depolarization.

and number. Type 1 fibers predominate and unlike the cores in CCD, MmD cores do not extend the full length of the fiber. Although MmD is phenotypically heterogeneous four subgroups have been described [5]. The classical form of MmD accounts for >80% of cases has a consistent phenotype marked by the axial predominance of muscle weakness and a high occurrence of severe respiratory insufficiency and scoliosis.

## Therapeutic Principles

There is no specific treatment for CCD. However, physical therapy and prescribed exercises may be beneficial for decreasing muscle weakness. Aquatic exercises are considered worthwhile for patients with CCD. However, the full benefit of exercise for this condition remains to be determined. For MmD close monitoring and precocious treatment of the factors leading to it, including scoliosis correction and ventilation, are highly recommended [5].

## Centronuclear (Myotubular) Myopathies

Carina Wallgren-Pettersson
Departments of Medical Genetics, University of Helsinki and Folkhälsan, Helsinki, Finland

### Definition and Characteristics

This group of congenital myopathies is characterized clinically by generalized muscle weakness and histologically by the presence of small rounded muscle fibers, with centrally located nuclei, which resemble fetal myotubes [1]. The most well-known form is X-linked myotubular myopathy [2] usually causing neonatally severe muscle weakness, hypotonia and respiratory insufficiency in affected boys. Familial cases with similar histology and likely autosomal recessive or autosomal dominant inheritance have also been reported [1] and, recently, three genes for autosomal forms has been identified [3–5].

### Prevalence

No prevalence figures have been published on these rare disorders.

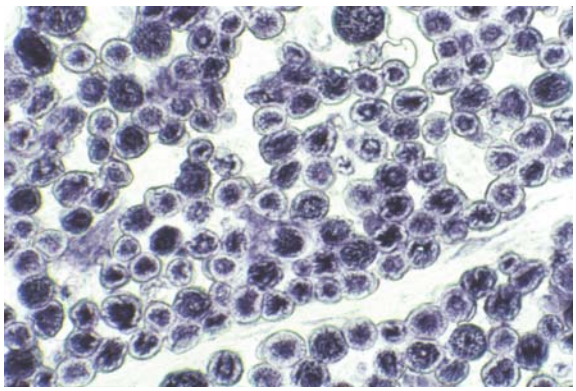
### Genes

The X-linked form is caused by mutations in the myotubularin gene MTM1 [3], while the autosomal forms appear to be genetically heterogeneous. To date, the identification of one such gene has been reported [2].

### Molecular and Systemic Pathophysiology

In the X-linked form, myogenesis and fiber type differentiation occurs and mature forms of myofibrillar proteins are produced, but structural maintenance of the muscle fibers appears to be defective [4]. The exact mechanism leading to muscle weakness however remains to be clarified. As in other congenital myopathies, there is often predominance of type 1 fibers, which may be hypotrophic. The myotube-like fibers contain central aggregations of mitochondria, showing as dense oxidative staining (Fig. 1).

The MTM1 gene includes 15 exons, and disease-causing mutations have been identified in most of them [3]. A majority consists of truncating point mutations, but some are missense mutations, a few of which have been associated with a milder phenotype. Overall however there is no strong correlation between the nature of the mutation and the clinical picture, and most cases are severe [5].



**Centronuclear (Myotubular) Myopathies. Figure 1**

The protein myotubularin (MTM1) is a lipid phosphatase acting on phosphatidylinositol 3-monophosphate. It is one of the family of myotubularins. Mutations have been found to affect any of four protein domains conserved in all myotubularins, suggesting that each domain is of functional importance.

Dominant missense mutations in the dynamin 2 gene DNM2 have been identified as one cause of an autosomal form [3]. One patient had a de novo missense mutation in the yanodine receptor gene (RYR1) [4] and the first, apparently rare recessive form has been found to be caused by mutations in the amphiphysin 2 gene (BIN1) [5] MTM1, DNM2 and BIN1 are implicated in the intracellular pathways of membrane and endosome trafficleing and remodelling of T-tubules [5].

### Diagnostic Principles

Any child showing muscle weakness and hypotonia in early life, and in whom a central or metabolic cause is deemed unlikely, requires a muscle biopsy to ascertain the presence or absence of diagnostic features for establishing the diagnosis. An important differential diagnosis is myotonic dystrophy. Confirmation of the diagnosis of the X-linked form is done by mutation detection in the MTM1 gene.

Female carriers of the X-linked form may rarely manifest the disorder, some even in overt form. This may be due to chromosomal rearrangements or skewed X-inactivation. Thus, in all cases, even female ones, analysis of the MTM1 gene is necessary before assuming autosomal inheritance, and all families should be offered genetic counseling. Mothers of affected boys are often found to be carriers, and if they are not, a risk of mosaicism needs to be taken into account.

### Therapeutic Principles

While there is no specific treatment preventing or eliminating the formation of myotube-like fibers and the associated muscle weakness, management and therapy at specialized centers should include regular life-long monitoring of respiratory capacity with vigorous treatment of infections and early ventilatory support where indicated, early surgery for scoliosis where necessary, and regular physiotherapy by a therapist familiar with the treatment of congenital neuromuscular disorders.

## Cerebral Amyloid Angiopathies, Hereditary

Joost Haan
Department of Neurology, Rijnland Hospital Leiden University Medical Centre, Leiden, The Netherlands

### Synonyms

Hereditary cerebral hemorrhage with amyloidosis; CAA; HCHWA; Dutch-type (also Katwijk-disease); Flemish-type; Arctic-type; Iowa-type; Italian-type-I; Italian-type-II; Italian-type-III; Icelandic-type. Severe symptomatic cerebral amyloid angiopathy (CAA) can also be seen in hereditary transthyretin amyloidosis, hereditary prion protein diseases, gelsolin amyloidosis, autosomal dominant Alzheimer's disease (presenilin-1 or -2 mutations), familial British dementia, and familial Danish dementia (heredopathia ophthalmo-oto-encephalica)

## Definition and Characteristics

HCHWA are autosomal dominant cerebral angiopathies leading to hemorrhagic stroke and vascular dementia. There is also an association with Alzheimer type dementia.

## Prevalence

Virtually all HCHWA-types are very rare diseases described in a single family, or in a small number of families.

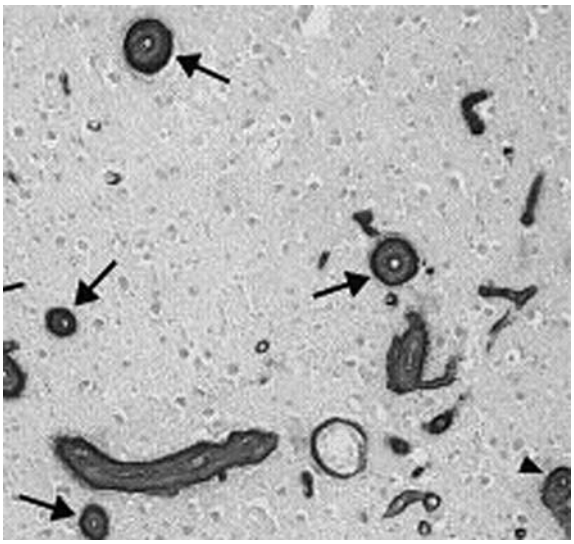
## Genes

All HCHWA-types are caused by a point mutation in the amyloid precursor protein (APP) gene on chromosome 21, except HCHWA-Icelandic [1,2]. HCHWA-Dutch: APP E693Q, HCHWA-Flemish: APP A692G, HCHWA-Arctic: APP E693G, HCHWA-Iowa: APP D694N, Italian-type-I: APP E693K, Italian-type-II: APP L705V, Italian-type-III: APP A713T. HCHWA-Icelandic is caused by a point-mutation (L68Q) in the Cystatin C gene on chromosome 20.

## Molecular and Systemic Pathophysiology

The term amyloid describes protein deposits with circumscript physical characteristics: β-pleated sheet configuration, apple green birefringence under polarized light after Congo red staining, fibrillary structure and high insolubility. There are many different proteins that can accumulate as amyloid, and there are many different disease processes that can lead to amyloid formation [3]. In general, there is a certain tissue affinity, leading to deposition in certain organs or at certain sites. In most CAA types, amyloid deposition occurs solely or predominantly in the cerebral blood vessels, with a preference for small cerebral arteries and arterioles (Fig. 1). In all HCHWA types except the Icelandic type, a mutated APP is abnormally metabolized by proteolytic pathways and accumulates as amyloid. In HCHWA-Icelandic, cystatin C is abnormally deposited. Cystatin C amylodosis is the only type with major systemic amyloid deposition.

Amyloid deposition in cerebral blood vessels can have several clinical consequences [4]. It can remain asymptomatic (approximately 50% of individuals over 80 years of age have asymptomatic cerebral amyloid angiopathy), it can weaken the vessel wall (causing rupture and hemorhage), and it can obliterate the vessel lumen (leading to cerebral infarction, "incomplete" infarction, and leukoencephalopathy). Through these vascular mechanisms, focal neurological deficits, disturbances of consciousness, step wise dementia (mostly of the vascular type), and death can occur. Amyloid angiopathy is also found in many patients with Alzheimer's disease, but its exact role in the pathogenesis of slowly progressive dementia is unknown.



**Cerebral Amyloid Angiopathies, Hereditary.**
**Figure 1** Cerebral amyloid angiopathy.

## Diagnostic Principles

The diagnosis of CAA can only be made with certainty after histologic investigation of affected brain tissue, obtained at autopsy or brain-biopsy [5]. There are several situations in which the presence of CAA can be strongly suspected: the occurrence of multiple lobar cerebral hemorrhages, recurrent lobar cerebral hemorrhages, lobar cerebral hemorrhage(-s) with leukoencephalopathy, dementia and cerebral hemorrhages, or cerebral symptoms in a member of a family with known hereditary CAA. Before making a clinical (non-histological) diagnosis of CAA, other possible causes for the patients' signs and symptoms must be investigated properly. In case of (familial) lobar hemorrhages, one could also think of familial arteriovenous malformations, familial cerebral aneurysms, familial cavernous hemangiomas, hereditary hemorrhagic telangiectasia, von Hippel-Lindau disease, and Moya-Moya disease.

## Therapeutic Principles

There is no known effective stroke prevention in CAA [5]. Although CAA can lead to cerebral ischemia, treatment with acetyl salicylic acid or coumarin is not advisable, as these treatments increase the chance of cerebral hemorrhages. It is not proven, but very likely, that reduction of additional vascular risk-factors, such as hypertension, smoking, hyperhomocystinemia or elevated cholesterol will reduce the risk for a stroke in CAA.

Genetic counseling in hereditary CAA diseases should aim at giving adequate information specific for the type of CAA. DNA diagnosis, possibly even prenatal, should be offered, accompanied by mental support to cope with the DNA test result. An important aspect of most of the

hereditary CAA diseases is that onset of symptoms is late in life. Very often, patients in whom a DNA diagnosis is made do have children already, so this test result will affect their offspring also. Prenatal diagnosis is still a matter of ethical considerations, as patients with a CAA mutation very often lead a completely normal life for 40 or 50 years, before symptoms of CAA occur.

# Cerebral Angiitis

►Vasculitis, Cerebral Forms

# Cerebral Artery Occlusion, Acute

Michael T. Wunderlich
Department of Neurology, Otto-von-Guericke-University Magdeburg, Magdeburg, Germany

## Synonyms

Ischemic stroke; Brain infarction

## Definition and Characteristics

"Stroke" is defined as an acute focal neurological deficit of the central nervous system and is basically differentiated into ischemic (80%) and hemorrhagic (20%) stroke. Acute ischemic stroke is caused by acute cerebral arterial occlusion and results in brain infarction with neurological deficits, depending on the location of the lesions.

## Prevalence

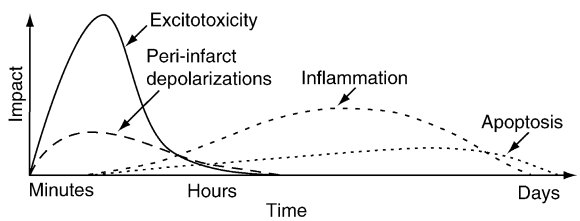
The worldwide incidence of ischemic stroke is 150 to 350/100,000 citizens per year. Stroke is the third common cause of death and most frequent reason of disability. Ischemia causes 80% of all strokes.

## Molecular and Systemic Pathophysiology

Acute cerebral artery occlusion by an embolus or by local thrombosis is the most common but an etiopathophysiological heterogeneous cause of stroke. Generally, etiology is differentiated into large vessel occlusion of the extra- and intracranial brain supplying arteries (40%), small vessel diseases (20%), cardioembolism (20%) most frequently due to atrial fibrillation and other causes, such as for example coagulopathies and vasculitis (20%). Large vessel diseases and cardioembolism typically lead to territorial infarctions and small vessel diseases to lacunar infarcts (Fig. 1).

The current pathophysiological understanding of ischemic stroke is based mainly on experimental studies in animal models. Hemodynamic and metabolic changes vary in ischemic areas and evolve from a complex series of pathophysiological pathways. Surrounding an ischemic core in the center of the perfusion deficit with severe and rapid tissue injury and cell death through early exitotoxicity, is the penumbra, a heterogeneous area with delayed mechanisms of damage. Neurons within the penumbra are functionally impaired but not irreversibly damaged. Without reperfusion, the cells in the penumbra die, and the area of irreversibly damaged brain increases. The penumbra is the target for reperfusion and neuroprotective therapy, and the underlying interactions of pathophysiological processes such as exitotoxicity, peri-infarct depolarization, inflammation and apoptosis are current concepts of ischemic brain damage [1,2].

After optimistic results of exogenous neuroprotective therapeutics in the animal model, various clinical trials have been conducted but none has proved successful. Although trial design may be one factor in these failures, this led to an increase of research for endogenous neuroprotective pathways inducing ischemic tolerance



**Cerebral Artery Occlusion, Acute. Figure 1** Putative cascade of damaging events in focal cerebral ischemia [1].

**Cerebral Artery Occlusion, Acute.**
**Figure 2** Computed tomography scan of a territorial infarction of the right middle cerebral artery.

through ischemic preconditioning. Potential mechanisms could be a cellular defense function by post-translational modification of proteins, expression of new proteins or a cellular stress response and synthesis of stress proteins, which could result in increased conservation of cell functions [3]. But again, clinical trials, investigating the potential protection from second after a prior ischemic stroke, led to heterogeneous results.

## Diagnostic Principles

After the clinical diagnosis of acute stroke, further clarification and differentiation between ischemic and hemorrhagic stroke through neuroradiological diagnostics (computed tomography (CCT)) or magnet resonance imaging (MRI) is mandatory (Fig. 2).

Additional information about the neurovascular status and pathophysiological classification between ischemic core and penumbra can be gathered by means of modern neuroradiologic methods (CT-perfusion, CT-angiography or MR-angiography and MR-diffusion/perfusion imaging) [4].

*Further diagnostic assessment*: Neurosonology of the arteries supplying the brain, electrocardiogram, ultrasound cardiography, and in certain cases, investigations for coagulopathies and vasculitis.

## Therapeutic Principles

At present, intravenous thrombolysis (within 3 h after stroke onset) and intra-arterial thrombolysis (within 6 h after stroke onset) are the only causal and proven therapeutic strategies in acute cerebral arterial occlusion [5]. The major goal of thrombolysis is the rapid recanalization of occluded vessels with consecutive reperfusion of ischemic brain. After this short therapeutic window, all further therapies serve the prevention or early identification of complications and secondary strokes.

Cerebral cavernoma; Cerebral cavernous angioma; CCM

## Definition and Characteristics

Cerebral cavernous malformation (CCM) is a vascular malformation that consists of clustered enlarged capillary-like channels usually located in the brain and more rarely in the spinal cord, retina and sometimes skin. It may cause neurological symptoms, headache, seizures, focal neurological deficits and cerebral hemorrhage, generally between the third and the fifth decade. Sporadic and hereditary autosomal dominant forms have been described, with variable expression and incomplete penetrance. Whereas sporadic forms are usually characterized by a solitary lesion, in familial forms multiple lesions are frequently present. The familial disease evolves with age; new lesions can appear and their size can increase due to successive hemorrhages (reviewed in [1]).

## Prevalence

Based on large magnetic resonance imaging and autopsy studies the CCM prevalence has been estimated to be 1:200–1:1.000. Familial cases represent about 50% in Hispanic American patients and 10–20% in other populations.

## Genes

Mutations in three genes are associated with familial CCM. In 1999, KRIT1 (Krev interaction trapped 1, 7q21.2) was identified as the CCM1 gene [2]. Mutations in this gene are found in approximately 40% of familial CCM cases. KRIT1 encodes a protein of 736 amino acids, containing an NPxY motif and several protein-protein interaction domains, four ankyrin repeats and a FERM domain. About 100 distinct disease-causing mutations have been identified so far. Apart from a founder mutation (c.1363C>T; p.Q455X) in Hispanic Americans, no other common mutation has been found in populations of other origins. In a large French study, the clinical penetrance of KRIT1-mediated CCM was 62% and the mean age at first symptom was 29.7 years.

In 2003, MGC4607 (7p13) was identified as the CCM2 gene [3]. Mutations in this gene are found in 13–20% of familial CCM cases. About 18 different mutations have been identified. It encodes a protein, malcavernin, of 444 amino acids, containing a phosphotyrosine-binding (PTB) domain similar to ICAP1α (integrin cytoplasmic domain-associated protein-1 alpha), a KRIT1 binding partner.

Finally, in 2004 PDCD10 (programmed cell death 10, 3q26.1) was identified as the CCM3 gene [4]. About 16 different mutations have been identified in this gene. It encodes a protein of 212 amino acids and it does not contain any known domains. Based on linkage studies performed in 20 families, mutations in CCM3 gene were expected in 40% of patients; however, mutations in PDCD10 are found only in a minority of CCM families.

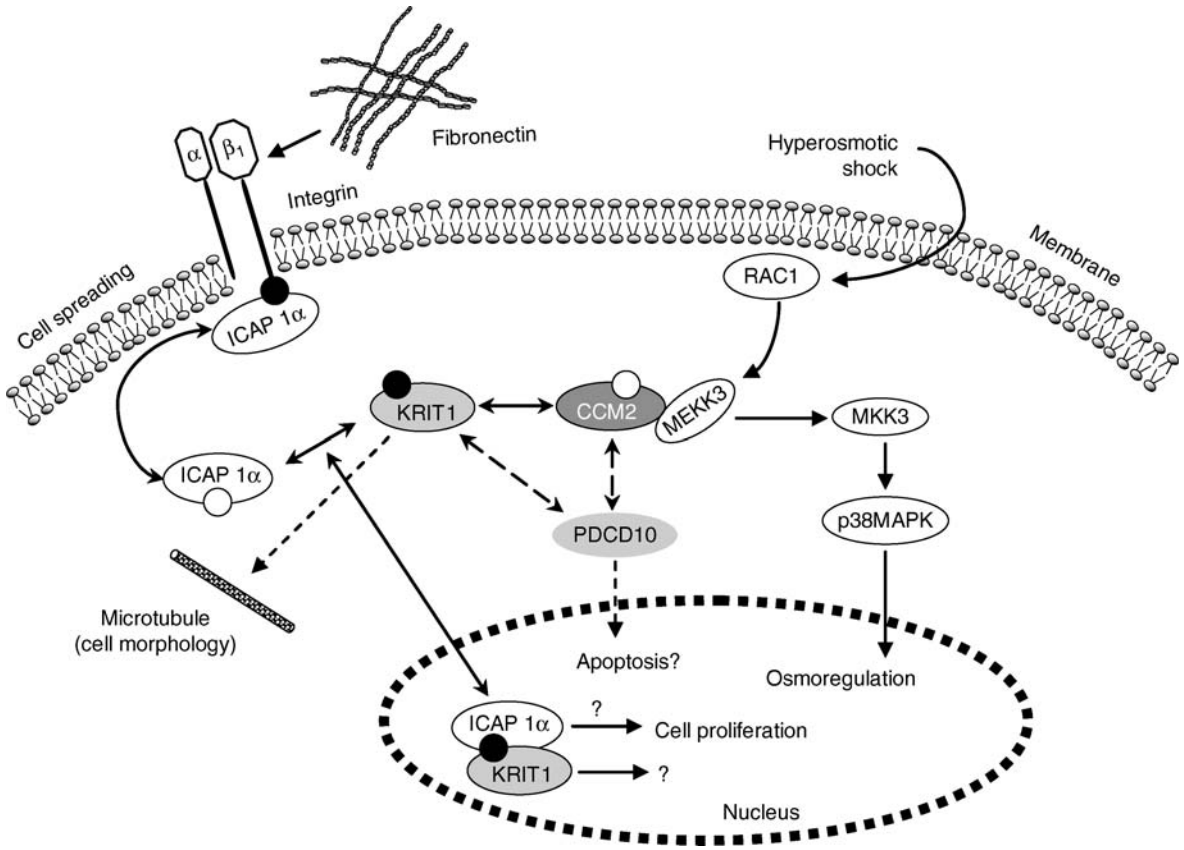
When these three genes are screened the mutation detection rate is >90% for familial cases and 60% for sporadic cases with multiple lesions [5]. Large deletions and the sensitivity of the techniques used could explain this. Moreover, the existence of a fourth locus has been suggested on 3q26.3–q27.2, near the PDCD10 gene. No mutations in the three CCM genes have been found in sporadic cases with a solitary lesion.

## Molecular and Systemic Pathophysiology

The molecular mechanisms that trigger CCM formation have not been completely dissected. While the familial forms are genetic in origin, the etiology of the sporadic forms is still unknown. In familial CCM, the vast majority of mutations identified so far cause a premature stop codon, suggesting loss-of-function as a major mechanism. It is not clear if haploinsufficiency is enough, or if a complete local loss-of-function is needed for the formation of a lesion. The latter was proved once for KRIT1, and could explain the number of lesions and their localized nature. Another possible mechanism could be trans-heterozygosity, a germ line mutation in one CCM gene plus a somatic mutation in another CCM gene.

Patients with familial CCM have similar neurological symptoms, no matter which gene is altered, suggesting that the CCM proteins may function in the same or overlapping pathways. Indeed, as indicated by their structure, in vitro and cellular studies showed that malcavernin and KRIT1 interact (Fig. 1). Moreover, the only CCM2 missense mutation (L198R) reported so far was able to inhibit this interaction, suggesting that its loss can contribute to CCM pathogenesis [5].

ICAP1α interacts with the β1integrin via the PTB domain/NPxY motif and controls cell spreading on fibronectin. KRIT1, which also interacts with ICAP1α via NPxY/PTB, is thought to play the role of modulator. This suggests that integrin signaling could play a



**Cerebral Cavernous Malformation. Figure 1** Schematic representation of molecular pathways involving the CCM proteins. ● NPxYmotif ○ Phosphotyrosine-binding (PTB) domain, dashed line – hypothetical interactions. (Modified from [1]).

role in CCM pathogenesis. ICAP1α and KRIT1 shuttle from the cytoplasm to the nucleus where ICAP1α has the capacity to sequester KRIT1. Their role in the nucleus is unknown. KRIT1, ICAP1α and malcavernin can form a ternary complex. The co-localization of KRIT1 with microtubules is controversial. The murine ortholog of malcavernin was shown to modulate the Mekk3-dependent p38Mapk activation induced by hyperosmotic shock. KRIT1 was identified in a ternary complex with malcavernin and MEKK3, suggesting a possible function of the CCM1/2 complex in p38MAPK activation. PDCD10 was involved in apoptosis in the human myeloid cell line TF-1. It is hypothesized that PDCD10 functions in a common pathway with KRIT1 and/or malcavernin.

In situ hybridization studies performed on the central nervous system in embryonic and adult mice have shown overlapping mRNA expression patterns for the three CCM genes in astrocytes and neurons. Moreover, Ccm2 and Ccm3 mRNA expression was transiently present postnatally in meningeal and parenchymal vessels. As vascular and neuronal development are closely linked, CCM lesions could be due to a defect in cross-talk between these two structures.

## Diagnostic Principles

CCM lesions are easily detected by magnetic resonance imaging, especially by the most sensitive gradient-echo sequences. The size of the lesions varies from a few millimeters to several centimeters. Molecular testing should be undertaken in familial cases and sporadic cases with multiple lesions. Molecular testing is probably not profitable in patients with one lesion and without a family history.

## Therapeutic Principles

Asymptomatic lesions are usually not treated. When treatment is necessary, the two approaches are anticonvulsant therapy and/or surgical removal of the symptomatic lesion. The decision is based on the number of lesions and their localization, symptoms and response to medical treatment.

## Definition and Characteristics

Autosomal recessive disorder of bile acid biosynthesis leading to lipid storage in the brain and tendon.

## Prevalence

Rare disease reported about 300 patients throughout the world.

## Genes

CYP27A1 coding for sterol 27-hydroxylase, localized on chromosome 2q35.

## Molecular and Systemic Pathophysiology

CYP27A1 consists of 498 amino acids and is a member of the mitochondrial cytochrome P450 family. At least 40 different mutations of the CYP27A1 gene have been identified in cerebrotendinous xanthomatosis (CTX) patients [1]. The enzyme hydroxylates a variety of sterol substrates at the C-27 position. It is an essential reaction for the hepatic biosynthesis of a primary bile acid, chenodeoxycholic acid (CDCA) (Fig. 1).

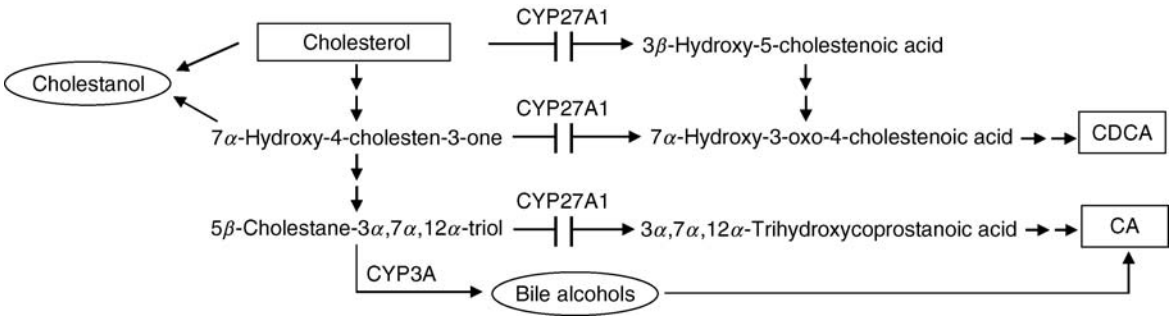
Another primary bile acid, cholic acid (CA), is synthesized not only by the CYP27A1 pathway but also alternatively by the CYP3A side chain hydroxylation pathway via bile alcohols as intermediates [2]. Thus, a markedly reduced CDCA pool with increased production of bile alcohols is a major biochemical abnormality. CDCA is the most powerful physiological ligand for the farnesoid X receptor (FXR), but FXR is not deactivated in CTX because bile alcohols activate FXR. On the other hand, reduced CDCA stimulates the bile acid biosynthetic pathway by inducing another nuclear receptor HNF4α, so that bile alcohol production is not inhibited in spite of the activation of FXR [3]. Another important finding in CTX patients is increased concentrations of plasma and tissue cholestanol, a 5α-dihydro derivative of cholesterol, with particularly large deposits in tendon and brain xanthomas. In the CTX liver, there is an overproduction of cholestanol as a consequence of the increased concentrations of cholesterol and bile acid intermediates due to CYP27A1 deficiency (Fig. 1). The mechanisms of the selective accumulation of cholestanol in tendons and brain have yet to be clarified. Since cholestanol is a substrate for CYP27A1 and this enzyme exists in macrophages from normal tendons, decreased efflux because of the lack of the 27-hydroxylation may explain the accumulation in tendons [4].

## Diagnostic Principles

Tendon and brain xanthomas, juvenile cataracts, premature atherosclerosis, mental retardation, dementia and cerebellar ataxia are classic symptoms, but the clinical diagnosis may be difficult early in life. The biochemical abnormalities including increased plasma and tissue cholestanol concentrations, a low ratio of CDCA to CA in the bile, and abundant amounts of bile alcohol glucuronides in bile, plasma and urine are expressed early and serve to confirm the diagnosis.

## Therapeutic Principles

Replacement therapy with CDCA suppresses cholestanol production as well as abnormal bile alcohol synthesis. The therapy improves the clinical presentations in CTX and prevents the progression of the disease.



**Cerebrotendinous Xanthomatosis. Figure 1** Bile acid biosynthesis from cholesterol in CTX. Reactions catalyzed by CYP27A1 are indicated by the interrupted lines.

# CHARGE Syndrome

Seema R. Lalani, John W. Belmont
Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA

## Synonyms

CHARGE association; Hall-Hittner syndrome

## Definition and Characteristics

CHARGE syndrome is a well-established multiple-malformation syndrome, characterized by the presence of ocular coloboma, choanal atresia, cranial nerve defects, distinctive external and inner ear abnormalities, hearing loss, cardiovascular malformations, urogenital anomalies, and postnatal growth retardation. Inner ear defect, including semicircular canal hypoplasia with or without Mondini malformation, is a distinct feature of this syndrome. Most individuals diagnosed with CHARGE syndrome have unaffected parents, although a few familial cases with autosomal dominant mode of inheritance have been described. About 65% of the individuals with CHARGE syndrome have de novo mutations in the CHD7 gene. Based on the recurrence of this condition in rare families with unaffected parents, germline mosaicism has been suggested. There is no clear correlation between the severity of the clinical findings and the type of mutation [1]. Variable expression has been observed in familial cases. Penetrance in those with CHD7 mutations is 100%.

## Prevalence

The prevalence of the syndrome is reported to be 1 in 8,500–10,000 individuals.

## Genes

About 2/3 of individuals with CHARGE syndrome have mutations in the CHD7 gene, which codes for a chromodomain helicase DNA binding protein, localized on chromosome 8q12 [2]. Rare patients have deletions in the region of 8q12 that includes the CHD7 gene. Some individuals with CHARGE or CHARGE-like phenotypes have also been described with other chromosomal abnormalities.

## Molecular and Systemic Pathophysiology

Chromatin remodeling is an important mechanism for regulation of gene expression. CHD proteins play an important role in regulating early embryonic development by affecting chromatin structure and gene expression. The CHD7 gene consists of 38 exons and has a genomic size of 188 kb. The gene encodes a 2,997-residue protein, with two N-terminal chromodomains, SNF2-like ATPase/helicase domain, and a DNA-binding domain. Pathogenic mutations are identified throughout the gene, most of which are truncating. The most likely genetic mechanism of the disease is haploinsufficiency.

## Diagnostic Principles

Although over 60% of individuals with CHARGE syndrome demonstrate mutations in CHD7, the diagnosis remains primarily clinical, based on a combination of distinctive major and minor characteristics [3]. Individuals who either have four major characteristics (coloboma, choanal atresia, characteristic ear abnormalities including inner ear anomalies, and cranial nerve dysfunction), or three major and three minor characteristics (genital hypoplasia, developmental delay, cardiovascular malformation, growth deficiency, orofacial cleft, tracheoesopageal fistula, and characteristic face) clearly have CHARGE syndrome. Individuals with one or two major criteria and several minor criteria possibly have the syndrome. Diagnostic evaluation of these individuals should include CT scan of temporal bones, ophthalmology exam, echocardiogram, swallowing study, assessment of choanae and palate, audiologic exam, evaluation for the presence of tracheoesophageal fistula, renal ultrasound and chromosomes.

## Therapeutic Principles

Management of children with CHARGE syndrome requires coordinated multidisciplinary care. Prompt evaluation and treatment of heart defects, choanal atresia, and tracheoesophageal fistula is important to reduce mortality and morbidity associated with this condition. Early evaluation of vision and hearing loss with timely intervention is critical. Diligent sequential monitoring of eyes, provide early detection of retinal detachment and appropriate surgical repair where necessary. For eyes with visual potential, spectacle correction may be necessary. Hearing aids and hearing habilitation, including sign language should be initiated as soon as hearing loss is documented. Cochlear implants have been successful in providing speech recognition in some of these individuals. Treatment of feeding dysfunction, often caused by cranial nerve

abnormalities requires a multidisciplinary approach, including speech-language pathologists, occupational therapists, and nutritionists. Early referral to endocrinology service is often needed for growth retardation and for the evaluation of genital abnormalities.

# CHED

►Corneal Hereditary Endothelial Dystrophy

# Chediak-Higashi Syndrome

Julian Ilcheff Borissoff, Hugo Ten Cate
Laboratory for Clinical Thrombosis and Hemostasis, Department of Internal Medicine, University of Maastricht, Maastricht, The Netherlands

## Synonyms

CHS; Beguez-Cesar disease; Chediak-Steinbrinck-Higashi syndrome; Neutropenia and hyperlymphocytosis with large granular lymphocytes

## Definition and Characteristics

Chediak-Higashi syndrome (CHS) is a rare autosomal recessive genetic disorder [1,2] whose clinical and hematological findings were described by Chediak and Higashi. On the other hand, the disorder was first described by Beguez-Cesar [3]. Characteristic features include decreased pigmentation of skin, hair, and eyes, large eosinophilic, peroxidase – positive inclusion bodies in circulating granulocytes and other cell types, neutropenia, and increased susceptibility to infection [2,3]. Other findings are platelet dysfunction with normal microtubules but absent or rare dense bodies, defective granulocyte chemotaxis, abnormal natural killer (NK) cell function, and defective structure or function of melanosomes in melanocytes. A lymphoproliferative histiocytosis (accelerated phase) often leads to death within the first decade. In survivors a peripheral neuropathy strikes in the second or third decade [3].

## Prevalance

Rare.

## Genes

The gene mutated in CHS was identified in 1996 after two groups isolated the murine gene for beige, a model of human CHS. The human gene, CHS1, was originally called LYST for Lysosomal Trafficking Regulator. It resides on chromosome 1q42.1–42.2, has 87.9% amino acid identity with the mouse gene, Lyst and consists of 53 exons (51 coding) with an open reading frame of 11,406 bp [3].

## Molecular and Systemic Pathophysiology

The coagulopathy of CHS results from defective platelets rather than a reduced platelet count, although thrombocytopenia may be present during the accelerated phase. CHS patients most commonly manifest easy bruisability, mucosal bleeding, epistaxis, and petechiae. The bleeding diathesis is usually mild to moderate, but can become severe during the accelerated phase. Studies of the coagulation cascade are normal, but bleeding times may be normal or prolonged [1]. Beginning during infancy, children with CHS suffer from recurrent infections, most commonly involving the skin and respiratory systems. Typical complications include periorbital cellulitis, otitis media, pneumonia, pyoderma, abscesses, sinus infections, and dental caries. Staphylococcus aureus and b-hemolytic Streptococcus are the predominant organisms, but gram negative organisms, Candida, and Aspergillus are also important pathogens. The infections respond to antibiotics, but more slowly than expected. In CHS, immunoglobulins and antibody production are normal, as is delayed hypersensitivity and reticuloendothelial clearance [1].

## Diagnostic Principles

Currently, the only laboratory test diagnostic for CHS is examination of granular cell morphology [1]. The morphologic abnormality of enlarged lysosomes is one of the diagnostic feature of CHS [4]. Molecular diagnosis of CHS remains difficult and is not commercially available [1].

## Therapeutic Principles

Most of the therapy available in CHS is symptomatic. Aspirin containing products should be avoided. Corticosteroids, chemotherapeutics, intravenous immunoglobulin and splenectomy have all been tried for management of the accelerated phase and may

## Synonyms

Cheyne-Stokes breathing; CSB; Cheyne-Stokes respiration with central sleep apnea; CSR-CSA; Central sleep apnea; CSA; CSR

## Definition and Characteristics

Cheyne-Stokes respiration (CSR) is characterized by a crescendo-decrescendo pattern of hyperventilation alternating with apnea or hypopnea that occurs at the nadir of the crescendo-decrescendo pattern during sleep (especially during shallow sleep, such as sleep stage 1

or 2) and sometimes when the patient is awake. Arousals from sleep are usually observed at the peak of hyperventilation rather than at the termination of apnea, when obstructive sleep apnea events occur (Fig. 1a).

## Prevalence

The reported prevalence rates of CSR in patients with heart failure (HF) vary (generally 30–80%), due to differences in sample size, patient selection, HF status, and the criteria and cut-off points used to diagnose CSR. There are no specific data about the prevalence of CSR in other diseases, except for one report which showed that 19% of stroke patients have CSR [1].

## Molecular and Systemic Pathophysiology

A variety of factors affect the development of CSR, including: increased ventilatory drive, which results in hyperventilation and lower sleeping eucapnic $PaCO_2$ that is close to the apnea threshold; increased chemosensitivity (especially an increased ventilatory response to $CO_2$); prolonged circulation time, which is associated with impaired cardiac function and results in delayed transport of oxygenated blood to the brain and possibly to the chemoreceptors of the carotid body; arousal from sleep; and attenuated cerebrovascular responsiveness to $CO_2$ (Fig. 1b). CSR adversely induces intermittent hypoxemia, sympathetic overactivity, and hemodynamic change; these affect primary disease progression and increase mortality.

## Diagnostic Principles

The diagnosis of CSR is based on the presence of the following criteria:

1. Presence of HF and neurological disease.
2. Polysomnography demonstrates:
   - At least three consecutive cycles of a cyclical crescendo-decrescendo change in the breathing amplitude. The cycle length is most commonly in the range of 60 s, although it may vary.
   - One or both of the following:
     - Five or more central sleep apneas or hypopneas per hour of sleep (a central apnea or hypopnea event is defined as the cessation or reduction of respiratory efforts with the cessation or reduction of air flow and esophageal pressure, which lasts at least 10 s).
     - A cyclic crescendo-decrescendo change in breathing amplitude that has a duration of at least ten consecutive minutes.

## Therapeutic Principles

It has been suggested that HF patients with CSR who have more than 20 events per hour of sleep should be considered for treatment of their abnormal breathing pattern [2]. On the other hand, the indications for treatment of CSR in patients with neurological disease have not yet been clarified. The treatment options include: intensive pharmacological and non-pharmacological treatment for HF, respiratory stimulants, respiratory depressants, oxygen, and several positive airway pressure (PAP) devices.

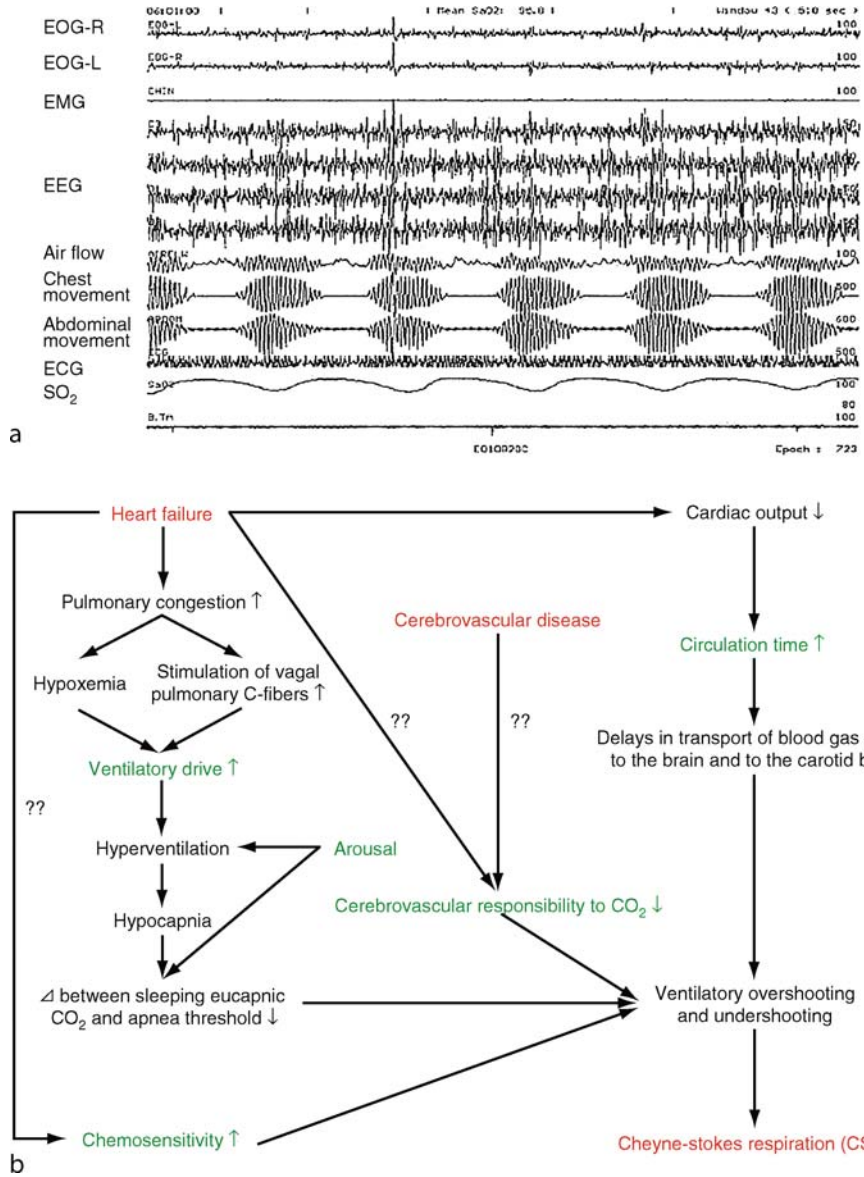
It has been reported that intensive treatments for HF, including drugs (captopril, carvedilol), cardiac valve surgery, and cardiac transplantation, reduce the severity of CSR and, of course, that of HF per se. While some previous reports showed that pacemaker implantation was beneficial for CSR, more recent studies do not support its effectiveness.

Respiratory stimulants, including theophylline, carbon dioxide, and acetazolamide, have been reported to improve the abnormal breathing pattern of CSR. However, no studies have determined whether these drugs improve patients' underlying HF. Theophylline is well known to have an arrhythmogenic effect; thus, theophylline may adversely affect the outcome of CSR patients, especially those with HF. Carbon dioxide inhalation is not feasible for clinical use. On the other hand, acetazolamide has recently been shown to reduce CSR and subjective sleepiness in HF patients. However, the efficacy of acetazolamide for HF per se and the long-term outcome are unknown.

Respiratory depressants, such as benzodiazepines, do not reduce the number of apneic events, although they do reduce the number of arousals.

Oxygen inhalation therapy during sleep has been shown to be beneficial for suppressing CSR by reducing peripheral chemosensitivity, which results in an increased $PaCO_2$ level that is above the apnea threshold. Additionally, oxygen therapy improves exercise tolerance among HF patients. However, no improvement in the other cardiac function parameters has been noted. Long-term follow-up studies are needed to confirm the efficacy of oxygen inhalation therapy in HF patients.

Several types of PAP therapy have been shown to be effective for both suppressing CSR and improving cardiac function. In particular, there are several studies that have shown the effectiveness of continuous positive airway pressure (CPAP). However, a recent large-scale, randomized, controlled study, the Canadian continuous positive airway pressure for patients with central sleep apnea and heart failure (CANPAP) showed that CPAP did not reduce long-term mortality [3]. However, another study reported that CPAP did not sufficiently suppress CSR in some patients, and that such patients were likely to have more arrhythmias. Indeed, in the CANPAP trial, the abnormal breathing patterns of several patients were not sufficiently treated with CPAP, and this could have led to the unexpected results. Nevertheless, other PAP modalities are being considered for the treatment of the abnormal breathing



**Cheyne-Stokes Respiration. Figure 1** Representative polysomnographic findings and pathophysiological mechanism of Cheyne-Stokes respiration. *Panel* (a): Representative polysomnographic findings of Cheyne-Stokes respiration. Typical Cheyne-Stokes respiration (CSR) on polysomnography; note the five central apnea episodes associated with desaturation (modified from Ref. [4]). EOG, electro-oculogram; EMG, submental electromyogram; EEG, electroencephalogram; Air flow, nasal air flow; ECG, electrocardiogram; $SO_2$, arterial oxygen saturation. *Panel* (b): Pathophysiological mechanism of Cheyne-Stokes respiration. Various factors affect the development of Cheyne-Stokes respiration (CSR). Heart failure (HF) and/or cerebrovascular disease are possible primary disorders that promote CSR. Reduced ventilatory drive and prolonged circulation time, which are associated with HF, are the key factors that promote and sustain CSR. Arousals from sleep induce hyperventilation and modification of the apnea threshold, which minimizes the differences between the apnea threshold and sleeping eucapnic $PaCO_2$. Increased chemosensitivity, which may be associated with HF, induces ventilatory overshooting and undershooting. Attenuated cerebrovascular responsiveness to $CO_2$, which might be associated with HF and/or cerebrovascular diseases, also induces ventilatory overshooting and undershooting.

pattern of CSR. Thus, bi-level PAP and a more advanced form of bi-level PAP, adaptive-servo ventilation (ASV), are being used clinically; there are several reports that suggest that these PAP modalities have a beneficial effect not only for CSR but also for the underlying HF [4,5]. A prospective study to determine the long-term outcomes using these devices is now warranted.

## Chloride Diarrhea, Congenital

Daniel Markovich
School of Biomedical Sciences, University of Queensland, Brisbane, QLD, Australia

### Synonyms

Familial chloride diarrhea; Congenital chloridorrhea; Congenital secretory chloride type diarrhea; CLD

### Definition and Characteristics

Rare autosomal recessive gastrointestinal transport defect leading to hyponatremia, hypokalemia, hypochloremia and metabolic alkalosis.

### Prevalence

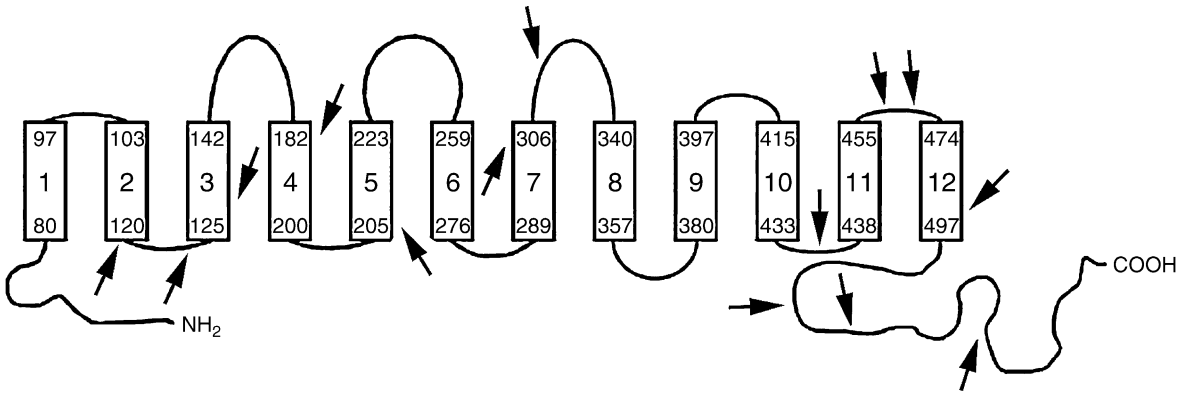
The prevalence of CLD is reported for Polish, Finish and Arab populations, the latter having highest incidence of 1 in 3,200 live births.

### Genes

SLC26A3 or DRA (downregulated in adenomas) encodes an anion transporter localized on chromosome 7q31 [1].

### Molecular and Systemic Pathophysiology

DRA encodes an 84.5 kD plasma membrane transport protein with 12 transmembrane spanning domains [2]. Figure 1 shows the described sites of mutations [2,3] associated with congenital chloride diarrhea (CLD). DRA functions as a sodium-independent anion transporter, which exchanges a variety of anions including chloride, bicarbonate, sulfate and oxalate [4]. It is mainly expressed on the apical brush border membrane of intestinal epithelium (mainly ileum and colon), but has also been found in eccrine sweat glands and seminal



**Chloride Diarrhea, Congenital. Figure 1** The sites (see *arrows*) of mutations found associated with congenital chloride diarrhea.

vesicles. The main clinical feature of CLD is prenatal onset of watery diarrhea that in utero leads to polyhydramnios caused by intrauterine diarrhea [5]. Children with CLD are often born premature. CLD can be detected in children from a few weeks of age having voluminous watery stools containing an excess of chloride (>90 mmol). All children born have abdominal distention and chronic diarrhea, which remains life long. Serum electrolytes in CLD patients before treatment reveals hyponatremia, hypokalemia, hypochloremia, and metabolic alkalosis. Diagnosis is generally confirmed by a stool chloride content that exceeds the sum of fecal sodium and potassium. In addition, juxtaglomerular hyperplasia, hyperreninemia and hyperaldosteronism, leading to hyperkaluria and hypokalemia, has been reported in CLD patients.

## Diagnostic Principles

The coincidence of hyponatremia, hypokalemia, hypochloremia, and metabolic alkalosis points to the disease. Plasma renin levels are high. Family history may reveal genetic origin. Detection of mutations in the DRA gene confirm the diagnosis of this rare disease.

## Therapeutic Principles

Potassium chloride is the main therapy. Electrolyte repletion (most importantly potassium and chloride) serves to normalize plasma electrolytes and acid base balance. Inhibitors of prostaglandin synthetase have been shown to have beneficial effects.

# Cholangitis

Michael Trauner
Division of Gastroenterology and Hepatology, Medical University of Graz, Graz, Austria

## Synonyms

Bacterial cholangitis

## Definition and Characteristics

Cholangitis is a bacterial infection of the biliary tree as a result of a biliary obstruction [1,2]. According to its etiology, cholangitis may present with different degrees of severity. Ascending cholangitis is the most frequent manifestation and is caused by partial biliary obstruction. Suppurative cholangitis is associated with (near) total biliary obstruction resulting in elevated intrabiliary pressure and accumulation of pus within ducts. The most severe manifestation is toxic/septic cholangitis with systemic features such as arterial hypotension and mental confusion/lethargy. Recurrent pyogenic cholangitis or oriental cholangiohepatitis refers to a variant usually seen in South East Asia populations

and is characterized by recurrent bacterial infections of the biliary tree in association with biliary strictures and stones. Patients with acquired immunodeficiency syndrome (AIDS) may develop biliary tract abnormalities including papillary stenosis and intra-/extrahepatic strictures (AIDS cholangitis).

## Prevalence

No detailed epidemiologic data are available. Patients with recurrent pyogenic cholangitis are much younger (30–40 years) than those in Western countries with cholangitis (70 years).

## Genes

No genetic factors identified so far; mRNA and protein levels of the canalicular phosphatidyl choline (PC) flippase (MDR3/ABCB4), as well as immunohistochemical staining of MDR3, are reduced in liver specimens from patients with oriental cholangiohepatitis compared with gallbladder stone patients and patients with obstructive cholestasis (of other origin) [3]. Biliary PC concentrations are also markedly reduced in hepatic bile from both affected and unaffected hepatic segments. These findings suggest that biliary cholesterol supersaturation and the formation of cholesterol-rich intrahepatic brown pigment stones may be attributed to decreased biliary excretion of PC. However, decreased MDR3 expression is not due to the mutations in the coding region of the MDR3 gene.

## Molecular and Systemic Pathophysiology

Acute cholangitis arises when bacterial infection develops in an obstructed biliary tree [1,2]. Causes include stones (80–90%), malignant tumors, iatrogenic strictures, juxtpapillary diverticula, biliary instrumentation, congenital anomalies, parasites (Ascaris lumbricoides, Clonorchis sinensis, Fasciola hepatica, Echinococcus granulosus and multilocularis), chronic pancreatitis, and sclerosing cholangitis [1,2,4]. Recurrent bouts of cholangitis may complicate biliary reconstruction such as sphincteroplasty, choledochoduodenostomy, choledochojejunostomy, and hepaticojejunostomy as a result of narrowing of the biliary-enteric anastomosis. Bacterial infection of stagnant bile may result from translocation of bacteria form the gastrointestinal tract into portal blood as a consequence of absence of bile acids in the gut lumen in biliary obstruction. Alternatively, bacteria may ascend from the duodenum via a transpapillary route. Raised biliary pressure in the presence of complete biliary obstruction results in reflux of bacteria into the hepatic venous and lymphatic systems with subsequent systemic/septic complications in toxic/septic cholangitis. The bacterial spectrum includes Gram-negative bacteria (Escherichia coli, Klebsiella spp., Enterobacter spp., Pseudomonas spp., Citrobacter spp., Proteus spp., Serratia spp.) and Gram-positive bacteria (Enterococcus, Streptococcus spp., anerobier (Bacteroides spp., Clostridium spp.) [1,2,4]. Recurrent pyogenic chlangitis is related to repeated biliary tract infection of small biliary radicals by enteric organisms. Infestations with flukes and worms as well as malnutrition may reduce the resistance to infection. Repeated bacterial infections results in deconjugation of bilirubin and precipitation with free calcium and formation of intraductal stones. This results in a vicious cycle with formation of biliary strictures, biliary sludge and stones which further act as a nidus for recurrent infection. AIDS-related cholangitis is related to infections with opportunistic organisms including cryptosporidium, cytomegalovirus, microsporidiia and Enterocytozoon bieneusi.

## Diagnostic Principles

The typical clinical presentation is Charcot's triad with fever, right upper quadrant pain and jaundice. In addition, arterial hypotension and mental confusion/lethargy (Reynold's pentad) may be present in severe toxic/septic cholangitis [2,4]. Firstline investigations should include a full blood count (leukocytosis), routine liver biochemical tests (elevated alkaline phosphatase, bilirubin), blood cultures (identification of causative bacteria) and abdominal ultrasound (dilated bile ducts). Computed tomography, magnetic resonance cholangiography and endoscopic retrograde or percutaneous cholangiography give additional information about the site and cause of biliary obstruction. In addition, cholangiography permitts direct aspiration of bile for cultures and biliary decompression.

## Therapeutic Principles

Therapy consists of general measures (substitution of fluid and electrolytes, analgesics), antibiotic therapy and biliary drainage [1,2,5].

Ascending cholangitis may be treated with oral broad spectrum antibiotics (chinolones, cotrimoxazol, cephalosporines or amoxycillin) [1,5]. Sever suppurative cholangitis should be treated intravenously with chinolones (e.g. ciprofloxacin, levofoxacin), mezlocillin or piperacillin (optionally in combination with β-lactamase inhibitors), or third-generation cephalosporines (e.g., ceftriaxone) [1,5]. In severe cases metronidazole or aminoglycosides may be added. Carbapenems (imipenem/cilastatin, meropenem) should be considered as initial antibiotic therapy in toxic/septic cholangitis (eventually in combination with quinolones). Patients with oriental cholangiohepatitis may benefit from long term prophylactic treatment with ursodeoxycholic acid, although so far no controlled trials have been performed to test this hypothesis.

Biliary decompression is the only causal therapy of acute suppurative cholangitis and can be achieved endoscopically, percutaneously or surgically [1,2]. Whenever possible endoscopic decompression (endoscopic sphincterotomy, stent implantation, nasobiliary catheter drainage) should be attempted as first-line procedure, since this approach gives the best results with the lowest mortality. In most cases (80%) transient stabilization of the patient with suppurative cholangitis through general measures and antibiotic therapy permits a semielective approach to biliary decompression. Lack of response to antibiotics or presence/development of toxic/septic cholangitis mandates immediate ("emergency") biliary decompression. Surgical biliary resconstruction should be considered for cases of recurrent ascending cholangitis which complicate biliary surgery (sphincteroplasty, choledochojejunostomy and hepaticojejunostomy). Surgical drainage is the mainstay of therapy of recurrent pyogenic cholangitis. More recently, percutaneous transhepatic cholangioscopy has been used to clear the biliary tract from stones and dilate/stent strictures in recurrent pyogenic cholangitis.

## Synonyms

Chronic non suppurative cholangitis; Primary biliary cirrhosis; PBC

## Definition and Characteristics

Primary biliary cirrhosis (PBC) is a chronic inflammatory cholestatic liver disease of unknown etiology where autoimmunity seems to be the most solid pathogenic mechanism [1]. The disease is most commonly asymptomatic at diagnosis; when symptoms are present, these include pruritus and fatigue. When the disease has progressed to liver cirrhosis, this is accompanied by the same symptoms and signs as advanced liver diseases of any etiology. Long standing cholestasis further leads to metabolic bone loss and hypercholesterolemia. Comorbidities with other autoimmune diseases, particularly Sjogren's syndrome and scleroderma, is found in a third of patients.

## Prevalence

Current data suggest that PBC follows a geoepidemiological pattern being most frequent in England, Scandinavia and in specific areas of the United States were prevalence rates have been reported to be as high as 402/million. Similar to most autoimmune diseases, PBC manifests a striking female predominance with women outnumbering men by 9:1. PBC is also more frequent in relatives of affected individuals with 1–6% of PBC cases presenting at least another family member with the disease. Risk factors for PBC include smoking, a history of urinary tract infections, and the use of hormonal replacement treatments [2].

## Genes

The importance of genetic susceptibility to PBC has been recently stressed by the high concordance (63%) among monozygotic twin sets compared to the null concordance among dizygotic pairs [3]. Different from most autoimmune diseases, there are no clear associations with human leukocyte antigen haplotypes while several other genetic associations have been proposed but solid data are still awaited. Most recently, a role for sex chromosome abnormalities has been proposed [4]. Other mechanisms such as molecular mimicry by either microorganisms (most recently Novosphingobium aromaticivorans) or xenobiotics may also intervene. As a result, the current hypothesis of PBC etiology is that environmental factors may initiate PBC in genetically predisposed individuals with epidemiological observations supporting this view, as supported by the clues represented in Table 1.

## Molecular and Systemic Pathophysiology

Several clinical and serological characteristics as well as experimental findings strongly imply an autoimmune pathogenesis for PBC while others make PBC a peculiar entity among autoimmune diseases [5]. The disease is characterized by the presence of detectable antimitochondrial autoantibodies (AMA) in

**Cholangitis, Autoimmune. Table 1** Proposed clues to the importance of genetic and environmental factors in PBC susceptibility

| Clues to genetic factors | Clues to environmental factors |
|---|---|
| Familial PBC ~6% | Proposed latitudinal gradient of PBC prevalence/incidence |
| HLA/non-HLA polymorphisms associated with PBC susceptibility | Local clustering |
| PBC concordance in monozygotic (5/8) vs. dizygotic (0/8) twins | Temporal clustering |
| Sex chromosome major defects | Identified risk factors |
| Recently described PBC murine models: TGF-βRII; IL2AR; C3-C4 NOD | Serum cross-reactivity/AMA onset with xenobiotics, Gram-negative bacteria |

approximately 90% of affected individuals, although we note that patients lacking AMA present a similar disease and progression compared to AMA-positive subjects seemingly arguing against a pathogenic role for these autoantibodies. Autoreactive T-cells, both $CD4^+$ and $CD8^+$, have been identified in PBC regardless of the AMA status and such lymphocytes and AMA recognize overlapping epitopes within the mitochondrial autoantigens. No direct proof has been provided for a direct pathogenic role of AMA or autoreactive cells in the bile duct injury. In most cases, indirect immunofluorescence is used for AMA screening. AMA are directed against components of the 2-oxoacid dehydrogenase (2-OADC) family of enzymes located on the inner membrane of mitochondria. Specifically, AMA recognize closely-related conformational epitopes including the inner lipoylated domain of PDC-E2, BCOADC-E2, and OGDC-E2. Several studies have attempted to associate AMA patterns or titers with a number of variables, including disease severity but have failed to clearly demonstrate any correlation. In a subset of patients with PBC (in some cases approaching 50%), serum ANA are detected. The two immunofluorescence patterns specific to PBC are "nuclear rim" and "multiple nuclear dots," based on the recognition by the autoantibodies of gp210 and nucleoporin 62 (within the nuclear pore complex) and nuclear body protein sp100 and PML, respectively. Several animal models have been most recently developed, including a NOD mouse variant, and TGF-βIIR or IL2AR knockout mice.

## Diagnostic Principles

The diagnosis is based on the presence of two out of the three internationally accepted criteria: detectable serum antimitochondrial autoantibodies (AMA, titer >1:40), increased alkaline phosphatase level for longer than 6 months, and/or a compatible or diagnostic liver histology. Liver histology shows vanishing bile ducts with inflammatory infiltrates and staging is performed according to Ludwig and colleagues into four stages, from mild periportal inflammation (stage I) to frank cirrhosis (stage IV).

## Therapeutic Principles

Ursodeoxycholic acid (UDCA) at the dose of 13–20 mg/kg/day is the only approved treatment for PBC and has been shown to improve symptoms and biochemistry and to slow the progression of the disease thus increasing patients survival. However, UDCA is not curative while orthotopic liver transplantation (OLT) is considered the only and ultimate treatment for end-stage PBC. Disappointing results are achieved with immunosuppressants while pruritus is treated with cholestiramine.

# Cholangitis, Primary Sclerosing

Michael Trauner
Division of Gastroenterology and Hepatology, Medical University of Graz, Graz, Austria

## Synonyms

PSC

## Definition and Characteristics

PSC is a chronic cholestatic disorder characterized by progressive inflammation, concentric obliterative fibrosis, and strictures of the extra- and intrahepatic bile ducts, which eventually lead to biliary cirrhosis and cholangiocarcinoma [1]. The term "primary" is used to distinguish PSC from other conditions that may lead to a similar clinical and cholangiographic syndrome ("secondary" sclerosing cholangitis; see below). Most patients present as classic large duct PSC (70% intra + extrahepatic, 10–25% only intrahepatic, 2–5% only extrahepatic). 5–10% have small duct PSC without macroscopically visible changes of large ducts and a more benign course, although few patients can progress to large duct PSC [1].

## Prevalence

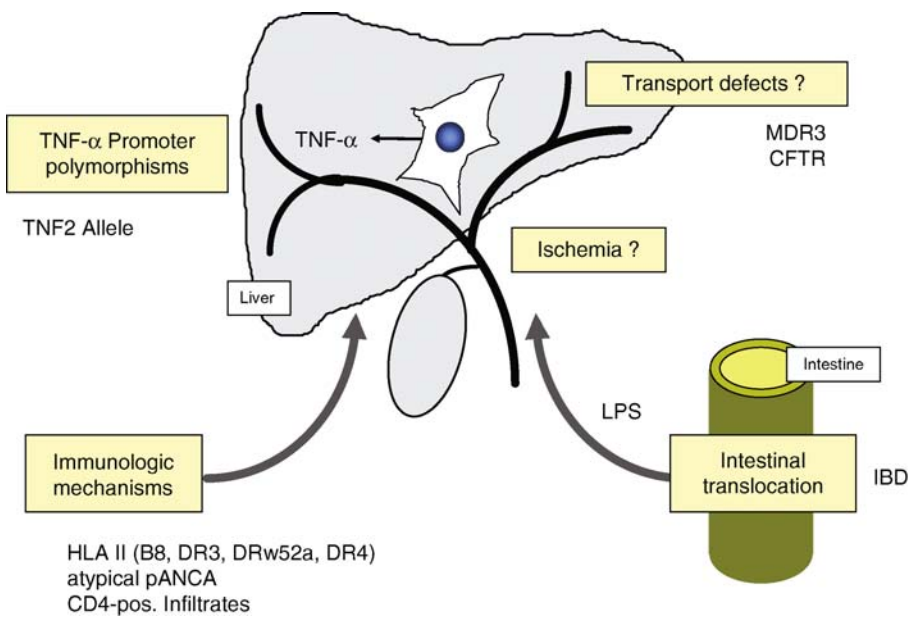
Seventy percent of patients are males with a mean age between 30 and 40 years. There are varying reports of the prevalence of PSC ranging from 0.78–2.24/$10^6$ in Spain to 85–95/$10^6$ in Scandinavia. Due to the close association with inflammatory bowel disease (IBD; in particular ulcerative colitis (UC); see below), estimates of the prevalence of PSC can also be made based on the prevalence of UC (400–2,250/$10^6$). UC has been reported in 25–90% of patients with PSC, while 5–7% of patients with UC have PSC. Thus, if 5% of UC patients have PSC and if apparent UC is present in 50% of PSC patients, the approximate prevalence of PSC should be 10–60/$10^6$, which is in line with actually reported figures [1].

## Genes

Multiple genetic polymorphisms have been investigated as a risk factor for the development and progression of PSC [2,3]. Several studies have shown associations with specific HLA haplotypes (positive associations with HLA-B8, -DR3, and -DRw52a; negative association with HLA-DR4). Tumor necrosis factor-α (TNF- α) 2 allele (associated with a functional increase in TNF- α production) is more common in PSC than in healthy controls. A specific polymorphism of MICA (an MHC class I-related molecule located between TNF-α and HLA-B) may also be strongly associated with PSC (MICA008 allele). No association was found with polymorphisms of non-MHC genes encoding interleukin (IL)-1, IL 10, Fas, and transforming growth factor-β (TGF-β). Since biliary tract lesions in cystic fibrosis resemble those in PSC, mutations of the cystic fibrosis transmembrane conductance regulator (CFTR/ABCC7) gene have been implicated in the pathogenesis of PSC. Moreover, genetic variations of the canalicular phospholipid export pump MDR3 (ABCB4) and the pregnane X receptor (PXR/SXR) gene may play a role as modifier genes in the pathogenesis of PSC. However, current data on the role of transporter gene variants are controversial and more studies are needed to make final conclusions [3].

## Molecular and Systemic Pathophysiology

The etiology and pathogenesis of PSC is still unknown and likely is multifactorial (Fig. 1) [1–3]. It has to



**Cholangitis, Primary Sclerosing. Figure 1** Proposed pathogenetic factors in PSC. ANCA, anti-neutrophilic cytoplasmatic antibodies; CFTR, cystic fibrosis transmembrane conductance regulator; IBD, inflammatory bowel disease; LPS, endotoxin; MDR3, canalicular phospholipid export pump; TNF, tumor necrosis factor.

be kept in mind that PSC could represent a mixed bag of different conditions with various etiologies. Autoimmune-mediated bile duct injury has been proposed due to associations with HLA haplotypes, detection of autoantibodies, and associated autoimmune disorders including inflammatory bowel disease (see below), diabetes mellitus (10%), Grave's disease (8%), pancreatitis, and fibrotic disorders such as retroperitoneal fibrosis and sclerosing sialdenitis (Kuttner tumors). Overlap syndromes of PBC with autoimmune hepatitis (5–10%) or – rarely – PSC with primary biliary cirrhosis (PBC) may also occur. In addition, a role for non-immune factors such as molecular alterations of tight junctions of biliary epithelial cells, bacterial infections, and ischemia have also been proposed. The close association with inflammatory bowel disease (70–90% ulcerative colitis; 5–8% Crohn's colitis) suggests a role for bacterial translocation (e.g., endotoxins, LPS) in the pathogenesis of PSC (Fig. 1). In addition, hepatobiliary transport defects resulting in a "toxic bile" could contribute to the pathogenesis of this disease (Fig. 1).

As such Mdr2 (rodent orthologue of human MDR3) knockout mice develop a sclerosing cholangitis, raising the possibility that ABCB4 (MDR3) genetic variants could contribute to the pathogenesis of PSC. Recently, MDR3 (ABCB4) haplotypes have been identified in PSC, suggesting that MDR3 variants could play a role as modifier gene [3]. Mutations of the cystic fibrosis transmembrane conductance regulator (CFTR/ABCC7) gene have also been suggested to play a role in the pathogenesis of PSC. Initial studies have reported CFTR mutations and a reduced chloride response on nasal potential testing to be more common in PSC than in controls, but these findings were not confirmed by subsequent studies. Polymorphisms of PXR/SXR – a nuclear receptor involved in the regulation of hepatobiliary transport and metabolism – may also play a role for disease progression of PSC. Hepatobiliary transporter gene variants could play an important role as modifier genes, for example, by altering bile composition and thereby the aggressiveness of bile, which could influence the secondary response to any "primary" (e.g., immune-mediated or ischemic) bile duct injury and thereby modify the pathogenesis and clinical course of PSC [3].

Complications include bacterial cholangitis, cholelithiasis, development of dominant bile duct strictures (15–20%), and malignancy (cause of death in 44% of PSC patients). Patients with classic (large duct) PSC have an increased risk for cholangiocellular carcinoma (CCC; 15–20% of PSC patients), pancreatic cancer (14-fold), and colorectal cancer (10-fold).

## Diagnostic Principles

Diagnosis of PSC is based on typical cholangiographic findings (strictures, outpouchings of large ducts) on endoscopic retrograde cholangiography (ERC) or magnetic resonance cholangiography (MRC) in the absence of other causes of secondary sclerosing cholangitis such as previous bile duct surgery, trauma, bile duct neoplasm, choledocholithiasis, recurrent bacterial cholangitis, congenital abnormalities, caustic/chemical sclerosis, or ischemic strictures [4,5]. Rarely, percutaneous transhepatic cholangiography is necessary for visualization of the biliary tract. ERC is still the gold standard and most centers use MRC as a non-invasive screening test for PSC. Recent studies have revealed comparable sensitivities and diagnostic accuracies of modern state-of the-art MRC and ERC. Liver biopsy is needed for diagnosis of small-duct PSC with a normal cholangiogram. Atypical perinuclear anti-neutrophilic cytoplasmatic antibodies (pANCA) are frequently present (in about 80%) but are non-specific and therefore of limited diagnostic value. IBD is usually diagnosed before PSC in about three fourths of patients. In some cases, PSC is diagnosed when patients with IBD are screened for elevated liver function tests.

## Therapeutic Principles

Ursodeoxycholic acid (15–20 mg/kg/day orally) improved liver biochemistry and histology in most studies (and appearance on cholangiography in some studies) without effect on survival, free of liver transplantation, in two large trials [4,5]. A variety of immunomodulatory and antifibrotic drugs have been tested but cannot be recommended [4,5].

Endoscopic retrograde cholangiography (ERC) with dilatation and short-term stenting of dominant strictures improves symptoms and improves survival predicted by the Mayo model when combined with ursodeoxycholic acid [4,5]. Bile duct surgery should be avoided. If endoscopic treatment is not feasible, surgical biliary reconstruction can be applied in selected cases. However, surgical therapies other than transplantation should be reserved mainly for patients with isolated focal extrahepatic strictures and with early non-cirrhotic stages of PSC. Liver transplantation is indicated for end-stage liver disease or refractory pruritus. Liver transplantation offers good long-term survival (75–85%, 5-year-survival), but recurrence of PSC in the transplanted liver has been reported in 8–20% of patients [4,5].

# Cholecystitis

Michael Trauner
Division of Gastroenterology and Hepatology, Medical University of Graz, Graz, Austria

## Definition and Characteristics

Cholecystitis is an acute or chronic inflammation of the gallbladder in the presence or absence of gallbladder stones. Acute calculous cholecystitis is caused by gallstones and accounts for 90% of cases. Acute acalculous cholecystitis occurs in the absence of stones and accounts for the remaining 10% of acute cases. Emphysematous cholecystitis is an unusual and severe manifestation of acute cholecystitis that is characterized by infection of the gallbladder wall by gas-forming bacteria. Chronic calculous cholecystitis usually follows several acute attacks resulting in ulceration and scarring of the gallbladder epithelium. Rarely, extensive dystrophic calcification of the gallbladder wall may result in a porcelain gallbladder (associated with an increased risk for gallbladder carcinoma). Rare forms of chronic acalculous cholecystitis include chronic lymphocytic cholecystitis which may be associated with primary sclerosing cholangitis.

## Prevalence

The prevalence of acute acalculous cholecystitis can be estimated from the prevalence of gallstones in the general population (10–20%) as the major risk factor. Risk factors of calculous cholecystitis therefore mirror those for cholelithiasis. As many as one third of patients with gallbladder stones may develop acute cholecystitis. Acute acalculours cholecystitis occurs in 0.4–4% of burn patients, 0.5–1.6% of postoperative and post-trauma patients, and up to 4% of patients receiving prolonged hyperalimentation (over 3 months).

## Genes

No genetic factors have been identified. However, gallstone formation is associated with genetic risk factors.

## Molecular and Systemic Pathophysiology

Acute calculous cholecystitis is precipitated by stone impaction in the cystic duct resulting in a progressive increase in luminal pressure and damage to the gallbladder wall by chemical irritant effects of bile (acids). Bacterial growth within the obstructed gallbladder lumen can contribute to the process and lead to gangrene and biliary sepsis. Emphysematous cholecystitis is due to secondary infection of the gallbladder wall with gasforming organisms, particularly anaerobes (Clostridium welchii, Escherichia coli, and anerobic streptococci). Diabetes mellitus and immunosuppression are typical risk factors for emphysematous cholecystitis. Risk factors for acute acalculous cholecystitis is the triad of prolonged fasting with stasis of the gallbladder content (e.g., total parenteral nutrition), mechanical ventilation and hemodynamic instability. As such it occurs typically in critically ill patients in the intensive care unit with septic shock, antecedent trauma, burns or major surgery. Sickle cell crisis and systemic vasculitides such as polyarteritis nodosa or lupus erythematosus may present as acute cholecystitis because of ischemic injury to the gallbladder. Intraarterial chemotherapy/chemoembolization via the hepatic artery may also lead to gallbladder ischemia. Elderly patients with arteriosclerotic vascular disease and women in the postpartum state after prolonged difficult labor are also be at risk. The common denominator is secondary bacterial infection of the gallbladder wall irrespective of the cause of acalculous cholecystitis. Rarely specific infections (Salmonella spp., Leptospira spp., staphylococci; cytomegalovirus, cryptosporidiosis, microsporidiosis in patients with AIDS) may be the primary cause of acalculous cholecystitis.

## Diagnostic Principles

Acute cholecystitis is characterized by right upper quadrant pain and tenderness of the gallbladder region. Fever, nausea and vomiting are frequently present. Guarding of the abdomen is commonly observed and palpation (on physical examination or ultrasound) usually elicits tenderness (positive Murphy sign). Laboratory features include leukocytosis and liver biochemical tests are usually be elevated. Abdominal ultrasound and computed tomography show thickening of the gallbladder wall and gallbladder stones if present. The onset of chronic cholecystitis is usually more indolent and may be associated with recurrent bouts of abdominal discomfort; complete blood count and liver biochemical tests are usually normal. Imaging studies may show calcifications of the gallbladder wall (porcelain gallbladder).

## Therapeutic Principles

The acutely ill patient should be treated with intravenous fluids, analgesics and broad-spectrum antibiotics (ampicillin with aminoglycoside or cephalosporin and metronidazole) cholecystectomy can be performed as soon as fluid deficits are corrected and infection is

controlled. Timing of cholecystectomy for the average patient is controversial (early operation within days versus delayed cholecystectomy after 6 to 8 weeks). Recent evidence suggested that early laparoscopic cholecystectomy reduces the total length of hospital stay and the risk of readmissions attributable to recurrent acute cholecystitis, and is therefore a more cost-effective approach for the management of acute cholecystitis. Laparascopic cholecystecomy has been reseverved for elective surgery but is increasingly being performed in the acute setting. Patients with acalculous cholecystitis have a very high mortality rate ranging from 10 to 50% which far exceeds the expected 1–3% mortality rate observed in patients with calculous cholecystitis. Acute acalculous cholecystitis carries a high perforation risk and therefore should undergo surgery within 48 hours whenever possible. Beyond 48 hours gallbladder perforation occurs in as many as 40% of cases.

High-risk, acutely ill patients may benefit from (ultrasound guided) percutaneous transhepatic drainage in local anesthesia, especially critical care patients with acute acalculous cholecystitis.

# Cholecystolithiasis

Malcolm A. Lyons, Kirk J. Maurer, Martin C. Carey
Gastroenterology Division, Harvard Medical School, Brigham and Womens Hospital, Boston, MA, USA

## Synonyms

Cholelithiasis; Gallbladder stones; Gallstones; Cholesterol gallstones; Pigment gallstones; Biliary calculi

## Definition and Characteristics

Cholecystolithiasis refers to the formation of solid calculi in gallbladder bile. Gallstones which develop in the gallbladder are classified as cholesterol stones (if >50% cholesterol) or "black" pigment stones (predominantly polymerized calcium bilirubinate if <30% cholesterol). A second type of pigment stone, trivially termed "brown", is most frequently found in the biliary tree associated with anaerobic bacterial infection; the antecedent is often parasitic infestation frequent in developing countries. Black pigment gallstones are nearly always small, multiple, and spiculated whereas cholesterol gallstones may appear singly or form in facetted multiples with a bile pigment nucleus. They are light brown to white in color depending upon the cholesterol concentration; large single stones exhibit the highest cholesterol concentrations [1].

## Prevalence

Since many gallstone patients are asymptomatic, clinical prevalence always underestimates true prevalence. Risk factors for cholesterol stones include female gender, increasing age, ethnicity, metabolic diseases (obesity, diabetes mellitus), sedentary lifestyle, pregnancy, some drugs and rapid weight loss. Non-admixed Native Americans display the highest gallstone prevalence rates of cholesterol stones. For example, male Pima Indians exhibit ~70% true prevalence of gallstones after age 55 and female Pima display ~80% prevalence after age 25. In contrast, African-Americans display lower prevalence rates (males 4–8%, females 15–18% after 60 years), and Caucasians display intermediate prevalence rates (males 6–32%, females 12–40% at 60 years). Furthermore, gallstone prevalence rates vary with geographical ancestry being rare in sub-Saharan Africans and common in Caucasians with Viking heritage [1,2].

Women exhibit approximately double the prevalence rates of men and cumulative prevalence increases linearly with age with the notable exception of female Pimas, who display an abrupt onset in their 20s [2]. Cholesterol gallstones appear to be formed principally in the third decade and early middle ages of life, whereas most pigment gallstones form in late middle and old age. An exception is pigment gallstones resulting from congenital hemolytic anemias which form in the early decades of life and prevalence is indifferent to gender.

## Genes

In the case of black pigment gallstones, monogenic causes are well documented. Specifically, hereditary spherocytosis, ANK1, SPTB, SPTA1, SLC4A1, EPB42; sickle cell disease, HBB; thalassemia major and intermedia, HBB; and erythrocyte enzyme deficiencies,

G6PD, PKLR, GSR, PGK1, GPI, TPI1, AK1 all cause hemolytic anemia and thus increase biliary bilirubin concentrations, the principal in situ compositional change leading to black pigment stones. In contrast, cholesterol gallstones are rarely monogenic and result from polygenic traits profoundly influenced by environmental factors. Polymorphisms in APOA1, APOB, APOE, CETP (possibly LRP2), and LDLR genes are associated with cholesterol gallstones and genes encoding proteins involved in biliary lipid homeostasis and gallbladder function which are associated with cholesterol gallstones include ABCB4 (canalicular phosphatidylcholine transporter), ABCB11 (canalicular bile salt export pump), CYP7A1 (cholesterol 7α-hydroxylase), and CCKAR (cholecystokinin A receptor) [2]. In mice, putative candidate Lith genes include Abcb11, Lrp2, Abcc2 (canalicular multi-specific organic anion transporter), Pparg (peroxisome proliferator activated receptor γ), Nr1h4 (nuclear bile salt receptor), and Abcg5/Abcg8 (heterodimeric canalicular cholesterol transporter) [3].

## Molecular and Systemic Pathophysiology

Cholesterol gallstones develop in gallbladder bile following precipitation of cholesterol from supersaturated bile and the predominant cause is hepatic hypersecretion of cholesterol. The etiology of cholesterol hypersecretion is not known. Emerging evidence suggest that it could have its origins in (i) insulin resistance, (ii) reverse cholesterol transport via HDL, (iii) dietary cholesterol-absorption, (iv) impaired bile salt synthesis. However, augmented de novo cholesterol synthesis is unlikely. Although cholesterol supersaturation is necessary for cholesterol gallstone formation its presence is not sufficient in itself. Both animal models and humans can develop supersaturated bile and nucleate "biliary sludge" without progressing to cholesterol gallstones. Non-lipid elements like mucin glycoproteins and gallbladder hypomotility are crucial in promoting progression of the disease. In animal models, enterohepatic Helicobacter infection, immunity and inflammation contribute to the development of cholesterol gallstones but whether these factors also apply in humans is unknown.

Any condition leading to excess bilirubin conjugates in gallbladder bile (substrates for endogenous β-glucuronidase hydrolysis) contributes to black pigment stone formation [4]. Hemolytic anemias and ineffective erythropoiesis are the most conspicuous sources of "hyperbilirubinbilia". A third pathway is ileal disease, exclusion, bypass or resection (ileectomy), leading to spillage of excess bile salts into the large intestine resulting in increased solubilization, absorption and enterohepatic cycling of bilirubin. Causes include ileal Crohn's disease, cystic fibrosis, SLC10A2 (ileal sodium-dependent bile salt transporter) mutations as well as surgical interventions on the distal small intestine [5].

## Diagnostic Principles

Diagnosis depends upon ultrasonography. In the past, diagnosis was made using oral cholecystography since most gallstones are radiolucent. Computerized tomography (CT) may differentiate cholesterol from pigment gallstones. In epidemiological studies, previous cholecystectomy must be included for calculation of true prevalence rates.

## Therapeutic Principles

The only definitive treatment for gallstones is surgical removal of the stones plus gallbladder (cholecystectomy), usually by the laparoscopic route. Oral therapy with 3α, 7β-dihydroxy-5β-cholanoic acid (ursodeoxycholic acid, UDCA), or less usefully 3α,7α-dihydroxy-5β-cholanoic acid (CDCA), may dissolve pure cholesterol stones <5 mm in diameter over 6 months to 1 year. However, upon discontinuation of therapy, stone recurrence is common (80%). Continued use of full dose UDCA (12–15 mg/kg/day) prevents recurrence as well as de novo cholesterol gallstone formation associated with rapid weight loss. Gallstones, usually pigment stones, associated with total parenteral nutrition (TPN) can be prevented by daily administration of the C-terminal octapeptide of cholecystokinin (Sincalide). Pigment gallstones cannot be dissolved by any current therapy. Extracorporeal shock wave lithotripsy (ESWL) for either type of stones is fraught with a number of risks and hence is licensed in only some countries (not USA). Even when successful, stone recurrence is the rule [1].

# Choledochal Cysts

Lee A. Denson
Division of Gastroenterology, Hepatology and Nutrition, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA

## Synonyms

Type III choledochal cyst (synonymous with duodenal diverticulum); Type V choledochal cyst (synonymous with Caroli's disease)

## Definition and Characteristics

Idiopathic congenital dilatation of the bile ducts. The Todani system of classification is used to define the five types of choledochal cysts [1] (see Fig. 1).

The two most common are type I (40–85%) and type IVa (18–20%). Type III, which is a cystic dilatation of the intramural portion of the common bile duct (CBD) lined by duodenal mucosa, may also be classified as a duodenal diverticulum. Type V is the same as Caroli's disease, which is covered in a separate section.

## Prevalence

1 in 100,000 to 1:150,000 live births. More common in females than males, with a ratio of 3:1 to 4:1. More common in Asia than Europe/North America.

## Genes

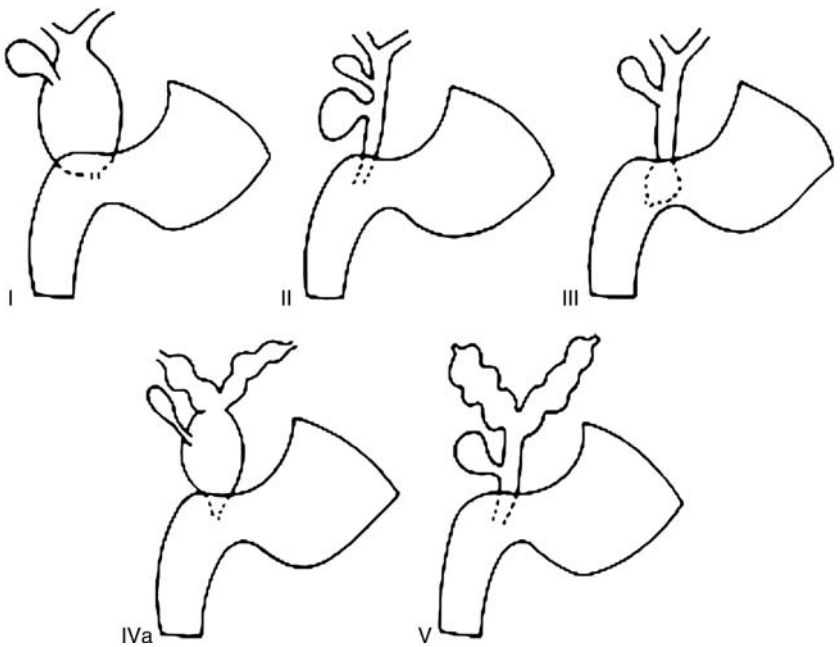
Unknown.

## Molecular and Systemic Pathophysiology

Most reported cases of choledochal cyst (57–96%) are associated with anomalous pancreatobiliary junction (APBDU) with a long common channel (<15 mm) [2]. It is proposed that this allows reflux of pancreatic juice into the CBD, which combined with increased ductal pressure leads to bile duct dilatation. Distal CBD obstruction due to congenital webs, sphincter of Oddi dysfunction, or reduced local innervation has also been proposed to cause ductal dilatation in some cases. There has been little evidence to support a strong genetic basis for the disorder. Ductal plate malformation has been implicated for the intrahepatic portion of type IVa, as well as type V. Several recent studies have begun to explore the molecular basis for the high incidence of cholangiocarcinoma associated with choledochal cysts. The incidence of cholangiocarcinoma is much higher in patients with APBDU than in those without it, implicating a role for pancreatic reflux. Mutations in the K-ras oncogene have been associated with biliary epithelial hyperplasia, while inactivation of the DPC-4 and p53 tumor suppressor genes have been identified in cases of carcinoma [3].

## Diagnostic Principles

This diagnosis should be considered in all infants with neonatal cholestasis, as well as older children and adults with abdominal pain, jaundice. and/or abdominal mass.



**Choledochal Cysts. Figure 1** Classification of choledochal cysts. (Reproduced by permission from [1].)

The majority of patients do not have the classic triad of pain, jaundice, and abdominal mass. Jaundice is the most common presenting feature in infants, while abdominal pain is the most common presenting feature in older children and adults. Abdominal ultrasound is the preferred screening examination. Magnetic resonance cholangiography (MRCP) is currently the best method for defining the anatomy of the biliary tree [4].

### Therapeutic Principles

Patients may frequently present with complications, which include gallstones, pancreatitis, cholangitis, biliary cirrhosis, and cholangiocarcinoma [5]. Biliary cirrhosis may develop in 40–50%, while cholangiocarcinoma has been reported in 10–30%. Therapy is then guided by the presenting condition. Primary therapy of extra-hepatic choledochal cysts is surgical excision with hepaticojejunostomy. Patients who have previously had internal drainage procedures will also benefit from this approach, which will reduce the risk of malignancy in the remaining cyst. Patients with type IV-A disease and localized intrahepatic cysts may similarly benefit from partial hepatectomy. The exception are type III cysts, which may be treated with internal drainage via endoscopic sphincterotomy, and not excision, because of the perceived reduced risk of malignancy.

### Synonyms

Bile duct stones

### Definition and Characteristics

Bile duct stones are classified according to their site of formation: Primary bile duct stones arise de novo in the intrahepatic or extrahepatic bile ducts, whereas secondary bile duct stones form in the gallbladder and subsequently migrate from the gallbladder into the ducts. Choledocholithiasis frequently leads to abdominal symptoms and severe complications (biliary obstruction, cholangitis, pancreatitis).

When stones develop in the intrahepatic bile ducts, the disease is termed hepatolithiasis. The clinical course of hepatolithiasis often requires repeated stone removal due to incomplete recovery after intervention or frequent stone recurrence. The main morphological feature of hepatolithiasis is chronic proliferative cholangitis and a common complication is the development of cholangiocarcinoma in 5–18% of the patients [1].

### Prevalence

In contrast to gallbladder stones (cholecystolithiasis), data on the prevalence of bile duct stones are scarce. In Europe and North America, secondary bile duct stones predominate, since 80–95% of patients with bile duct stones have concomitant gallbladder stones. It has been estimated that 3–18% of patients harboring gallbladder stones display choledocholithiasis; this prevalence increases to nearly 50% in patients aged 80 years and older [2]. Whereas intrahepatic bile duct stones are rare in Western countries, the proportion of patients with hepatolithiasis among all gallstone carriers in East Asian populations ranges from 2% (Japan) to 20% (China), but has decreased recently [1].

## Genes

Rosmorduc et al. [3] provided the first evidence for a monogenic risk factor for bile duct stones in a defined subgroup, i.e. young patients (<40 years) with a positive family history of gallstones who present with cholesterol gallbladder stones and intrahepatic microlithiasis (hyperechoic foci on ultrasonography) as well as recurrence of biliary symptoms after cholecystectomy. Physical–chemical analysis of hepatic biles revealed marked supersaturation with cholesterol together with low phospholipid concentrations, and thus the disorder was called "Low Phospholipid-Associated Cholelithiasis" (LPAC syndrome). These observations led to a mutation search in the ABCB4 gene encoding the hepatocanalicular phosphatidylcholine transporter, formerly known as MDR3 (Multidrug Resistance P-glycoprotein 3). Heterozygous and homozygous ABCB4 gene point mutations were identified in 18 out of 32 patients (56%) who presented with the clinical characteristics of the LPAC syndrome [3]. Of note, Asian patients with primary cholesterol hepatolithiasis display markedly reduced biliary phospholipid concentrations and low hepatic expression levels of ABCB4, pointing to a common pathophysiological mechanisms of intrahepatic cholesterol stones and LPAC syndrome.

Abnormalities of the biliary tract including periampullary duodenal diverticula, choledochol cysts and Caroli's syndrome predispose to the formation of primary bile duct stones. Caroli's syndrome is characterized by congenital polycystic bile duct dilatation and subtypes are associated with autosomal recessive polycystic kidney disease (ARPKD or polycystic kidney and hepatic disease 1). Recently ARPKD was shown to be caused by mutations in the PKHD1 gene encoding fibrocystin (polyductin), a putative receptor protein expressed in primary cilia that plays a role in collecting-duct and bile duct differentiation [4]. Accordingly, PKHD1 mutations have been identified in single infants with Caroli's syndrome, confirming that early onset Caroli's syndrome is part of the spectrum of ARPKD. Finally, in some patients presenting with the LPAC syndrome, localized or diffuse intrahepatic bile duct dilatations filled with cholesterol gallstones have been observed, indicating a potential link between various genetic defects.

## Molecular and Systemic Pathophysiology

Most bile duct stones originate from the gallbladder. The core and shell of these secondary bile duct stones display distinct chemical compositions, consistent with the non-infectious gallbladder origin of the cholesterol-rich nucleus and the infectious origin of the cholesterol-poor outer layer [5]. Primary bile duct stones are often referred to as brown pigment stones, in contrast to the black pigment stones that form in the gallbladder due to hemolytic disorders or other conditions associated with hyperbilirubinemia. The soft, friable earthy stones are composed of calcium bilirubinate, calcium fatty acid salts, mucin glycoproteins and bacteria, indicating that they are infectious in origin. Calcium bilirubinate is present as a loosely packed amorphous precipitate. Brown pigment stones form as a result of stasis and infection within the biliary system, usually in the presence of Escherichia coli, Klebsiella spp., Clostridium perfringens or Bacteroides fragilis. These bacteria produce β-glucuronidase, which converts soluble conjugated bilirubin back to the insoluble unconjugated state, and phospholipase $A_1$, hydrolyzing phosphatidylcholine to produce the free saturated long-chain fatty acids palmitate and stearate, which are sparingly soluble and precipitate as calcium salts.

Hepatolithiasis is often related to parasitic infestation from roundworms (Ascaris lumbricoides, Clonorchis sinensis). Of note, these intrahepatic stones contain less bilirubin and more cholesterol and can even be composed of cholesterol, indicating the complex nature of hepatolithiasis [1]. Decreased hepatobiliary phospholipid secretion, probably due to decreased expression of the ABCB4 transporter and the intracellular phosphatidylcholine transfer protein, in the setting of increased hepatic cholesterol and decreased bile salt synthesis, could be the predisposing metabolic conditions [1]. This primary defect might be secondarily modified by local factors (e.g. cholangitis, mucin hypersecretion), all of which interact to form cholesterol-rich brown pigment stones in the intrahepatic bile ducts.

## Diagnostic Principles

Gallstones obstructing the bile duct can cause biliary colic. In case of bile duct obstruction, acute bacterial cholangitis may develop, which is typically characterized by fever, abdominal pain, and jaundice (Charcot's triad). Biliary obstruction is indicated by elevated serum bilirubin as well as γ-glutamyl transpeptidase and alkaline phosphatase activities. Ultrasonography may detect dilated bile ducts and/or bile duct stones directly.

Endoscopic retrograde cholangiography (ERC) is the "gold standard" in the imaging of bile duct stones (sensitivity >95%) and offers the possibility for therapeutic interventions [5]. Both endoscopic ultrasound (EUS) and non-invasive magnetic resonance cholangiography (MRC) are comparable to ERC in diagnosing bile duct stones and may be used in patients with low a priori probability of bile duct stones. In recent studies EUS showed slightly better sensitivity (93%) and specificity (96%) than MRC (85% and 93%, respectively), in particular for small stones in the distal common bile duct [5]. MRC appears to be the most effective diagnostic method for the evaluation of intrahepatic bile duct stones.

## Therapeutic Principles

Most commonly bile duct stones are removed by ERC after endoscopic sphincterotomy (EST). If stone extraction is not possible with Dormia baskets or balloons after EST, additional lithotripsy methods (mechanical, laser, electrohydraulic or extracorporeal shock-wave lithotripsy) result in stone-free bile ducts in >95% of patients with choledocholithiasis [5]. After successful endoscopic stone extraction, laparoscopic cholecystectomy is indicated in patients with gallbladder stones, since the incidence of symptoms in patients who are randomized to "wait-and-see" is higher than in patients who undergo elective laparoscopic cholecystectomy [5]. Alternatively, cholecystectomy and removal of bile duct stones are performed as one-step procedure in experienced surgical centers.

Complete extraction of intrahepatic stones in patients with hepatolithiasis can be technically impossible at ERC, and such patients may require surgery for stone removal and adequate drainage of the biliary tree. The prevalence of hepatolithiasis is higher in countries with low-protein/low-fat malnutrition, which promotes biliary stasis and infection, but a "Westernized" diet is a common risk factor for cholesterol gallbladder stones. Ursodeoxycholic acid (UDCA) treatment has been shown to be beneficial in a few cases of hepatolithiasis associated with Caroli's syndrome, and primary stone prevention and/or treatment with UDCA might also be reasonable in patients with LPAC syndrome [5].

According to few prospective trials on the long-term results of endoscopic treatment of extrahepatic bile duct stones, 5–20% of patients develop recurrent stones, most of which are amenable to endoscopic re-interventions. The reformation of bile duct stones appears to be facilitated by bacterial overgrowth of the biliary tree after EST, but secondary prevention with antibiotics or UDCA is not effective [5].

## Synonyms

Hepatocellular or intrahepatic cholestasis; Obstructive cholestasis

## Definition and Characteristics

Reduced bile flow may be caused by multiple genetic, inflammatory/infectious, metabolic, toxic, or structural etiologies [1]. The transport proteins which determine hepatobiliary bile flow and the enterohepatic circulation of bile are shown in Fig. 1 [2].

Most intrahepatic cholestatic disorders may be understood in terms of genetic or acquired defects in the function of one or more of these transport proteins. Obstructive cholestasis is due to abnormalities in the intra- or extrahepatic bile ducts which reduce bile flow.

## Genes

The cholestatic disorders which can be ascribed to autosomal recessive single gene defects resulting in abnormal bile flow and/or composition are summarized in Table 1.

Disorders which may be associated with secondary acquired defects in these transport proteins are briefly summarized in the pathophysiology section.

## Molecular and Systemic Pathophysiology

Bile flow is an osmotic process, driven by solutes which are actively transported across the apical (canalicular) membrane of hepatocytes and cholangiocytes. This is primarily due to bile salt transport across the apical membrane of the hepatocyte, which then generates water flow. Bile acids are subsequently efficiently reclaimed in the terminal ileum, and then returned to the hepatocyte via the NTCP transporter on the basolateral (sinusoidal) membrane. The other important constituents of bile include phospholipids, cholesterol, bilirubin, and, in certain settings, multiple drugs or toxins.

**Cholestasis. Table 1** Genetic causes of cholestasis

| Transporter/ protein | Gene | Substrate/function | Disease |
|---|---|---|---|
| FIC1 | *ATP8B1* | Not known | PFIC 1 and BRIC |
| BSEP | *ABCB11* | Bile salts | PFIC 2 |
| MDR3 | *ABCB4* | Phosphatidylcholine | PFIC 3 with homozygote; ICP or gallstones with heterozygote or missense homozygote |
| MRP2 | *ABCC2* | Amphipathic drugs and bilirubin | Dubin Johnson syndrome |
| ABCG5 | *ABCG5* | Phytosterols | Sitosterolaemia |
| CIRHIN | *FLJ14728* | Not known | North American Indian Childhood Cirrhosis |
| TJP2 | *TJP2 (ZO-2)* | Tight junction protein | Familial Hypercholanemia |
| BAAT | *BAAT* | Bile acid conjugation | Familial Hypercholanemia |
| 3βHSD | *3βHSD* | Bile acid synthesis | Intrahepatic cholestasis |
| CFTR | *CFTR* | Chloride secretion | Cystic Fibrosis |

These are important in terms of understanding both the pathophysiology and complications of cholestatic disorders. A class of ligand activated transcription factors, nuclear receptors, have been described which regulate expression of the key transport proteins involved in bile formation. Ligands which activate these nuclear receptors include bile acids, lipids, and xenobiotics, while inflammatory cytokines have been shown to down regulate nuclear receptor expression. In this manner, expression of genes involved in bile formation is regulated by hepatocellular concentrations of these substances in health and disease.

Intrahepatic cholestasis in most cases can be attributed to genetic and/or acquired defects in apical hepatobiliary transport proteins. An important class of genetic disorders which has yielded significant insight into hepatobiliary pathophysiology is progressive familial intrahepatic cholestasis (PFIC 1–3). PFIC 1

(Byler's disease) was originally characterized in an Amish kindred and is due to mutations in FIC1. FIC1 may function as a plasma membrane aminophospholipid flippase; how this leads to cholestasis and diarrhea is not known. It is expressed in both liver and intestine, which may account for the extra-hepatic clinical manifestations. BRIC (benign recurrent intrahepatic cholestasis) is also due to mutations in FIC1; these are typically missense mutations, as opposed to the more severe deletions, frame shifts, and nonsense mutations in PFIC 1. PFIC 2 is due to mutations in BSEP, the apical bile salt export pump. PFIC 3 is due to mutations in MDR3, which functions in the translocation of phosphatidylcholine into bile. The reduction in biliary phospholipids is believed to then increase the cytotoxic effect of hydrophobic bile salt detergents, leading to progressive liver injury. Heterozygote or missense homozygote mutations in MDR3 have now also been associated with intrahepatic cholestasis of pregnancy (ICP) and gallstone disease.

North American Indian childhood cirrhosis (NAIC) and familial hypercholanemia (FHC) are two disorders in which the mutated genes are not directly involved in bile formation. Mutations in FLJ14728, which encodes for Cirhin, a WD repeat-containing protein which is expressed in the liver during development and may be targeted to mitochondria, have been implicated in NAIC. Further study of Cirhin will likely provide novel insights into mechanisms of cholestasis. TJP2, which encodes for a tight junction protein, has been implicated in most cases of FHC, with mutations in BAAT then modifying penetrance. Defects in Tjp2 are predicted to cause cholestasis by allowing reflux of bile salts from bile into plasma across leaky tight junctions. Defects in BAAT prevent conjugation of bile salts; as unconjugated bile acids are not substrates for Bsep, these may then diffuse from hepatocytes into plasma. 3βHSD deficiency is the most common of the bile acid synthetic disorders, which are due to defects in synthesis of the normal bile salts, leading to overproduction of toxic bile acid metabolites. Mutations in CFTR cause cystic fibrosis, which can be associated with progressive cholestatic liver disease, presumably due to defective chloride secretion into bile.

Intrahepatic cholestasis of pregnancy (ICP) may develop in the third trimester of pregnancy with an overall incidence of 10–100 cases per 10,000 pregnancies, although the incidence is much higher in some parts of the world. In most cases, it is felt that a generalized reduction in bile formation during pregnancy is due to the reversible effect of increased circulating levels of hormones in the third trimester upon apical transporter expression and/or function. In some cases, defects in genes involved in bile formation have also been identified, including MDR3, FIC1, and MRP2. In this respect, women with a history of ICP are also more prone to cholestasis due to oral contraceptives. Inflammatory cholestasis is frequently observed in generalized inflammatory conditions or sepsis. Experimental studies have indicated that this is likely due to reversible down regulation of apical transporters including Bsep and Mrp2. Further study will be required to determine whether this is also the case in humans.

Recently, secondary alterations in expression of genes involved in bile formation have begun to be characterized in cholestatic disorders. These may, in some cases, afford a protective function, by reducing the accumulation of toxic bile acids within the hepatocyte, while increasing systemic accumulation of bile acids. These studies also provide insight into mechanisms by which targeted drug therapy may some day afford similar hepatoprotective changes in bile acid transporter expression. For example, in infants with biliary atresia (BA), a progressive inflammatory obstructive cholestasis, NTCP has been shown to be down regulated, while MRP3, which encodes a basolateral bile acid transport protein, has been shown to be upregulated. Up regulation of MRP3 has also been observed in adults with obstructive cholestasis, primary biliary cirrhosis (PBC), and Dubin Johnson syndrome. This mechanism may then account for increases in both conjugated bilirubin and bile salts in the circulation in cholestasis. Conversely, expression of the canalicular transporters BSEP, MRP3, and MDR3 is typically maintained in human disorders including cholestatic alcoholic hepatitis, BA and PBC.

Approximately 17% of all hepatic adverse drug reactions cause a form of cholestasis. Several agents which have been implicated in drug-induced cholestasis, including cyclosporine A and triglitzone, have been shown to directly inhibit ATP-dependent bile acid transport in vitro, presumably through inhibition of Bsep function. Estrogens and anabolic steroids may cause primarily cholestasis without significant inflammation, while drugs including ketoconazole and amoxicillin-clavulanate may cause a cholestatic hepatitis. Most cases are reversible with removal of the offending agent; however chronic cholestasis due to small or large bile duct injury may ensue.

Primary biliary cirrhosis (PBC) and primary sclerosing cholangitis are chronic cholestatic disorders of presumed autoimmune etiology due to progressive destruction of the small intralobular or large intra- and/or extrahepatic bile ducts, respectively. The bile duct destruction in PBC is mediated by T lymphocytes, and over time can lead to secondary hepatocyte injury due to accumulation of toxic bile acids, and biliary cirrhosis. The major autoantigen in PBC is a 9-amino acid

sequence in the PDH E2 subunit which is normally expressed on mitochondrial membranes and is aberrantly expressed on bile duct epithelial cells. Some children and adults with PSC will have an overlap condition in which features of autoimmune hepatitis (AIH) such as autoantibodies are also present.

The principle conditions causing obstructive cholestasis in infants are BA and choledochal cyst, which are reviewed in separate sections. In older children and adults, causes include neoplasms of the pancreas, liver, and bile ducts, metastatic cancer, cholelithiasis, and benign pancreatic disorders including pseudocyst. Malignancies are more common in older adults, and benign causes in children and young adults.

## Diagnostic Principles

Patients typically present with jaundice and pruritis, with elevated serum bile salt levels and conjugated hyperbilirubinemia. Patients with obstructive cholestasis may have relatively higher levels of alkaline phosphatase (ALP) or GGT, than those with hepatocellular cholestasis. The presence of significant hepatic synthetic dysfunction will both direct the evaluation toward specific metabolic or toxic etiologies, as well as accelerating the diagnostic work-up in those who may develop liver failure. Evaluation for fat soluble vitamin deficiency, particularly coagulopathy due to vitamin K deficiency, should be performed. Infectious etiologies such as bacteremia or UTI which require prompt therapy should also be sought. The next priority is to determine whether the cholestasis is due to an extrahepatic structural abnormality, such as choledochal cyst or BA in infants or gallstone disease, sclerosing cholangitis, or malignancy in older patients which may amenable to surgical or endoscopic intervention. Acholic stools will direct the evaluation toward causes of extrahepatic obstruction, although these may also occur with severe intrahepatic cholestasis. Abdominal ultrasound is a reasonable initial screening examination for evaluating potential obstructive bile duct disease, while magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde cholangiopancreatography (ERCP) will better define the underlining pathology. While ERCP remains the gold standard, MRCP in many cases will provide a diagnosis without the attendant risks of pancreatitis and other procedural complications. A recent meta-analysis demonstrated that the sensitivity and specificity of MRCP for demonstrating the presence (99%) and level (96%) of biliary obstruction was excellent, while it was somewhat less sensitive for detecting gallstones (92%) or differentiating benign from malignant (85%) obstruction.

Because of the normal developmental reduction in bile formation in infants, they are susceptible to developing cholestasis in response to a number of conditions which may not cause this in older children and adults. The number of entities which may present in infancy and childhood continues to grow and the reader is referred to a recent review by Bezerra for details regarding presentation and evaluation. A tabulation of the most common diagnoses is presented in Table 2 [3]. Children with PFIC 1 and PFIC 2 have low serum γ-glutamyltransferase (GGT) cholestasis, with elevated serum and low biliary bile acids. Steatorrhea with watery diarrhea is a prominent feature in those with PFIC 1. PFIC 3 should be considered in children with high GGT cholestasis and biliary cirrhosis. The presence of anti-mitochondrial antibodies is characteristic for PBC, while the presence of anti-nuclear (ANA), anti-smooth muscle (SM), or anti-liver-kidney-microsomal (LKM) antibodies may support the diagnosis of autoimmune sclerosing cholangitis. Either MRCP or ERCP may be used to define the biliary structural

**Cholestasis. Table 2** Etiology of neonatal cholestasis

| Clinical form | Cumulative percentage | Frequency (per 10,000 live births) |
|---|---|---|
| Idiopathic neonatal hepatitis | 35–40 | 1.25 |
| Biliary atresia | 25–30 | 0.70 |
| $\alpha_1$-Antityrpsin deficiency | 7–10 | 0.25 |
| Intrahepatic cholestasis (± bile duct paucity) | 5–6 | 0.14 |

abnormalities in PSC; MRCP has been estimated to have a sensitivity of 90% in this setting.

## Therapeutic Principles

Therapy for intrahepatic cholestasis is largely supportive and directed at complications of cholestasis and portal hypertension. The reader is referred to a recent review by Cohran for specific recommendations [4]. Fat soluble vitamin deficiency (A, D, E, and K) should be identified and treated. Infants will benefit from a formula containing medium chain triglycerides. Pruritis can be a debilitating feature of chronic cholestatic disorders; studies have indicated that this may be due to elevated circulating levels of opiods – encephalins. Accordingly, opiod antagonists including naltrexone have been used in some cases with good results. More commonly, some combination of UDCA, antihistamines including hydroxyzine, bile acid sequestering agents such as cholestyramine, or rifampicin are used. Biliary diversion may significantly reduce pruritis and improve clinical outcome for patients with low GGT PFIC. This may then prevent the progression to cirrhosis and need for transplantation. Ursodeoxycholic acid (UDCA) may reduce the severity of several of these disorders, if sufficient biliary enrichment is achieved with this much less toxic hydrophilic bile acid. Replacement with cholic acid may be beneficial in bile acid synthesis disorders. Patients with autoimmune sclerosing cholangitis may benefit from prednisone and/or azathioprine, in addition to UDCA therapy. Fatigue is a common, but poorly understood complaint for which specific therapies are not available. Metabolic bone disease may be treated with calcium and Vitamin D supplementation and bisphosphonates. Hypercholesterolemia commonly complicates the course of some cholestatic disorders, particularly those associated with biliary obstruction. In the future, pharmaceutical agents may become available which will directly target expression of critical transporters such as Mrp3, thereby specifically alleviating cholestasis. Liver transplantation is offered to patients who progress to biliary cirrhosis and liver failure. Palliative therapy for malignant obstructive jaundice may include either transhepatic or endoscopic drainage procedures.

# Cholestasis of Pregnancy, Intrahepatic

Peter L. M. Jansen
Department of Gastroenterology and Hepatology, Academic Medical Center, Amsterdam, The Netherlands

## Synonyms

Icterus gravidarum; Pruritus gravidarum; ICP

## Definition and Characteristics

Pruritus with or without jaundice in third trimester of pregnancy. Elevated serum bile acids, elevated transaminases (ALAT > ASAT) with or without elevated serum bilirubin. The abnormalities promptly normalize after delivery.

## Prevalence

High incidence in Scandinavia and Chile, low incidence in African and Asiatic women. Incidence in Sweden: 100–150/10,000 pregnancies; Chile Caucasians: 1,510; Araucanian Indians: 2,760/10,000 pregnancies; France 20–60/10,000 pregnancies.

## Genes

ABCB4 (MDR3); ATP8B1 (FIC1); ABCB11 (BSEP). In addition to these known genes, unknown genes are involved since only in a minority of established cases of intrahepatic cholestasis of pregnancy (ICP) mutations in one of the mentioned genes are found. ICP can be defined as an autosomal dominant disease since patients with ICP are heterozygous for mutations in any of these genes.

## Molecular and Systemic Pathophysiology

Disturbed hepatobiliary transport of bile salts and/or phosphatidylcholine is the likely cause of ICP. Since the disease occurs in the last trimester of pregnancy, a relation between the disturbed hepatic secretion and estrogens or progestagens is likely. Some metabolites of these hormones (e.g., estradiol 17β-D-glucuronide) are direct inhibitors of hepatobiliary bile salt transport. In addition, interactions of these hormones with nuclear hormone receptors (e.g., pregnane X-receptor) may profoundly influence metabolic pathways in the liver.

The genes associated with ICP encode for hepatic transporter proteins. These genes are also involved in any of the following diseases: benign recurrent intrahepatic cholestasis type 1 (BRIC type 1) and progressive familial intrahepatic cholestasis (PFIC) type 1, PFIC type 3 and low phospholipid-associated cholelithiasis, BRIC type 2 and PFIC type 2 [1–4]. The PFICs are autosomal

recessive diseases; patients usually are homozygous for mutations of the implicated genes.

The pathophysiological background of the increased incidence of fetal distress, premature birth, and stillbirth in ICP has not been clarified yet. Like the mothers with ICP, their fetuses have elevated levels of conjugated cholic acid and chenodeoxycholic acid, and these bile acids might be more toxic to the fetus than the mother.

## Diagnostic Principles

Pruritus, elevated serum bile acid levels with or without jaundice, increased serum bilirubin levels, and elevated serum transaminase activities during the last trimester of pregnancy suggest ICP. In particular, ALAT is a sensitive test for ICP. Pruritus gravidarum most likely is a mild manifestation of ICP. When the cholestasis is severe, steatorrhea may occur with weight loss and clotting abnormalities due to vitamin K deficiency. Alkaline phosphatase activity is not a good parameter since the serum enzyme level is increased during pregnancy. A liver biopsy is usually not indicated. ICP disappears promptly after delivery within 1–2 days. If the cholestasis does not disappear within 4 weeks after delivery, the cause most likely is an underlying chronic liver disease.

ICP has to be differentiated from the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) and from acute fatty liver of pregnancy. The latter is characterized by markedly elevated transaminases, hypoglycemia, encephalopathy, disseminated intravascular coagulation, and a fatty liver on ultrasonography.

## Therapeutic Principles

Close obstetric surveillance, with frequent monitoring of the fetus, is the mainstay of management of these patients. The optimal time of delivery, 38 weeks or full term 40 weeks, has not been defined. There is currently no evidence-based medical therapy. In a small randomized trial, ursodeoxycholic acid therapy (1 g/day in divided doses) has been shown to have a beneficial effect on pruritus and laboratory values [5]. In another small trial, the levels of cholic acid and chenodeoxycholic acid in blood of both mother and fetus were lower in the ursodeoxycholic-acid-treated group than in the untreated group. Ursodeoxycholic acid does not seem to be harmful for the fetus but more data are needed. *S*-adenosylmethionine, phenobarbital, and corticosteroids are not of proved benefit. In case of severe steatorrhea, vitamin K has to be supplemented to prevent bleeding complications both in mother and child during and after delivery.

ICP usually recurs in subsequent pregnancies. Breastfeeding after ICP is not contraindicated since jaundice associated with breastfeeding has another etiology. Oral contraceptives can be started cautiously but should be stopped upon recurrence of pruritus.

# Cholestasis, Benign Recurrent Intrahepatic Type 1

Peter L. M. Jansen
Department of Gastroenterology and Hepatology, Academic Medical Center, Amsterdam, The Netherlands

## Synonyms

Summerskil syndrome; Recurrent familial intrahepatic cholestasis

## Definition and Characteristics

Autosomal recessive disease characterised by relapsing cholestasis with steatorrhea and weight loss.

## Prevalence

Rare.

## Genes

ATP8B1 or FIC1 on chromosome 18q21.

## Molecular and Systemic Pathophysiology

Relapsing cholestasis. The cholestatic episodes usually start around adolescence. The frequency of the episodes is about one to two per year and last 6 weeks -3 months.

At older age the attacks become less frequent. Despite recurrent attacks of cholestasis there is no progression to chronic liver disease. During the attacks the patients are jaundiced and have pruritus, steatorrhoea and weight loss. Despite the cholestasis, the serum gamma-glutamyltransferase is not elevated. Pancreatitis also more often occurs in these patients.

As in PFIC type 1, the gene involved in recurrent familial intrahepatic cholestasis has been mapped to the ATP8B1 gene at the FIC1 locus [1]. PFIC type 1 and BRIC type 1 are autosomal recessive diseases. It should be realised that PFIC type 1 and BRIC type 1 represent two ends of a spectrum with permanent cholestasis at one end and relapsing cholestasis at the other end [2]. In-between patterns may exist depending on the mutation. Mutations that only partially inactivate FIC 1 may cause clinical syndromes with recurrent cholestasis but more or less fibrosis on histology.

## Diagnostic Principles

Characteristic clinical syndrome. Cholestatic laboratory tests with elevated serum bile acids, conjugated bilirubin and alkaline phosphatase but normal serum gamma-glutamyltransferase during cholestatic episodes. Serum bile acids characteristically rise before bilirubin. Normal tests during anicteric intervals. Liver histology shows bland cholestasis during cholestatic episodes and no abnormalities during anicteric intervals.

## Therapeutic Principles

Cholestyramine is used for the treatment of pruritus. Reduction of cholestatic episodes can be attempted with rifampicin or MARS dialysis [3,4]. These therapies are experimental.

# Cholestasis, Progressive Familial Intrahepatic

Peter L. M. Jansen
Department of Gastroenterology and Hepatology
Academic Medical Center, Amsterdam,
The Netherlands

## Synonyms

PFIC type 1 – Byler's disease (Amish population), Greenland familial cholestasis (Inuit population), Byler's syndrome (non-Amish population); PFIC type 2; PFIC type 3; Familial hypercholanemia; Aagenaes syndrome – Lymphedema-cholestasis syndrome

## Definition and Characteristics

Autosomal recessive diseases characterized by progressive neonatal cholestasis and low serum gamma-glutamyltransferase activity (PFIC type 1 and type 2) or elevated serum gamma-glutamyltransferase activity (PFIC type 3). In Aagenaes syndrome serum GGT is normal, in familial hypercholanemia GGT may either be elevated or normal.

## Prevalence

Rare.

## Genes

- PFIC type 1, FIC1/ATP8B1 on chromosome 18q21;
- PFIC type 2, BSEP/ABCB11 on chromosome 2q24;
- PFIC type 3, MDR3/ABCB4 on chromosome 7q21.1;
- Congenital bile acid synthesis defects:
  - 3β-Δ5;5-C27-hydroxysteroid oxidoreductase gene (HSD3B7) on chromosome 16p12-p11;
  - Δ4-3-oxosteroid-5β reductase gene on chromosome 7q32;
  - 7α-hydroxylase gene (CYP7B1) on chromosome 8q21.
- Aagenaes syndrome, a locus on chromosome 15.

## Molecular and Systemic Pathophysiology

Bile acids are the predominant organic solutes in bile. Their vectorial secretion from liver to bile represents the major driving force for bile formation. Disturbances of intrahepatic bile acid transport leads to bile acid accumulation in the liver with as consequence cytotoxic damage of hepatocytes and bile duct epithelial cells, Kupffer cell activation, inflammation and fibrosis. In bile the cytotoxicity of bile acids is neutralized by phospholipids. Disturbed canalicular phospholipid

transport leads to phospholipid-poor but bile acid-rich toxic bile with intrahepatic bile duct(ular) damage as a result. Defective bile acid secretion not only leads to progressive liver damage, but also to malnutrition secondary to reduced intestinal absorption of lipids and fat-soluble vitamins and hemorrhagic diathesis due to vitamin K deficiency.

*Progressive Familial Intrahepatic Cholestasis Type 1*: PFIC type 1 presents with episodes of cholestasis. Liver histology reveals bland cholestasis. Electron-microscopy shows coarse granular bile, called Byler's bile. The disease eventually progresses to permanent cholestasis with fibrosis, cirrhosis and liver failure [1]. Children with PFIC are small for their age, they often are jaundiced and complain of pruritis. They may have diarrhea, pancreatitis and occasionally hearing loss. Characteristically the serum gamma-GT activity is not elevated whilst serum levels of primary bile acid levels are strongly increased. Serum cholesterol levels are usually normal. Benign recurrent intrahepatic cholestasis type 1 is a benign variant of this disease.

*Progressive Familial Intrahepatic Cholestasis Type 2*: Genetic studies revealed that the FIC1 locus is not involved in all patients with a PFIC phenotype and low serum gamma-GT. In a large number of patients (the majority in Europe) the disease was mapped to the ABCB11 (BSEP) gene on chromosome 2q24 [2]. Liver specimens of patients with PFIC type 2 stain negative for canalicular BSEP. As in PFIC type 1, the serum gamma-GT activity in these patients is not elevated and bile duct proliferation is absent. However, there are also some differences: in PFIC2, the disease often presents as non-specific giant cell hepatitis that morphologically is indistinguishable from idiopathic neonatal giant cell hepatitis. In PFIC type 2, the liver histology shows more inflammation than in PFIC type 1, with giant cell transformation, lobular and portal fibrosis. Bile of PFIC type 2 patients is amorphous on transmission electron-microscopy. Extrahepatic manifestations are uncommon. Benign recurrent intrahepatic cholestasis type 2 is a benign variant of this disease.

*Congenital Bile Acid Synthesis Defects*: Defects of bile acid synthesis may phenotypically resemble PFIC type 2. Clayton et al. described a defect of 3β-Δ5-C27-hydroxysteroid oxidoreductase as a cause of giant cell hepatitis [3]. Deficiency of Δ4-3-oxosteroid-5β reductase and 3β-hydroxy C27steroid dehydrogenase/isomerase and mutations of the 7α-hydroxylase gene may be causes of neonatal hepatitis and cholestasis.

*Progressive Familial Intrahepatic Cholestasis Type 3*: The third PFIC subtype, PFIC type 3, is quite different from the other PFIC subtypes. Symptoms present somewhat later in life than in PFIC types 1 and 2 and liver failure also occurs at a later age. Jaundice may be less apparent. The serum gamma-GT activity is usually markedly elevated in these patients and the liver histology shows extensive bile duct proliferation, portal and periportal fibrosis. The MDR3/ABCB4 gene is mutated in this disease [4]. Intrahepatic cholestasis of pregnancy and "low phospholipid associated cholelithiasis" are heterozygous manifestations of ABCB4 gene defects.

*Other Forms of Intrahepatic Cholestasis*: Aagenaes syndrome is a combination of severe progressive lymphedema and episodic intrahepatic cholestasis [5]. The locus for this disease has been mapped to one, or perhaps two loci, on chromosome 15q. Recently, Carlton et al described patients with familial hypercholanemia characterized by elevated serum bile acids, pruritus, fat malabsorption, failure to thrive, rickets and vitamin K-coagulopathy. This disease is associated with a mutation of the tight-junction protein 2 gene (TJP2 or ZO-2) with or without additional mutations in a gene encoding the bile acid coenzyme A:amino acid N-acyltransferase gene (BAAT). Patients with TJP2 mutations have higher GGT serum levels than patients with BAAT gene mutations only. Serum of patients with BAAT mutations did not contain bile acid amino acid-conjugates.

## Diagnostic Principles

Recognition of the clinical syndrome, laboratory tests showing cholestasis, a serum gamma-glutamyltransferase activity that is normal in PFIC type 1 and 2 and elevated in PFIC type 3, and a liver biopsy will reveal the diagnosis. Immune-histochemistry with staining for defective transporters is of limited value. Genetic tests are available in specialized centers. Lymphedema of feet and legs is characteristic of Aagenaes syndrome. Fast bombardment mass spectrometry of urinary bile acids is necessary to diagnose bile acid synthesis defects.

## Therapeutic Principles

Some patients with PFIC type 1 or 2 respond to partial external biliary diversion but others need a liver transplantation. Patients with a MDR3 defect may respond to ursodeoxycholic acid therapy. However, the majority of patients with these diseases have to be transplanted. After transplantation diarrhea may persist in patients with PFIC type 1; in patients with Aagenaes syndrome, the lymphedema will persist.

# Cholesteatoma

Holger Sudhoff
Department of Otorhinolarygology, Head and Neck Surgery, University of Bochum, Bochum, Germany

## Synonyms

Middle ear cholesteatoma

## Definition and Characteristics

Middle ear cholesteatomas are epidermal inclusion cysts of the middle ear or mastoid containing the desquamated debris from the keratinizing squamous epithelium. It is defined as the ingrowth of squamous epithelium into the middle ear compartments and its continued growth that destroys tissues in the middle ear and adjacent structures. The precursors of cholesteatoma may include retraction pockets, adhesive processes and associated crevices, and surgical cavities.

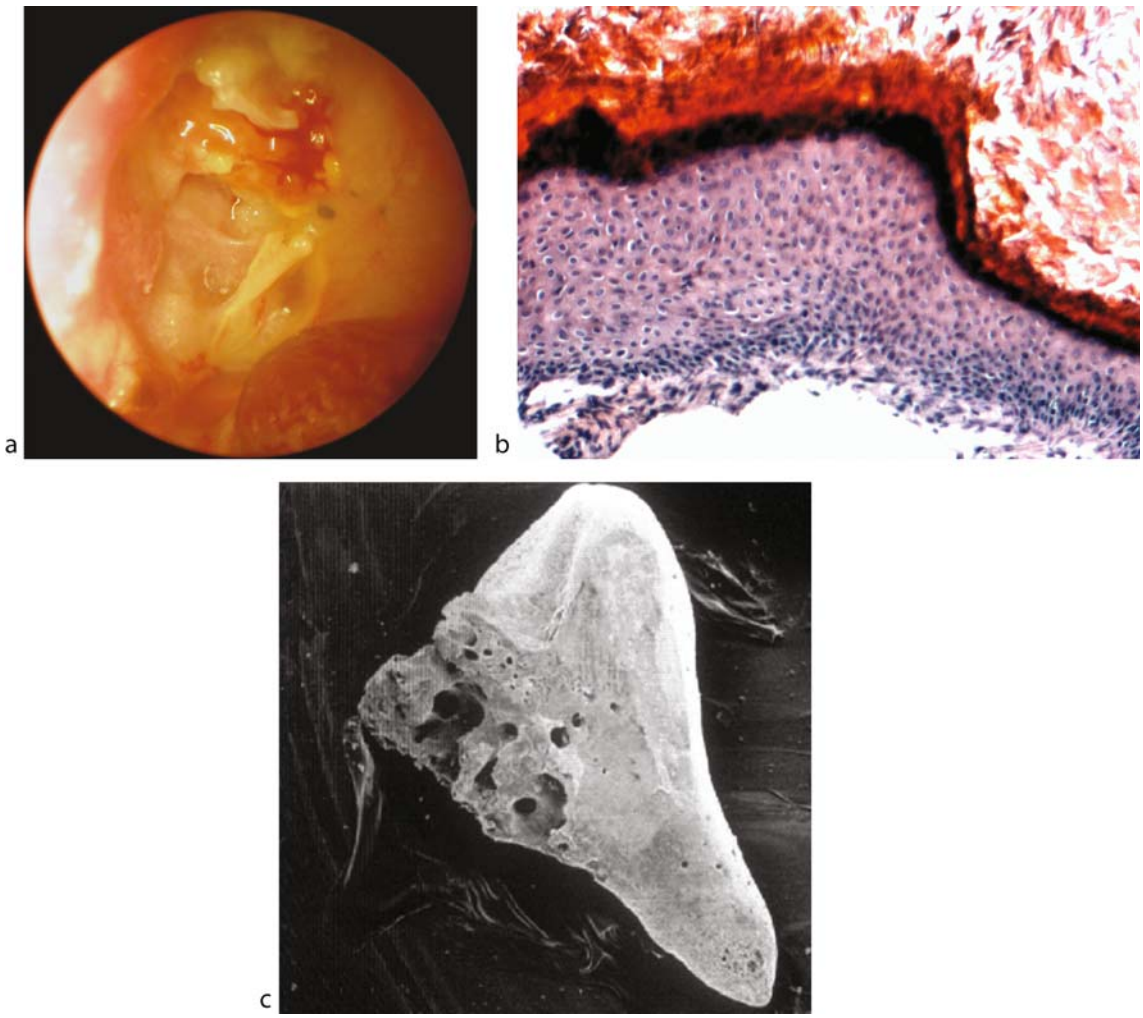
## Prevalence

The exact prevalence of cholesteatoma is unknown.

## Molecular and Systemic Pathophysiology

It is generally accepted that cholesteatomas may be congenital or acquired. Congenital cholesteatomas, by definition, originate from areas of keratinizing epithelium within the middle ear cleft [1]. Michaels and Hellquist showed that a small area in the anterior tympanum in the developing fetus often contains a small area of keratinizing epithelium and found epidermoid formation in 37 of 68 temporal bones of fetuses at 10–33 weeks of gestation [1]. The pathogenesis of acquired cholesteatoma has been debated for more than a century (Fig. 1) [2,3].

There are four basic theories of the pathogenesis of acquired aural cholesteatoma: (i) invagination of the tympanic membrane (retraction pocket cholesteatoma), (ii) basal cell hyperplasia, (iii) epithelial ingrowth through a perforation (the migration theory), and (iv) squamous metaplasia of middle ear epithelium. Recently, Sudhoff and Tos proposed a combination of the invagination and basal cell theories as an explanation for retraction pocket cholesteatoma formation [3]. The expansion of cholesteatoma may result in the bone erosion of the ossicles, otic capsule, facial nerve canal, tegmen tympani, and tegmen mastoideum. These complications may then cause intracranial complications. Erosion of ossicles, most commonly in the incus, may result in conductive hearing loss (Fig. 1c). The severity of hearing loss is related to the status of the ossicles and the position of cholesteatoma sac. Erosion of the otic capsule occurs most commonly in the lateral semicircular canal and rarely in the cochlea. A labyrinthine fistula may be found in up to 10% of cholesteatomas in adults and children. This may result in sensorineural hearing loss and vertigo [4]. Sensorineural hearing loss may result from the secondary suppurative labyrinthitis or from the cochlear hair cell loss adjacent to cholesteatoma. Cholesteatoma is accompanied by a chronic inflammatory process characterized by a progressive growth and by the progressive destruction of epithelial and bony structures of the middle ear. The mechanisms and factors that underlie the hyperproliferative behavior of cholesteatoma epithelium are not yet fully understood [2,3]. Several studies have shown alterations in the proliferation, differentiation, and migration of keratinocytes in the cholesteatoma matrix along with the activation of perimatrix fibroblasts. This process is perpetuated by the accumulation and breakdown of cellular debris on the epithelial side of the squamous epithelium that has invaded the middle ear spaces. Removal of the debris is beneficial, as it creates a site where a number of different factors that induce cholesteatoma growth are synthesized and released. From a surgical standpoint, it is important that the squamous epithelium of the cholesteatoma is basically similar to the epithelium of the external ear canal. If free drainage and free aeration can be established by surgical means, the process will lose its aggressiveness. Hence, there is no objection to using the epithelium to line a mastoid cavity, for example, provided it is free of deep papillary extensions. Growth factors and cytokines play a major role in cellular interactions, especially in the regulation of cell growth and differentiation. An overexpression of various growth factors and cytokines has been described for benign “hyperproliferative” diseases such



**Cholesteatoma. Figure 1** (a) Tympanic membrane showing a pars flaccida or Shrapnell's membrane cholesteatoma (37-year-old patient). (b) Acquired cholesteatoma with keratinizing stratified squamous epithelium. (c) Scanning electron photography showing an eroded incus removed during cholesteaoma surgery.

as psoriasis and for a variety of malignant tumors. The "aggressive" behavior of the cholesteatoma matrix appears to be influenced by the release of cytokines and growth factors from cells of the inflammatory infiltrate within the subepithelial connective tissue [2,3].

## Diagnostic Principles

The diagnosis "cholesteatoma" is made by otoscopy, including endoscopic and microscopic evaluation or surgical exploration. Imaging procedures, apart from routine Schuller's X-ray, such as high-resolution computed tomography (CT) scanning and magnetic resonance imaging (MRI), especially single-shot (SS) turbo spin-echo (TSE) diffusion-weighted (DW) MRI, may suggest the presence of cholesteatomas within the temporal bone and may be used to complete the clinical examination. High-resolution CT scanning is useful for operative planning and is recommended for all revision mastoid operations.

## Therapeutic Principles

The basic goal of cholesteatoma surgery is to remove the squamous epithelium as completely as possible to minimize the risk of recurrence, and secondarily, reconstruction of the middle ear [4,5]. In principle, cholesteatoma is a life-threatening disease because, without surgery, there may be intracranial complications leading to death. The judgment of the operative procedure depends on the nature and extent of disease, the existence of complications, mastoid pneumatization, eustachian-tube function, hearing states of both ears, the

reliability of the patient, and the experience and skill of the surgeon. Surgical approaches include atticotomy, simple mastoidectomy, canal wall-up or canal wall-down procedures, radical mastoidectomy, modified radical mastoidectomy, and Bondy procedure [5]. The open (canal wall down) and the close (intact canal with facial recess) procedures have advantages and disadvantages. The reported results of both procedures are variable. Residual disease and recurrent disease are 11–27% and 5–13% in those undergoing the closed procedure, whereas residual or recurrent disease occurs in 2–10% of those undergoing the open procedure [4]. In the cases of labyrinthine fistula, facial nerve paralysis, and intracranial complications, surgery should be performed as soon as possible. In some patients, a cholesteatoma can be debrided of entrapped keratin by direct removal or by irrigation. Any otosurgical operation, especially cholesteatoma surgery, carries a risk of deafness in the operated ear. Special recommendations apply when surgery is performed on a last-hearing ear [5]. In many cases, a "spontaneous radical cavity" should be smoothed laterally and carefully cleaned. With extensive cholesteatomas, the incudostapedial joint should be divided at an early stage. Unnecessary manipulations of the stapes (e.g., in an effort to improve hearing) should be avoided. When reconstructing the ossicular chain, we use only very safe and proven techniques, such as a classic type III operation with a cartilage plate or stably placed implant [5].

## Synonyms

Lysosomal acid lipase (LAL) deficiency; LIPA deficiency; LAL deficiency; Acid cholesterol ester hydrolase deficiency; Wolman-type; Cholesterol ester hydrolase deficiency, CESD; Cholesteryl ester storage disease; Acid cholesteryl ester hydrolase deficiency, type 2; CESD

## Definition and Characteristics

Cholesterol ester storage disease (CESD, MIM 278000) and Wolman disease (WD) are autosomal-recessive defects of acid lysosomal lipase, resulting in the lysosomal accumulation of triglycerides and cholesterol esters in many tissues [1,2]. In WD, LAL activity is usually absent, whereas CESD usually presents some residual LAL activity.

## Prevalence

By definition, CESD is a lysosomal orphan disease, with a prevalence of <50/100,000. Currently, less than 400 cases have been described in the world literature.

## Genes

Human lysosomal acid lipase is encoded for by the LIPA gene (gene locus 10q24–25). The LAL cDNA consists of 2,626 nucleotides, encoding a protein of 399 amino acids. Currently, more than 50 mutations have been described, being homozygous or being compound heterozygous, including splice junction mutations, missense mutations, deletions, insertions and transitions. A homozygous mutation at position 3 of the exon 8 splice donor site with a C→T transition leads to a nonsense codon and to a premature termination of the LAL protein at amino acid 277. Here the protein synthesis proceeds to the natural termination codon, but the enzyme generated has an internal deletion of 24 amino acids (254–277). L336P, another variant, appears to be associated with a phenotypically mild form of CESD. In HeLa cells, four major molecular forms, at least two of high molecular mass (54 and 50–51 kDa) and two of low molecular mass (42 and 43 kDa), were identified. It is assumed that post-translational processing interferes with the catalytic activity of LAL. The more severe course of WD is caused by genetic defects of LAL that leave no residual enzymatic activity.

## Molecular and Systemic Pathophysiology

Human lysosomal acid lipase/cholesteryl ester hydrolase (hLAL, EC 3.1.1.13) is essential for the intralysosomal metabolism of cholesteryl esters and triglycerides taken up by receptor-mediated endocytosis of lipoprotein particles. The enzyme has been purified to apparent homogeneity from human liver [2]. It is a monomer of 42 kDa. It is most active at low pH (4.5–5.0) and shows Asn-linked glycosylation with high-mannose oligosaccharides. Deglycosylation of normal LAL reduces the acid hydrolase activity towards both trioleyl glycerol and cholesteryl oleate significantly, suggesting that N-linked carbohydrate residues have a role during biosynthesis of the enzyme. However, carbohydrates are not required for LAL activity. Hepatic LAL differs from fibroblast acid lipase at the N-terminus and shows extensive similarities with human gastric lipase and rat lingual lipase, confirming a gene family of acid lipases. Expression of LAL mRNA is most abundant in brain, lung, kidney and mammary gland, while liver and heart show low levels of expression. Intracellularly, LAL hydrolyses exogenous triacylglycerides and cholesteryl esters. The LAL null (lal(–/–))mouse mimics aspects of human WD and CESD [3].

## Diagnostic Principles

Poor weight gain, massive hepatomegaly, calcified adrenal glands, vomiting, diarrhea and failure to thrive are indicative of Wolman disease. The clinical picture is more unspecific in CESD, with hepatomegaly often being the only symptom (Table 1). The bone marrow may show lipid-laden foam cells, e.g. sea-blue histiocytes [4], storage macrophages, which must be differentiated from Gaucher or Pseudo-Gaucher cells. Lipids in the plasma are normal or only slightly elevated. In CESD, total cholesterol and LDL cholesterol are increased, HDL cholesterol is decreased and triglycerides are slightly elevated. Many organs show a massive increase in cholesterol esters and the hepatic or leucocyte LAL activity is reduced (CESD) or almost absent (WD). Sometimes, CESD is associated with mesenteric lipodystrophy [4]. In a subset of CESD patients, cirrhosis and sequelae of portal hypertension develop.

## Therapeutic Principles

Treatment of WD is supportive, but does not affect the lethal outcome. Current therapy of CESD consists of a low-fat diet and lipid-lowering drugs like lovastatin and cholestyramine. Single reports show an increased efficacy by adding ezetimibe to the statin compound. Patients with decompensated liver cirrhosis may require liver transplanation, with reasonable success. Recently, adenoviral vectors containing human LAL cDNA (Ad-hLAL) were injected intravenously into lal(–/–) mice. Compared with phosphate-buffered saline-injected controls, the mice receiving Ad-hLAL had

**Cholesterol Ester Storage Disease/Wolman Disease. Table 1** Characteristics of CESD and Wolman disease

| Cholesterol ester storage disease | Wolman disease |
|---|---|
| LAL activity decreased | LAL activity almost absent |
| Diagnosis in adults | Diagnosis in newborns, failure to thrive |
| Hypercholesterinemia | – |
| Asymptomatic hepatomegaly, subset of patients develop cirrhosis | Symptomatic hepatomegaly |
| Premature coronary artery disease | Adrenal calcifications |
| GI symptoms infrequent | Diarrhea, steatorrhea |
| Benign course | Early death within first year of life |
| Symptomatic treatment | Fatal outcome despite supportive treatment |

increased hepatic LAL activity, decreased hepatomegaly, and a partial normalization of hiscathology. Human LAL protein and mRNA were detected by immunohistochemical staining and in situ hybridization in hepatic parenchymal and sinusoid lining cells, splenic sinusoidal cells, lung macrophages, and adrenal cortical cells. Mice showed TG reductions in liver, spleen, and small intestine of 68, 54, and 50%, respectively, and cholesterol reductions of 55, 52, and 34%, respectively, at 20 days postinjection [5].

## Synonyms

Grebe type chondrodysplasia; Hunter-Thompson type and DuPan syndrome; Acromesomelic chondrodysplasia

## Definition and Characteristics

Autosomal recessive defect producing disproportionate short limbs, short stature, and appendicular bone dysmorphogenesis with normal craniofacial and axial bones.

## Prevalence

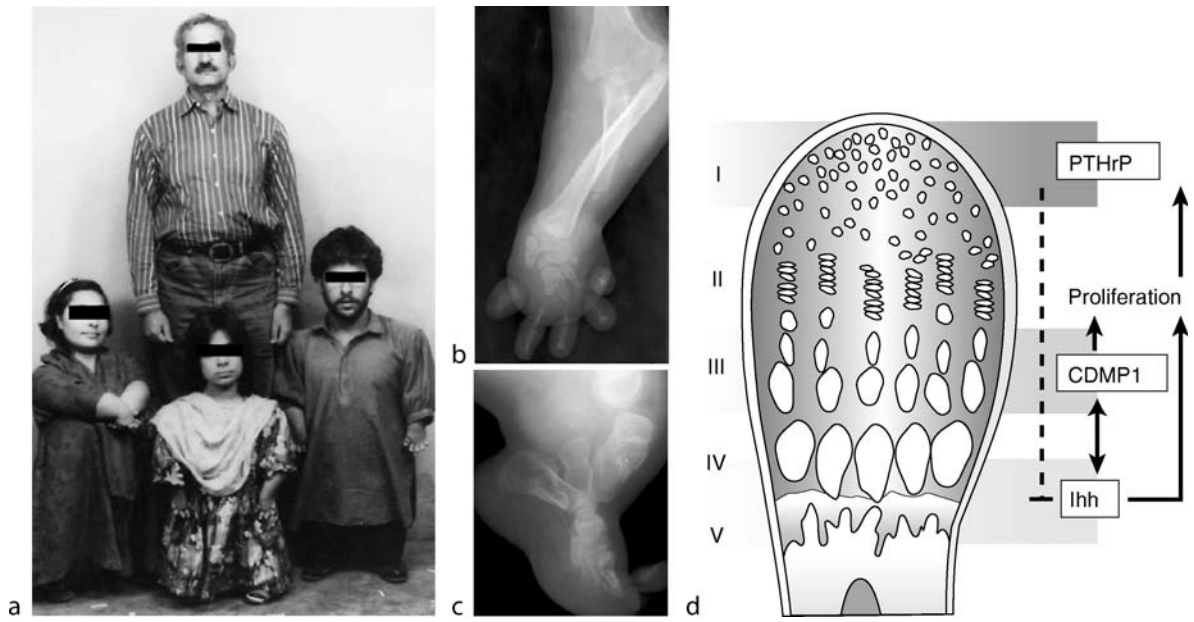
Affected individuals have been reported from Asian, European and Brazilian populations.

## Genes

Cartilage Derived Morphogenetic Protein-1 (CDMP1) gene on chromosome 20q11.2. Also described as Growth/Differentiation Factor 5 (GDF5).

## Molecular and Systemic Pathophysiology

Grebe type chondrodysplasia is characterized by defects in the appendicular and long bone chondrogenesis with severe reduction or aplasia of bones and loss of normal condylor tuberosity (Fig. 1a–c). During the longitudinal growth of bone in endochondral bone development, the terminal hypertrophic cartilage is constantly replaced with the newly formed bone. In this process, in the growth plate of developing bone, differentiation of columnar chondrocytes into non-proliferating hypertrophic cells is controlled by parathyroid hormone (PTH), PTH-related protein (PTHrP), indian hedgehog (Ihh) and bone morphogenetic proteins [1], Fig. 1d. The tight regulation of this pathway is critical for a balanced growth and ossification of the developing bone. Cartilage derived morphogenetic protein1 (CDMP1), also known as growth/differentiation factor-5 (GDF5) is closely related to the bone morphogenetic protein signalling molecules of the transforming growth factor-beta super family. This protein plays an important role in chondrogenesis, growth and patterning of the developing bones [2]. It is predominantly expressed at the stages of precartilaginous



**Chondrodysplasia, Acromesomelic, Resembling Grebe-Type. Figure 1** Grebe Type Chondrodysplasia. (a) Phenotype of affected individuals is compared with a person of normal stature. (b and c) Radiographs of hand (*A/P view*) and feet (*lateral view*), respectively. (d) Sketch showing the developing growth plate of a long bone. Areas exhibiting the PTHrP, Ihh and CDMP1 expression are shaded. Various stages of skeletal morphogenesis show resting (I), proliferating (II), prehypertrophic (III), hypertrophic (IV), and apoptotic (V) chondrocytes.

mesenchymal condensation and throughout the cartilaginous matters of the developing long bones [2]. In mice lacking GDF5, and its closely related member, GDF6, defects resembling the human Grebe type chondrodysplasia were observed [3]. Mutations in the CDMP1 gene have been reported in persons affected with the Grebe type chondrodysplasia, DuPan syndrome, acromesomelic chondrodysplasia of the Hunter-Thompson type and autosomal dominant brachydactyly type C [1]. These mutations result in functionally defective CDMP-1 proteins that produce skeletal abnormalities by altering the normal pattern of chondrogeneis in developing appendicular and long bones.

## Diagnostic Principles

The Grebe, Hunter-Thompson and DuPan types of acromesomelic chondrodysplasia are related disorders, which share a spectrum of phenotypic abnormalities and mutations in the CDMP1 gene. Affected individuals are of normal intelligence and exhibit appendicular bone dysmorphogenesis with unaffected axial bones, reduction or absence of bones in limbs, small non-functional free-rotating knob like digits on hands and feet and occasional preaxial polydactyly. The severity of defects increases from proximal to distal extremities. The carrier heterozygous parents are phenotypically normal with some exceptions where mild digital anomalies like brachydactyly, polydactyly and malpositioning are noticed.

## Therapeutic Principles

None available.

# Chondrodysplasia, Blomstrand Lethal

Caroline Silve
Unité Inserm, Paris, France

## Definition and Characteristics

Autosomal recessive chondrodysplasia characterized by early lethality, accelerated chondrocyte differentiation and advanced endochondral bone maturation.

## Prevalence

Very rare (<20 cases described).

## Genes

PTHR1 gene, coding for the receptor for both parathyroid hormone (PTH) and parathyroid hormone-related protein (PTHrP) (also referred to as PTHR1, or PTH/PTHrP receptor), localized on chromosome 3p22–21.1.

## Molecular and Systemic Pathophysiology

Blomstrand chondrodysplasia is associated with homozygote or compound heterozygote inactivating mutations in the PTHR1 gene. PTHR1 belongs to the class B family of seven putative transmembrane domain G protein-coupled receptors. It is equipotently activated by PTH and PTHrP, and stimulates at least two distinct second messengers, cAMP/PKA and IP3/$Ca^{2+}$/PKC. It is expressed at a high level in the kidney, bone and growth plate, and at lower levels in a large variety of other tissues. During post-natal life, it plays a key role in the regulation of calcium and phosphate ion homeostasis by mediating the PTH endocrine actions in bone and kidney. During fetal life, it plays a key role in endochondral bone formation by mediating the PTHrP-dependent autocrine/paracrine regulation of chondrocyte growth and differentiation. Its activation, presumably through cAMP-dependent mechanisms, stimulates the proliferation of the fetal growth plate chondrocytes, and inhibits their differentiation into hypertrophic chondrocytes. Thus, the absence of functional PTHR1 is associated with a profound acceleration of growth plate mineralization due to a dramatic acceleration of chondrocyte differentiation. These growth plate abnormalities are, in many aspects, the opposite of those found in Jansen metaphyseal chondrodysplasia, which is associated with dominant heterozygote activatory mutations in the PTHR1 gene. The cause of lethality in Blomstrand chondrodysplasia is attributed to the defect in skeletal development, although abnormalities in the cardiovascular development have been described in mice models.

## Diagnostic Principles

Severe skeletal dysplasia (usually very short stature and micromelia of the four limbs) macroglossia, and hydramnios on ultrasonography; shortness of the long bones and advanced skeletal maturation on radiographs; reduction of the epiphyseal cartilage, thickening of cortical bone, widened metaphysis, and narrowed diaphysis on osteochondral histology, with no major abnormalities of the viscera. Detection of mutations in the PTHR1 gene confirms the diagnosis of this rare disease.

## Therapeutic Principles

No treatment available.

Piero Pavone[1], Rosario Rich Trifiletti[2]
[1]Department of Pediatrics, University of Catania, Catania, Italy
[2]Department of Pediatrics and Neurology, Morristown Memorial Hospital Atlantic Health System, Morristown, NJ, USA

### Synonyms

St. Vitus' dance; Acute chorea; Chorea minor; Rheumatic chorea

### Definition and Characteristics

Sydenham's chorea is a neurologic movement disorder characterized by irregular, abrupt, relatively rapid, involuntary movements of the muscles of the face, neck, trunk, arms, and legs. Additional findings often include diminished muscle tone (hypotonia), muscle weakness, and emotional and behavioral disturbances, particularly obsessive–compulsive behaviors. Sydenham's chorea most frequently occurs in children or adolescents between the ages of 5 and 15 following an episode of acute rheumatic fever (ARF). ARF is an inflammatory disease that develops subsequent to infection of the pharynx with certain strains of streptococcal bacteria (i.e., group A beta-hemolytic streptococci).

In patients with Sydenham's chorea, choreic movements usually begin gradually and progressively worsen over a few weeks to a month. Associated findings may be extremely variable, ranging from relatively mild incoordination to severe disruption in conducting voluntary movements of multiple muscle groups, potentially affecting speech, arm movements, walking, and the ability to perform certain activities of daily living. In some patients, Sydenham's chorea may be a self-limited condition, usually resolving spontaneously within an average of nine months to approximately two years in 50% of patients; therefore, treatment with certain medications may be restricted to patients with significantly impaired function resulting from severe chorea.

### Prevalence

The prevalence of Syndeham's chorea is 0.2–0.8/100,000 in the general population. The frequency of ARF dramatically declined in the USA and Western Europe during the 1960s and 1970s. However, for unknown reasons, the frequency of ARF has recently been increasing in the USA and Western Europe.

### Molecular and Systemic Pathophysiology

Sydenham's chorea is considered the prototype for disorders in which an infectious agent (i.e., group A β-hemolytic streptococcal infection) triggers an autoimmune disorder that, in turn, causes a variety of neuropsychiatric symptoms. Sydenham's chorea has a clearly defined association with ARF and with a preceding group A β-hemolytic streptococcal infection, a connection between the two was described over 50 years ago. Members of certain families appear to have an increased risk of ARF and rheumatic heart disease. In addition to possible hereditary factors, certain environmental factors, including overcrowded living conditions and malnutrition, are also thought to play a role in increasing susceptibility to streptococcal infections, as well as the risk of subsequent ARF. Also, as mentioned previously, some investigators have suggested that sex hormones (e.g., the female hormone estrogen) may be a contributing factor in some instances of Sydenham's chorea. This is based upon various findings, including the fact that females are

more commonly affected than males, particularly in the years around puberty, and that recurrences have been associated with estrogen therapy or pregnancy.

The specific underlying mechanism(s) responsible for the of ARF remains unknown. However, evidence suggests that the disorder may result from an abnormal immune reaction in which antibodies produced in response to the invading bacterium act against certain of the body's own cells. Husby et al. [1] found anti-brain, specifically human caudate and subthalamic nucleus, antibodies in 46% of sera of children with rheumatic chorea, but only 1.8–4% of children with unrelated conditions. Moreover, these serum antibodies were absorbable with cell wall preparations from group A, but not group D streptococci. This landmark study lead to the concept of "molecular mimicry," with direct cross-reactivity between group A β-hemolytic streptococcal infection surface antigens and brain as the model for explaining the pathology in Sydenham's chorea. Several other laboratories have since confirmed these findings. Bronze and Dale [2] demonstrated that the streptococcal M protein, specifically Type 6 and to a lesser extent Types 5 and 19, most likely accounted for the cross-reactivity. In another study, researchers determined that, during acute attacks, 80% of patients with ARF had antibodies against cardiolipin (anticardiolipin antibodies). Furthermore, some researchers have reported detection of certain antibodies (e.g., immunoglobulin G [IgG] antibodies) in children with Sydenham's chorea that interact with certain cellular proteins (i.e., neuronal antigens) in the basal ganglia, such as the caudate nuclei and subthalamic nucleus. Abnormalities in cellular immunity have also been described. D8/17 is a monoclonal antibody directed non-HLA B-lymphocyte alloantigen which was created by immunizing mice with lymphocytes from patients with rheumatic fever. D8/17 positive lymphocytes are clonally expanded in individuals with rheumatic fever or rheumatic heart disease as compared to controls. Although the measurement of D8/17 has been of limited use clinically and is not yet commercially available, it is of considerable theoretical interest, as it has been determined in a number of patients with PANDAS and PANDAS variants [3].

As mentioned above, Sydenham's chorea appears to result from an autoimmune or antibody-mediated inflammatory response involving certain regions of the basal ganglia. Experts indicate that the results of certain neuroimaging studies may provide further information concerning the underlying disease processes (i.e., pathophysiology) involved in Sydenham's chorea. For example, such studies have demonstrated abnormally increased metabolism (hypermetabolism) in certain regions of the brain, findings that may reflect the autoimmune process. More specifically, positron emission tomography (PET) scanning has shown increased glucose metabolism within major substructures of the basal ganglia (i.e., the striatum), a finding that was reversed with clinical improvement. This is in marked contrast to Huntington's disease (HD), and other hereditary forms of chorea, in which PET demonstrated decreased glucose and oxygen metabolism. In addition, magnetic resonance imaging (MRI) of patients with Sydenham's chorea has shown an abnormally increased size of the three major substructures that form the basal ganglia, including the caudate nuclei, the globus pallidus, and the putamen, possibly providing evidence of an inflammatory process.

## Diagnostic Principles

A diagnosis of Sydenham's chorea is primarily based upon a thorough clinical evaluation (i.e., the Jones criteria), detection of characteristic symptoms and findings, and a careful patient history.

*Major criteria*: carditis, polyarthritis, chorea, subcutaneous nodules, and erythema marginatum.

*Minor criteria*: (i) previous episode of rheumatic fever or rheumatic heart disease; (ii) arthralgia; (iii) fever; (iv) elevated erythrocyte sedimentation rate, elevated C-reactive protein, or leukocytosis; and (v) prolonged PR interval on an electrocardiogram.

## Therapeutic Principles

Adequate antibiotic therapy for children with streptococcal infections may help to prevent the onset of an initial attack of ARF. More specifically, such preventive therapy (i.e., primary prophylaxis) introduced up to approximately one week after the onset of streptococcal pharyngitis can prevent the onset of ARF. In other cases, the most sophisticated treatment with intravenous immunoglobulins or plasmapheresis can be useful.

# Chorea, Benign Hereditary

Friedrich Asmus
Dystonia Genetics Unit, Department of Neurodegeneration, Hertie-Institute for Clinical Brain Research, Tuebingen, Germany

## Synonyms

BHC; Hereditary progressive chorea without dementia; Benign familial chorea; Choreoathetosis with hypothyroidism and respiratory distress; Brain-thyroid-lung-syndrome

## Definition and Characteristics

Benign hereditary chorea (BHC) (MIM #118700) is a rare movement disorder characterized by childhood-onset chorea with predominance in neck and limbs, delayed motor development and pyramidal signs in some patients. In contrast to neurodegenerative choreas, BHC lacks the continuous progression of symptoms and the inevitable severe cognitive decline of Huntington's disease. In some patients choreoathetosis even improves in adulthood.

The existence of BHC as a separate disease entity has been questioned until the cloning of the first BHC gene, the thyroid transcription factor 1 (Titf-1), a homeobox transcription factor, involved in midbrain, thyroid and lung development [1]. However, BHC is a genetically heterogeneous disorder. Titf-1 mutations have neither been described in adult-onset BHC nor in "senile" chorea patients.

## Prevalence

Benign hereditary chorea is a very rare movement disorder. The exact prevalence of BHC caused by Titf-1 mutations remains to be elucidated. Since 2002 [1], only 19 different mutations have been described worldwide.

## Genes

Initially, in four different families with autosomal-dominant BHC linkage to a candidate region on the long arm of chromosome 14 could be detected [1]. The candidate region could be narrowed down by the observation of a lack of transmission of the maternal allele of marker D14S1017 in one family. By FISH analysis, a 1.2 Mb, heterozygous genomic deletion around this STR marker could be observed. This deletion included the Titf-1 gene. Mutations in this gene could be found to segregate with BHC in three additional families with typical infancy-onset, non-progressive chorea and linkage to chromosome 14q13.3 [1].

The thyroid transcription factor 1 (Titf-1, Nkx2.1) gene spans a 3.8 kb interval and consists of three exons. By the alternative use of start codons in exon 1 and exon 2 (see Fig. 1) two different isoforms are transcribed, which differ in 30 amino acids (371 or 401 amino acids, respectively).

The Titf-1 gene belongs to the Nk-2 homeobox family. It harbors three typical domains: the tinman-like domain (TN) in exon 2, the homeobox domain for binding to the target site and the Nk-specific site for the activation of a Titf-1 specific subset of genes. All mutations detected to date are heterozygous. Missense mutations reside only in the homeobox domain (V205F, W208L and R213S). Nonsense mutations are scattered over exon 2 and exon 3 (see Fig. 1).

Within different point mutations no clear genotype-phenotype correlations can be observed in respect of symptom severity or organ specificity.

In patients with large heterozygous deletions in the 14q13 region including the gene for Pax9, Nkx2.8 and MBIP, the phenotype appears to be more complex but also highly variable with additional clinical features like ataxia, microcephaly, a cystic mass in the sella turcica, hypodontia, hypoparathyroidism or osteoporosis [2].

Every pedigree appears to have its 'private' mutation and in over one third of patients (7/19), mutations of Titf-1 have occurred de novo.

## Molecular and Systemic Pathophysiology

Insight into the molecular pathophysiology of BHC can be obtained from the clinical phenotype and brain pathology in human as well as from the murine Titf-1 knockout model.

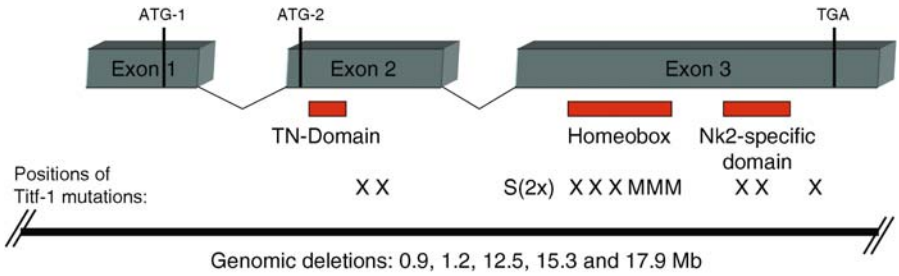
In all patients Titf-1 mutations have been proposed to be heterozygous null mutations, suggesting haploinsufficiency to be the major mutational mechanism.

In Titf-1 knockout mice a ventral to dorsal transformation of the basal forebrain, altered tangential migration of certain striatal interneurons from the medial ganglionic eminence to the precursor of the striatum as well as alterations in pituitary, lung and thyroid gland were observed. These mice die at birth.

In two brains of Titf-1 mutation carriers no gross morphological abnormalities could be observed. However, in these patients the reduction of striatal interneurons and the reduced densities of striatal efferent fibers, parallel the alterations in mice and fit in the picture of a dysregulation of the basal ganglia resulting in choreatic movements.

## Diagnostic Principles

BHC should be suspected in patients with early onset, non-progressive chorea, if routine laboratory testings are not indicative of other forms of acquired or inherited chorea. Neuroacanthocytosis can be excluded, if blood smears are unremarkable and creatin kinase



| Exon 2 | | Intron2 | Exon 3 | | | |

| | | | W208L | M | 859insC | x |

**Chorea, Benign Hereditary. Figure 1** Titf-1, the gene for the thyroid-transcription factor 1 (Nkx2.1) has three exons. Alternative use of two different ATG's in exon 1 and exon 2 leads to two isoforms, which differ in 30 amino acids at the N-terminus. 19 different heterozygous point mutations including five large genomic deletions of the Titf-1 gene have been reported in patients with benign hereditary chorea or more complex syndromic phenotypes (X, nonsense mutation, M- missense mutation, TN-domain, tinman-like decapeptide domain of homoebox proteins, Homeobox (domain) and Nk2-specific c-terminal domain).

measurements are normal. In BHC alpha-fetoprotein measurements and urine copper excretion are within normal ranges. In patients with a history of dominant, progressive chorea or dubious clinical history in first degree relatives genetic testing for Huntingon's disease is recommended.

Strong clinical evidence for Titf-1 mutations in BHC can be obtained by abnormal thyroid state or perinatal and childhood-onset respiratory distress with repeated pneumonias [1,3].

Brain MRI in BHC is most often normal, although unspecific structural abnormalities like T-2 hyperintensities in vermis and basal ganglia have been reported in two patients [3,4].

Criteria for clinically differentiating BHC from hyperkinetic dystonias like Myoclonus-Dystonia have been proposed, recently [6].

## Therapeutic Principles

Recommendations for treatment in BHC can be only based on the review of case descriptions in genetic studies of several pedigrees or index patients. Chorea has been reported to be improved by antipsychotics like chlorpromazine, haloperidol, by benzodiazepines or by tetrabenazine. In two pedigrees with Titf-1 mutations positive effects of levodopa, anticholinergics [5] or methylphenidate [2] were reported.

A rigorous assessment of the thyroid state is mandatory; especially if thyroid parenchyma is absent or if thyroid gland volume is reduced on ultrasound examination. Children with borderline cognitive abilities should be referred to specialized educational units.

# Choreoathetosis with Hypothyroidism and Respiratory Distress

►Chorea, Benign Hereditary

## Chorioretinitis

►Uveitis

## Choroidal Sclerosis

►Choroideremia

## Choroideremia

Petra Weckerle
University Eye Hospital Tuebingen, Tuebingen, Germany

### Synonyms

Progressive tapetochoroidal dystrophy; Choroidal sclerosis

### Definition and Characteristics

Choroideremia is a rare X-linked recessive dystrophy of the choroidea, pigment epithelium and retina.

In the first two decades of life, affected males develop night blindness. The pigment epithelium is mottled in the beginning. Then the choriocapillaris, the retinal pigment epithelium and the photoreceptors become atrophic, beginning around the optic disc and the equatorial region. Later on, choriocapillaris and retina show a diffuse, progressive dystrophy, spreading from the periphery centrally (Fig. 1).

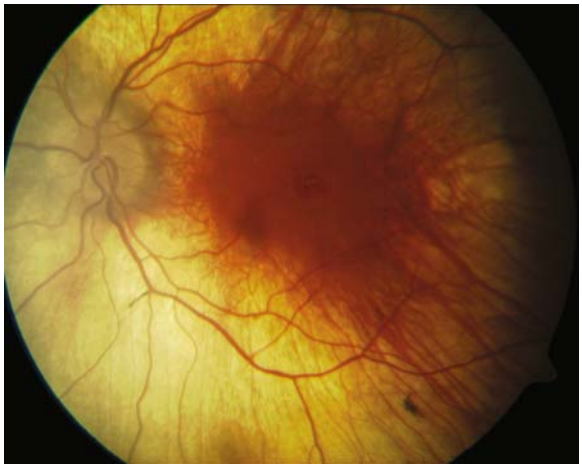
In advanced stages the choroidal vessels become atrophic, the sclera can be seen.

Initially central vision is normal. Visual field defects develop first in the mid-periphery, leading to tunnel vision. At age 40–50, when the dystrophic areas reach the macula, central vision declines and further progression leads to total blindness of the patients.

Female carriers are asymptomatic but can have fundus changes. The electro-retinogram shows a normal photoreceptor function.

### Prevalence

Rare disorder, incidence 1:100,000



**Choroideremia. Figure 1** Fundus picture of right eye of a progressed choroideremia.

### Genes

The CHM gene on chromosome Xq21.2 consists of 15 exons and encodes for the 653 amino acids polypeptide Rab protein geranylgeranyltransferase component A 1, now termed Rab escort protein-1 (REP-1). Virtually, all known mutations in CHM result in the truncation and therefore functional loss of the CHM gene product, REP-1 [1].

### Molecular and Systemic Pathophysiology

The Rab-geranylgeranyl- transferase is a holoenzyme consisting of component A and B. It attaches (3) H-geranylgeranyl residues to cysteine residues of RabGTPases, in particular Rab27A [2]. RAB proteins are small GTP-binding proteins that play a role in organelle formation and trafficking of vesicles in exocytic and endocytic pathways. Rab escort protein-2 (REB-2), a protein that is functionally similar to REP-1, may compensate for the loss of REP-1 function in all but the retinal cells of an individual with choroideremia [3].

Larijani et al. [4] showed that the REP-1-Rab27A complex was prenylated more efficiently in vitro than the REP-2-Rab27A complex. GDP-bound Rabs are the preferred substrate for REPs, whereas Rab27A was shown to have a slower rate of intrinsic hydrolysis compared to other Rabs. A two-fold mechanism underlying CHM is therefore proposed:

1. Rab27A relies solely on prenylation by the already less efficient REP-2.
2. The innately slower GTP hydrolysis of Rab27A results in a higher proportion of the inactive form of this molecule which is unable to bind REPs.

Alternatively, Rak et al. [5] demonstrated that Rab7 successfully out-competed Rab27A in vitro for prenylation and proposed that when REP-1 function is lost, all prenylation function is provided by REP-2; however,

Rab molecules with a higher affinity for REP-2 compete with Rab27A for prenylation.

### Diagnostic Principles

Diagnosis of choroideremia is based on the ophthalmologic examination, including funduscopy, fluorescent angiography, perimetry, and electrophysiological examinations, i.e., electro-retinogram and electro-oculogram.

### Therapeutic Principles

In the absence of causal therapy, the treatment of choroideremia includes dark or special filter glasses, low vision aids, including optical, electronic, and computer-based devices, and occupational aids. Surveillance includes regular ophthalmologic examination. To avoid additional light damage to the retina, appropriate protective (dark) glasses in bright light are recommended.

## Chromosome 13q14 Mutations

Gesa Schwanitz, Barbara Busert
Institute of Human Genetics, University of Bonn, Bonn, Germany

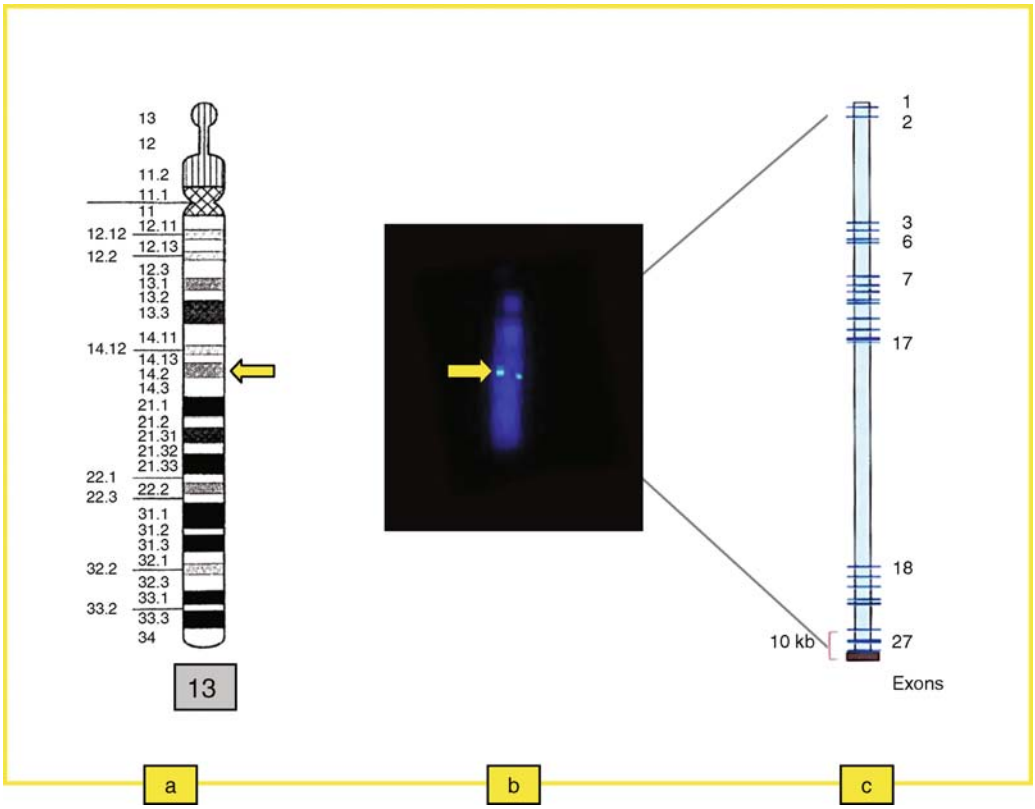
### Definition and Characteristics

The acrocentric satellite carrying chromosome has a relative length of 3,74 (in percentage of the total haploid autosome length) and a centromere index of 17,08 (length of the short arm divided by total chromosome length × 100) (Fig. 1). The physical length is about 114 Mb. In 13q13.2 and in 13q21 common fragile sites are localized, which do not predispose, according to our present knowledge, to the formation of structural aberrations [1–3].

The total short arm is heterochromatic and consists of four different regions of repetitive DNA (Fig. 1a) in the region p12, the nucleolus organizer region (NOR), RNA is synthesized and different nuclear functions are regulated.

### Prevalence

*Rb1*: prevalence: 1:20,000, (Germany). Incidence: 18,000.
*Head-neck-tumor*: prevalence: 10/100,000 (Germany), incidence: 2–20/100,000 (increasing frequency; age, sex and ethnic differences).
*MM*: prevalence: 3–4/100,000 (Germany), incidence: 2–4/100,000 (age and ethnic differences).
*Osteosarcoma*: prevalence: 2–3/1,000,000 (Germany), incidence: 2–3/1,000,000.



**Chromosome 13q14 Mutations. Figure 1** 13q14 as presented by conventional banding techniques, FISH, and molecular genetic analysis. (a) Ideogram of chromosome 13 at a resolution of 850 bands per genome. (b) Hybridization of the region 13q14 (green signal, 600 kb) by a commercial DNA-probe; (Abbot/Vysis). (c) The exon/intron structure of the Rb1 gene with 27 coding regions. The euchromatin of the long arm consists preferentially of AT-rich regions and is therefore late replicating in the S-phase of the cell cycle in meristematic cells.

## Genes

Passage through the cell cycle is regulated by the so-called tumor suppressor genes. In the region 13q14 (subband q14.2; Fig. 1b) one of these genes, the retinoblastoma gene (Rb1) could be localized. Rb1 is a large gene with 27 exons, spanning more than 200 Kb (Fig. 1c). The product of Rb1 is a phosphorprotein which suppresses the transition of G1- to S-phase in the cell cycle by inhibiting E2F. This factor is responsible for the transactivation of a number of genes which initiate DNA-synthesis. If the phosphorylated Rb is inactivated and cannot react with E2F, then the cell can enter the S-phase. Interleukin-6 changes pRb from the dephosphorylated into the phosphorylated form and thus stimulates the growth of tumor cells. Mutations in tumor suppressor genes are usually recessive, meaning that one normal allele is sufficient for the normal function of the gene. Therefore, the loss of heterozygosity (LOH) requires a second mutation in the normal allele or in a second tumor suppressor gene which is assumed to be localized distal of q14 on the long arm of chromosome 13.

Some of the mutations in the Rb1 gene are gross deletions and translocations, but the majority are point mutations of submicroscopic deletions and insertions, which lead to a premature truncation of the protein product. In addition, missense and splicing mutations have been identified, but in general, no clear genotype-phenotype correlation can be delineated. In cases of hereditary cancer, including mutations in 13q14, molecular genetic investigations, relatives at risk are recommended and permitted preventive therapy [2].

## Molecular and Systemic Pathophysiology

Retinoblastoma is a malignant embryonal tumor originating from a mutation in 13q14, which leads to changes in the retina. It can develop prenatally. The majority of cases are diagnosed between birth and

4 years of age, though the incidence of the tumor is $2 \times 10^{-4}$. About 60% of the cases occur de novo in the patient, in 40% a familial disposition exists. Sporadic cases are more often unilateral and unifocal. Early diagnosis can differentiate between uni- and multifocal cases. The evolution of the tumor can lead to an involvement of the N. opticus and the brain. Metastases have been observed in bone narrow, lymph nodes and liver. Early diagnosis and therapy can prevent the fatal course of the disease and even preserve vision. Systematic controls are necessary as a second, independent tumor can develop at a different site of the same or the other eye. Knudson developed the model of the "two hit hypothesis" for the formation of the tumor. In hereditary cases only a second somatic mutation is required in the patient, whereas two independent somatic mutations are necessary in sporadic cases. Because of this "two hit hypothesis" the frequency of carriers of retinoblastoma in descendents of a patient varies. The analysis of data from a large number of carriers by Carlsson and Desnik made it obvious that mutation mosaics also play an important role in the origin of retinoblastoma. Ontogenetic studies in the novo cases showed that the time and cell type of mutation influences the expression of the tumor [2].

## Diagnostic Principles

*Investigation methods*: Chromosome aberrations are nowadays characterized by a combination of conventional banding techniques (GTG, QFQ, RBA) with molecular-cytogenetic analyses as Fluorescence in situ hybridization (FISH) by applying single copy probes, with multiplex FISH (M-FISH; SKY), and comparative genomic hybridization (CGH), or by molecular genetic methods such as microsatellite typing of DNA sequencing.

*Constitutional chromosome aberrations*: The most frequent structural aberration in man (RT 13/14) is a centric fusion in the heterochromatic short arm region. Regarding the eurochromatic long arm of chromosome 13, structural aberrations show an unequal intrachromosomal distribution, with a majority (about 21%) of aberrations in 13q14, followed by 13q22, q12 and q32. All these regions are GC-rich bands [3].

*Aberrations in cancer*: Deletions and, in a lower frequency, duplications in 13q14 are analyzed in hematological disorders and in solid tumors. In some tumor types deletions in 13q14 play an important role in tumor development and progression. Among the malignant neurogenic neoplasms they are retinoblastoma Rb 1 and osteosarcoma adenoma sqamous cell carcinoma, and among chronic lymphoproliferative disorders, multiple myeloma (MM). In other neoplasms the deleted region includes 13q14 but the breakpoints are more proximal and distal (13q12 to q21) as in CML, ANLL, Polycythemia vera, and germ cell neoplasms. Duplications are observed as adeno carcinoma or in benign neurogenic neoplasms.

HSR-regions or double minutes (dmin) originating from 13q14 have not been observed.

## Therapeutic Principles

*Rb1*: Limited localization of the tumor: Proton radiotherapy, resection, enucleation. Chemotherapy in tumor progression: Fotemustin, Treosulfan/Gemcitabin.
*Osteosarcoma*: Surgery, combined chemotherapy: Dexorubicin/Cisplatin, Methotrexat, Ifosfamid/Etoposid. No stem cell treatment.
*Head-neck-tumor*: Resection, local radiotherapy, biomodulation (Bestatin).
*Progredient tumor*: irradiation + chemotherapy + surgery.
*Combined therapy*: Cisplatin/5-Fluorouracil, Cisplatin/Doxetacil/Fluorouracil.
New development: photodynamic therapy.
Early development of resistance to tolerable drug concentrations.
*MM*: (Therapy dependent on age and prognosis). Primary treatment: Dex, MP, Thal/Dex, VAP, AD, T/M/P, Bo/Dex. Refractory and recurrent disease: TCID, TCEC, Revlimid, VRID; autologous and allogeneic stem cell transplantation.
Gene therapy for all carcinoma in development: the aims are immunomodulation, reduced expression or inactivation of oncogenes, regulation of tumor suppressor genes, apoptosis of tumor cells [4].

## Synonyms

Chromosome 18 long arm deletion; De Grouchy syndrome/18q- syndrome/18q-; Chromosome 18 short arm deletion; 18p- syndrome/short arm deletion of 18/18p-; Ring chromosome 18/r(18)

## Definition and Characteristics

Partial deletions of chromosome 18, especially the short arm, are relatively common [1]. They may arise as a result of unequal crossing-over (interstitial deletions), a terminal deletion, or a parental translocation (often with an acrocentric chromosome). A ring chromosome arises from breaks in both arms of a chromosome: the terminal ends (telomere) are lost and the two proximal sticky ends unite to form a ring, in most cases with some euchromatin loss. The phenotype is determined by deletion locus and size. Other chromosomal abnormalities are often combined with 18p- and 18q- deletions. Clinical manifestations overlap between 18p-, 18q- syndromes and r(18) although the features and prevalence of associated abnormalities may vary.

## Prevalence

Although rare chromosome 18 deletions rank after 5p- and 4p- as the most frequently reported autosomal deletions. The true incidence is uncertain and awaits large scale studies of copy number variation. Literature reports exist for well over 150 cases each for both 18q- and 18p-. For these the male to female ratio is around 0.7. The mean parental ages lie between 30 and 34 years. Over 70 cases of r(18) have been reported again with a female excess (0.75) and mean parental age 27–30 [1].

## Genes

About 66% of 18p- and 75% of 18q- cases arise de novo (50:50 maternal:paternal origin). Others result from familial and complex translocations, inversions or direct transmission. Vertical (maternal) transmission of 18q-, 18p- and r(19) have all been reported [1]. Breakpoint clusters have been suggested at 18p11.1, and 18q21.1 to q22.2. A study relating deletion size to phenotype suggested that 18q22.3-qtel was critical to the development of common 18q deletion features (foot anomalies, aural atresia, palatal changes, dysmyelination, nystagmus) [2]. Microcephaly and genitourinary anomalies may map proximal to this interval. Genic haploinsufficiency is usually proposed to underly 18 deletion phenotypes, variability by dosage compensation from other chromosomal loci and allelic variability on the homologue. At least one gene (TCEB3C, 18q21) has been reported as imprinted in human cells. Several candidates exist for phenotype components, e.g., HPE4 (18p11.3) and holoprosencephaly, GALNR1 (18q23) with growth hormone deficiency, MBP (18q23) with dysmyelination, and DCC (18q21.2) suggested to relate to neurological impairment-severity for the 18q- phenotype in individuals with large deletions [3]. However, dosage compensation mechanisms may have an important role in determining the absence or presence of certain characteristics in these deletions - MBP was deleted in all seven non-mosaic r(18) cases in one study but abnormal myelination in only three [3].

## Molecular and Systemic Pathophysiology

*18p deletions*: No clinical features are universal. The pattern of dysmorphisms becomes clearer after around 3 years of age. Ptosis, strabismus and mild/moderate short stature are common, but outer ear anomalies, broad nose, hypertelorism, short/webbed neck, micrognathia and clinodactyly of fifth finger may also occur. MR is common and its severity (or absence) may relate to the exact 18p locus [4]. Verbal performance is reportedly worse than non-verbal. In some holoprosencephaly has been suggested by midline incisors and panhypopituitarism. Heart anomalies (mainly Fallot's tetralogy, septal defects) occur in 10%. Autoimmune disorders (thyroid, alopecia) and infections are increased in frequency. Neurological outcomes other than MR include speech delay and slowness in movements and actions. Autism is often diagnosed in childhood.

*18q deletions*: The highly variable phenotype [2] can include MR, microcephaly, postnatal growth impairment (growth hormone deficiency in up to 70%), strabismus, midface hypoplasia, hypotonia, atresia/stenosis of the external auditory canals (up to 50%), hearing impairment, foot anomalies (esp. proximally inserted halluces) and abnormalities of the genitourinary tract (in both sexes). A triangular or "carp"-shaped mouth is sometimes reported. Congenital heart anomalies are more frequent at around 25% than in 18p-. As in 18p- autoimmune disorders have been described (hypothyroidism, coeliac disease, vitiligo, juvenile RA, early-onset IDDM). Specific deficiency of IgA occurs in about 25% of cases, but has

also been reported for 18p-. Neurological outcomes in addition to MR include poor co-ordination, tremor, chorea in some cases, nystagmus and seizure (20%). MRI findings include white matter signal intensity changes, and may relate to the exact locus of the deletion [2].

*r(18)*: Most cases show features of 18q deletion but a minority 18p deletion or combination of both; again there is much clinical variability. Severe holoprosencephaly (10%) and complex cardiac anomalies (20%) have been reported, but some cases have an almost normal phenotype. Those with mainly18q features show a reduced symptom cluster compared to those with full (non-ring) 18q deletions. There may be two groups of r(18), one with a centromeric break leading to deletion of all 18p and another type with deletion of distal 18q only [3].

*Fertility*: Although gonadal dysgenesis can occur in all three deletion syndromes and oligospermia in r(18), puberty and fertility can occur in both sexes. Vertical (all maternal) transmission of 18p deletion has been observed in six families [5].

## Diagnostic Principles

Cytogenetic investigations should follow in anyone with a suspected phenotype. Combining routine chromosomal analysis with fluorescence in situ hybridization (FISH) techniques using specific DNA probes allows accurate detection of breakpoints/deletions.

## Therapeutic Principles

Management is aimed at ameliorating the effects of associated abnormalities such as congenital malformations and autoimmune disorders, where possible. The prognosis is largely determined by the severity of physical and mental impairments. Genetic counseling is advised due to transmission of the deleted chromosomal segment from mother to child in a small but significant percentage.

## Chronic Fatigue Syndrome

Anthony J. Cleare
Institute of Psychiatry, Kings College London, London, UK

### Synonyms

Myalgic encephalomyelitis; Postviral fatigue syndrome; PVFS; Chronic fatigue and immune dysfunction syndrome; CFIDS; ME/CFS

### Definition and Characteristics

Two operational definitions of chronic fatigue syndrome (CFS) are widely used, the main one being from the Centers for Disease Control (CDC) in the USA [1]. This specifies that there must be clinically evaluated, medically unexplained fatigue of at least 6 months duration that: (i) is of new onset; (ii) is not a result of ongoing exertion; (iii) is not substantially alleviated by rest; and (iv) leads to a substantial reduction in previous levels of activity. At least 4 of

8 additional symptoms must be present. The CDC has recently suggested that the definition be refined based on empirical data [2].

## Prevalence

Estimates at the prevalence of CFS in the community vary from 0.5 to 1.5% [3]. It is more common in women, the relative risk varying between 1.3 and 1.7. While those seen in specialist clinics are more often from higher social classes, this is likely to be a referral bias, since population surveys do not find that CFS is less likely to occur in groups of lower socio-economic status or in ethnic minorities.

## Genes

Recent studies suggest that there is a genetic propensity to suffer from chronic fatigue, with the concordance between monozygotic twins more than twice that of dizygotic twins [4]. It remains unclear the extent to which the genetic vulnerability is shared with the tendency to suffer from anxiety or depression.

## Molecular and Systemic Pathophysiology

The aetiology of the condition is not fully understood, and work is ongoing to understand more about the biological correlates of the disorder. Nevertheless, CFS is most likely a multifactorial condition in which biological, psychological and social factors are all important. Likely aetiological factors include the following.

*Predisposing Factors*: Risk factors for developing CFS include: genetic and other unknown biological vulnerability; a previous history of fatigue or other medically unexplained physical symptoms; previous history of psychological disorder; and female gender.

*Precipitating Factors*: The onset may be insidious, or a result of triggering factors such as severe viral infection (EBV, hepatitis, meningitis, but not common URTI viruses), life events, or other bodily stresses (such as major surgery or cancer treatment).

*Maintaining Factors*: Psychiatric disorder, particularly depression and anxiety, is common, occurring in 50–75% of cases. Biological changes may also occur, including mild hypocortisolism, dysautonomia and changes related to prolonged inactivity and deconditioning. It is often possible to identify cognitive and behavioural factors that may be perpetuating the condition, including: over-reliance on rest as a management strategy; inconsistent, "stop-start" patterns of rest and activity; over-focussing on bodily symptoms; and unhelpful illness beliefs. These may be reversible and modification of presumed perpetuating factors forms the basis of current treatment strategies for CFS.

## Diagnostic Principles

The hallmark of CFS is severe fatigability, of both mental and physical function, after minimal exertion. It is accompanied by other common symptoms, including myalgia, sleep disturbance, and headache. CFS should not be diagnosed without some complaints of physical fatigue and fatiguability (reduced functional capacity, symptoms after minor exertion, post exertional myalgia) and mental fatigue and fatiguability (poor concentration, symptoms made worse by mental effort, subjective memory disturbances). Because there are many other causes of chronic fatigue, it is essential that an appropriate physical examination, mental state examination and simple investigations are carried out before diagnosing CFS. Recommended investigations are: *All patients*: full blood count; erythrocyte sedimentation rate or C-reactive protein; urea and electrolytes; thyroid function tests; anti-gliaden antibodies; urine for protein and sugar. *Can be helpful*: Epstein Barr virus serology; chest X-ray; rheumatoid factor; antinuclear factor; serological testing for cytomegalovirus, Q fever, toxoplasmosis, borreliosis or HIV.

## Therapeutic Principles

In the absence of any biological target, treatment is presently based on addressing modifiable factors felt to be perpetuating the illness. Cognitive-behavioural therapy is effective in about 60–70% of cases, and leads to improvement in function and reduction in symptoms, though a smaller proportion can be regarded as "cured." Graded exercise therapy is also effective, although sometimes less acceptable to patients; it should be specifically targeted to patients' present level of functional capacity. There is some evidence that a variety of biological treatments can have positive effects, but insufficient yet to recommend their use in routine practice (for review see [5]).

## Chylomicron Retention Disease

Hubert Scharnagl[1], Winfried März[2]
[1]Clinical Institute of Medical and Chemical Laboratory Diagnosis, Medical University of Graz, Graz, Austria
[2]Synlab Center of Laboratory Diagnostics, Heidelberg, Germany

### Synonyms

CMRD; Anderson's Disease

### Definition and Characteristics

Chylomicron retention disease is a recessive disorder characterized by the absence of postprandial chylomicrons. The concentration of triglycerides does not increase significantly after meals.

The clinical characteristics are similar to those of abetalipoproteinemia or hypobetalipoproteinemia: fat malabsorption, malnutrition, severe diarrhea in childhood, growth retardation. However, hypocholesterolemia is less severe and fasting triglyceride levels are within the normal range.

### Prevalence

Rare.

### Genes

SARA2 gene localized on chromosome 5q31 coding for the GTPase Sar1b [1].

### Molecular and Systemic Pathophysiology

Chylomicrons are large, buoyant lipoprotein particles synthesized by enterocytes of the small intestine [2]. They are produced during the postprandial state and transport dietary lipids, mainly triglycerides, and fat soluble vitamins into the blood. The major structural protein constituent of chylomicrons is apoB-48. ApoB-48 is translated from apoB-100 mRNA, which is posttranscriptionally edited to cause a premature end of the protein synthesis. Dietary lipids are hydrolysed in the intestinal lumen and are taken up by enterocytes through the luminal plasma membrane. The assembly of apoB-48 with lipids in the endoplasmic reticulum (ER) of the enterocytes requires the microsomal triglyceride transfer protein (MTP). The transport of chylomicron particles from the ER to the Golgi apparatus is mediated by the multi-subunit coat protein complex COPII. Two isoforms of small GTPase Sar1, designated Sar1a and Sar1b, promote the formation of this transport carrier [3]. Missense mutations in the SARA2 gene coding for Sar1b map to the GDP/GPT binding site of the protein and diminish the affinity of Sar1b for GDP and GTP. The binding of GTP to Sar1b and hydrolysis is required for the transport of vesicles from ER to Golgi apparatus.

As a result of the impaired intracellular transport, chylomicron-like particles accumulate in the enterocytes [4] and apoB-48 containing lipoproteins are virtually absent in plasma. The assembly and secretion of lipoproteins containing apoB-100 in the liver is not affected. However, the concentration of LDL and HDL particles are about half of the normal value and LDL particles were found to be enriched in triglycerides and depleted in cholesteryl ester [4,5].

### Diagnostic Principles

CMRD can be diagnosed by the absence of chylomicrons after a fat-containing meal. The concentrations of fasting triglycerides are normal, the plasma levels of LDL cholesterol, HDL cholesterol, apo B and apo AI are below 50% of normal values. Intracellular lipid accumulation can be identified by staining of enterocytes from intestine mucosa biopsies.

### Therapeutic Principles

The intake of dietary fat should be restricted, especially in infancy. Adequate amounts of essential fatty acids should be supplied, however. The supplementation with fat-soluble-vitamins should be maintained to prevent neurological deficits.

# Cirrhose Cardiaque

►Cirrhosis, Cardiac

# Cirrhosis, Cardiac

Ralf Kubitz, Dieter Häussinger
Clinic for Gastroenterology, Hepatology and Infectiology, Heinrich-Heine-University, Duesseldorf, Germany

## Synonyms

Congestive hepatopathy; Cirrhose cardiaque; Congestive liver fibrosis; Congestive hepatic fibrosis

## Definition and Characteristics

Cardiac cirrhosis or congestive hepatopathy is due to longstanding passive hepatic congestion in the context of right heart failure. In contrast to other forms of hepatic cirrhosis rigidification and downsizing of the liver is not a major feature of cardiac cirrhosis. Often, passive hepatic congestion and left-sided heart failure run in parallel and thus hepatic ischemia (due to left-sided heart failure) may be present together with congestive hepatopathy.

## Prevalence

The prevalence of cardiac cirrhosis is difficult to estimate, because clinically the leading problem is the heart disease and disturbed liver functions often remains undiscovered. In autopsy the incidence of cardiac cirrhosis has decreased over time which may be attributed to changes in the prevalence and treatment of the underlying heart diseases. The most frequent underlying heart diseases are: ischemic heart disease, cardiomyopathy, valvular heart disease, "cor pulmonale" and pericardial disease such as pericarditis constrictiva.

## Genes

There are no studies on an association between single genes and the development of cardiac cirrhosis.

## Molecular and Systemic Pathophysiology

Pathophysiologically, right heart failure affects the liver in three ways: by increased venous pressure, decreased blood flow and by reduced oxygen saturation. Sinusoidal blood flow into terminal hepatic venules is impaired in venous congestion, leading to stasis and prolonged centrilobular retention of deoxygenated blood. This may induce cellular atrophy in the pericentral zone, anaerobic metabolism, collagen production and fibrosis. The development of focal thrombi, which is promoted by reduced blood flow, can be responsible for the inhomogeneous development of fibrosis. Right heart failure alone does not induce cellular necrosis of pericentral hepatocytes, rather left-sided heart failure seems to be a prerequisite for necrosis as a result of decreased oxygen supply.

The elevation of venous pressure increases the size of the sinusoidal fenestrae, favoring the exsudation of serum proteins into the space of Dissé. Thereby, perisinusoidal edema occurs which further impairs delivery of oxygen to parenchymal cells [1,2].

## Diagnostic Principles

On physical examination the liver may be enlarged. When right heart failure occurred acutely, the liver is tender on palpation.

The degree of liver impairment can be estimated as in other liver diseases by alanine- aminotransferase (ALT) and aspartate-aminotransferase (AST) serum levels, as well as alkaline phosphatase, bilirubin (frequently elevated), albumin levels and prothrombin time. Changes of these laboratory values are commonly modest and point otherwise to further pathology (such as ischemia related to low cardiac output). Changes in laboratory values become obvious when right atrial pressure exceeds 10 mmHg. Abnormal values restore when heart failure is compensated.

Ascites may develop in cardiac cirrhosis. Typically, ascites due to right heart failure has a protein content of >2.5 g/dl and a serum to ascites ratio for albumin >1.1.

Ultrasound provides several clues in the diagnosis of hepatic congestion: signs of right heart failure include a dilated inferior vena cava (>25 mm in diameter) and enlarged liver veins (>11 mm in diameter). Pulsatility of the portal vein negatively correlates with right atrial pressure.

## Therapeutic Principles

Primarily, heart failure must be treated. In general, treatment options include diuretics, angiotensin converting enzyme inhibitors, digitalis, β-blocker and aldosteron antagonists. Otherwise, treatment may concern the underlying pathology (e.g. valve replacement).

# Clefts of the Lip, Alveolus and Palate

Norbert Schwenzer
Department of Oral and Maxillofacial Surgery, Eberhard-Karls-University of Tuebingen, Tuebingen, Germany

## Synonyms

Cheilognathopalatoschisis

## Definition and Characteristics

We distinguish clefts of the lip, clefts of lip and alveolus, clefts of lip, alveolus, and palate and isolated palatal clefts; various tissue sections from the upper lip, jaw, and palate can be divided, from the suggestion of a cleft, a partial cleft to a wide, total cleft; they can appear unilaterally and bilaterally.

## Prevalence

Cleft frequency is 1:500. The proportion of male to female is 3:2. The most common kinds of cleft are the clefts of lip, alveolus, and palate (40–60%). Clefts of the lip and clefts of lip and alveolus occur 20–25% of cases; isolated palatal clefts, in 30%.

## Genes

The genetic component is between 15 and 30%.

## Molecular and Systemic Pathophysiology

Caused by disorders of the organizational centers responsible for the development of the head in lip and alveolus clefts, by disturbances in the development of the primitive nose between the 36th and 42nd day, in palatal clefts, by the failure of the lateral palatal processes to join in the 8th embryonal week. Nongenetic causes are multiple including vitamin deficiency, undernourishment, glucocorticoids, virus infections during early pregnancy, toxoplasmosis, etc. [1].

## Diagnostic Principles

The diagnosis is a clinical one.

## Therapeutical Principles

For both aesthetic and functional reasons, the establishment of normal anatomical conditions (cleft closure) as a prerequisite for normal breathing, food uptake and speaking is always indicated. If the palate is involved, affection of the middle ear and upper airways as well as rhinophonia can be avoided by appropriate closure (Table 1).

Various specialists are involved in the therapy [2,3]. The maxillofacial surgeon performs cleft closures. The

**Clefts of the Lip, Alveolus, and Palate. Table 1** Therapeutic stages

| Age | Therapy |
|---|---|
| 24–48 h | Orthodontic drinking plate; nasoalveolar molding in cases of total cleft |
| 3–5 months | Audiometry; lip closure (lip adhesion or definitive); velum closure; tympanic drainage, if necessary |
| 1 year | Logopedic treatment (sucking, chewing, swallowing, velum exercises) |
| 1–2 years | Hard-palate closure; logopedic and phoniatric treatment |
| 11–12 years | Osteoplasty in cases of bone deficiency before eruption of permanent canine |
| From 16 years on | Rhinoplasty |

Note: the indications of age are to be considered only as guidelines. The time of surgery should be based upon development.

orthodontist treats disorders of the jaw and teeth resulting from the cleft; the ENT specialist treats associated disorders of the middle ear and upper airways. The logopedist is responsible for speech therapy, especially in the case of cleft palates.

So-called rare facial clefts can be divided in median, lateral, and oblique clefts (frequency 1–5:100,000).

# Cloacal Exstrophy

Alexander K. C. Leung[1], William Lane M. Robson[2], Andrew L. Wong[3]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]The Childrens' Clinic, Calgary, AB, Canada
[3]Department of Surgery, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

Vesicointestinal fissure; Exstrophia splanchnica; Ileovesical fissure; Ectopia cloacae

## Definition and Characteristics

The classic presentation of cloacal exstrophy is a central exstrophic bowel field that contains two orifices [1]. The proximal orifice leads to the ileocecal junction. An ileum that prolapse from the ileocecal junction gives the appearance of an elephant trunk. The distal orifice leads to the hindgut. The anus is usually absent. The exstrophic bowel field is flanked by two hemibladders (Fig. 1).

The bladder is usually smaller than normal. An omphalocele is present in 90% of cases. The rectus muscles are separated and the pubic symphysis is widened. In males, the penis is typically short, bifid, and epispadic; the scrotum is bifid; and the testicles are undescended. In females, the clitoris is usually bifid. The vagina may be duplex and the uterus bicornuate. Associated anomalies include imperforate anus, spina bifida, meningomyelocele, pelvic kidney, horseshoe kidney, renal agenesis, and vesicoureteral reflux [2]. Complications include fecal incontinence, urinary tract infection, bladder stone, hydronephrosis, carcinoma of the bladder, and infertility.

## Prevalence

Cloacal exstrophy occurs in only about 1 of every 200,000–400,000 live births [3]. There is no sex preponderance.

## Molecular and Systemic Pathophysiology

The cloacal membrane is invaded by the medial migration of mesenchymal tissue at about the fourth week of gestation. Cloacal exstrophy is believed to result from either abnormal persistence of the caudal portion of the body stalk on the embryo, or overdevelopment of the cloacal membrane which produces a wedge effect and prevents the medial migration of the mesenchymal tissue between the inner endodermal layer and the outer ectodermal layer [4]. About the fifth

**Cloacal Exstrophy. Figure 1** Note the exstrophic bowel field flanked by two hemibladders.

to eighth week of gestation, the urorectal septum divides the cloaca into the urogenital sinus anteriorly and the anorectal canal posteriorly. The cloacal membrane usually ruptures during the eighth week gestation. Rupture before the cloaca is divided by the urorectal septum results in the classic presentation of cloacal exstrophy.

## Diagnostic Principles

The diagnosis is mainly clinical. A prenatal diagnosis can be established with ultrasonography which may show a large midline infraumbilical anterior wall defect, a cystic anterior wall structure (persistent cloacal membrane), an omphalocele, nonvisualization of the bladder, and lumbosacral anomalies [3].

## Therapeutic Principles

The spectrum of possible defects requires an individualized treatment plan; a team approach is important. Parenteral nutrition should be started promptly in the neonatal period. Antibiotic prophylaxis should be administered. Intestinal diversion with either an ileostomy or colostomy is necessary. Optimally, a pull-through procedure should be performed when the child is older to re-establish as near-normal bowel anatomy as possible. However, a pull-through procedure might not be possible, if the child is not able to form solid stools, has only minimal colonic tissue available, or has severe spinal dysraphism or poor pelvic musculature. The decision to reassign sex should be made by the family in consultation with specialists in the field. A chromosomal study should be performed to clarify the genetic sex. In genetically male patients with a satisfactory phallus, male sex assignment is appropriate. In genetically female patients, a vaginoplasty is usually carried out at about the time of puberty. Hormonal therapy is usually offered to stimulate the development of secondary sexual characteristics.

# Clot

►Thrombosis

# Clozapine-induced Agranulocytosis

Yener Güzelcan
Reinier van Arkel Group/Jeroen Bosch Hospital, Department of Psychiatry, 's-Hertogenbosch, The Netherlands

## Synonyms

CIA

## Definition and Characteristics

Clozapine, a dibenzodiazepine derivative, is an atypical antipsychotic medication that is more effective in cases of therapy resistant schizophrenia than

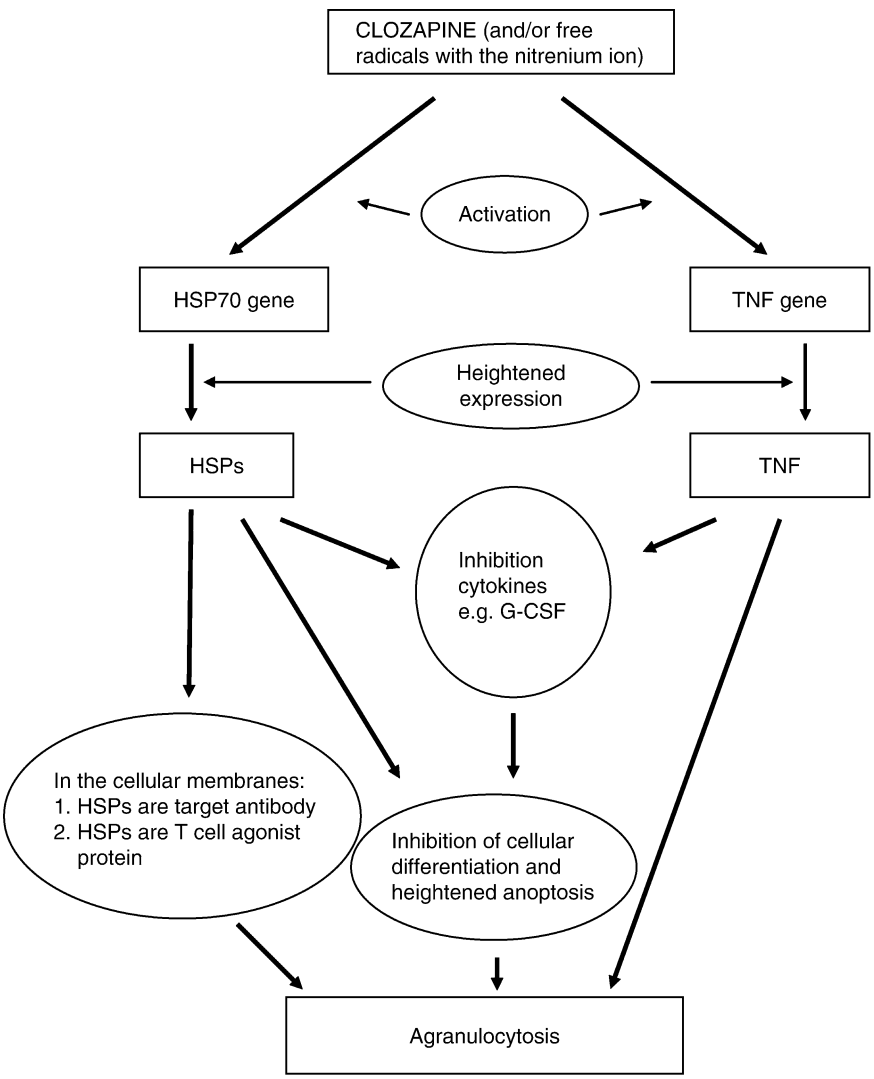
other anti-psychotic medication. It can lead to an improvement in 30% of the patients with therapy resistant schizophrenia [1]. Compared to classic anti-psychotic medication, extra-pyramidal side effects occur less frequently with clozapine. Clozapine can however induce agranulocytosis (number of neutrophil granulocytes $<0.5 \times 10^9$/l). It is clear from these results that although it only affects a small number of patients, agranulocytosis is a severe and possibly fatal side effect of clozapine. This is why clozapine is not the medication of choice in treating psychoses and is only used if other anti-psychotic medication has proved to be ineffective.

## Prevalence

The risk of agranulocytosis due to the use of clozapine is approximately 0.8%. According to the Clozapine National Registration Programme in the United States from 1990 to 1994, 382 (0.38%) of a total of 99,502 clozapine users developed agranulocytosis, 12 of whom died as a direct result of it [2].

## Genes

CIA is accompanied by HLA-B38, DQB1*0402, DRB4*0101, DQB1*0201 and DQB1*0302 haplotypes in Jewish patients and HLA-DR*02, DRB1*1601,



HSP-70: heat-shock protein-7, HSPs: heat-shock proteins, G-CSF: granulocyte colony stimulating factor, TNF: tumor necrosis factor

**Clozapine-induced Agranulocytosis. Figure 1** Immunotoxic explanatory model for the occurrence of agranulocytosis among clozapine users.

DRB5*02, DQB1*0502, DQB1*0201, DQB5*02 and HLA-Cw*7 haplotypes in non-Jewish patients [2]. Cloza et al. [3] note a significant correlation between HLA-B7, B38 and B44 haplotypes and HSP70–29.0 kb variant genes and between HSP70–2 8.5 kb and HLA-DR2 and HLA-DR3 haplotypes. A clear correlation was observed in 123 Jewish patients between the TNF b4, d3 microsatellite alleles, HLA-DRB1, DRB4, DQB1, DQA1 haplotypes and HSP70. In the same study, more significant correlations were observed between TNF b4, d3 and HLA-DR2 haplotypes in 21 non-Jewish patients with CIA.

## Molecular and Systemic Pathophysiology

The pathogenesis of CIA has not yet been clarified; there are various mechanisms that might play a role. The first possibility might be a direct cytotoxic effect of clozapine and its metabolites, desmethylclozapine and free radicals. Clozapine and desmethylclozapine appear to have no toxic effect on the cells, though the free radicals with the nitrenium ion do have a toxic effect [2]. The mechanism underlying this toxic effect has yet to be fully clarified. It might be a direct effect or operate via immuno-genetic mechanisms.

The second and even more important possibility is an immuno-genetic mechanism that might be related to HLA (human leukocyte antigen) haplotypes. It has been demonstrated in a number of studies that CIA is associated with HLA haplotypes [2]. In addition, HSP-70 (heat-shock protein) and TNF (tumor necrosis factor) are viewed as candidates that are often accompanied by these HLA haplotypes and CIA.

There are also HSP and TNF genes in the MCH. It has been demonstrated in CIA that a few HSP-70 genes are in linkage disequilibrium with HLA-B and DR alleles. Three genes code for the HSP-70 map localized exactly in the middle of the MCH I and II regions. It has also been demonstrated that a few genetic variants of TNF genes tend to be accompanied by CIA. Various variants of TNF genes are in linkage disequilibrium with HLA-B and DR alleles [2].

In the event of changes in the interior environment, a number of proteins are produced as a reaction. They are referred to as heat shock proteins (HSPs) or stress proteins. HSPs are activated by a wide range of factors such as medication, hormones, glycolysis blockers, hypoglycemia, hypoxia or other pathological conditions. The activation of HSPs causes various changes inside and outside the stressed cell and in the DNA. TNF, a protein cytokine, has different effects in tissues in vitro and in vivo. In addition to an immunological effect, TNF stimulates cell growth and cell differentiation and also has a cytotoxic effect.

HSP-70 variants can be activated as receptor by clozapine in PMNs (human polymorphonuclear leukocytes) or their precursors in the bone marrow. HSP-70 activates a receptor for the immuno-suppressant 15-deoxyspergualin in T-cells. Clozapine linking leads to changes in the HSP-70 gene, thus inducing the expression of the HSP-70 in the cell. This is how HSP-70 becomes a target for autoantibodies or autoreactive T-cell agonist stress proteins.

Excessive production of HSP by clozapine can induce apoptosis in PMSs or their precursors. HSPs play an important role in cellular differentiation and cell death due to apoptosis. The balance between the expression of Bax (a pro-apoptotic protein) and Mcl-1 (an anti-apoptotic protein) is extremely important in the apoptosis of PMNs. Cytokines induce Mcl-1 and disturb this balance. TNF itself is a cytokine. The concentration of TNF increases in the first six weeks of clozapine use. TNF can cause cell death itself and can also influence other cytokine systems. HPS-70 can inhibit a number of cytokines and thus disturb the balance in the cytokine system. During treatment with clozapine, various changes occur in the cytokine system [2]. The above-mentioned free radicals of clozapine, particularly the free radical with the nitrenium ion, might cause cellular damage via these mechanisms (see Fig. 1).

## Diagnostic Principles

There are clear connections between HLA haplotyping, ethnic background and CIA. The pathophysiology is probably immunological and HSP70 and TNF play an important role in this connection. To minimize the risk of CIA in a certain group of patients, the HLA haplotype could be determined before prescribing clozapine. The findings indicate that extra cautionary measures as regards CIA are called for in those patients, who developed agranulocytosis or leucopenia in the past due to the use of other medication or had this happen to a member of their family.

## Therapeutic Principles

Recombinant granulocyte colony stimulating factor (rG-CSF) (filgrastim) is an effective treatment for CIA [4].

# Clubbing

Francesco Trotta, Andrea Lo Monaco
Section of Rheumatology, Department of Clinical and Experimental Medicine, University of Ferrara Medical School, Ferrara, Italy

## Synonyms

Digital clubbing; Hippocratic fingers; Drumstick fingers; Hypertrophic osteoarthropathy; HOA; Pierre Marie-Bamberger syndrome; Acropachy; Pachydermoperiostosis

## Definition and Characteristics

Clubbing, the most ancient clinical sign of medicine (Hippocrates, fifth century BC), is characterized by thickening and widening of the tips of the fingers and/or toes due to excessive lay down of collagen and interstitial edema. The nails become convexes ("watch-crystal nail"). Although most often symmetrical, clubbing can be unilateral or even unidigital. Clubbing can occur in isolation or associated with HOA that represents the fully developed expression of the disorder. HOA is defined by the presence of digital clubbing (DC) and periosteal proliferation (periostosis) of the distal end of the tubular bones [1].

DC is usually painless. If associated with HOA, burning of the fingertips or deep-seated pain may occur. Particularly in association with malignancies, painful arthropathy may be the presenting symptom in advance of clubbing. Sometimes, the patient develops noninflammatory synovial effusion.

DC and HOA are classified as primary (hereditary or idiopathic) and secondary [2]. The primary forms include congenital clubbing and pachydermoperiostosis (pachydermia: thickened and furrowed skin), a rare, hereditary disorder with different subset. Congenital DC may represent a limited form of pachydermoperiostosis.

Secondary disease could be localized or generalized. The former should be associated to hemiplegia, aneurisms, infection of arterial graft, and patent ductus arteriosus. Generalized forms are associated with many serious conditions: pulmonary (cystic fibrosis, pulmonary fibrosis, chronic infections, empyema, cancer, arteriovenous fistulae, and mesothelioma), cardiac (congenital cyanotic diseases, infective endocarditis), hepatic (cirrhosis particularly biliary and juvenile, carcinoma), intestinal (Crohn's disease, ulcerative colitis, chronic infections, laxative abuse, malignant tumors, and Whipple's disease), mediastinal (esophageal carcinoma, tymoma), and others (including Greave's disease and POEMS syndrome). Malignant lung tumors are the most frequent cause of HOA in adults.

## Prevalence

There are no systematic studies on the prevalence in the general population. Because of the association with many internal illnesses, it is not rare in clinical practice.

## Genes

*Primary DC/HOA*: although an autosomal dominant model with incomplete penetrance and variable expression has been proved, both autosomal recessive and X-linked inheritance have been suggested.

## Molecular and Systemic Pathophysiology

The exact mechanism of DC remained elusive for a long time, and various hypotheses have been proposed to unify the pathogenesis of this sign that is present in such different diseases [3]. Emerging evidence suggests that the vascular endothelial growth factor (VEGF) could play a central role. VEGF is a platelet-derived growth factor (PDGF) induced by hypoxia, that promotes edema, microvascular hyperplasia, excessive fibroblast proliferation, and new bone formation. All these features are the histological hallmark of HOA [1,4]. In different group of patients, increased circulation levels and increased tissue expression of VEGF have been reported [4].

In diseases with prominent extrapulmonary shunting of blood or in diseases in which platelet aggregates arise on the left side of the heart, large megakaryocytes or platelet clusters could bypass the lung capillary network and gain access to the systemic circulation, directly reaching the most distal sites on peripheral vasculature. Their interaction with endothelial cells induces the release of several molecules, in particular VEGF, able to increase vascularity, permeability, and connective tissue changes.

Other molecules are probably related to the development of the disease. As well as VEGF, PDGF is released on platelet aggregation and is hypoxically regulated. PDGF may synergize with VEGF in inducing the stromal changes, including maturation of newly formed microvessels [4]. Moreover, in specific clinical conditions, a complicated network among several other molecules including PGF2α and PGE, basic fibroblast growth factor, transforming growth factor-β1, and endothelins could contribute to induce the disease [4].

## Diagnostic Principles

The established form of clubbing is clearly detectable by visual inspection. By gently rocking, a gentle fluctuation of the nail bed within the soft tissue is perceived. In cases of diagnostic uncertainty, different methods have been proposed with fair to moderate accuracy [5].

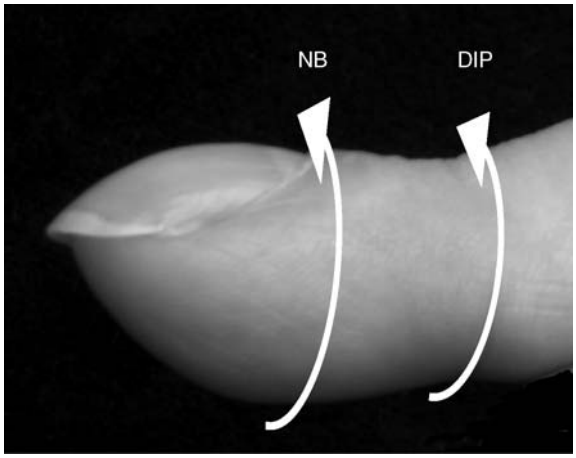
*Digital index*: the perimeter is measured at nail bed (NB) and at the distal interphalangeal joint (DIP). In the normal finger, the NB perimeter is smaller than the DIP

perimeter: in clubbing, the pulp in the terminal phalanx is expanded and the ratio becomes reversed. If the sum of the 10 NB/DIP ratios is more than 10, clubbing is present (Fig. 1).

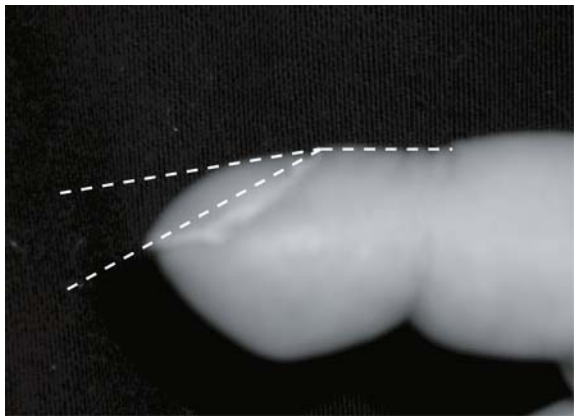
A calliper can be used for the evaluation.

*Schamroth sign*: When dorsal surfaces of normal terminal phalanges of similar fingers are opposed, a diamond-shaped window is detectable. In clubbed fingers, the diamond disappears because of the loss of the profile angle and the increase in soft tissue.

*Nail-fold angle*: In normal fingers, the nail projects from the nail bed at an angle of 160°. This angle exceeds 180° in clubbed fingers (Fig. 2).



**Clubbing. Figure 1** The digital index: the circumference of each finger is measured at nail bed (NB) and at the DIP. If the sum of the 10 NB/DIP ratios is more than 10, digital clubbing is present.



**Clubbing. Figure 2** In the clubbed finger, increased profile and hyponychial nail-fold angle (>180) are evident.

On X-ray, the bone changes observed include acroosteolysis and tuft overgrowth. In HOA, irregular periosteal thickening is characteristic: periostosis have a symmetrical distribution and progress in centripetal fashion. Isotope bone scans show increased uptake by the cortices of the shaft of affected bones (so-called "tramline sign"). Early demonstration of periostosis and soft tissue edema can easily be obtained with MRI and CT scan.

## Therapeutic Principles

Clubbing is usually asymptomatic and does not require therapy. In cases of painful HOA, analgesic or nonsteroidal anti-inflammmatory drugs are effective. Colchicine, isotretinoine, pamidronate, ocreotide, and tamoxifen citrate have been used with interesting results.

A complete reversibility of the syndrome has been observed following the successful treatment of the underlying disease. The removal of megakaryocytes/platelet particles from the axial stream of the circulation could lead to the reported regression. Reversal of these changes was described following chemotherapy or removal of lung tumors or after resection of affected intestine in Crohn's disease, and even after the cure of Whipple's disease and infected aortic artery prosthesis.

# Clubfoot

Alexander K. C. Leung[1], Reginald S. Sauve[2]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Department of Pediatrics, Health Sciences Center, The University of Calgary, Calgary, AB, Canada

## Synonyms

Congenital talipes; Equinovarus; Talipes equinovarus

## Definition and Characteristics

Clubfoot is a congenital deformity of the limb characterized by varus (inversion) of the heel, equinus (plantar flexion) of the foot, and adduction of the midfoot and forefoot [1]. Cavus (increased longitudinal arch) of the midfoot is very common [1]. Other features include tightness of muscles in the foot, deeper skin creases on the medial side of the foot, smaller calf muscles, hypoplasia of the femur and tibia, thickened ligaments (calcaneonavicular ligament, spring ligament, and posterior tibial tendon sheath), and contracture of joint capsules [1,2].

Untreated, the affected child may walk on the dorsolateral aspect of the affected foot with resulting callus and subcutaneous bursa formation [3]. The disease is bilateral in approximately 50% of cases [2]. The majority of clubfeet are idiopathic, occurring in apparently healthy children. Some cases are associated with unfavorable postures. Others may be secondary to myelomeningocele or arthrogryosis. Syndromes associated with clubfoot include Freeman-Sheldon syndrome, prune belly syndrome, Möbius syndrome, Opitz syndrome, and Larsen syndrome [1].

## Prevalence

The incidence varies from 0.4 to 8 per 1,000 live births [2]. The male to female ratio is 2:1 [3].

## Genes

The homeobox (HOX) genes exert a controlling effect on limb development [4]. The candidate genes have been mapped to chromosome 2, 3, 4, 7, 13 and 18 [4].

## Molecular and Systemic Pathophysiology

The high concordance rate in monozygotic versus dizygotic twins (32.5% vs. 2.9%) and the occurrence rate 17 times higher for first-degree relatives and six times higher for second-degree relatives than in the general population suggest a genetic component [2]. A multifactorial mode of inheritance is most likely. Embryologically, a thickened apical epidermal ridge, formed at the distal end of the limb buds, controls the limb growth. The control genes for bone and joint development reside in the HOXA and HOXD complexes [4]. Control is exerted via secreted bone morphogenetic proteins. Bone morphogenetic proteins 2 through 8 and growth differentiation factor-5 act synergistically to affect limb development [4]. Clubfoot shows a strong association with maternal smoking, maternal alcohol consumption, maternal folic acid deficiency, maternal hyperhomocystinaemia, oligohydramnios, and abnormal foetal positioning [4] (Fig 1).

**Clubfoot. Figure 1** A newborn infant with clubfoot deformity.

## Diagnostic Principles

The routine use of prenatal ultrasonography has lead to an increase in the antenatal diagnosis of clubfoot. Postnatally, the diagnosis is mainly clinical. Clubfoot has to be differentiated from metatarsus adductus. The latter is characterized by adduction of the forefoot but the heel is not in equinus and varus [2,3].

## Therapeutic Principles

The goal is to correct all components of the deformity so that the patient can walk with a pain-free, plantigrade foot with good mobility [2]. Initial treatment should be nonoperative and consist mainly of physiotherapy or serial casting/splinting [3]. The Ponseti method is a safe and effective treatment and radically decreases the need for extensive surgical correction [5]. The Ponseti method involves serial manipulations to bring the forefoot in line with the hindfoot and four or five casts after obtaining full abduction of the foot [5]. If 15° of dorsiflexion cannot be obtained after the serial casting, a percutaneous tendoachillis tenotomy is performed. The last cast is left in slight dorsiflexion and full abduction for 3 weeks, regardless of whether a tenotomy is required, followed by the application

of a foot abduction orthosis for three to four years [5]. The Ponseti method is the gold standard for the treatment of clubfoot and can be used successfully in children up to two years of age with no previous surgical treatment. Older patients with pain, foot or heel problems can be considered for surgical correction.

# Cluster Headache

Todd D. Rozen
Michigan Head-Pain and Neurological Institute, Ann Arbor, MI, USA

## Synonyms

Migrainous neuralgia; Histaminic cephalgia; Horton's headache

## Definition and Characteristics

Cluster headache is a stereotypic episodic headache disorder marked by frequent attacks of short-lasting, severe, unilateral head pain with associated autonomic symptoms. A cluster headache is defined as an individual attack of head pain, while a cluster period or cycle is the time during which a patient is having daily cluster headaches. Most patients experience episodic cluster headache (80–90%) defined as cluster headache cycles occurring in periods lasting from 7 days to 1 year separated by pain free or remission periods lasting 1 month or longer. Patients with cluster cycles occurring for more than 1 year without remission or with remission lasting less than 1 month have chronic cluster headache (10%). The typical cluster headache location is retro-orbital, periorbital and occipitonuchal. Pain quality is described as boring, stabbing, burning or squeezing. Cluster headache intensity is always severe, although headache pain intensity may be less at the beginning and end of cluster periods. Cluster sufferers will normally experience cluster headaches on the same side of the head for their entire life. The duration of individual cluster headaches is between 15 and 180 min with greater than 75% attacks being less than 60 min. Attack frequency is between 1 and 3 headaches per day with most patients experiencing two or less headaches in a day. Peak time periods for daily cluster headache onset are 1–2 A.M., 1–3 P.M. and after 9 P.M. Cluster period duration normally lasts between 2 and 12 weeks and patients generally experience one or two cluster periods per year. Remission periods average 6 months to 2 years [1]. Cluster headache is marked by its associated autonomic symptoms that typically occur on the same side as the head pain but can be bilateral. Lacrimation is the most common associated symptom followed by conjunctival injection, nasal congestion, nasal rhinorrhea and a partial Horner's syndrome. Symptoms generally attributed to migraine can also occur during a cluster headache including nausea, vomiting, photophobia and phonophobia. During an individual cluster headache, patients are unable to remain still. Cluster headache unlike migraine is a state of agitation; remaining still appears to make the pain worse. Cluster headache has several distinct triggers including alcohol and nitroglycerin. The face of cluster patients has been described as having a "leonine appearance" with thick, coarse facial skin, peau d'orange appearance, marked wrinkling of the forehead and a face with deep furrowed brows. In addition two thirds of cluster sufferers in a large patient series had hazel-colored eyes.

## Prevalence

Exact prevalence is unknown; suggested prevalence is 0.4% of the population. Cluster is a male predominant syndrome with male to female gender ratios ranging from 2:1 to 4:1.

## Genes

No specific genes for cluster headache have been identified yet. Recently, the G1246A polymorphism in the gene of the hypocretin receptor 2 (HCRTR2) was linked to cluster headache [2]. German investigators examined this association in a large sample of 226 patients with cluster headache and 266 controls. Homozygous carriers of the G-allele had a twofold increase in risk of developing cluster headache. Unfortunately the association of the HCRTR2 gene was not replicated in a large dataset of patients of Danish, Swedish or British origin. A point mutation in a platelet mitochondrial $tRNA^{leu\ (UUR)}$ was noted in a single cluster patient. Analysis of the nitric oxide synthase gene in cluster headache patients did not reveal any genetic variations. Mutations of the P/Q type calcium channel alpha1 subunit (CACNA1A) gene that has been linked to familial hemiplegic migraine were not identified in a number of patients with sporadic cluster

headache. Cluster headache can be an inherited condition. A family history of cluster headache can be identified in about 4–7% of cluster sufferers. An autosomal dominant inheritance pattern has been noted in some cluster families with a 14-fold increased risk of developing cluster in first degree relatives of probands and a twofold risk in second degree relatives [3].

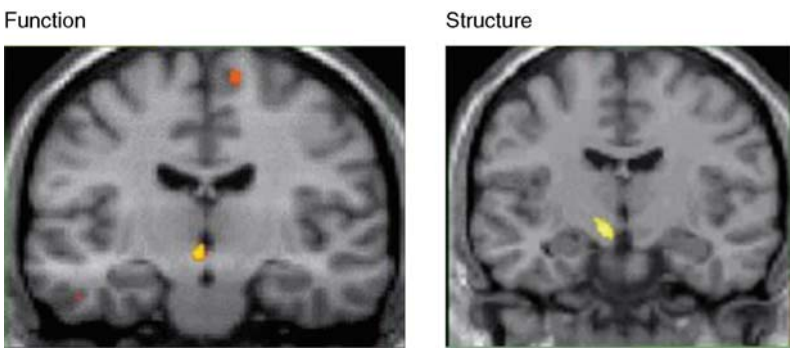
## Molecular and Systemic Pathophysiology

The true pathogenesis of cluster headache is unknown. The pain of cluster is typically centered in or around the eye so there must be activation of the ophthalmic branches of the trigeminal nerve during an attack. Cluster headache is also marked by autonomic symptoms indicating activation of the cranial parasympathetic fibers, which originate in first-order neurons within the superior salivatory nucleus. A presumed brainstem connection between the trigeminal system and the superior salivatory nucleus (trigeminal autonomic reflex pathway) helps to explain anatomically how cluster patients can experience both trigeminal innervated pain and cranial parasympathetic symptoms. There is now human evidence that the trigeminal-autonomic system is activated during cluster headache attacks based on the findings of elevated levels of calcitonin gene related peptide (marker of trigeminal nerve activation) and vasoactive intestinal peptide (marker of parasympathetic activation) in the cranial venous circulation during a cluster headache. Finally cluster headache is marked by its circadian rhythmicity. Episodic cluster periods will start the same time each year, individual cluster headaches will occur the same time each day and the duration of each cluster headache will be almost the same for every attack. This suggests that the hypothalamus is involved in cluster pathogenesis specifically the suprachiasmatic nucleus (circadian clock). Marked activation in ipsilateral hypothalamic gray matter has been documented to occur on PET imaging during a nitroglycerin triggered cluster headache [4] Also voxel-based morphometric analysis of T1 weighted MRI scans in 25 cluster patients demonstrated an increase in volume of hypothalamic gray matter versus controls (Fig. 1).

It has been suggested that the hypothalamus is the generator of cluster headache attacks.

## Diagnostic Principles

Cluster headache is grouped into the trigeminal autonomic ephalalgias, which consist of headache disorders with head pain and associated autonomic symptoms. The trigeminal autonomic cephalgias (TACS) include SUNCT (short-lasting unilateral headache with neuralgiform features, conjunctival injection and tearing), chronic paroxysmal hemicrania and cluster headache. When differentiating cluster from the other TACS, one must take a good headache history especially concentrating on duration of the individual headaches and the frequency of attacks. SUNCT episodes are extremely short lasting between 5 and 250 s. The usual attack frequency ranges anywhere from 1 to more than 80 episodes a day with mean attack frequency of 28 attacks per day. There are three major distinctions that help the physician make the correct diagnosis of cluster headache over SUNCT, cluster pain, unlike SUNCT pain, is always severe never moderate, cluster attacks are longer in duration than SUNCT attacks, lasting between 15 and 180 min (mean attack duration 45 min) and most cluster sufferers will experience between 1 and 2 attacks a day and rarely if ever more than 8 a day, (much less frequent than SUNCT). Chronic paroxysmal hemicrania (CPH) is a strictly unilateral head pain syndrome of moderate to severe intensity



**Cluster Headache. Figure 1** Hypothalamus in Cluster Headache - function and structure: The image on the left shows hypothalamic activation during a cluster attack on PET. The image on the right is a voxel based morphometric analysis of T1 weighted MRI scans revealing increased volume in the hypothalamic gray matter. (Adapted from the Neurology Ambassador Program with permission from the American Headache Society).

with associated autonomic symptoms. Each attack lasts between 2 and 45 min. Chronic paroxysmal hemicrania can occur between 1 and 40 times a day. Neck movements and external pressure to the transverse processes of C4–C5 or the C2 nerve root can trigger CPH. By clinical history alone a physician maybe unable to separate CPH from cluster, but there are two distinguishing features, CPH is a female predominate syndrome and by definition it is completely alleviated by indomethacin.

## Therapeutic Principles

All cluster patients require treatment. Other primary headache syndromes can sometimes be managed non-medicinally but with regard to cluster, medication, sometimes even polypharmacy is indicated. Cluster treatment can be divided into three classes [5]. Abortive therapy is given at the time of an attack to treat that individual attack alone. The most effective abortive therapies are injectable sumatriptan and inhaled 100% oxygen via a non-rebreather facemask. Transitional therapy can be considered as intermittent or short-term preventive treatment. An agent is started at the same time as the patient's true maintenance preventive. Transitional therapy will provide the cluster patient with attack relief while the maintenance preventive is being built up to the correct preventive dose. Transitional agents include corticosteroids, dihydroergotamine injections and greater occipital nerve blockade. Preventive therapy consists of daily medication, which is supposed to reduce the frequency of headache attacks, lower attack intensity and lessen attack duration. The main goal of cluster preventive therapy should be to make a patient cluster-free on preventives, even though they are still in a cluster cycle. Cluster preventives include verapamil, melatonin, lithium carbonate, topiramate, methysergide, and valproic acid. Surgical treatment for cluster is also available in individuals who are refractory to medication. Procedures can be directed toward the sensory trigeminal nerve or the autonomic pathways. Recently, hypothalamic stimulation has been shown to successfully prevent cluster attacks in several treatment refractory chronic cluster headache sufferers.

## Coal Workers' Pneumoconiosis

Gloria L. David, Darryl C. Zeldin
Laboratory of Respiratory Biology, NIH/NIEHS
Research Triangle Park, NC, USA

### Synonyms

Coal miners' pneumoconiosis; Black lung disease; Anthracosis; CWP

### Definition and Characteristics

Simple coal workers' pneumoconiosis (CWP) is characterized by diffuse nodular opacities in the lungs as a result of chronic exposure to coal dust, usually in the coal mining industry. Simple CWP is usually asymptomatic, but may develop into progressive massive fibrosis (PMF) which often leads to respiratory insufficiency and secondary cardiac complications [1].

### Prevalence

CWP occurs following long-term exposure to coal dust, usually among workers in the coal mining industry. Underground coal miners are at greater risk of developing CWP than strip or surface miners, and anthracite coal miners are at higher risk than bituminous miners. In the United States, approximately 60,000 individuals >15 years of age died between 1968 and 1992 as a result of CWP. CWP mortality has declined from >2,500 deaths annually in 1982 to <1,500 deaths in 1996.

### Genes

No known genetic pattern exists. Tumor necrosis factor (TNF)-α, lymphotoxin α (LTA), and HLA-DR genotypes have been associated with increased risk of CWP. Specifically, the –308 polymorphism in the TNF-α promoter may be associated with genetic susceptibility to CWP [2,3]. HLA-DR genotypes which correlate with the production of TNF-α have also been associated with CWP risk. An LTA NcoI polymorphism was significantly associated with CWP prevalence in coal miners with low catalase activity.

### Molecular and Systemic Pathophysiology

CWP is caused by inhalation of coal dust, particularly particles <3 μm in diameter [4,5]. Simple CWP is characterized by the deposition of coal dust around the respiratory bronchioles to form coal macules, the basic pathologic lesion of CWP. These macules occur mostly in the upper lobes and are often associated with focal centrilobular emphysema. Increased exposure to coal dust leads to the development of nodular lesions in addition to the macules. The macules and nodules contain coal particles that have been engulfed by macrophages. Simple CWP may progress in a small percentage of cases (<5%) to PMF, which is characterized by larger lesions, extensive fibrosis, and emphysema. The risk of developing PMF is related to the severity of simple CWP and is increased by concurrent exposure to crystalline free silica.

Upon deposition in the lung, coal dust particles are engulfed by macrophages which produce reactive oxygen species (ROS) and reactive nitrogen species that lead to lipid peroxidation of cell membranes, oxidation of proteins, and DNA damage. Free radicals are also found on the fracture surfaces of freshly ground coal and may be produced by the Fenton-reaction due to the iron content of coal. ROS can act as regulators of intracellular signaling cascades leading to the production of proinflammatory cytokines. Alveolar macrophages and alveolar type II epithelial cells produce lipid mediators, cytokines, chemokines, and growth factors, including platelet-activating factor (PAF), leukotriene $B_4$ ($LTB_4$), interleukin (IL)-1, IL-6, TNF-α, macrophage inflammatory proteins (MIP-1 or MIP-2), platelet-derived growth factor (PDGF), transforming growth factor (TGF)-β, and monocyte chemotactic protein-1 (MCP-1). Together, these mediators lead to the activation of fibroblasts and the overproduction of extracellular matrix.

The importance of TNF-α in pulmonary fibrosis due to coal dust is demonstrated by the fact that administration of TNF-α inhibitory antibodies prevents lung fibrosis, and overexpression of the TNF-α

transgene causes pulmonary fibrosis in mouse models of the disease.

PMF is sometimes associated with the development of rheumatoid arthritis and increased serum levels of antinuclear antibodies, lung autoantibodies, and rheumatoid factor. The exact mechanisms underlying this association remain unknown.

## Diagnostic Principles

Simple CWP is usually asymptomatic; however, symptoms of chronic bronchitis including cough, wheezing, and sputum production may be observed. Patients with PMF may complain of exertional dyspnea, hemoptysis and melanoptysis. Patients are predisposed to recurrent lung infections and may have Caplan's syndrome (defined as the association of rheumatoid arthritis, pulmonary necrobiotic nodules, and CWP). Pulmonary function studies reveal severe airway obstruction, restriction, and reduced diffusing capacity. PMF often results in progressive loss of respiratory function with hypoxemia, pulmonary hypertension, right-sided heart failure, and death from cor pulmonale. Diagnosis of simple CWP depends on a history of exposure to coal dust and the characteristic presence of small rounded opacities in both lungs, usually in the upper lobes, on chest radiographs. Simple CWP is classified by the size, shape, and profusion (concentration) of small opacities according to standards developed by the International Labor Office (ILO) (Table 1). Profusion is read on a 12 point scale (0/–, 0/0, 0/1 up to 3/2, 3/3, 3/+). In PMF, the observed opacities are >1.0 cm in diameter.

**Coal Workers' Pneumoconiosis. Table 1** ILO classification scheme for chest radiographs of pneumoconioses

| **Small opacities** | | |
|---|---|---|
| | Rounded | Irregular |
| <1.5 mm | p | s |
| 1.5–3 mm | q | t |
| >3mm | r | u |
| **Large opacities** | | |
| category A | 1 or more opacities 1 cm in diameter, combined diameter not exceeding 5 cm | |
| category B | 1 or more opacities >10 cm in diameter, combined diameter not exceeding one upper zone | |
| category C | Larger than category B | |
| **Pleural thickening** | | |
| Width | | |
| A | <5 mm | |
| B | 5–10 mm | |
| C | >10 mm | |
| Extent of lateral chest wall thickening | | |
| 1 | <1/4 | |
| 2 | 1/4–1/2 | |
| 3 | >1/2 | |

## Therapeutic Principles

There is no specific treatment for CWP; therefore, effective management depends on prevention. Respirators should be worn to reduce exposure. PMF may be prevented by removing patients with radiographic changes typical of simple CWP from further exposure to coal dust. Antitussive and bronchodilator drugs may be used to treat symptomatic bronchitis. Complicating infections can be treated with appropriate antibiotics. In individuals with associated rheumatoid arthritis, anti-inflammatory drugs may be effective.

# Coarctation of the Aorta

P. Syamasundar Rao
Division of Pediatric Cardiology, The University of Texas/Houston Medical School, Children's Memorial Hermann Hospital, Houston, TX, USA

## Synonyms

Aortic coarctation; Isthmic coarctation; CoA

## Definition and Characteristics

Coarctation of the aorta (CoA) is defined as a congenital cardiac anomaly consisting of a constricted aortic segment comprising localized medial thickening with some infolding of the media and superimposed neointimal tissue [1]. The localized constriction may form a shelf-like structure with an eccentric opening or it may be a membranous curtain-like structure with a central or eccentric opening. The coarctation may be discrete, or a long segment of the aorta may be narrowed; former is more common. The classic CoA is located in the thoracic aorta distal to the origin of the left subclavian artery, at about the level of the ductal structure. However, rarely, a coarcted segment may be present in the lower thoracic or abdominal aorta. In such instances, the coarcted segment may be long and fusiform with irregular lumen and may be considered inflammatory and/or autoimmune in origin, and as such, they may be variants of Takayasu's arteritis.

Varying degrees of hypoplasia of the isthmus of the aorta (the portion of the aorta between the origin of the left subclavian artery and ductus arteriosus) and transverse aortic arch (the portion of the aorta between the origins of left common carotid and left subclavian artery) are present in the majority of patients with thoracic coarctation; this hypoplasia may be significant in symptomatic coarctation of the neonate and infant, while in children and adults, there may be only a mild degree of narrowing of the isthmus and transverse aortic arch. Collateral vessels that connect arteries from the upper part of the body to the vessels below the level of coarctation may be seen; these may be present as early as a few weeks to few months of life.

## Prevalence

The prevalence of CoA was found to vary between 5 and 8% of all congenital heart defects (CHD). Given the prevalence of congenital heart disease in 0.8% of live births, the estimated prevalence is 4–6 in 10,000 live births. The prevalence of CoA appears to be lower (less than 2% of all CHD) in Asian countries than in European and North American countries.

## Genes

The etiology of CoA is unknown. A multifactorial inheritance hypothesis is offered to explain all CHD, including CoA. This hypothesis states that the disease results if a predisposed fetus is exposed to a given environmental trigger (to which the fetus is sensitive) during a critical period of cardiac morphogenesis. This genetic and environmental interaction is most likely the pathogenic mechanism for CHD in general and for CoA in particular. However, it should be noted that the CoA is the most common cardiac defect seen with Turner (XO) syndrome. Although concordant occurrences in monozygotic twins and inheritance by autosomal dominant trait have been reported in occasional cases, the majority of coarctations are thought to be explained on the basis of multifactorial inheritance.

## Molecular and Systemic Pathophysiology

The mechanism for development of hypertension in CoA patients is not clearly understood; mechanical obstruction and renin–angiotensin-mediated humoral mechanisms have been postulated. The mechanical obstruction theory explains the increased blood pressure by postulating that a higher blood pressure is required to maintain flow through the coarcted segment and collateral vessels. The stroke volume, ejected into the limited aortic receptacle, produces a higher pressure proximal to coarctation. However, this theory does not explain (i) lack of relationship between the degree of elevation of blood pressure and the magnitude of obstruction, (ii) increased peripheral vascular resistance distal to the site of obstruction, and (iii) delayed or lack of reduction of blood pressure following relief of obstruction.

Humoral theory postulates activation of renin–angiotensin system secondary to reduction of renal blood flow and appears to explain most of the clinical features. However, measurement of plasma renin activity both in animal models and human subjects did not show consistently elevated plasma renin levels. The reasons for the inability to demonstrate elevation of renin levels may be related to lack of inadequate accounting for salt intake, posture, extracellular fluid volume, and sympathetic influences on renin release. More recent studies did demonstrate abnormalities in the renin–angiotensin–aldosterone system. In addition, activation of the central sympathetic nervous system may also be responsible for hypertension of aortic coarctation.

## Diagnostic Principles

The age of the patient and presence of associated intracardiac defects determine the timing of clinical presentation and severity of symptoms. In children, adolescents and adults, the presenting findings are either hypertension or a cardiac murmur detected on routine examination or during evaluation for an unrelated problem. Clinical diagnosis of CoA is best made by simultaneous palpation of femoral and brachial pulses and measurement of blood pressure in both arms and one leg. Palpation of the brachial and femoral artery pulses simultaneously will reveal decreased and delayed or absent femoral pulses. Blood pressure difference of more than 20 mmHg in favor of the arms may be considered evidence for CoA.

Chest X-ray and electrocardiogram may provide clues to the diagnosis, but echocardiographic studies

confirm the diagnosis. Echocardiographic imaging usually reveals the coarctation in suprasternal notch, two-dimensional echocardiographic views. Increased Doppler flow velocity in the descending aorta by continuous wave Doppler and diastolic extension of the Doppler flow are usually present. Instantaneous peak pressure gradients across the aortic coarctation can be calculated by employing a modified Bernoulli equation:

$$\Delta P = 4(V_2^2 - V_1^2)$$

where $\Delta P$ is the peak instantaneous gradient and $V_2$ and $V_1$ are peak flow velocities in the descending aorta distal to coarctation (continuous wave Doppler) and proximal to the coarctation (pulsed Doppler), respectively [2].

Magnetic resonance imaging and three-dimensional reconstruction may be useful in selected cases. Cardiac catheterization and selective cineangiography, while not required for diagnosis, are helpful in demonstrating the anatomic nature of the aortic obstruction (discrete vs. long segment), assessing the extent of collateral circulation, determining the presence and severity of associated lesions, and more recently as a prerequisite to the consideration of balloon angioplasty and/or stent implantation. A peak-to-peak gradient in excess of 20 mmHg across the coarctation is generally considered indicative of significant obstruction.

## Therapeutic Principles

Significant hypertension and/or congestive heart failure are indications of intervention [1,3]. If hypertension (rather than heart failure) is the clinical problem, it is better to relieve the aortic obstruction promptly rather that attempting to "treat" hypertension with antihypertensive medications. Surgical relief of the aortic obstruction and catheter interventional techniques (balloon angioplasty and stents) are available alternatives. Symptomatic neonates and infants should undergo intervention on an urgent basis soon after the infant is stabilized. Asymptomatic infants, children, and adults should undergo the procedure electively. If neither hypertension nor heart failure is present, elective surgical or balloon therapy between the ages of 2 and 5 is suggested. Waiting beyond 5 years of age is not advisable because of evidence for residual hypertension if the aortic obstruction is relieved after 5 years of age.

Since the introduction of surgical correction by Crafoord and Nylin and Gross and Hufnagel in early 1940s, surgical therapy has been the treatment of choice for aortic coarctation. A variety of techniques have been used in repairing aortic coarctation, and these include resection and end-to-end anastomosis, subclavian flap angioplasty, prosthetic patch aortoplasty, and tubular bypass grafts. Several modifications of the initially described techniques have been utilized to improve the results of the operation. Since the advent of balloon angioplasty, surgical therapy is selectively applied in the neonates and infants.

Gruntzig's technique of balloon angioplasty was adopted by Singer and Sperling and their associates to enlarge coarcted aortic segments in postsurgical recoarctation and native coarctation, respectively [3]. The procedure consists of inserting a balloon angioplasty catheter across the site of coarctation and inflating the balloon with diluted contrast material. Both immediate and follow-up results are reasonably good [3].

Residual and recurrent obstructions following surgery [4] and prior balloon angioplasty [3] are also amenable for balloon angioplasty.

Despite reasonably good short-term results and long-term results of balloon angioplasty, some problems remain and include restenosis, probability of aortic rupture, formation of aneurysms, and inability to effectively treat long-segment tubular narrowing. Because of these and other reasons, endovascular stenting of aortic coarctation has gained acceptance over the last decade [5]. The indications for employing stents are as follows: (i) long-segment coarctation, (ii) associated hypoplasia of the isthmus or aortic arch, (iii) tortuous coarctation with malalignment of proximal with distal aortic segment, and (iv) recurrent aortic coarctation or an aneurysm following prior surgical or balloon therapy. The balloon catheter, with the stent mounted on it, is advanced over a stiff guide wire and positioned across the coarctation segment and the balloon inflated, thus implanting the stent. Most cardiologists use stents in adolescents and adults and restrict their use in younger children because of issues related to growth. Stent therapy appears to be an attractive method for treatment of native or recurrent coarctation in adolescents and adults, aneurysm formation following prior surgical or balloon intervention and for long-segment hypoplasia.

# Cobalamine Deficiency

Anne M. Molloy, John M. Scott
Department of Biochemistry, Trinity College Dublin, Dublin, Ireland

## Synonyms

Vitamin B12 deficiency

## Definition and Characteristics

Cobalamine deficiency can be defined as blood or tissue levels of cobalamine that are insufficient to maintain adequate function of the two enzymes that utilize this vitamin as a cofactor (methionine synthase and methylmalonylCoA mutase). Biochemical characteristics of deficiency include low serum cobalamine; raised plasma homocysteine caused by deficient activity of the synthase and raised plasma methylmalonic acid, indicating dysfunction of the mutase. Clinically, cobalamine deficiency can lead to manifestations of a macrocytic anemia identical to that seen in folate deficiency [1]. Cobalamine deficiency also causes a broad range of neurological and neuropsychiatric effects. Severe long-term deficiency leads to a specific, irreversible neurological lesion known as subacute combined degeneration, characterized by demyelination of central and peripheral nerves [2]. Pernicious anemia is a unique form of cobalamine deficiency, characterized by autoimmune destruction of the gastric parietal cells that synthesize intrinsic factor (IF), the specific transport glycoprotein required for active intestinal absorption of cobalamine. The result is severe malabsorption with consequent systemic and tissue deficiency. Pernicious anemia has also been documented as a cause of male and female infertility.

## Prevalence

Poor dietary intake and malabsorption are the most common causes of cobalamine deficiency, although several rare genetic defects in cobalamine processing enzymes cause impairment of cellular uptake or utilization, leading to functional deficiency. Cobalamine deficiency is very rare in children and young adults on good mixed diets. People who have vegan diets or otherwise limit their intake of dairy products and meat often have mild to moderate deficiency. The prevalence of pernicious anemia has been estimated to be ~1.9% in elderly populations. In addition to this, mild to moderate gastric or pancreatic insufficiency leads to inadequate or frankly deficient cobalamine status in up to 15% of elderly populations. Overall, some 20–30% of people over the age of 80 may have inadequate cobalamine status, based on the responsiveness of plasma biomarkers of cobalamine function (i.e. homocysteine and methylmalonic acid) to therapy [3]. In pregnant women, the blood level of cobalamine is lower than in the non-pregnant state but it is not clear to what extent this represents a lower maternal tissue status, a redistribution of the plasma vitamin level between fetal and maternal compartments or an alteration in maternal blood volume.

## Genes

Inborn errors have been described in the genes encoding for most of the known cobalamine related enzymes and transporters.

## Molecular and Systemic Pathophysiology

Only microorganisms can synthesize cobalamines. Human requirements are obtained from foods of animal origin. Dietary cobalamines are attached to binders in food and liberated in the stomach by pepsin and HCl. At this pH, free cobalamines are preferentially bound to haptocorrins originating in the salivary glands. Pancreatic proteases partially degrade the haptocorrins causing them to release cobalamine, which is transferred to Intrinsic Factor (IF). IF is secreted by the parietal cells of the stomach but only binds cobalamines at the more neutral pH found in the duodenum. The IF-cobalamine complex passes to the ileum where it is attached to specific receptors and absorbed by pinocytosis. Cobalamine absorption can be compromised by gastric or pancreatic insufficiency, parietal cell atrophy (pernicious anemia) or genetic mutations in the IF-cobalamine receptors of the ileum (Imerslund Grasbeck syndrome) [4]. Cobalamine in the blood circulation is protein-bound; either to transcobalamine (TC) or to haptocorrins. The fraction destined for uptake into tissues is bound to TC (holoTC) and delivered to cells by receptor mediated uptake and incorporation into the lysosomal fraction. It is released by lysosomal enzyme action and converted to two enzymatically active forms, methyl-cobalamine as the cofactor to methionine synthase in the cytoplasm and 5′ deoxyadenosyl cobalamine as a cofactor to methylmalonyl CoA mutase in the mitochondria. Genetic defects in lysosomal cobalamine activating enzymes result in functional cobalamine deficiency. Genetic defects in methylmalonyl-CoA mutase cause mild to severe clinical effects including infant mortality and growth retardation. The clinical consequences of impaired mutase function due to cobalamine deficiency are not clear. Many of the severe clinical and biochemical consequences resulting from cobalamine deficiency can be attributed to impairment of methionine synthase. Methionine synthase regenerates methionine from homocysteine and thereby supplies methyl groups, via s-adenosylmethionine (SAM), for a wide range of methyltransferases. The

methyl group for homocysteine remethylation comes from 5-methyltetrahydrofolate and the reaction is crucial to the incorporation and metabolism of folate within the cell and the maintenance of low plasma homocysteine levels. Reduced activity of methionine synthase interrupts methylation reactions both by reducing the availability of the methyl group donor SAM and by causing the level of s-adenosylhomocysteine (SAH) to rise. SAH is a powerful inhibitor of all methyltransferase enzymes. Reduction in the activity of one or more of these methyltransferases is thought to cause the clinical progression to an irreversible demyelinating neuropathy associated with chronic untreated cobalamine deficiency. Elevated homocysteine, which is a highly toxic molecule, is also thought to contribute to the neurological and neuropsychiatric disorders. Reduced activity of methionine synthase also causes trapping of folate cofactors as 5-methyltetrahydrofolate, resulting in a pseudo folate deficiency where the proportion of folate cofactors in the form needed to maintain de novo purine and pyrimidine synthesis is reduced. This affects all replicating cells but is most easily seen as a macrocytic anemia in the rapidly dividing cells of the bone marrow, identical to that seen in folate deficiency. If cobalamine deficiency is treated with folic acid, DNA synthesis will resume and the anemia will disappear but the neuropathy will not be treated. Thus the cobalamine deficiency may remain undiagnosed until the neuropathy progresses to where it is irreversible.

## Diagnostic Principles

Abnormal hematology including hypersegmented polymorphonuclear leucocytes and macrocytosis may occur. However, neurological symptoms rather than hematological symptoms often mark cobalamine deficiency in elderly patients. These include gait disturbances, tingling and numbness of the extremities, and a variety of neuropsychiatric abnormalities such as depression, mood swings and cognitive dysfunction [2,5]. Diagnosis is generally based on evidence of abnormally low serum cobalamine levels. Traditionally, a serum total cobalamine concentration below 100–120 pg/ml was considered to be a cut-off for clinical deficiency with values less than 150 pg/ml (110 pmol/l) in an indeterminate range. Plasma homocysteine and plasma methylmalonic acid are sensitive biological markers of enzyme function, with inadequate function leading to elevated levels of these biomarkers. Serum total cobalamine concentrations less than 200 pg/ml (150 pmol/l) are commonly associated with elevated biomarker levels, suggesting functional impairment [5]. Recently, clinical assays for plasma holoTC have become available. HoloTC is now being evaluated as a more sensitive indicator of cobalamine status than the total serum cobalamine concentration [5].

## Therapeutic Principles

In malabsorption due to pernicious anemia or post gastrectomy regular (monthly) intramuscular injections of cyanocobalamine. (1000 mg/ml; I ml ampoules) are prescribed for maintenance of normal cobalamine status. In nutritional deficiency or tropical sprue, oral cobalamine is alternatively prescribed (Liquid and film coated tablets 4 mg per 5 ml or per tablet.) Cobalamine deficiency due to inadequate intake can also be rectified by increasing the dietary intake of foods of animal origin (meat, milk, eggs, butter, cheese, etc).

# Cobalamine Reductase Deficiency

Göksel Somay
Department of Neurology, Haydarpaşa Numune Educational and Research Hospital, Istanbul, Turkey

## Synonyms

Methylmalonic acidemia; MMA; Vitamin $B_{12}$ responsive due to defect in synthesis of adenosylcobalamin; cblA complementation type; Type cb1A, MMAA

## Definition and Characteristics

CblA is due to deficiency of mitochondrial cobalamin reductase resulting in deficiency of adenosylcobalamin (AdoCbl). CblA disorder is characterized by vitamin $B_{12}$ (Cobalamin, cbl) responsive methylmalonic aciduria and deficient synthesis of AdoCbl, required for activity of the mitochondrial enzyme methylmalonyl-coA mutase

(MCM). Methylmalonic acidemia is inherited in an autosomal-recessive manner. It affects both boys and girls equally. The clinical spectrum of methylmalonic aciduria is wide, ranging from a benign condition to fatal neonatal disease.

## Prevalence

The prevalence of methylmalonic acidemia is difficult to define precisely. In Massachusetts, an occurrence of 1:48,000 infants was suggested. Urine screening in Quebec identified symptomatic methylmalonic aciduria in ~1:80,000 newborns screened. In Japan, the birth prevalence may be as high as 1:50,000. A much greater prevalence between 1:1,000 and 1:2,000 has been reported in Middle Eastern populations [1,2].

## Genes

CblA caused by mutation in the MMAA gene on chromosome 4q 31.1–q 31.2.

## Molecular and Systemic Pathophysiology

In mammals, vitamin $B_{12}$ functions as a coenzyme for the enzymes methionine synthase and MCM. Methylcobalamin (MeCbl) is the coenzyme for methionine synthase and functions in methyl transfer to homocysteine to form methionine. Adenosylcobalamin (AdoCbl) is the coenzyme for MCM and participates in the rearrangement reaction that converts methylmalonyl-coA to succinyl-coA. MCM is a mitochondrial enzyme, and the final steps of AdoCbl synthesis occur in the mitochondrion [3].

A number of inborn errors of metabolism have been identified that result in decreased MCM activity, either as the result of mutations affecting the gene encoding the enzyme itself (the mut class of mutations) or as the result of mutations that cause decreased synthesis of the Adocbl cofactor required for its activity [3,4]. Eight complementation groups (cblA to cblH) have been identified among patients with blocks in the cellular metabolism of vitamin $B_{12}$. Three of these, cblA, cblB, and cblH, are blocked uniquely in the synthesis of Adocbl. All are expected to involve mitochondrial functions, since this is the subcellular location of MCM. The gene responsible for the cblA complementation group, MMAA, encodes a protein of unidentified function that may be involved in vitamin $B_{12}$ transport into mitochondria [3]. It has been proposed that cblA corresponds to a defect of a mitochondrial, NADPH-dependent aquacobalamin reductase, or that it may have a block in mitochondrial binding or transport of cbl. The cblB complementation group, MMAB, encodes cobalamin transferase, which is involved in the synthesis of AdoCbl. Two other identified genes are involved in the functional expression of methionine synthase. These are the MTR gene, encoding methionine synthase and defined by the cblG complementation group, and MTRR, encoding the reactivating enzyme, methionine synthase reductase, and defined by the cblE complementation group. The other groups, cblC, cblD, and cblF, affect both MeCbl and AdoCbl synthesis, likely involving lysosomal efflux of Cbl into the cytosol (cblF) and initial steps in the reduction of Cbl (cblC and cblD) (Fig. 1).

Patients with decreased synthesis of Adocbl present with cobalamin responsive methylmalonic aciduria. Patients with cb1A disease have defective AdoCbl synthesis. Patients may lack a specific mitochondrial cobalamin reductase [5].

## Diagnostic Principles

Specialized metabolic testing is required to diagnose methylmalonic acidemia.

Definitive diagnosis relies on analysis of organic acids in plasma and/or urine by gas–liquid chromatography (GC) and mass spectrometry (MS); the concentrations of methylmalonic acid is greatly increased in the plasma, urine, and cerebrospinal fluid of severely affected individuals.

Nonspecific findings on biochemical testing include: 3-hidroxypropionate, methylcitrate, and tiglylglycine detected in GC/MS analysis of urine; ketone bodies and lactate detected in the urine in the decomposed state; increased concentration of glycine detected on plasma amino acid analysis; elevated propionylcarnitine in the acylcarnitine ester profile analyzed by MS.

Prenatal diagnosis for methylmalonic acidemia is possible by biochemical analysis. Enzyme analysis of cultured fetal cells obtained by amniocentesis usually performed at about 15–18 weeks gestation or chorionic villus sampling at about 10–12 weeks gestation.

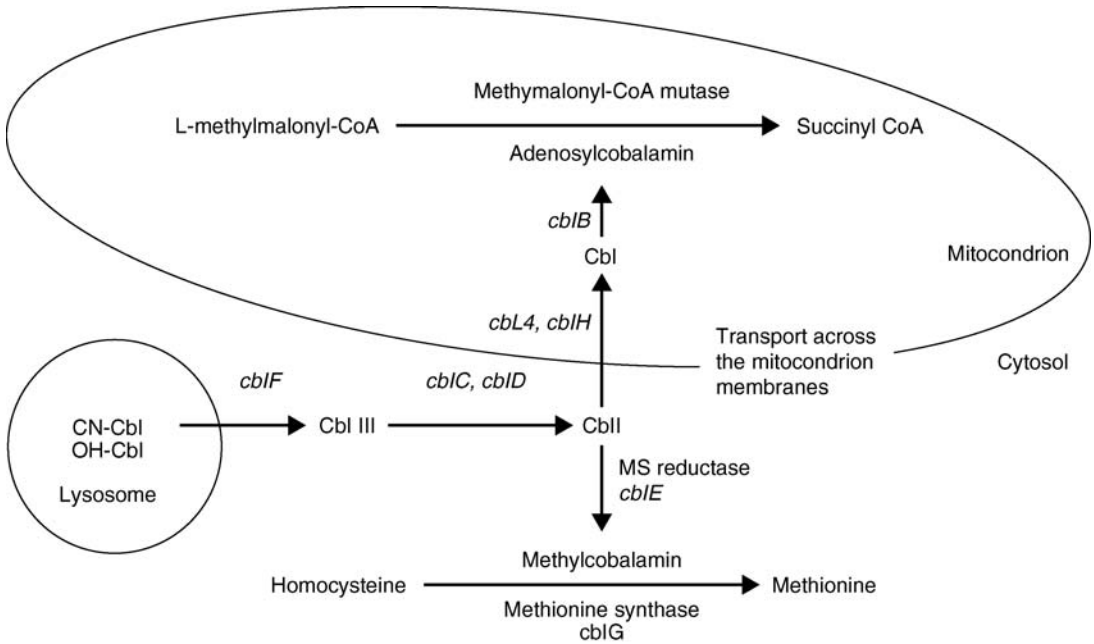
## Therapeutic Principles

Nutritional management is critical. This typically includes instituting a low-protein (1.5 g/kg/day), high-caloric diet.

Cobalamin supplementation may help because cobalamin is a cofactor in the enzymatic conversion of methylmalonyl-CoA to succinyl-CoA. This therapy can be started while the diagnosis is being confirmed. Hydroxycobalamin injections should be given as soon as the diagnosis of methylmalonic acidemia is seriously considered. If cobalamin supplementation is not helpful, restrict the patient's propriogenic amino acid precursors (isoleucine, threonine, methionine, and valine) intake.

L-carnitine may be useful to replete with intracellular and extracelluler stores of free carnitine, since these patients usually have low carnitine levels.

A variety of antibiotic regimens (such as neomycin or metronidazole) to reduce the production of propionate from gut flora can be used.



**Cobalamine Reductase Deficiency. Figure 1** Intracellular processing of cobalamin. In the mitochondria, cobalamin is converted to adenosylcobalamin, a coenzyme involved in the conversion of methylmalonyl-CoA to succinyl-CoA. In the cytoplasm, cobalamin functions as a coenzyme for the reaction catalyzed by methionine synthase.

Liver transplantation or combined liver/kidney transplantation can increase metabolic homeostasis and protect against metabolic decompensation.

# Cobalt Deficiency

Sultan Ayoub Meo
Department of Physiology, College of Medicine, King Khalid University Hospital, King Saud University, Riyadh, Kingdom of Saudi Arabia

## Definition and Characteristics

Cobalt [Co] is a hard, silver-white, hexagonal element; its active biological form is called cobalamin [vitamin B12] [1]. As a component of vitamin B12 it can cause anemia. The common symptoms due to acute cobalt deficiency are paleness, weakness, fatigue, loss of appetite, weight loss, and subsequent poor growth, shortness of breath, dizziness, scaly ears and watery discharge from the eyes. Furthermore, a marked deficiency can cause tingling or loss of sensation in the hands and feet, muscle weakness, muscle cramps, diminished reflexes, difficulty in walking, confusion, dementia [2] and decreased thyroid function.

## Prevalence

The prevalence of cobalt deficiency is uncommon. Cobalt deficiency is rare in the adult population. However, low birth weight and preterm children, who are

born with low cobalt stores, are at greater risk of acquiring the cobalt deficiency disease. Moreover, its prevalence is higher among children consuming vegan-type diets and with inborn errors of cobalamin metabolism. Cobalamin deficiency is more prevalent in children in developing countries. Some 12% of breast-fed infants and 30–50% of children had low plasma cobalamin concentrations [3] No population-based surveys measuring all of these variables in adults or children have been reported.

## Genes

Co metal is genotoxic in vitro and in vivo, many cobalt compounds are genotoxic in mammals, mammalian and bacterial test systems. Cobalt (II) compounds are positive for genetic conversions in Saccharomyces cerevisiae. Possibly production of active oxygen species and/or DNA repair inhibition are the mechanisms involved. The two different mechanisms of genotoxicity DNA breakage induced by cobalt metal and especially hard metal particles, and inhibition of DNA repair by cobalt (II) ions contribute to the carcinogenic potential of cobalt compounds [4].

## Molecular and Systemic Pathophysiology

Cobalt is essential for formation of hydroxycobalamin, which is enzymatically active as part of methylmalonyl coenzyme A (CoA) mutase for conversion of propionyl to succinyl CoA. The succinyl CoA is an intermediate product in the citrate cycle and a 5-methytetrahydrofolate-homocysteine methyltransferase that modulates metabolism of methionine in DNA synthesis [1].

Cytotoxic hydroxy radicals may form when cobalt ions interact with reactive oxygen species. Hydroxy radicals cause the production of further free radicals which reduce cellular glutathione concentrations and NADPH activity. The resulting oxidative stress leads to DNA and cellular protein damage [4]. Cobalt is immunogenic and acts as a hapten in the induction of bronchial and dermal hypersensitivity. In cobalt pneumoconiosis non-respiratory symptoms may be due to cobalt-induced release of a tumor necrosis factor from sensitized pulmonary lymphocytes. Cobalt myocardial toxicity is distinguished by vacuolation and loss of myofibers with mitochondrial damage. Cobalt depresses mitochondrial oxygen uptake in the myocardium by complexing with sulphydryl groups and preventing the oxidation of pyruvate in the citric acid cycle. Tissue hypoxia is the also probably the stimulus of erythropoietin secretion in cobalt-induced polycythemia. Cobalt decreases synthesis of several enzymes including cellular cytochrome $P_{450}$ and inhibits aminolaevulinic acid synthetase and increases the activity of heme oxygenase which breaks down heme to biliverdin [4].

## Diagnostic Principles

Detailed clinical history, complete blood picture and blood cell morphology play a significant role in the diagnosis of cobalt deficiency. The proposed values for healthy subjects reported by Minoia et al. (1990) [5] are 0.18–0.96 g/L in urine; 0.01–0.9 g/L in whole blood; and 0.08–0.40 g/L in serum should be considered. Furthermore, serum Methylmalonic acid (MMA) concentration may provide a more reliable diagnostic test for cobalt deficiency and may offer advantages over serum vitamin B12 concentrations in the diagnosis of a cobalt/vitamin B12 responsiveness.

## Therapeutic Principles

In the case of pernicious anemia the patient should be treated with vitamin B12 according to the symptoms. Moreover, in cobalt deficiency supportive treatment with fluids and electrolytes and symptomatic treatment is also suggested.

# Cobalt Excess

Sultan Ayoub Meo
Department of Physiology, College of Medicine, King Khalid University Hospital, King Saud University, Riyadh, Kingdom of Saudi Arabia

## Definition and Characteristics

Cobalt (Co) is a solid, silver color like element. Exposure to cobalt occurs during its production, diamond

polishing [1], dentistry materials, soil and natural dust, seawater spray, volcanic eruptions, forest fires, marine biogenic emissions. Moreover, airport and highway traffic pollution may also become a cause of cobalt exposure. Cobalt enters into the body through inhalation (pulmonary), ingestion (gastrointestinal) and contacts (skin) and is excreted in urine and feces [2].

The excessive inhalation of cobalt may cause panic-anxiety attacks, coughing, and difficulty in breathing, interstitial lung disease, allergic alveolitis, respiratory deficiency, impaired lung function, bronchial asthma and pneumoconiosis. It may also cause goiter and reduced thyroid activity [1]. Toxicity of ingested cobalt includes nausea, vomiting, abdominal pain, and congestive cardiomyopathy [3]. Cardiovascular toxicity of cobalt includes angina, congestive cardiomyopathy (beer drinker's cardiomyopathy characterized by pericardial effusion, elevated hemoglobin), myofibril degeneration and cor pulmonale. The neurological problems include weight loss, vertigo, impaired hearing, and a decreased sense of vibration, unsteady gait, and paraesthesia [4]. Similarly, hematopoietic toxicity of cobalt causes an increased red blood cell count and decreased leukocyte (polymorphonuclear neutrophils) count. This decline of polymorphonuclear neutrophils may further impair phagocytic function and immunity. The contact toxicity may cause contact allergy, contact dermatitis, pain and burning with edema and erosive lesions following exposure to cobalt. Furthermore, cobalt chloride is a potent teratogenic; Exposed embryos showed concentration-related malformations including gut malrotation, ocular anomalies, kinked tail, craniofacial dysplasia, cardiac deformities, dermal blisters, stunted growth, edema, ventral distention and hypopigmentation [5].

## Prevalence

The association of disease with cobalt excess is uncommon. The significant excess of lung cancer found among workers involved in the production of cobalt, standardized mortality ratio (SMR) 4.66, 95%CI 1.46 to 10.64. Moreover, cobalt is implicated in (4%) occupational contact dermatitis. However, literature is lacking about the prevalence of various cobalt excess diseases.

## Genes

The cobalt compounds are genotoxic by production of active oxygen species and/or DNA repair inhibition are mechanisms involved. The two different mechanisms of genotoxicity DNA breakage induced by cobalt metal and especially hard metal particles, and inhibition of DNA repair by cobalt (II) ions contribute to the carcinogenic potential of cobalt compounds [1].

## Molecular and Systemic Pathophysiology

Due to distribution of cobalt in the environment, subjects may be exposed to cobalt by breathing air, drinking water, and eating food containing cobalt, and children may also be exposed to cobalt by eating dirt. Additionally, subjects may also be exposed by skin contact with soil, water, cobalt alloys, or other substances that contain cobalt. Mechanisms underlying cobalt toxicity are poorly understood. Cytotoxic hydroxy radicals may form when cobalt ions interact with reactive oxygen species. Hydroxy radicals cause the production of further free radicals which reduce cellular glutathione concentrations and NADPH activity. The resulting oxidative stress leads to DNA and cellular protein damage [1]. Cobalt is immunogenic and acts as a hapten in the induction of bronchial and dermal hypersensitivity. In cobalt pneumoconiosis non-respiratory symptoms may be due to cobalt-induced release of a tumor necrosis factor from sensitized pulmonary lymphocytes. Cobalt myocardial toxicity was characterized by vacuolation and loss of myofibers with histo-chemical evidence of severe mitochondrial damage. Cobalt depresses mitochondrial oxygen uptake in the myocardium by complexing with sulphydryl groups and preventing the oxidation of pyruvate in the citric acid cycle. Tissue hypoxia is the also probably the stimulus of erythropoietin secretion in cobalt-induced polycythemia. Cobalt decreases synthesis of several enzymes including cellular cytochrome $P_{450}$. Cobalt inhibits aminolaevulinic acid synthetase and increases the activity of heme oxygenase which breaks down heme to biliverdin [1].

## Diagnostic Principles

Detailed clinical history, complete blood count and blood cell morphology play a significant role in the diagnosis of cobalt excess. The proposed values for healthy subjects reported by Minoia et al. (1990) [3] are 0.18–0.96 g/L in urine; 0.01–0.9 g/L in whole blood; and 0.08–0.40 g/L in serum should be considered. Furthermore, serum methylmalonic acid (MMA) concentration may provide a more reliable diagnostic test for cobalt deficiency/excess and may offer advantages over serum vitamin B12 concentrations in the diagnosis of a cobalt/vitamin B12 responsiveness. However, in case of respiratory toxicity chest X-ray, CT-scan, lung function test is helpful. Furthermore, in cardiac toxicity, cardiac enzymes, ECG and echocardiography can facilitate the diagnosis.

## Therapeutic Principles

In acute toxicity the first line of management is to eradicate the patient from the exposure, treat the cause, supportive treatment with fluid and electrolytes, and also treat the patient symptomatically. However, in the

case of chronic excess to cobalt such as in the case of inhalation and ingestion treat the patient based on the types of disease such as congestive cardiomyopathy, asthma, pneumoconiosis.

# Coccidioidomycosis

Joshua Fierer
Division of Infectious Diseases, Department of Medicine, University of California at San Diego, San Diego, CA, USA

## Synonyms

San Joaquin valley fever; Desert rheumatism

## Definition and Characteristics

This infection may be asymptomatic, a self-limited "flu-like" illness, or a typical pneumonia, often with mediastinal adenopathy. Pneumonia usually resolves completely but in 5–10% of cases there is a residual granuloma or thin walled cavity. Chronic upper lobe bronchiectasis is the least common outcome. Some patients with primary coccidioidomycosis have skin rashes (erythema nodosum or marginatum) with arthralgias or frank arthritis. These symptoms are due to an immunological reaction to the fungus, not to spread of infection; these patients have an excellent prognosis.

Dissemination outside the lung is the most serious manifestation of this disease. It can occur early in the course of infection and present like miliary tuberculosis. More often patients present with symptoms related to extra-pulmonary dissemination. The most common sites of dissemination are skin, bones and joints, and the meninges. In adults infection of the spine is common.

Coccidioidal meningitis is the most serious form of dissemination. Presentation is usually sub-acute and headache is the most common symptom. Altered mental status, personality changes, nausea, vomiting, and focal neurological deficits may be present at the onset or develop. Some degree of meningismus is present in 50% of the cases. Hydrocephalus may occur. Less commonly there may be a granulomatous vasculitis at the base of the brain that can lead to a stroke. Focal granulomas of the brain parenchyma are extremely rare.

## Prevalence

The true incidence is unknown but it is estimated that there are 100,000 new infections each year in the United States. The highest rates of infection are in the San Joaquin valley of California and the region between Tucson and Phoenix in Arizona.

## Genes

The two species of coccidioides are distinguished only by microsatellite markers and multilocus sequence analysis [1]. Little is known about virulence genes in the fungus. The lesions produced by the infection are quite alkaline and the organism posses a urease that is required for virulence in mice. There are cell wall-associated glucosidases and chitinases that play a role in the morphogenesis of the fungus, and a β-glucan synthase is an essential gene [2]. Expression of a nitrate reductase is upregulated in the spherule form, suggesting that it is able to switch to anaerobic metabolism [3].

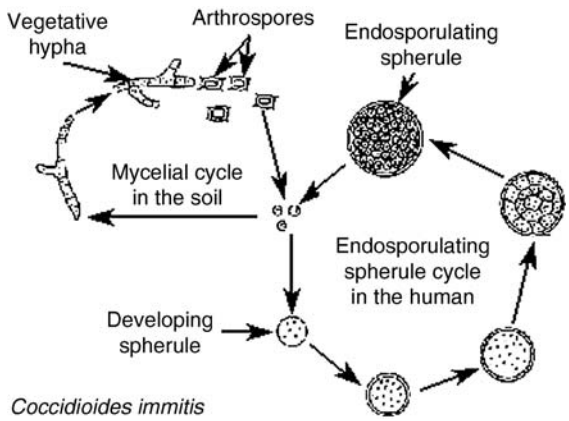
The host response is probably genetically controlled because the risk of dissemination is five to tenfold higher in Filipinos and African Americans than in Caucasians. Inbred strains of mice also vary widely in their susceptibility, and resistance is the dominant phenotype, but is multigenic [4].

## Molecular and Systemic Pathophysiology

C. immitis and C. posadasii (outside of California) live in the soil of the Lower Sonoran life zone in the New World. Infection is initialed by inhaling arthroconidia. Within hours the fungus changes, developing into a spherule (Fig. 1).

It is uncertain whether there is sub-clinical hematogenous extra-pulmonary dissemination in all cases of coccidioidomycosis or whether that only occurs in patients who have disseminated infection. The tropism for certain organs is not understood.

In experimental animals TNF-α, IL-12, and interferon gamma are required for resistance, and high levels



**Coccidioidomycosis. Figure 1** The life cycle of *Coccidioides* spp (courtesy of Gary E. Kaiser, Ph.D.). The fungus grows in the soil as a mold, making arthroconidia inside the hyphae. Arthroconidia are smaller than 4 μm in diameter so they can reach alveoli when inhaled. Once in the host they discard their out wall and develop into round cells that enlarge and become spherules. A fully mature spherule can be as large as 100 μm. The spherule cytoplasm undergoes deductive divisions until it is filled with endospores that will be released when the spherule ruptures. The event is very chemotactic for neutrophils.

of IL-10 increase susceptibility. Acquired immunity is T lymphocytes dependent. Patients with low CD4 counts are susceptible to disseminated infections.

## Diagnostic Principles

If a patient has been in the endemic area recently and develops pneumonia, coccidioidomycosis should be in the differential. Diagnosis is made either by culture, serology, or histopathology. Coccidioides spp grow on all standard fungal media. If the specimen is heavily infected the organism will grow on media such as blood agar, which is a potential biohazard for laboratory workers. A mold can be presumptively identified as coccidioides if there are alternating arthroconidia inside the hyphae. Definitive identification is best done with a commercial DNA probe. It is very rare to isolate organisms from the cerebral spinal fluid in patients with meningitis. Real-time PCR has been used to detect fungal DNA in clinical specimens.

Serological testing is a common way to diagnose coccidioidomycosis. Serology can be done using commercially available immunodiffusion plates or ELISA assays, or with the traditional complement fixation test (CF). About 50% of patients will have detectable IgM antibodies within a week of the time they present with pneumonia and by three weeks after onset of pneumonia 90% will be positive. IgG CF antibodies are detectable in most patients 3–6 weeks after onset of pneumonia. IgM antibodies usually remain positive for 2–3 months, but may be persist in some patients with residual pulmonary granulomas. CF antibody will persist up to 2 years in patients who have uncomplicated pneumonia. CF antibody titers of >1:16 are highly predictive of dissemination, and the higher the titer, the worse the prognosis. CF antibody may persist indefinitely in patients with disseminated infections. Patients who are severely immunocompromised such as those with AIDS or after a solid organ transplant may not have a positive serology even when they have disseminated infection.

Meningitis is nearly always diagnosed based on compatible findings in the CSF (low glucose, high protein, and a lymphocytic pleocytosis, occasionally with eosinophils) and a positive CSF serology. Any CF antibody titer in the CSF should be regarded as highly suspicious of meningitis. Neuro-imaging may be helpful to diagnose vasculitis or hydrocephalus.

The pathological response to the fungus is granulomatous inflammation. Spherules may be clearly visible on H&E stain, but are more easily seen with a silver stain such as Gomori-methenamine.

## Therapeutic Principles

It is not established whether treatment shortens the duration of a primary pneumonia or lessens the risk of complications. Solitary granulomas need not be treated but are often removed surgically because without serial radiographs it is impossible to exclude a malignancy. Thin walled cavities do not usually respond to medical treatment and unless there are complications such as hemoptysis these do not have to be treated. Severe symptomatic primary pneumonias should be treated with either amphotericin B or an azole such as fluconazole or itraconazole.

The serology (CF titer) is a very important guide to starting treatment and for monitoring response to therapy. Anyone who has a CF titer of ≥1:32 is presumed to have disseminated infection and should be treated. The drugs that are effective against coccidioidomycosis are amphotericin B deoxycholate (and all the lipid formulations), the azoles, and the echinocandins. Ketoconazole is the only FDA approved drug in the United States for treatment of coccidioidomycosis, but it is the least effective. Most clinicians in the endemic area begin treatment of acutely ill patients with 2 g of amphotericin B deoxycholate or about five times as much of a lipid formulation. Patients who have milder illness or a chronic infection are usually treated with fluconazole or itraconazole. Posaconazole and voriconazole are newer alternatives, but there is little published data about their use in this disease. There is no consensus about how long to treat patients. Patients often relapse shortly after treatment with an azole has been discontinued [5].

Systemic amphotericin B does not reach adequate concentrations in the CSF to treat coccidioidal meningitis and so it must be given by intrathecal injection; that is very toxic and often causes arachnoiditis, even when administered with corticosteroids. Fluconazole was shown to be effective treatment for meningitis and 400–1,000 mg are given daily. Other azoles may also be effective and should be tried in the rare patient who does not respond to fluconazole. Echinocandins do not cross the blood brain barrier. Neurosurgical shunting is required for patients who develop hydrocephalus. No treatment has been shown to cure meningitis so suppressive therapy should be continued indefinitely.

[2]Department of Dermatology, University Hospital of Schleswig-Holstein, Campus Kiel, Kiel, Germany

### Synonyms

Excision repair cross complementing (ERCC) group 6 (CS-B); CS

### Definition and Characteristics

Typical facial appearance with deep set eyes, large ears and microcephaly, growth and mental retardation, signs of premature aging with reduced subcutaneous tissue, photosensitivity, gait abnormalities and tooth defects. Neurological defects such as demyelinisation of nerves, calcification of basal ganglia as well as ocular abnormalities such as cataracts and retinopathia pigmentosa occur later in life [1].

### Prevalence

In Western European populations the incidence is 1.8 per 1 million livebirths [2].

### Molecular and Systemic Pathophysiology

Mutations in CS-A (Chr.5) and CS-B (10q11) genes cause isolated CS. Mutations in the XP-B, XP-D and XP-G genes cause ►Xeroderma Pigmentosum in combination with Cockayne syndrome. The exact functions of the CS-A and CS-B proteins are unclear. Cells obtained from CS patients are defective in the repair of actively transcribed genes (transcription coupled repair, TCR) by nucleotide excision repair (NER) of ultraviolet-radiation induced and oxidative DNA damage. In contrast to XP patients, there is no increased risk to develop skin cancer [3–5].

### Diagnostic Principles

Clinical picture of patients with typical facial appearance and growth and mental retardation leads to the diagnosis. Patients suffer from increased photosensitivity. The diagnosis is confirmed if recovery of RNA synthesis in fibroblasts derived from the patient's skin is abnormally low following irradiation with ultraviolet rays.

### Therapeutic Principles

Patients need to be protected from exposure to ultraviolet radiation (protective clothing, plastic window-covers filtering ultraviolet radiation, ultrapotent sunscreens).

## Colitis, Ulcerative

Jürgen Schölmerich
Department of Internal Medicine I, University Medical Center Regensburg, Regensburg, Germany

### Definition and Characteristics

An inflammatory disease of the colon with continuous expansion from the rectum to the more proximal regions. Most patients have proctitis, rectosigmoiditis or left-sided colitis only. Mucosal inflammation is associated with extraintestinal manifestations on skin, eyes, joints and bile ducts as well as many other organs. Dominant symptom is bloody diarrhea.

### Prevalence

Incidence and prevalence vary widely depending on the region and the race. In Central Europe incidence is 8–12/100,000/year, prevalence is between 100 and 200/100,000 inhabitants. Age and initial manifestation is mostly between 20 and 40 years, however, all age groups can be affected. The disease is more frequent in countries with European/North American lifestyle and appears in other countries about 10–15 years earlier than Crohn's disease (CD) (see ►Crohn's Disease). Twin concordance rate and family history are less impressive than in CD but sufficient to strongly suggest genetic susceptibility.

### Genes

Among the many gene loci found associated with inflammatory bowel disease (IBD) none has yet been unequivocally and consistently found to be responsible for manifestation of ulcerative colitis. HLA genes have been linked to ulcerative colitis (IBD3 region on chromosome 6) but none has been consistently confirmed [1]. It seems possible that HLA play a greater role in determining disease phenotype than disease susceptibility. The multi-drug resistance 1 gene (MDR-1) on chromosome 7q22 has been associated with (extensive) ulcerative colitis [2]. A mouse model of MDR-1 knockout develops enterocolitis. Genetic variation in myosin IXB is associated with UC [3]. Mucine genes have been suggested to play a role among many others [4] (Table 1).

### Molecular and Systemic Pathophysiology

There must be environmental factors involved in the manifestation of ulcerative colitis. While smoking has a preventive effect, appendicectomy promotes the development of the disease. The rise of the incidence in countries developing a "modern western lifestyle"

**Colitis, Ulcerative. Table 1** IBD candidate genes involved in the innate immune response [4]

| HBD-2 | 8p23 | – |

indicates other factors, which have not been defined thus far. In the acute phase inflammation is characterized by neutrophil infiltration (crypt abscesses), in the chronic phase lymphocytes are predominant.

## Diagnostic Principles

Diagnosis is easily done by rectosigmoidoscopy and biopsy after elimination of infectious causes of the diarrhea. Extension is defined by colonoscopy. Differentiation from Crohn's disease is difficult in about 10% of patients, which are called "indeterminate colitis." There are no specific laboratory markers although about 60% of patients show pANCA in serum.

## Therapeutic Principles

5-Aminosalicylic acid (5-ASA) is the most important drug used. For distal colitis rectal application is preferable leading to a higher local concentration of this topically acting substance. Glucocorticosteroids are used in 5-ASA refractory patients. The disease can be cured by surgical resection of the colon (mostly done with construction of an ileoanal pouch). Alternatively in refractory disease cyclosporine A or the TNF antibody infliximab can be used to induce and azathioprine to maintain remission [5].

# Collagen VI Related Muscle Disorders

Anne Katrin Lampe[1], Kate Bushby[2]
[1]South East of Scotland Clinical Genetic Service, Western General Hospital, Edinburgh, UK
[2]Institute of Human Genetics, Newcastle University, International Centre for Life, Newcastle upon Tyne, UK

## Synonyms

Ullrich congenital muscular dystrophy; UCMD; Bethlem myopathy (BM) (subtypes)

## Definition and Characteristics

Mutations in the genes encoding any of the three collagen VI chains (COL6A1, COL6A2, COL6A3) have been demonstrated in Bethlem myopathy (BM; MIM 158810) and Ullrich congenital muscular dystrophy (UCMD; MIM 254090), conditions which were previously believed to be completely separate entities. BM is a relatively mild dominantly inherited disorder, characterised by proximal muscle weakness and joint contractures mainly involving the elbows, ankles and fingers [1]. Where contractures are prominent, this disorder may resemble an Emery Dreifuss muscular dystrophy. In other patients the contractures may be relatively subtle, leading to potential confusion in diagnosis with cases of limb-girdle muscular dystrophy. By contrast, UCMD causes severe muscle weakness of early onset and is associated with a high probability of respiratory failure, with proximal joint contractures and striking hyperelasticity of distal joints [2]. It was originally regarded as an exclusively autosomal recessive condition but recently cases with dominant mutations have been described [3].

## Prevalence

Estimated to be 0.5:100,000 in BM; 0.1:100,000 in UCMD; (personal communication by Fiona Norwood, Bromley Hospitals NHS Trust, Orpington, UK).

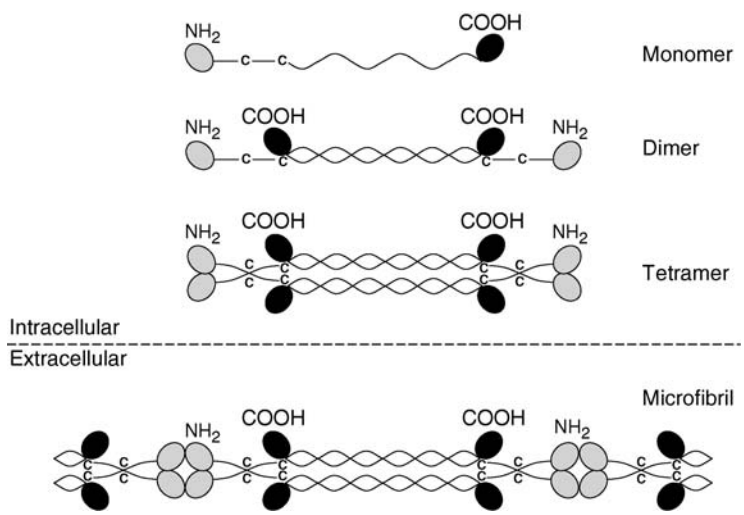
## Genes

COL6A1, COL6A2 (situated head to tail on chromosome 21q22.3) and COL6A3 (located on chromosome 2q37) encode the α1(VI), α2(VI) and α3(VI) chains of collagen VI, a ubiquitous extracellular matrix protein that is present in the stroma but also forms a microfibrillar network in close association with the basement membrane of most tissues. All three chains contain a central short triple helical domain of 335–336 amino acids with repeating Gly-Xaa-Yaa sequences, flanked by two large N- and C-terminal globular domains made up of motifs of 200 amino acids each, which are homologous to von Willebrand factor type A domains. Equimolar assembly of α1(VI), α2(VI) and α3(VI) to form a triple helical monomer is followed by staggered assembly into disulphide bonded antiparallel dimers, which then align to form tetramers, also stabilized by disulphide bonds (Fig. 1).

Outside the cell, tetramers – the secreted form of collagen VI – associate end to end through overlapping N-terminal domains to form beaded microfibrils.

## Molecular and Systemic Pathophysiology

Collagen VI forms a highly branched filamentous network in the extracellular matrix that encircles



**Collagen VI Related Muscle Disorders. Figure 1** Schematic model of collagen VI assembly, modification from Furthmayr et al. (1983) Biochem J 211:303–311 and Zhang et al (2002) J Biol Chem 277:43557–43564.

interstitial collagen fibers and is in intimate contact with basement membranes surrounding muscle fibers. It interacts with several other extracellular matrix constituents and functions attributed to it include (i) anchoring of the basement membrane to the underlying connective tissue, (ii) acting as a scaffold for the formation of fibrillar collagen networks, (iii) modulating fibrillogenesis, (iv) mediating cell-cycle signaling and (v) maintaining tissue homeostasis. Mutations for both BM and UCMD patients occur in any of the three collagen VI genes but specific mutations tend to be strictly associated with either a BM or UCMD phenotype [4]. Whereas exonic deletions and missense mutations (especially triple helical glycine substitutions) causing BM appear particularly frequent in the COL6A1 region encoding the N-terminal part of the triple helical domain of the α1(VI) chain, it is in-frame deletions as well as frameshifting insertions or deletions in COL6A2 and COL6A3 which form the bulk of UCMD mutations. Ancillary data elucidating their pathogenic mechanism are only available for a minority of these mutations. For BM patients, glycine substitutions towards the N-terminus of the triple helix may cause kinking of the tetramers, thus reducing their ability to form microfibrils and exerting a dominant negative effect [5]. A COL6A1 exon 14 deletion in a BM patient produces shortened α1 (VI) chains that allow intracellular monomer formation but lack a unique cysteine and prevent further assembly of the mutated chains into dimers and tetramers, resulting in reduced amounts of extracellular collagen VI [3]. This contrasts with the mechanism documented for a number of heterozygously occurring N-terminal triple helical deletions in UCMD patients where the mutated chain preserves a cysteine important for dimer or tetramer assembly, allowing secretion of abnormal tetramers with a consequent dominant negative effect on microfibrillar assembly. A large number of recessively acting UCMD mutations appear to result in premature termination codons with consequent nonsense-mediated mRNA decay and loss of the mutated chain.

### Diagnostic Principles

Mutation analysis remains the gold standard for diagnosis but can be problematic due to the large size of the genes. Typical clinical features with normal or only mildly increased serum creatine kinase and myopathic or dystrophic changes on muscle biopsy suggest the diagnosis of BM or UCMD. Collagen VI immunolabeling of the endomysium and basal lamina on muscle biopsy is usually normal in BM and ranges from absent to moderately reduced in UCMD with studies on dermal fibroblasts serving as a useful adjunct.

### Therapeutic Principles

Treatment for both BM and UCMD is supportive and includes stretching and splinting to keep contractures at bay and maintain mobility. Repeated surgical release may become necessary as contractures tend to be aggressive once established but early contractures in BM may be strikingly dynamic in nature. In UCMD patients, early mobilization in standing frames to achieve upright posture is vital but spinal surgery may be required to prevent progression of scoliosis. Regular assessments are mandatory to detect asymptomatic decline into respiratory failure. Nocturnal ventilatory support usually becomes necessary in the first or second decade in UCMD patients and, due to the presence of diaphragmatic weakness, may be required in BM patients even before loss of ambulation.

## Definition and Characteristics

Colonic diverticula are acquired mucosal outpouchings through the muscle of the colonic wall. The mere presence of diverticula is called diverticulosis but when they are associated with symptoms the term diverticular disease is used; diverticulitis is inflammation associated with a diverticulum.

## Prevalence

It is the most common structural abnormality of the colon. Its exact incidence is not known but it is endemic in the elderly populations of developed countries. It is estimated that the condition affects around 5% of people in the fifth decade of life, rising to around 50% in the ninth. Clinical manifestations are thought to arise in approximately 10–20% of these people.

## Molecular and Systemic Pathophysiology

Epidemiological and physiological data suggest that high colonic intraluminal pressures develop as a result of lack of dietary bulk, causing mucosal herniations. Once the diverticula have developed, dietary fiber seems to have little role in preventing complications. A reduction in the tensile strength of the colonic wall with age probably contributes to their formation. Genetic factors have been postulated in the formation of diverticula, particularly the right sided diverticula seen in Far Eastern communities.

It is usual to find two rows of diverticula, one on either side of the mesenteric side of the antimesenteric teniae (the condensations of the longitudinal muscle coats). The diverticula form at the site of vasa recta perforation which is a site of relative weakness in the colonic wall.

High intraluminal pressures cause circular and longitudinal muscle thickening, primarily due to elastin deposition, with resultant shortening and a concertina effect on the affected bowel.

In western communities, the sigmoid colon is most frequently affected as wall pressure increases as the colonic diameter decreases (law of Laplace). This is in contrast to the right sided diverticula seen in far eastern communities.

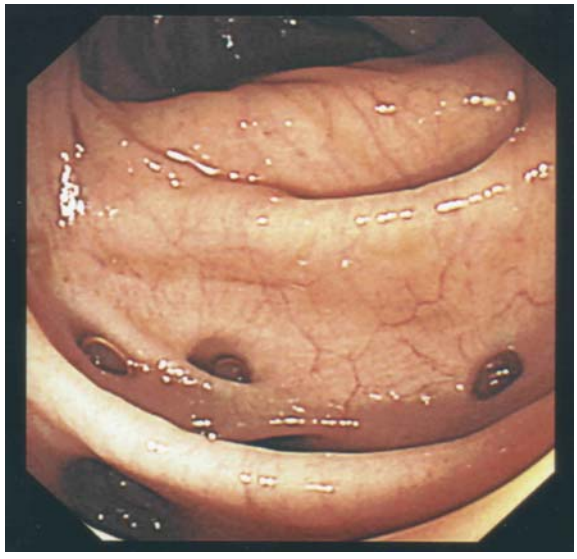
The majority (80–90%) of people with colonic diverticula are asymptomatic. The most common complaint is vague abdominal pain and alteration in bowel habit which may be indistinguishable from the irritable bowel syndrome. Diverticulitis causes left lower quadrant pain associated with a fever. It typically responds to antibiotics and bowel rest. Diverticulitis may be complicated by perforation, abscess or stricture formation and fistulation to adjacent organs. Hemorrhage from diverticula can also occur.

## Diagnostic Principles

The diagnosis is made on colonoscopy (Fig. 1), barium enema (Fig. 2) or computed tomography.

## Therapeutic Principles

Bowel rest, intravenous fluid and antibiotics may be required. Repeated or severe attacks may require surgical resection of the affected segment.



**Colonic Diverticular Disease. Figure 1** Colonoscopy showing diverticula.

**Colonic Diverticular Disease. Figure 2** Barium enema showing diverticula.

# Colonic Pseudoobstruction

►Ogilvie's Syndrome

# Colorectal Cancer

Hope E. Uronis, Gerard C. Blobe
Medicine, Pharmacology and Cancer Biology, Duke University, Durham, NC, USA

## Synonyms

CRC; Colorectal carcinoma

## Definition and Characteristics

Includes cancers of the colon (ascending, transverse, descending and sigmoid) and rectum (from sigmoid colon to anus). Relative to colon cancers, rectal cancers have a higher risk of local/regional involvement, local recurrence and hematogenous spread to the lung. Colorectal cancers can be either sporadic (~95%) or familial (including familial adenomatous polyposis (FAP, 1%) and hereditary nonpolyposis colon cancer (HNPCC, 3–5%)). FAP and HNPCC are autosomal dominant disorders characterized by early onset of colon cancer. FAP patients form hundreds of adenomatous polyps while HNPCC patients form fewer polyps. HNPCC can be suspected based on family history and is diagnosed by testing for microsatellite instability [1]. Both sporadic and familial cases of colorectal cancer follow a similar pathophysiologic course.

## Prevalence

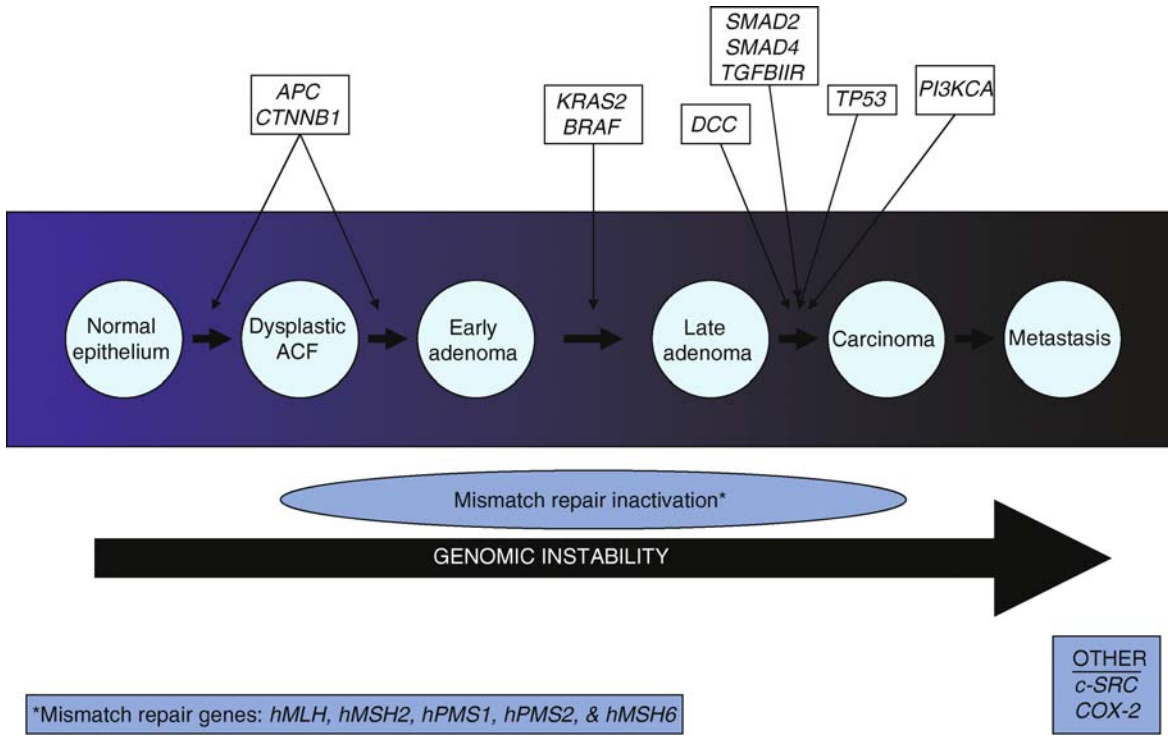
1,023,256 new cases and 529,020 deaths worldwide per year [2].

## Genes

Germline or somatic mutations (inactivating) in the tumor suppressor gene APC (with LOH at 5q21); germline mutations result in FAP [3].
Somatic mutation in CTNNB1, encoding β-catenin.
Somatic mutations (activating) in KRAS2, encoding a small guanosine triphosphate hydrolase or BRAF, encoding a kinase in the Ras-Raf-MAPK pathway.
Germline or somatic mutations (inactivating) of hMSH2, hMLH1, hPMS1, hPMS2, and hMSH6, or promoter silencing of hMLH1, encoding DNA mismatch repair genes; germline mutations implicated in HNPCC.
Somatic mutations (inactivating) in DCC (with LOH at 18q21), encoding a cell adhesion protein.
Somatic mutations (inactivating) in SMAD4 or SMAD2 (with LOH at 18q21) encoding transcription factors in the TGFβ signaling pathway.
Somatic frameshift mutations (inactivating) in TGFBR2, encoding the TGFβ type II receptor.
Somatic mutations in the tumor suppressor gene TP53 (with LOH at 17p).
Somatic mutations in PIK3CA (activating), encoding a kinase in the PI3K pathway.

## Molecular and Systemic Pathophysiology

Colorectal cancers evolve from normal epithelium in a multi-step process facilitated by genomic instability resulting in inactivation of tumor suppressor pathways and activation of oncogenic pathways (Fig. 1) [3]. As specific pathways are characteristically altered at discrete steps, it is the accumulation of mutations that drives the process. One of the earliest and most



**Colorectal Cancer. Figure 1** Colorectal cancer pathogenesis: Adenoma to carcinoma sequence. Colorectal carcinomas develop as a result of the accumulation of multiple mutations that occur in a step-wise fashion. Underlying this process is the loss of the cell's ability to maintain DNA fidelity (i.e. genomic instability). The earliest identified mutations occur in the *APC* tumor suppressor, which regulates the *Wnt*/B-catenin pathway, and in *CTNNB1*, the gene encoding β-catenin. Dysregulation in the *Wnt* signaling pathway leads to uncontrolled cell growth and tumorigenesis. Subsequent mutations occur in *KRAS2* and *BRAF*, which regulate the Ras-Raf-MAPK pathway. Later mutations occur in *DCC*, which promotes cell-cell interaction. Disruption of TGF-β mediated growth inhibition occurs with mutations in *SMAD2*, *SMAD4* and/or *TGFBR2*. Mutations in *TP53* lead to loss of its tumor suppressor function. Finally, activation of the *PI3K* pathway may increase proliferation and cell motility. Inactivation of mismatch repair genes leads to genomic instability and facilitates mutations occurring during the adenoma to carcinoma sequence.

universal mutations occurs in the APC tumor suppressor and results in activation of the Wnt/β-catenin signaling pathway. Mutations in CTNNB1, which encodes β-catenin, also dysregulate this pathway. Mutations in KRAS2 or BRAF, which activate the Ras-Raf-MAPK pathway, also occur relatively early and promote the progression of colorectal cancer. Subsequent alterations are facilitated by mutations in DNA mismatch repair genes (see above), or other causes of genomic instability, ultimately resulting in mutations in DCC, SMAD4, SMAD2, TGFBR2, TP53 and PIK3CA. DCC encodes a cell adhesion molecule that promotes cell-cell interaction; its loss may lead to greater metastatic potential. Mutations in SMAD2, SMAD4 and TGFβII-R all confer resistance to TGF-β mediated growth inhibition which has been associated with malignant progression of colorectal cancer. TP53 encodes a transcription factor that regulates cell growth and the cell cycle in response to genotoxic stress, normally "guarding" the genome to allow DNA repair, or inducing apoptosis if repair is not possible. Activation of the PI3K pathway through mutation of PIK3CA may serve to increase proliferation and cell motility while protecting the cell from apoptosis.

Other genes whose role in the adenoma to carcinoma sequence is unclear include c-Src, a non-receptor tyrosine kinase, and COX-2, an inducible cyclooxygenase that inhibits differentiation, reduces apoptosis, and promotes angiogenesis.

## Diagnostic Principles

Early colorectal cancers are often only detected by screening. For average risk individuals over 50, screening consists of any of the following: yearly fecal occult blood testing, flexible sigmoidoscopy or double contrast barium enema every 5 years, or colonoscopy every 10 years. Colonoscopy is the gold standard as

well as the preferred method of pursuing any abnormality noted on other screening tests. Those with familial syndromes should be screened earlier and more aggressively.

Advanced cancers present with pain, change in bowel habits, gastrointestinal blood loss/iron deficiency anemia, and/or constitutional symptoms. A mass is seen on colonoscopy and biopsy reveals adenocarcinoma. All patients should undergo computed tomography of the abdomen and pelvis to evaluate for metastatic disease, most common in liver and lung. Patients with rectal cancer should undergo endoscopic ultrasound to determine extent of local disease.

### Therapeutic Principles

Treatment of colorectal cancer depends on the stage at presentation. Patients presenting with localized disease should be referred to surgery for resection of the primary mass as well as lymph node sampling. Patients with no evidence of lymph node involvement (Stages I–II) do not require adjuvant therapy and should establish a program of periodic surveillance [4]. Consideration for adjuvant chemotherapy should be given to Stage II patients with high risk features including histologic grade 3–4, lymphatic invasion, bowel obstruction, <12 nodes examined, localized perforation or positive/close margins [4]. Patients with evidence of lymph node involvement (Stage III) should receive 6 months of adjuvant chemotherapy with a fluoropyrimidine-based regimen [4]. Patients with metastatic (Stage IV) disease should be offered chemotherapy (fluoropyrimidine, irinotecan, or oxaliplatin) plus bevacizumab, an anti-angiogenic agent [5]. Agents that target the epidermal growth factor receptor pathway (cetuximab and panitumumab) have a role in refractory disease. Patients with rectal cancers usually receive radiation to the tumor bed either before or after surgery, with a fluoropyrimidine as a radiation sensitizer.

## Common Atrium

Diego Franco, Amelia Aránega
Department of Experimental Biology, University of Jaen, Jaen, Spain

### Synonyms

Embryonic common atrium

### Definition and Characteristics

Developmental defect caused by a closure impairment of the atrial septa. The common embryonic atrium is located at the venous pole of the developing heart and functions as a drainage chamber of circulating blood during cardiac contraction. With further development, distinct left and right components are distinguished by the formation of a set of septal structures, i.e. primary and secondary atrial septa. Developmental arrest or impairment on the formation and/or fusion of the atrial septa derives into a common atrium condition. A gradual condition can be observed that ranges from severe common atrium (primary atrial septal defect) to less severe patent foramen ovale (secondary atrial septal defect) (Fig. 1).

### Prevalence

The lack of the atrial septa is a rare event, with a low prevalence in the human population. However a partial arrest on the formation of the primary and/or secondary atrial septum is highly prevalent (~7/10,000 newborns) and it is associated in many cases with other cardiac developmental defects such as isomerism and ventricular septal defects [1].

### Genes

TBX5, NKX2.5, GATA4, MHYC and ACTC.

### Molecular and Systemic Pathophysiology

Several genes, such as TBX5, NKX2.5, GATA4, MHYC and ACTC, have been implicated with distinct degrees of common atrium, most of them associated with mild conditions (i.e. atrial septal defect) [2]. Experimental models have demonstrated a similar cardiac defect in mutant mice lacking these genes, and have also further increased the list of candidate genes associated with common atrium conditions, such as those involved in left-right signaling (lefty1, Pitx2) and those conditions leading to ventricular septal defects (e.g. TGF-beta2) [3].

The severity of any atrial septal defect (ASD) depends of the size of interatrial communication that causes a left-to right or right-to-left shunt. Conditions that affects the relative diastolic filling properties of the ventricles will have implications in the direction and the amount of shunting. Therefore, a reduction in left ventricular compliance (e.g. left ventricular hypertrophy) and mitral stenosis will increase left-to right shunting; while a reduced right ventricular compliance (e.g. pulmonary hypertension or pulmonary stenosis) and tricuspid stenosis will have the opposite effect. Patients with ADS carry the risk to develop other cardiac impairments such as atrial fibrillation, right ventricle volume overload (often in the context of substantial tricuspid regurgitation), pulmonary hypertension (developing slowly in response to excessive pulmonary blood flow over a long period of time), and more rarely paradoxical embolic events.

### Diagnostic Principles

The coincidence in a patient of pink coloration at rest and during exercise, a systolic ejection murmur or pansystolic murmur, signs of atrial fibrillation or atrial flutter in the electrocardiogram and cardiomegaly in a chest radiograph points to the disease. Transthoracic echocardiography documents the type and size of the common atrium condition, the direction of the shunt

**Common Atrium. and the presence of anomalous pulmonary venous return. A diagnostic catheter study may be required to evaluate pulmonary artery pressures, left heart function and hemodynamics [4].

## Therapeutic Principles

Transcatheter placement of occlusion devices with transesophageal or intracardiac echocardiography guidance has become the treatment of choice for secondary ASD [5]. Surgical closure is indicated in patients with primary ASD and in patients with secondary ASD whose anatomy is unsuitable for device closure.

## Condylomata Acuminata

Eggert Stockfleth[1], Ingo Nindl[2]
[1]Department of Dermatology, Skin Cancer Center Charité, University Hospital of Berlin, Berlin, Germany
[2]Applied Tumorvirology, German Cancer Research Center (DKFZ), Heidelberg, Germany

### Synonyms

Fig warts

### Definition and Characteristics

Infectious HPV-positive warts occurring in intertriginous areas of mainly mucous membranes.

### Prevalence

HPV infection is the most common sexually transmitted viral disease and affects 30 million people/year worldwide. Up to 2% of the sexually active population between 15 and 49 years suffer from this disease [1].

### Genes

The early proteins E6 and E7 seem to be responsible for the benign lesions indicated by the increased proliferation rate of the cells.

### Molecular and Systemic Pathophysiology

Moisture, mazeration, and epithelial defects are important factors in order to create a certain milieu for condylomata acuminata. Consequently, patients suffering from phimosis, vaginal discharge, intertrigo, or anal eczema bear an increased risk of getting this infection caused by HPV types 6 and 11. The incubation period ranges between 3 and 6 weeks. The mode of viral DNA replication, genome amplification as well as viral particle expression is restricted to the keratinocytes of squamous epithelia. Apoptotic and subsequently shed off keratinocytes contain large amounts of virus particles and are therefore highly infectious.

### Diagnostic Principles

Clinical inspection. Most commonly localized on the genitalia. The initially small papules gradually increase in number and size and develop into papillomatous or cauliflower-like structures. Upon bilateral pressure, condylomata become flattened and might appear like a cockscomb. If maceration develops, these warts turn into sticky and foul-smelling tumors, which finally become necrotic.

Warts in intertriginous areas of mucous membranes are differentiated into three types:

1. Condylomata acuminata: pointed condylomata

2. Condylomata plana: commonly on the cervix uteri and preputium
3. Condylomata gigantea: destructive form of giant condylomata (Buschke-Löwenstein tumor)

If the anal region is affected, diseases of the rectum must always be excluded (e.g., internal hemorrhoids, chronic proctitis). Underlying diseases (e.g., bacterial discharge, mycotic disease, immune suppression, AIDS) must be considered. Simultaneous treatment of the partner is essential.

For further diagnostic options, particularly with regard to differentiation of HPV types, ►Human Papilloma Virus.

## Therapeutic Principles

Cytotoxic agents (i.e., podophyllin, trichloroacetic acid,); 5-fluorouracil (5-FU); immunotherapy; interferons; immunomodulators (i.e., imidazoquinolines like imiquimod[2]); therapeutic vaccination; antiviral therapy; cidovir, see [1].

Local destruction (i.e., diathermy loop, cryotherapy, laser vaporization, excision), photodynamic therapy (PDT), dry paint, insertion of linen or gauze strips.

# Cone Rod Dystrophies

Christian Hamel
CHU Montpellier, Centre of Reference for Genetic Sensory Diseases, Montpellier, France

## Synonyms

Inverse retinitis pigmentosa; Central retinitis pigmentosa; CRDs

## Definition and Characteristics

Cone rod dystrophies (CRDs) are inherited, progressive retinal dystrophies belonging to the group of pigmentary retinopathies. They present first as a macular disease or as a diffuse retinopathy with predominance of the macular involvement. The symptoms are decrease in visual acuity and in light sensitivity in the central visual field while that of the periphery remains spared, intense photophobia, color vision defects. As a result, patients have no difficulties to move. Night blindness is usually not mentioned by patients but, when present, is moderate. Fundus examination shows pigment deposits and retinal atrophy in the macular region of the retina (Fig. 1). The electroretinogram (ERG) reveals a decrease in both cone and rod responses, cone being more severely affected. As the disease worsens, night blindness and loss in the peripheral visual field appear. At the end, patients have difficulties to move autonomously, visual acuity reaches a level where reading is no longer possible. Nystagmus is then often present and patients are legally blind (visual acuity <1/20). CRD is most frequently isolated, but may also be part of syndromes like the Bardet Biedl syndrome, the spinocerebellar ataxia type 7 (SCA7), and various ectodermal diseases.

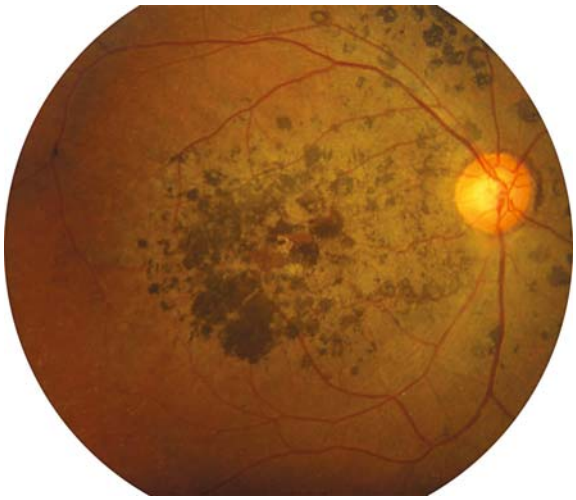
## Prevalence

It is estimated 1/40,000 [1].

## Genes

CRD is genetically heterogeneous with 16 genes responsible for nonsyndromic forms, which can be classified into two categories, and 5 loci.

The first category includes genes mostly responsible for CRDs cases. The homeobox protein CRX, which controls rod and cone photoreceptor cell differentiation and survival, is involved in 5–10% of dominant CRDs.



**Cone Rod Dystrophies. Figure 1** Fundus of a patient with cone rod dystrophy. Note the presence of various-shaped pigment deposits in macular area (centre of photograph), while the retina appears less damaged in periphery.

Some severe cases are described as dominant Leber congenital amaurosis (LCA). Two genes have been found in only one family: RIM1 and HRG4, both encoding photoreceptor synaptic proteins.

The second category includes genes mostly found in other retinal dystrophies.

- *Macular dystrophies*: ABCA4, involved in the retinoid metabolism and causing the Stargardt disease (amino acid changes), also causes 30–60% of the autosomal recessive CRD (truncating mutations) cases. GUCA1A, which encodes a guanylate cyclase activator, is much less frequent.
- *LCA*: Families with mutations in RPGRIP1, AIPL1, GUCY2D have been reported.
- *Retinitis pigmentosa*: RDS codes for the outer segment structural protein peripherin/RDS, usually involved in autosomal dominant RP, and RPGR, coding for a cilium protein usually causing X-linked RPs, may both cause CRDS. The CACNA1F gene, coding for a $Ca^{2+}$ channel, usually causing a stationary night blindness, can also cause X-linked CRD.

The five loci are CORD1 and CORD4 (autosomal dominant), CORD8 and CORD9 (autosomal recessive), CORDX2 (X-linked). There are 12 BBS genes encoding mostly proteins of the cilium structure. SCA7 is due to expansions of polyglutamines in the ataxin 7 protein.

## Molecular and Systemic Pathophysiology

CRDs are due to progressive death of photoreceptor cells, with a predominant impairment of cones. In primates, the precise vision is driven through the fovea, an anatomical structure placed at the centre of the macula and containing only cones (photoreceptors responsible for day light and color vision) therefore accounting for the characteristic decrease in visual acuity observed in CRD. This contrasts with the rod cone dystrophies (RCDs, typical retinitis pigmentosa) resulting from primary rod death followed by secondary cone death, in which the hallmark symptoms are night blindness and loss of peripheral vision with relatively spared visual acuity. Accordingly, CRDs are due to mutations of genes expressed in both cones and rods, while RCDs result from mutations in rod genes. Some CRDs and RCDs are also due to mutations of genes of the photoreceptor supporting tissue, i.e., the retinal pigment epithelium.

One important issue is to understand why the same genes cause CRDs and other types of retinal dystrophies. Deleterious mutations of retinal dystrophy genes can cause very severe diseases, and hence CRDs. Data from animal models and clinical studies suggest that photoreceptors die by apoptosis at a linear rate throughout life (named the "one-hit hypothesis"), implying that they have a given, variable probability to undergo apoptosis depending on the type of gene or mutation [2]. It is likely that several apoptotic pathways are involved in the photoreceptor loss, sometimes concurrently.

## Diagnostic Principles

Diagnosis is based on clinical data and ERG. At present, a systematic molecular testing is not routinely performed, due to the genetic heterogeneity of the disease. However, rapid and large-scale mutation screening techniques are developing.

## Therapeutic Principles

Currently, there is no therapy that restores the vision or even stops the progressing degeneration. Yet, many strategies are currently studied. Since the retina is an easily accessible tissue closed by efficient barriers, gene therapy is an issue [3]. The first clinical trial started in 2007. However, it requires the knowledge of the causative genes and will probably be operating at early stages. Therefore, efforts have been placed on finding neuroprotecting agents. The efficacy of growth factors like the ciliary neutrophic factor (clinical trial) and of the rod-derived cone viability factor (preclinical studies) is currently evaluated. It is also anticipated that the knowledge of the disease mechanisms that will emerge from long-term studies will guide toward specific pharmacological approaches. Finally, ongoing studies aiming at restoring a useful vision like photoreceptor transplantation or retinal prosthesis seem to a more long-term issue.

# Congenital Absence of the Aortic Arch

►Interrupted Aortic Arch

# Congenital Adrenal Hyperplasia

Felix G. Riepe
Division of Pediatric Endocrinology and Diabetes, Department of Pediatrics, University Hospital Schleswig-Holstein, Christian-Albrechts-University, Kiel, Germany

## Synonyms

CAH

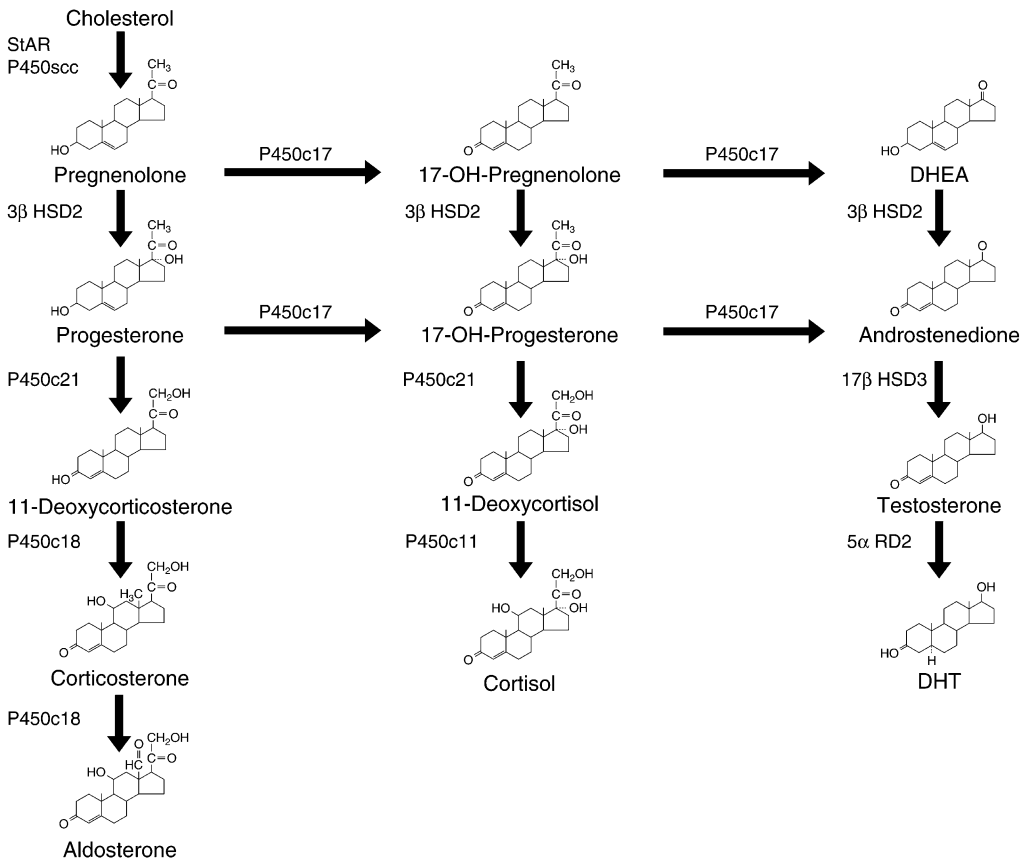
## Definition and Characteristics

Congenital adrenal hyperplasia (CAH) is caused by a defect in one of the enzymes of adrenal steroid biosynthesis (Fig. 1).

Due to defective cortisol synthesis, ACTH levels increase and result in the accumulation of precursor steroids proximal to the block. The increased adrenal stimulation leads to a hyperplasia of the adrenal cortex aggravated by the storage of cholesterol and its by-products in lipoid congenital adrenal hyperplasia. Depending on the level of the enzymatic block the result is an over- or underproduction of adrenal androgens, causing virilization in females or lack of virilization in males. Mineralocorticoid deficiency may cause a salt losing phenotype. Classic and late-onset forms are described for each type of CAH, depending on the residual activity of the mutated steroidogenic enzyme.

## Prevalence

1:15,000 in 21-hydroxylase deficiency, 1:50,000 in 17-α-hydroxylase/17,20-lyase deficiency, 1:200,000 in 11-β-hydroxylase deficiency, significantly lower frequencies in 3-β-hydroxysteroid-dehydrogenase deficiency, cytochrome P450 oxidoreductase deficiency and lipoid congenital adrenal hyperplasia.



**Congenital Adrenal Hyperplasia. Figure 1** Scheme of the major human steroidogenic pathways. DHEA, dehydroepiandrosterone; DHT, dihydrotestosterone. StAR, steroid acute regulatory protein; P450scc, cytochrome P450 side-chain cleavage; 3βHSD2, hydroxysteroid dehydrogenase/3-beta-isomerase type 2; P450c21, 21-hydroxylase; P450c18, 18-hydroxylase; P450c17, 17-alpha-hydroxylase/17,20-lyase; P450c11, 11-beta-hydroxylase; 17βHSD3, 17-beta-hydroxysteroid dehydrogenase type 3; 5αRD2, 5-alpha-reductase type 2. P450s are cytochrome enzymes.

## Genes

Point mutations, insertions, deletions and rearrangements of CYP11B1 (8q24.3) encoding steroid 11-beta-hydroxylase (P450c11); CYP17A1 (10q24.32) encoding steroid 17-alpha-hydroxylase/17,20-lyase (P450c17); HSD3B2 (1p12) encoding hydroxysteroid dehydrogenase/3 beta isomerase 2 (3βHSD2); POR (7q11.23) encoding cytochrome P450 oxidoreductase (P450or); STAR (8p12) encoding steroidogenic acute regulatory protein (StAR) and CYP11A1 (15q24.1) encoding cytochrome P450 side-chain cleavage enzyme (P450scc).

## Molecular and Systemic Pathophysiology

In 90–95% of cases CAH is due to impaired 21-hydroxylation in the adrenal cortex which means that 17-hydroxyprogesterone is not converted to 11-deoxycortisol and progesterone is not converted to deoxycorticosterone. This leads to glucocorticoid and mineralocorticoid deficiency and adrenal androgen excess (→ 21-hydroxlyase deficiency).

About 5–8% of CAH is caused by 11-hydroxylase deficiency. The deficiency of 11-hydroxylase results in decreased conversion of 11-deoxycortisol (S) to cortisol. Accumulation of 11-deoxycorticosterone causes hypertension. The steroid precursors are utilized for increased androgen synthesis, leading to marked virilization of external genitalia in newborn females and precocious pseudopuberty in both sexes [1].

P450c17 exhibits 17-hydroxylase and 17,20-lyase activity. The lack of 17-hydroxylase activity causes a decreased conversion of pregnenolone and progesterone to 17-hydroxypregnenolone and 17-hydroxyprogesterone, respectively. Deficient 17,20-lyase activity leads to an absence of conversion of 17-hydroxypregnenolone to dehydroepiandrosterone and of 17-hydroxyprogesterone to androstenedione. Depending on the localisation of the mutation the two distinct activities are more or less disturbed, resulting in a more or less pronounced cortisol deficiency and compensatory hypersecretion of ACTH. Overproduction of aldosterone causes hypertension and hypokalemia. Due to the glucocorticoid activity of corticosterone adrenal crises rarely occur. Females with P450c17 deficiency present with primary amenorrhea and lack of pubertal development whereas males show a complete sex reversal and no pubertal development [2].

3-β-Hydroxysteroid-dehydrogenase deficiency results in a disturbed conversion of pregnenolone to progesterone, 17-hydroxypregnenolone to 17-hydroxyprogesterone and dehydroepiandrosterone to androstenedione. The effect is a salt-wasting form of adrenal insufficiency. Male patients present with severe hypospadias. Female individuals show no alteration of the external genitalia. Pubertal development is absent in both sexes with the classical form [3].

Cytochrome P450 oxidoreductase is a flavoprotein that donates electrons to all microsomal cytochrome P450 enzymes. Therefore mutations of *POR* cause partial deficiencies in steroid 17-α-hydroxylase/17,20-lyase and 21-hydroxylase with and without Antley-Bixler syndrome (ABS). Major characteristics of ABS are craniosynostosis, radio-humeral synostosis and ambiguous genitalia. Individuals with *POR* mutations show normal or poor masculinization during fetal development and puberty in males, virilization during pregnancy and poor pubertal development without worsening of virilization in female patients. Maternal virilization during pregnancy may occur [4].

Lipoid congenital adrenal hyperplasia is the most severe form of CAH and is caused by mutations of StAR or CYP11A1. The synthesis of all adrenal and gonadal steroids is impaired. StAR mediates the transport of cholesterol within the mitochondria whereas P450scc converts cholesterol to pregnenolone. Individuals with lipoid CAH are phenotypically female and suffer from severe salt wasting and adrenal insufficiency. Patients with 46, XY karyotype have no pubertal development but patients with 46, XX karyotype may develop breast tissue, pubic hair and irregular menstruation [5].

## Diagnostic Principles

Specific measurement of adrenal steroid precursors in plasma before and after stimulation with ACTH or detection of steroid metabolites in a 24-h urine sample. Karyotype, ultrasound investigation of adrenals and sexual organs. Molecular gene analysis.

## Therapeutic Principles

Treatment with glucocorticoids (approx. 10–20 mg/m$^2$ body surface/day cortisol) and mineralocorticoids (approx. 100–150 µg/m$^2$ body surface/day fludrocortisone) to prevent adrenal and salt losing crises where appropriate. Through this suppression of ACTH overstimulation and overproduction of adrenal androgens to prevent virilization. Induction of pubertal development with cyclic estrogens and gestagens or testosterone as necessary.

## Conjunctivitis, Allergic

Erich C. Strauss
Gladstone Institute of Virology and Immunology, University of California, San Francisco, CA, USA

### Synonyms

Seasonal or perennial conjunctivitis; Hay fever conjunctivitis

### Definition and Characteristics

Signs and symptoms of allergic conjunctivitis may include pruritus, conjunctival hyperemia and chemosis, papillary response, mucoid discharge and eyelid edema. Allergic conjunctivitis is typically caused by seasonal allergens such as ragweed and grass or tree pollens. Allergens implicated in the perennial form of allergic conjunctivitis are commonly present in the environment year round. Common examples of perennial allergens include animal dander and dust mites. Signs and symptoms are usually bilateral but may be asymmetric. Allergic conjunctivitis is not usually associated with permanent visual impairment.

### Prevalence

Although reliable prevalence data remains to be determined, allergic conjunctivitis is common and the most prevalent form of the ocular allergic diseases.

### Molecular and Systemic Pathophysiology

Allergic conjunctivitis represents an immediate or type 1 hypersensitivity response. The pathophysiology involves multiple steps that include allergen presentation to the ocular mucosal surface, systemic sensitization with the production of IgE antibodies directed against the sensitizing allergen, subsequent contact with the same sensitizing allergen, binding of the allergen to adjacent IgE molecules on the surface of mast cells and IgE mediated mast cell degranulation with the release of mediators of acute inflammation such as histamine, prostaglandins, leukotrienes, cytokines and chemokines. The late phase response occurs hours after the acute phase reaction and is characterized by inflammatory cells, principally eosinophils.

### Diagnostic Principles

The diagnosis of allergic conjunctivitis is generally determined clinically based on a synthesis of the presenting signs and symptoms. However, conjunctival scraping, staining and light microscopy may reveal eosinophils and facilitate the diagnosis.

### Therapeutic Principles

Therapeutic interventions include allergen avoidance, cold compresses, topical antihistamines and mast cell stabilizers including combination agents and non-steroidal anti-inflammatory medications. Short-term use of topical corticosteroids is very effective and may be considered for severe or refractory cases.

## Synonyms

X-linked dominant chondrodysplasia punctata type II; CDPX2; CDPXD; Conradi-Hünermann syndrome; Happle syndrome

## Definition and Characteristics

Conradi-Hünermann-Happle syndrome (CHH, MIM *302960) is a rare X-linked dominant disorder characterized by linear ichthyosis, cataracts, and chondrodysplasia punctata (CDP) causing skeletal abnormalities like asymmetric shortening of the long bones, sometimes very severe kyphoscoliosis, facial dysplasia, or congenital hip dysplasia. At birth, patients often exhibit severe erythroderma with striated hyperkeratosis arranged in whorls and swirls following the lines of Blaschko. The disease is lethal in the majority of male embryos, but rare cases of affected surviving males have been reported [1].

## Prevalence

Accurate data not available, approximately 1:200,000. Worldwide occurrence.

## Genes

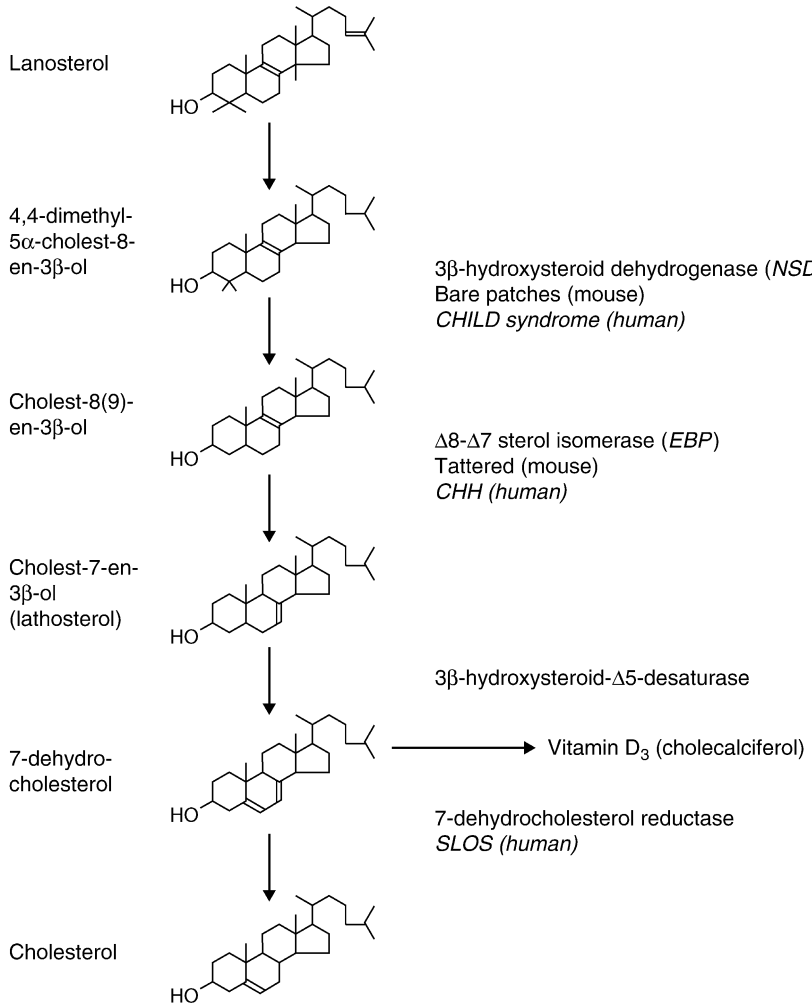
EBP (emopamil binding protein/chromosome Xp11.22-p11.23). EBP spans 7.0 kb of genomic DNA and comprises five exons encoding a 1.0-kb mature transcript with ubiquitous expression.

## Molecular and Systemic Pathophysiology

Biochemical studies of patients with CHH demonstrated significantly increased plasma or tissue level of 8-dehydrocholesterol (8DHC) and cholest-8(9)-en-3 β-ol (8(9)-cholestenol), which suggested a deficiency of cholesterol biosynthesis at the level of 3 β-hydroxysteroid-Δ8, Δ7-isomerase (Δ8-Δ7 sterol isomerase). Subsequent genetic analyses showed that CHH is caused by mutations in the human *EBP* gene, which functions as binding protein for the $Ca^{2+}$ antagonist emopamil and also acts as "Δ8-Δ7 sterol isomerase" [2]. Over 50 mutations in females with CHH have been identified so far [3,4]. Approximately 75% are nonsense, frameshift, or splice site mutations leading to a truncated protein, 25% are missense mutations of essential amino acids. Inter- and intrafamilial phenotypic variability is most probably due to differences in X-chromosome inactivation between different tissues. Gonosomal aneuploidy that gives rise to two X chromosomes (47, XXY) could result in the rescue of lethal mutations in affected males. The mechanism behind the intrauterine loss of affected males and the development of skeletal dysplasia and skin lesions in CHH females is unclear and may result from the accumulation of toxic sterol intermediates and/or deficiency in cholesterol or vitamin D. 7-Dihydrocholesterol-reductase (7-reductase) is an other important enzyme in the cholesterol biosynthesis pathway distal to "Δ8-Δ7 sterol isomerase." Autosomal recessive mutations of "7-reductase" cause Smith–Lemli–Opitz syndrome (SLOS, MIM *270400), which shows rhizomelic limb shortness [5]. It is likely that abnormalities in SLOS as well as in CHH possibly result from dysfunction of cholesterol-modified "sonic hedgehog" or other related embryonic signalling proteins. Moreover CHH is biochemically related to the CHILD syndrome (MIM *308050), which is caused by an enzyme block upstream of "Δ8-Δ7 sterol isomerase" (see Fig. 1).

## Diagnostic Principles

Due to the individual difference in X-inactivation and/or the presence of gonadal mosaicisms, disease expression is very variable within families. Anticipation – a stepwise increase in disease expression from one generation to the other – is a striking clinical feature, but may be also explained by an ascertainment bias. Sometimes affected individuals only show minor symptoms such as mild localized scaling or hypo-/hyperpigmentation, linear ichthyosis, or short stature. Sectorial cataract or localized follicular atrophoderma (i.e., large skin pores) are pathognomonic. Radiographic investigations may reveal punctate calcifications of the epiphyseal regions, which is called CDP and also seen in many other conditions. In CHH biochemical analysis (i.e., gas chromatography-mass spectrometry) reveals markedly elevated level of "8DHC" and of "8(9)-cholestenol," which can help to identify somatic mosaicism in clinically unaffected individuals. When possible, diagnosis should be confirmed by direct sequencing of the EBP gene. Neither sterol profiles nor mutations can predict the severity of the clinical phenotype. Chromosomal analyses are necessary if male family members are affected.



**Conradi-Hünermann-Happle Syndrome. Figure 1** Overview of the sterol metabolism.

## Therapeutic Principles

Affected individuals are treated interdisciplinarily (i.e., pediatricians, dermatologists, ophthalmologists, orthopedics, etc.). Early orthopedic intervention is advisable. Patients should also be examined concerning ventricular septal defects or patent ductus arteriosus. Stigmatization by severe scarring alopecia can be avoided by wearing a wig. Genetic counselling including molecular diagnostic should be offered to all families. Calculation of risk and genetic counselling is difficult because of the variation of phenotype within families and the phenomenon of anticipation.

# Constipation

►Constipation, Functional

# Constipation, Functional

Thomas Frieling
Medical Clinic II, Helios Klinikum Krefeld, Krefeld, Germany

## Synonyms

Constipation; Functional constipation; Outlet obstruction; Slow-transit constipation

## Definition and Characteristics

The Rome III Consensus Conference classified functional constipation into the group of functional bowel disorders characterized by symptoms attributable to the middle or lower gastrointestinal tract. These disorders include the irritable bowel syndrome (IBS), functional bloating, functional constipation, functional diarrhea, and unspecified functional bowel disorder [1].

Definition of constipation is difficult; it can be done by subjective (straining/unproductive calls/infrequent stools/incomplete evacuation) or measurable definitions (daily stool weight <35g per day/<3 bowel movements per week/prolonged whole-gut or colonic transit). According to Rome III consensus, functional constipation is characterized by persistently difficult, infrequent, or seemingly incomplete defecation. Diagnostic criteria (fulfilled for ≥3 months with symptom onset ≥6 months prior to diagnosis) for functional constipation must include:

- Two or more of the following: straining during ≥25% of defecation/lumpy or hard stools in ≥25% of defecation/sensation of incomplete evacuation for ≥25% of defecations/manual maneuvers to facilitate ≥25% of defecations/<3 defecations per week.
- Loose stools are rarely present without the use of laxatives.
- Insufficient criteria for IBS (pain or abdominal discomfort associated with ≥2 of the following: improvement with defecation/onset associated with change in stool frequency/onset associated with change in form of stool).

## Prevalence

Constipation affects all ages and is most common in females and nonwhite persons. It occurs in up to 27% of the population depending on demographic factors, sampling and definition. Constipation increases with age; childhood constipation persists in approximately 30% of adults. The majority do not contact doctors.

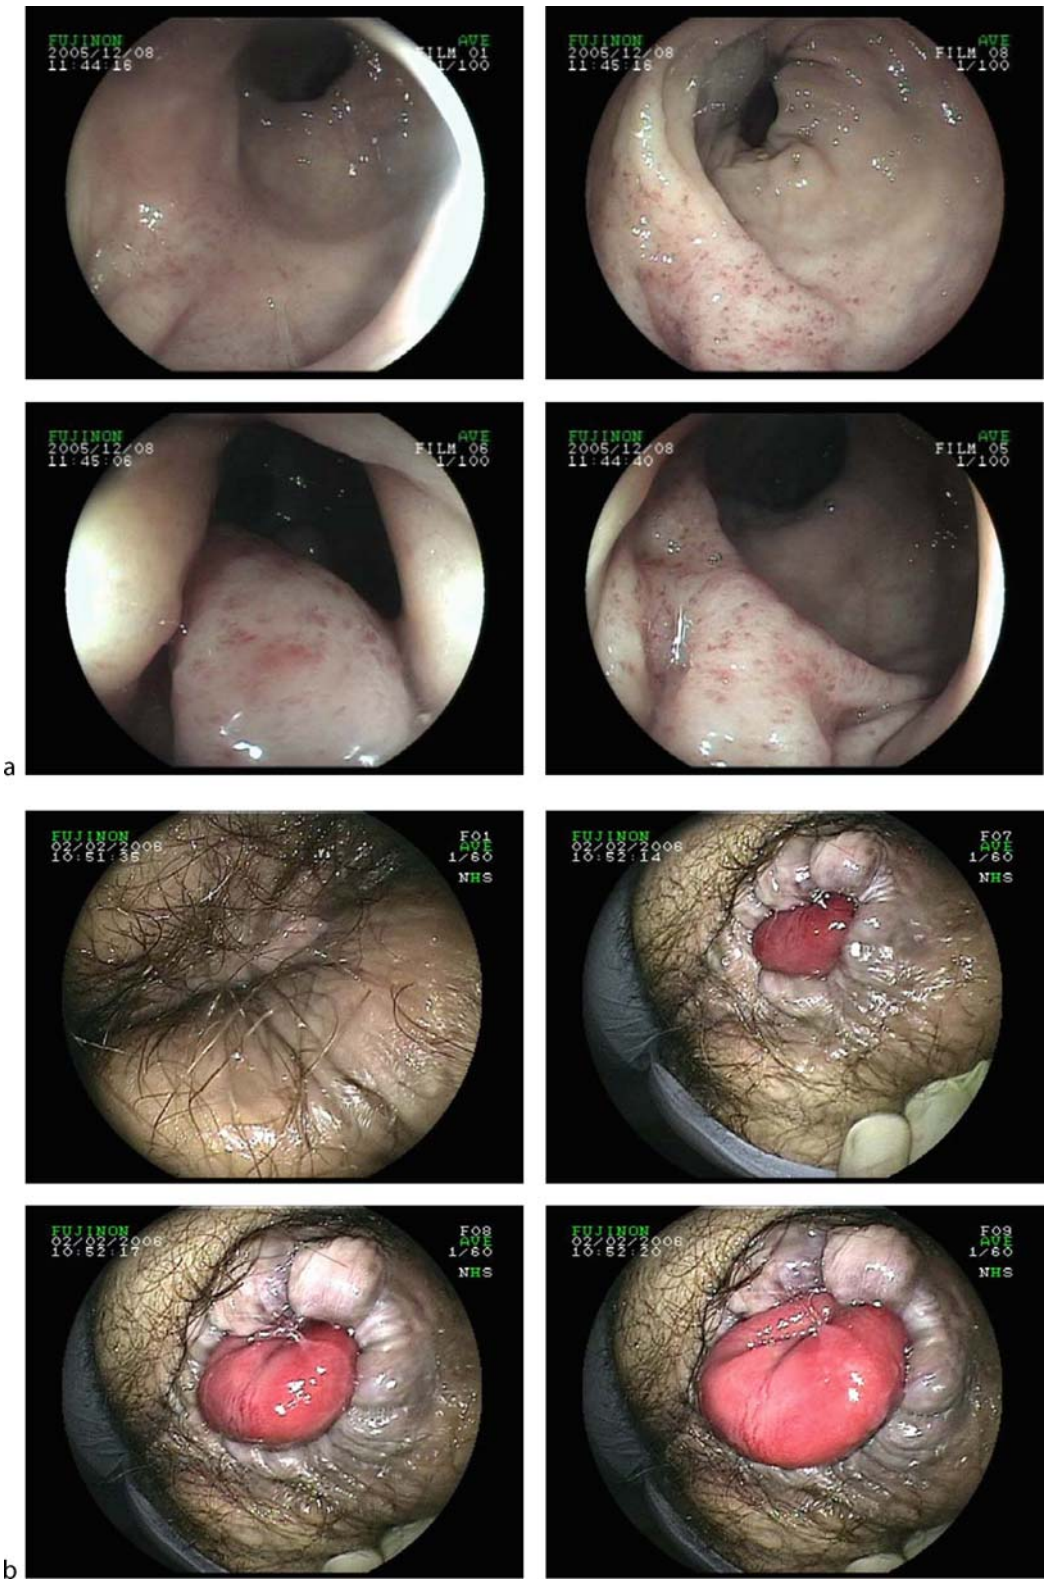
## Molecular and Systemic Pathophysiology

Functional constipation may be classified into two physiological abnormalities: slow-transit constipation and outlet obstruction. Slow-transit constipation suggests impaired colonic motor activity due to disorders of smooth muscle, the enteric nervous system (ENS), abnormal autonomic function, disturbed CNS-ENS interaction, reduced interstitial cells of Cajal (ICC) and/or reduced colonic enteroglucagon- and serotonin-containing endocrine cells. Anorectal dysfunction comprises abnormal function of the anal sphincter or pelvic floor with stool retention within the rectal ampulla. This may cause fecal incontinence that is frequently associated with chronic constipation. Slow-transit constipation and anorectal dysfunction may coexist. There is little or no relationship between dietary fiber or fluid intake or physical activity or body weight and whole gut transit time. Severe constipation may be accompanied by delayed gastric emptying. Whether disturbances of electrolyte transport with increased colonic water absorption may cause constipation is unproven yet. While sex hormones (e.g., progesterone) do not have a major effect on bowel function under normal physiological conditions, they may contribute to constipation and symptoms during pregnancy. Release of nonsex gastrointestinal hormones (motilin, pancreatic polypeptide, gastrin, somatostatin, pancreatic glucagons, and enteroglucagon) may be impaired in constipated patients; however, which of these changes are primary and which are secondary to the condition is unknown.

Several myths and misconceptions about chronic constipation exist. However, there is no evidence for "autointoxication" by stool retention, for elongated colon (dolichocolon) or poor fiber intake as a cause for constipation, for successful treatment by increasing fluid intake, for major impact of increased physical activity, for harmful effects of stimulant laxatives or tolerance to stimulant laxatives at recommended doses, and for "rebound constipation" after stopping laxative intake [2].

## Diagnostic Principles

It is crucial to maintain careful patient history (e.g., diary of bowel movements and nutritional intake) and to rule out organic diseases, especially colorectal carcinoma. Alarm features ("red flags") are recent onset of symptoms (<6 months), bleeding, weight loss, anemia, elevated blood sedimation rate, and family history of colon cancer. Guidelines of colon cancer screening should be fulfilled. Colonoscopy in constipated patients identifies structural lesions, such as colon cancer, as frequently as in nonconstipated persons. Factors associated with constipation are poor general health, physical inactivity, medication use (e.g., calcium- and aluminium-containing antacids, antihypertensives such as calcium-antagonists



**Constipation, Functional. Figure 1** (a) Dynamic proctoscopy in a patient with outlet obstruction. The mucosa of the ventral rectum shows petechial bleeding and prolaps into the proctoscope during straining. (b) Dynamic proctoscopy in a patient with outlet obstruction. A rectal prolapse can be provoked during straining. An estimate of transit time can be obtained from the Bristol Stool Form scale as a surrogate measure of transit time [3] (Fig. 2).

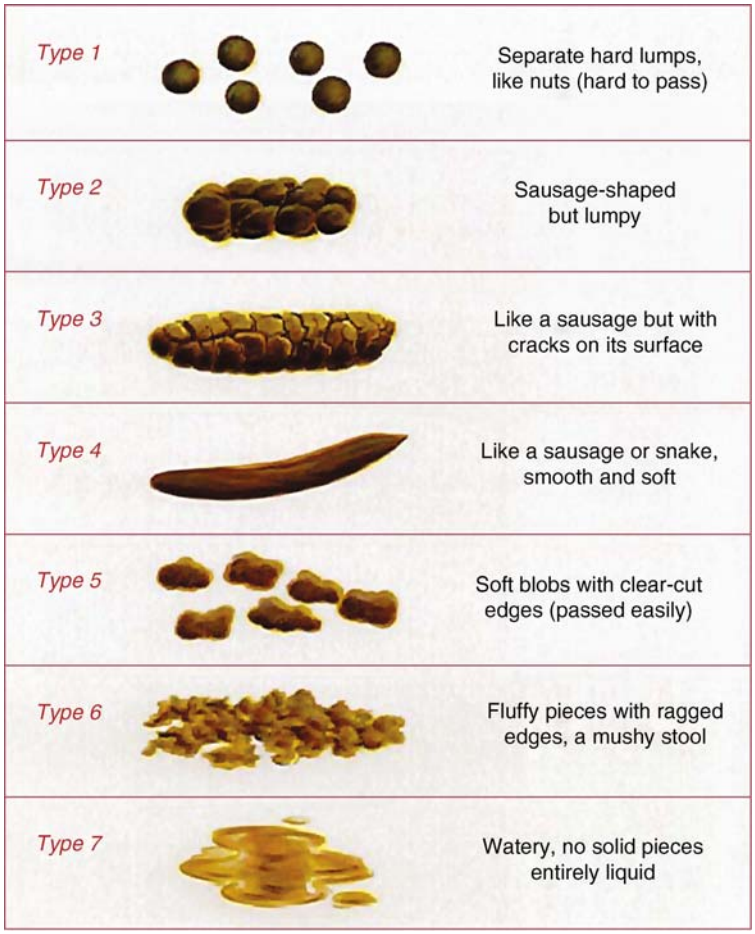
and clonidine, antidepressives, ferrum, antiepileptics, opiods, anti-parkinson medication, and neuroleptic drugs), psychosocial status, a history of sexual abuse, low-fiber diet and medical disease (e.g., diabetes, hypothyroidism, hyperparathyroidism, multiple sclerosis, and Parkinson's disease). However, the search for endocrinological or neurological diseases and their treatment have only a minor impact on constipation. Constipation behavior can be learned in early life due to faulty toilet training (pelvic floor dyssynergia, encropesis).

Physical examination should include perianal and digital rectal examination to detect fecal impaction, anal stricture, rectal prolapse or mass, and abnormal perineal descent with straining (Figs. 1–3).

If symptoms and marker studies suggest anorectal dysfunction, anorectal manometry and balloon expulsion testing may identify Hirschsprung's disease and pelvic floor dyssynergia. Defecography may detect intussusception, rectocele with stool retention, failure to decrease anorectal angle with straining and abnormal pelvic floor descent. Electromyography may detect paradoxical activation of external sphincter muscle during defecation (pelvic floor dyssynergia). Measurement of pudendal nerve latency may detect alteration of external nerve supply.

## Therapeutic Principles

Treatment of functional constipation may include reassurance to patients that failure to evacuate for several days is not harmful and to discontinue medication that induces constipation. Although not



**Constipation, Functional. Figure 2** The Bristol Stool Form Scale differentiates different stool forms and allows an estimate of transit time. Additional studies may include measurement of colon transit by radiopaque markers. This technique includes several methods (e.g., Hinton test) that are simple and easy to perform and that produce similar results. Retention markers in the proximal colon suggest colonic dysfunction, whereas retention in the rectosigmoid area suggest obstructed defecation (Fig. 3).

**Constipation, Functional. Figure 3** Measurement of colonic transit shows retention of radiopaque pellets in the proximal colon suggesting slow-transit constipation (*left*) and in the rectosigmoid area suggesting anorectal dysfunction and outlet obstruction.

proved, increase of fluid and fiber intake may be helpful. Fibers that do not induce flatulence, distension or bloating should be recommended. Laxatives include osmotic laxatives (unabsorbed mono- and disaccharides), saline laxatives (incompletely absorbed salts), water-binding compounds (polyethylene glycol, PEG), and stimulant laxatives (diphenylmethane derivates and conjugated anthraquinone derivates). They decrease absorption and stimulate motility and prostaglandine release. Melanosis coli is a harmless and reversible consequence of prolonged anthraquinone intake that results from apoptosis of colonic epithelial cells and deposition of pigment in macrophages. The effect of prokinetic agents such as 5-$HT_4$ receptor agonists (tegaserod), prostaglandine $E_1$ agonists (misoprostol), macrolide antibiotics, and bethanechol is unproved. Constipation due to outlet obstruction may be treated by "toilet training" that includes explanation of the pathomechanisms of anorectal dysfunction and to avoid straining (e.g., anorectal prolapse), to optimize position during evacuation ("squat position"), and to facilitate controlled evacuation by application of $CO_2$-producing suppositories or enemas. In case of pelvic floor dyssynergia, biofeedback training to avoid paradoxic contraction may be helpful. Indication for subtotal colectomy in patients with slow transit constipation should be restricted because the results are disappointing. Although stool frequency often improves, other symptoms, including bloating and abdominal pain may persist. Therefore, colectomy should be performed only in disabled patients with normal motility above the colon when all nonsurgical treatments have failed. Similarly, surgical treatment for anorectal dysfunction from paradoxical contraction of the puborectalis has been disappointing.

## Synonyms

Allergic contact dermatitis; Contact hypersensitivity

## Definition and Characteristics

Itchy skin reaction with erythema, edema and vesicles occurring at the site of penetration of chemicals in pre-sensitized individuals. In the chronic phase, increased epidermal thickness with scales and painful fissures are frequent.

## Prevalence

Widely common disease in both professional and extraprofessional settings. Prevalence in general population varies dramatically depending on the source considered. It has been reported that 2–15% of individuals residing in industrialized countries are skin sensitized at least to one substance, but the general assumption is that prevalence is greatly underestimated.

## Molecular and Systemic Pathophysiology

Contact allergy is the consequence of an unbalanced T cell immune reaction against small chemicals, named haptens, contacting the skin. In the sensitization process, the hapten penetrating the skin promotes the mobilization and functional maturation of resident dendritic cells, Langerhans cells and dermal dendritic cells. Once in the lymph nodes, hapten-loaded dendritic cells induce expansion and differentiation of specific T cell precursors. Effector T cells acquire the capacity to recirculate to the skin due to the expression of skin homing receptors, such as the cutaneous lymphocyte-associated antigen. Re-exposure to the hapten rapidly induces recruitment of T lymphocytes which mediate the tissue damage through cytotoxic mechanism against hapten-loaded keratinocytes. $CD8^+$T lymphocytes are the major effector cell population in contact allergy. $CD4^+$ cells have a more limited cytotoxic capacity, but contribute to the amplification of the allergic reaction through the release of pro-inflammatory cytokines, IFN-γ in particular. T cell derived cytokines promote the activation of keratinocytes, including the expression of MHC class II molecules and ICAM-1, and the release of chemokines which further increase T cell accumulation at the site of hapten challenge. Resolution of the allergic reaction occurs through the intervention of specialized subsets of regulatory T cells, such as the T regulatory cell 1 (Tr1), which release abundant IL-10 and block the function of antigen presenting cells, and $CD4^+$ $CD25^+$T regulatory cells, which strongly suppress T cell activation in a cell-cell contact dependent mechanism. In healthy, non allergic individuals, $CD4^+$ $CD25^+$T cells may also have a role in preventing undesired immune reactions towards ubiquitous chemicals contacting the skin by limiting the emergence and/or activation of pathogenetic $CD8^+$ effector T lymphocytes.

## Diagnostic Principles

Diagnosis is mainly clinical, based on the characteristic of the lesions, the distribution pattern of the cutaneous involvement, and the referred contact with potential sensitizers. Epicutaneous tests performed by applying the suspected substance in occlusive conditions on the back of the individual are confirmatory. In vitro testing based on specific T cell responses to common allergens is under investigation.

## Therapeutic Principles

Avoidance of the suspected substance is mandatory. Topical and/or systemic corticosteroids are often required in the acute phase of the reaction. Barrier creams may be useful to prevent or limit the skin penetration of the sensitizer. No dietary therapy is efficacious, including the avoidance of nickel-rich foods by nickel-allergic patients. No gene therapy is available.

## Contact Dermatitis, Allergic

Randolf Brehler
Department of Dermatology, University Hospital of Muenster, Muenster, Germany

### Synonyms

Allergic contact eczema; ACD

### Definition and Characteristics

Allergic contact dermatitis (ACD) is a delayed-type hypersensitivity (Type IV) reaction resulting from the interaction of an external agent and the skin. The acute ACD is characterized by erythema, edema, vesiculation, and pruritus elicited over a period of a few days after a contact allergen is applied to the skin of a previously sensitized individual. Chronic ACD presents as pruritic, erythematous, scaly and lichenified skin lesions frequently with excoriations.

### Prevalence

Fifteen to twenty percent of the whole population suffers from contact hypersensitivity to at least one allergen. Five to ten percent of the whole population suffers from allergic contact dermatitis at least once a year.

### Genes

A genetic predisposition for the development of delayed-type hypersensitivity to nickel is evident from epidemiological studies. A correlation between the function of pro- and anti-inflammatory cytokines, such as TNF-alpha, and the individual susceptibility to develop contact allergy is still under discussion. Functional polymorphisms in encoding genes may enhance or hamper sensitization to contact allergens. As yet, exact data are not available.

### Molecular and Systemic Pathophysiology

Molecules responsible for ACD are usually simple, low-molecular-weight (500 Da) allergen haptens forming a hapten–carrier protein complex after penetration in the skin. An allergen-unspecific inflammatory reaction induces the release of cytokines and chemokines associated with the expression of MCH class-II molecules, Langerhans and mast cell activation, and induction of T-cell proliferation. The cytokine cascade starts with the expression of IL-1β followed by the induction of TFN-α, IFN-γ, IP-10, MIP-2, IL-1α, IL-12, 15, and 18. Activated Langerhans cells process the hapten–carrier protein complex, move out of the epidermis into the draining lymphatics and in the regional lymph nodes, and present the allergen in association with MHC class II molecules to T-cells. Allergen-specific T-cells with corresponding T-cell receptors expand and migrate. This whole process of sensitization occurs in 5–21 days.

Reexposure to the allergen results in the activation and proliferation of the specific T-cells that migrate into the skin at the location of the exposure. The release of different mediators attracts mononuclear and T-cells responsible for the inflammatory skin reaction.

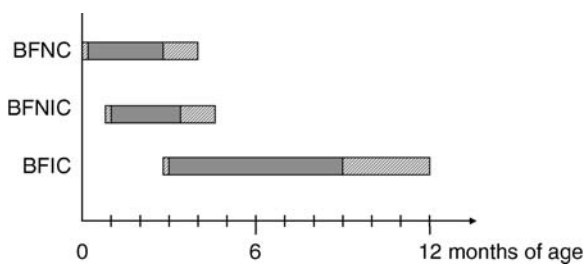
## Definition and Characteristics

Benign familial neonatal convulsions (BFNC) is an autosomal dominantly inherited seizure disorder characterized by unprovoked, generalized or multifocal, tonic-clonic convulsions, starting within the first days of life and disappearing spontaneously after weeks to months [1]. About 12% of patients will have seizures again later in life. The outcome of BFNC is usually benign, but delayed psychomotor development or, in rare cases epileptic encephalopathy, have been observed in some patients. In the autosomal dominantly inherited syndrome of benign familial infantile convulsions (BFIC), seizures usually start between 3 and 9 months of life. The seizures are of focal origin, with or without secondary generalization, and resolve within the first year of life. In some families BFIC has found to be associated with other neurological disorders such as hemiplegic migraine or paroxysmal dyskinesia. A clinically intermediate variant is benign familial neonatal-infantile convulsions (BFNIC) with a mean age of onset between 1 and 3 months (Fig. 1).

## Prevalence

Rare.



**Convulsions, Neonatal, Neonatal-infantile or Infantile, Benign Familial. Figure 1** Schematic presentation of the typical ages of onset (filled boxes, mean range).

## Genes

BFNC: point mutations, deletions and insertions in KCNQ2 (22q13.3) [MIM121200 (MIM, Mendelian inheritance in man)], amino acid exchanges in KCNQ3 (8q24) [MIM121201]. Both genes encode subunits of the same voltage gated potassium channel.
BFIC: linkage to 19q [MIM601764], 16p12–q12 [MIM605751], no genes identified yet.
BFNIC: amino acid exchanges in the SCN2A gene on 2q24 have been reported [MIM607745].

## Molecular and Systemic Pathophysiology

BFNC and BFNIC are channelopathies resulting from defects in particular ion channels [1,2]. Extensive functional studies of single mutations have so far only been performed for BFNC. The two subunits of the potassium channel that can cause BFNC, KCNQ2 and KCNQ3, coassemble as tetramers that are a main source for the M-current. The M-current controls the number of action potentials in neurons by opposing sustained membrane depolarization and repetitive firing, thus preventing hyperexcitability. Mutations associated with BFNC cause haploinsufficiency of the KCNQ2/3-channel with reductions in the size of the potassium current of 20–30%. At least in one BFNC family it has been shown that the underlying KCNQ2 mutation results in enhanced degradation of KCNQ2 subunits, and is therefore likely to cause a reduction of the M-current by decreasing the number of KCNQ-channels present at neuronal plasma membranes. Other mutations might reduce heteromerization of channel subunits or interfere with channel opening and closing mechanisms. Two KCNQ2 mutations have been demonstrated to exert a dominant negative effect on channel function. One of these mutations, R207W is located within the channels voltage sensor in transmembrane region S4, causing a syndrome in which BFNC is followed later in life by myokymia (repeated involuntary contractions of skeletal muscles) [3] [MIM606437]. The KCNQ2/3 channel has also been demonstrated to serve as a target for retigabine, one of the newer antiepileptic drugs [4]. The anticonvulsant retigabine binds to the cytoplasmic part of KCNQ2-transmembrane regions S5 and S6 and stabilizes neuronal excitability by activation of the M current. KCNQ-openers such as retigabine are considered as potential drugs for the treatment of CNS disorders characterized by neuronal hyperexcitability including migraine and epilepsy, but also for the treatment of disorders such as dementia, anxiety and bipolar disorder.

## Diagnostic Principles

The sporadic forms of benign neonatal, benign neonatal-infantile and benign infantile convulsions

are much more common than the rare familial forms. De novo mutations in sporadic patients have been reported for BFNC. In all three syndromes the age of onset can vary even within the same family and overlap in the age of onset exists between the syndromes. BFNIC can only be distinguished from BFNC and BFIC by molecular studies [5].

### Therapeutic Principles

With or without treatment, all three syndromes (BFNC, BFNIC, BFIC) usually show spontaneous remission, and it is still a matter of debate if patients benefit from antiepileptic drug treatment. This can be a problem, especially in BFNC where some families are known in which one or more members had a less than fortunate outcome. The decision for or against drug treatment is often based on the seizure frequency as well as on the personal and family history of the patient.

## Copper Deficiency

Janet Y. Uriu-Adams
Department of Nutrition, University of California at Davis, Davis, CA, USA

### Definition and Characteristics

Anemia which is refractory to iron (Fe), neutropenia, osteopenia, bone fractures, hypopigmentation, and abnormal vessels [1]. Pancytopenia and neuropathy with gait difficulty and lower limb paresthesias are seen in high zinc (Zn) ingestion-induced Cu deficiency. Infants with Menkes disease, a genetic Cu disorder, show hypothermia, neurological damage, mental retardation, connective tissue defects affecting hair, skin, bone, and vasculature, with death typically occurring during early childhood [2]. Symptoms of occipital horn syndrome (OHS), a milder variant of Menkes disease, include occipital exostoses, lax skin and joints, bladder diverticula, vessel tortuosity and neurologic abnormalities. Clinical signs of aceruloplasminema (lack of ferroxidase activity of the cuproenzyme, ceruloplasmin), can include diabetes, and retinal and neurodegeneration.

### Prevalence

Cu deficiency is rare in the adult population [3]. Low birth weight and preterm babies, who are born with low Cu stores, have a higher risk of acquired Cu deficiency, particularly if exclusively fed with cow's milk which has low Cu content and bioavailability. Infants recovering from malnutrition are at risk of Cu deficiency due to low intake, and increased loss (diarrhea, infection) and growth rate. Decreased Cu absorption (diarrhea, malabsorption syndromes, gastric surgery), or increased renal or biliary Cu excretion, can lead to deficiency. Cu deficiency occurs in patients receiving long-term total parenteral nutrition with insufficient Cu, or Cu chelators to treat various diseases. High Zn or Fe ingestion can decrease Cu absorption and precipitate a deficiency. Menkes disease is estimated to affect 1 in 200,000 live births.

## Genes

Menkes disease results from mutations in the gene encoding the Menkes protein (ATP7A or MNK), located on chromosome Xq13.3. ATP7A is a Cu transporting P-type ATPase that traffics Cu to the secretory pathway for efflux. OHS results from ATP7A mutations that permit production of small amounts of normal protein. Aceruloplasminemia is an autosomal recessive defect of the ceruloplasmin gene mapped on chromosome 3q23-q24.

## Molecular and Systemic Pathophysiology

Redox-active Cu is involved in electron transfer reactions. Many of the clinical symptoms of Cu deficiency are related to decreased activity of Cu-dependent enzymes e.g. lysyl oxidase (collagen and elastin cross-linking), CuZn superoxide dismutase (SOD) (oxidant defense), cytochrome c oxidase (cellular respiration), dopamine β-hydroxylase (neurotransmitter function), ceruloplasmin (Fe metabolism), and tyrosinase (amino acid and pigment metabolism). In Menkes disease, intestinal Cu absorption and transport across the blood brain barrier are decreased. While phenotypically normal at birth, early signs include temperature instability and jaundice. By 3 months, neurological symptoms are evident. Abnormalities in muscle tone, hair, skin, bone, vasculature and central nervous system progressively worsen. Death usually occurs by age 5. In OHS patients, milder mutations of the Menkes gene lead to milder Menkes phenotypes. Aceruloplasminemic individuals have Fe accumulation in pancreas, brain and eye resulting in diabetes, dementia and retinal degeneration.

## Diagnostic Principles

Indicators used to assess Cu status have limitations thus more than one index should be used. Methods include plasma, serum, or platelet Cu concentration, plasma ceruloplasmin protein and activity, erythrocyte SOD activity, and platelet cytochrome c oxidase activity [3]. Serum Cu and ceruloplasmin increase during pregnancy, inflammation and other diseases, which may mask Cu deficiency. The best evidence of deficiency is normalization of the measured parameter with Cu supplementation. Major clinical findings in Menkes disease and OHS include abnormal hair, wormian bones, neuronal cell loss and demyelination, massive bladder diverticulae, laxity of skin and joints, tortuous vessels, and low serum Cu and ceruloplasmin [2]. Definitive diagnosis can be made with direct mutation analysis. Aceruloplasminemic patients have low serum Cu and Fe, absent or nonfunctional plasma ceruloplasmin, and high serum ferritin. Liver, brain, and pancreas are high in Fe; symptoms do not become apparent until adulthood.

## Therapeutic Principles

Cases of Cu deficiency are managed by Cu supplementation. Early treatment may prevent the development of neurological defects. In Menkes disease patients with "null" mutations, parenteral Cu replacement therapy is largely ineffective. However, if some residual Menkes protein activity is present, Cu histidine therapy is sometimes successful. OHS patients produce a certain level of normal functional Cu transporter.

# Copper Excess

Janet Y. Uriu-Adams
Department of Nutrition, University of California at Davis, Davis, CA, USA

## Definition and Characteristics

Acute copper (Cu) toxicity signs include abdominal pain, nausea, vomiting, headache, lethargy, diarrhea, tachycardia, respiratory difficulties, hemolytic anemia, GI bleeding, liver and kidney failure, and in some cases, coma and death [1]. Wilson disease, an autosomal recessive disorder, is characterized by decreased biliary excretion leading to pathological Cu accumulation in liver (cirrhosis), brain (neurological degeneration), and cornea (Kayser-Fleischer rings). Children diagnosed with Indian childhood cirrhosis (ICC) and idiopathic Cu toxicosis (ICT) have massive hepatic Cu accumulation leading to death.

## Prevalence

Acute Cu toxicity, due to the ingestion of contaminated beverages (including water), or accidental or suicidal ingestion of high quantities of Cu salt, is rare [1]. Chronic choleostasis can decrease Cu excretion and lead to toxicity. Wilson disease is the most common inherited disorder of Cu metabolism affecting 1 in 30,000 live births; heterozygous carriers may be as high as 1 in 2,000 individuals. Rates of ICC and ICT have decreased over the last few decades.

### Genes

►Wilson Disease results from mutations in the gene encoding the Wilson protein (ATP7B or WND), located on chromosome 13q14.3. ATP7B is a Cu transporting P-type ATPase, responsible for insertion of Cu into ceruloplasmin, and exocytosis into bile. The relative contribution of genetic factors and/or increased Cu ingestion to ICC and ICT remains undefined.

### Molecular and Systemic Pathophysiology

The redox activity of Cu can increase free radical production and oxidative damage. In Wilson disease, decreased biliary Cu excretion leads to hepatic Cu accumulation, cirrhosis and liver failure if left untreated. Hepatocyte necrosis increases systemic Cu leading to increased tissue Cu and neuropsychiatric abnormalities. Clinical symptoms generally appear after late childhood and hepatic injury commonly develops insidiously. The onset or clinical severity of Wilson disease depends on the severity of the mutation. ICC typically affects children (predominately males) between 6 months and 3 years. Early signs are generally nonspecific followed by jaundice, liver failure, coma and death.

### Diagnostic Principles

For Wilson disease, a combination of tests including evaluation of symptoms (Kayser-Fleischer rings, neuropsychiatric symptoms or brain MRI), lab tests (anemia, high serum and liver Cu by quantitative analysis, high urinary Cu before and after penicillamine challenge, low serum ceruloplasmin), and mutation analysis, are recommended since not all symptoms are specific to, or occur in, Wilson patients [2]. ICC or ICT have increased serum and hepatic Cu, but in contrast to Wilson disease, ceruloplasmin is normal or elevated. Hepatic histopathology is critical to diagnosis.

### Therapeutic Principles

Cu chelation therapy (penicillamine, trientine) is used to promote Cu excretion in Wilson disease and ICC. High doses of Zn (40–50 mg/day) are used to decrease Cu absorption. Liver transplantation is the treatment of choice in cases of acute hepatic failure. Diagnosis of Wilson disease should prompt family screening and aggressive medical therapy.

## Coproporphyria

►Coproporphyria, Hereditary

## Coproporphyria, Hereditary

Jean-Charles Deybach, Hervé Puy
Centre Français des Porphyries, INSERM, Hôpital Louis Mourier, Colombes, France

### Synonyms

Coproporphyria; Harderoporphyria

### Definition and Characteristics

Hereditary coproporphyria (HC) [MIM 121300], an autosomal acute hepatic porphyria, results from mutations in the gene that encodes coproporphyrinogen III oxidase (CPO; EC 1.3.3.3). HC (heterozygous or rarely homozygous) patients present with acute attacks of neurological dysfunction often provoked by drugs, fasting, menstrual cycle or infectious diseases. Skin photosensitivity may also be present. Five patients are clinically distinct from those with HC, hematologic disorders predominate with jaundice, severe chronic hemolytic anemia of early onset is associated with hepatosplenomegaly, and skin photosensitivity is present. This variant form is called “harderoporphyria.”

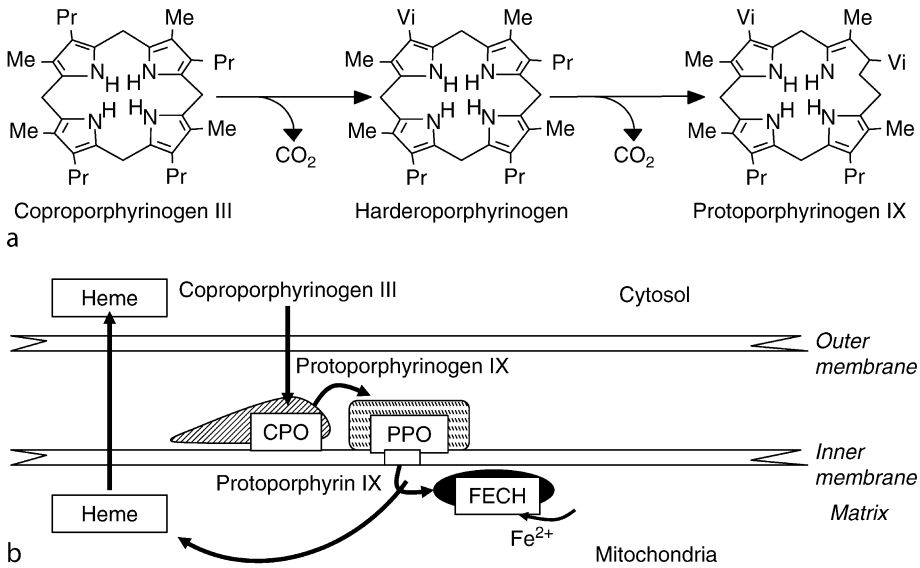
### Prevalence

Although the prevalence has not been carefully estimated, HC is the least common autosomal dominant acute hepatic porphyria. Clinical penetrance is low (<2%) and symptoms are very rare before puberty.

### Genes

Human CPO is a mitochondrial enzyme (Fig. 1) encoded by a 14 kb CPO gene containing seven exons located on chromosome 3q11.2. Over 44 mutations in the CPO gene have been identified in HCP families (Human Gene Mutation Database, http://archive.uwcm.ac.uk/uwcm/mg/hgmd0.html).

So far, in HC, mutations have been found to be family specific, without any hotspot or phenotype/genotype correlations, whereas in Harderoporphyria, the affected individuals described to date have all been homoallelic or heteroallelic for the same missense mutation in the CPO gene (K404E in exon 6), suggesting that disruption of this region of CPO impairs



**Coproporphyria, Hereditary. Figure 1** (a) Biosynthesis of protoporphyrinogen IX from coproporphyrinogen III. This stepwise decarboxylation is catalyzed by CPO. Me, methyl (-CH3); Pr, propionyl (-CH3-CH2-COOH); Vi, vinyl (-CH=CH2). (b) Heme biosynthetic pathway. Association of the three terminal enzymes (coproporphyrinogen oxidase CPO, protoporphyrinogen oxidase PPOX, ferrochelatase FECH) with the inner mitochondrial membrane.

the second stage of the conversion of coproporphyrinogen III to protoporphyrinogen IX.

## Molecular and Systemic Pathophysiology

The enzyme catalyses the stepwise oxidative decarboxylation of the heme precursor, coproporphyrinogen III to protoporphyrinogen IX via a tricarboxylic intermediate known as "harderoporphyrinogen" (Fig. 1). The leading hypothesis of neural damage is that heme precursors, 5-aminolevulinic acid (ALA) and/or porphobilinogen (PBG), overproduced by the liver during acute attacks, is neurotoxic. Conversely, formation of hemoproteins (such as heme oxygenase, tryptophane pyrrolase, NO synthase) may also be compromised due to the inherited enzyme deficiency.

## Diagnostic Principles

High levels of urinary precursors (ALA and mostly PBG), are the most important diagnostic tool for acute porphyria attacks. Treatment can be instituted immediately, while further laboratory investigations define the HC type by analyzing porphyrin excretion patterns in urine, feces and plasma. Urinary uro- and coproporphyrin may be secondarily increased in acutely ill patients or in several other conditions such as hepatobiliary disease, alcohol abuse, and infections. Thus, excess urinary porphyrin excretion alone lacks diagnostic specificity and is therefore insufficient evidence for symptoms to be ascribed to porphyria, even in a known porphyric. Hyponatraemia is common and may be severe enough to provoke convulsions. A diagnosis of HC is confirmed by porphyrin analysis. The prominent findings are increased urinary and fecal coproporphyrin III. The ratio of fecal coproporphyrin III to coproporphyrin I is more likely to be increased in latent heterozygotes than total fecal coproporphyrin. Harderoporphyria is characterized by a marked increase in fecal excretion of harderoporphyrin (tricarboxyl porphyrin), as well as coproporphyrin. Reliable assays for CPO are not widely available but allow a relevant detection of presymptomatic patients in family studies.

## Therapeutic Principles

Treatment of skin manifestation in HC is based purely on skin protection and removal of precipitating factors.

A careful search should be made for any precipitating factor, especially drugs (including oral contraceptives), underlying infection, and hypocaloric diet. These precipitants should be withdrawn as soon as possible. Opiates are usually required, often in high doses, together with an antiemetic and a phenothiazine such as chlorpromazine for anxiety, restlessness and to decrease the analgesic requirement. Adequate fluid intake is essential with regular monitoring of electrolyte status. Attention should also be paid to calorie intake. Both these requirements can be accommodated using 2 l of normal saline per day to which 5% glucose has been added. Other complications such as persistent hypertension and tachycardia, severe motor neuropathy and seizures should be treated as they occur, using

drugs recommended from a safe drugs list (www.porphyria-europe.com).

Two specific therapies are mainly used: glucose and hematin. Before heme became available, carbohydrate loading was the only treatment for an acute attack. An adequate supplement (100–300 g/day) should be administered, usually by slow intravenous perfusion; to minimize the danger of precipitating hyponatremia, glucose must be administered with careful management of intravenous fluids, with electrolyte measurement at least daily, and avoidance of hypotonic solutions. Heme arginate (Normosang®) is supplied as a concentrated stock solution that requires dilution in normal saline immediately before use. This solution should be infused at a dose of 3–4 mg/kg body weight per 24 h over 20 min, and usually over 4 days. All the types of treatment described must be used early in the attack before any nervous or respiratory complication develops. Neither carbohydrate loading nor intravenous heme will reverse an established peripheral neuropathy.

# Cor Pulmonale

Michael L. S. Ma[1], Patrick T. S. Ma[2], Alexander K. C. Leung[3]

[1]Trinity College, Dublin, Ireland

[2]Heart Health Institute and Department of Cardiac Science, The University of Calgary, Calgary, AB, Canada

[3]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Synonyms

CPM

## Definition and Characteristics

Cor pulmonale (CPM) is defined as the enlargement of the right ventricle (RV) and deterioration of RV function that is due to pulmonary hypertension (PH) caused by diseases of the thorax, lungs, pulmonary ventilation or vasculature. It can lead to RV failure, with an elevation of transmural RV end-diastolic pressure. Symptoms of CPM include fatigue, lethargy, dypsnoea on exertion, tachypnoea, chest pain, exertional syncope, dyspnoea at rest, nonproductive cough, haemoptysis, hoarseness, and anorexia. Nonexertional chest pain can be secondary to acute dilatation of the root of the pulmonary artery. Exertional chest pain in the absence of epicardial coronary artery disease can be secondary to endocardial ischaemia induced by hypoxaemia and increased transmural wall tension, or by dynamic compression of the left main coronary artery by an enlarged pulmonary artery. Exertional syncope is likely a result of the inability to increase cardiac output because of vascular obstruction in the pulmonary arterioles. Physical findings include cyanosis, RV heave, loud pulmonary component of the second sound, fixed narrow splitting of the second sound, RV gallop and tricuspid regurgitation. Patients with RV failure may develop elevated jugular pressure, a large V wave and a positive hepatojugular reflux and peripheral oedema. Oedema can occur without RV failure as hypercapnia can lead to increase in renal bicarbonate reabsorption, which in turn causes sodium and water retention. In addition, hypoxaemia can cause renal vasoconstriction, which may lead to reduction of urinary sodium excretion. Acute CPM can result from a sudden large pulmonary embolus when there is an abrupt onset of severe dyspnoea, cardiovascular collapse and sudden death resulting from the RV's inability to generate the pressure necessary to draw blood through the acutely compromised pulmonary circulation.

## Prevalence

The most frequent cause of CPM is chronic obstructive pulmonary disease (COPD). It is estimated that CPM is present in 40% of patients with an $FEV_1$ <1.0, and in 70% of patients with an $FEV_1$ of <0.6 [1].

## Molecular and Systemic Pathophysiology

The RV stroke volume is a function of its preload, contractility and afterload. The RV is usually thin and compliant with restricted contractile reserve. The severity of CPM is directly a function of the RV afterload, which is increased in: (i) pulmonary vasoconstriction (secondary to alveolar hypoxia or blood acidosis), (ii) anatomical reduction of the pulmonary vascular bed (emphysema, pulmonary embolus, pulmonary vasculitis), (iii) increased blood viscosity (polycythaemia, sickle cell disease), and (iv) increased pulmonary blood flow (congenital heart disease with left to right heart shunting).

## Diagnostic Principles

In CPM the chest radiograph may show enlargement of the central pulmonary arteries, attenuation of the

peripheral vessels leading to oligaemic lung fields, RV and right atrial dilatation, and various stigmata of COPD or interstitial lung disease. The electrocardiogram may reveal signs of RV hypertrophy. The echocardiographic criteria for CPM include right ventricular free wall thickness >0.6 cm in the sub-xiphiod view, pulmonary arteriole systolic pressure >40 mmHg by tricuspid jet Doppler with saline contrast, and an increase of RV/LV size ratio [2]. Echocardiography can be important to assess the presence or absence of congenital heart disease.

Cardiac catheterization is the gold standard for the diagnosis, quantification and characterization of pulmonary arterial hypertension.

## Therapeutic Principles

For patients with CPM, reversible elements of pulmonary hypertension and lung disease must be treated. This includes treatment of respiratory infection with appropriate use of antibiotics, relief of airflow obstruction with bronchodilators, long-term oxygen therapy in patients with severe COPD, and use of diuretics to treat RV failure.

# Cor Triatriatum

Alexander A. C. Leung[1], Patrick T. S. Ma[2], Alexander K. C. Leung[3]
[1]Department of Medicine, The University of Alberta, Edmonton, AB, Canada
[2]Department of Medicine, The University of Calgary, Calgary, AB, Canada
[3]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

## Definition and Characteristics

Cor triatriatum (CT) is a congenital anomaly, in which the left or right atrium is divided into two chambers by a membrane, referred to as cor triatriatum sinister (CTS) or dexter (CTD), respectively. CTS, described by Church in 1868, is frequently seen with other cardiac anomalies including atrial septal defect, patent foramen ovale, persistent left superior vena cava, anomalous pulmonary venous return, and mitral regurgitation [1,2]. Patients classically present during infancy with manifestations similar to mitral stenosis, characterized by dyspnea, hemoptysis, and orthopnea; but some cases may remain asymptomatic until adulthood [1]. Atrial fibrillation commonly develops [2]. Rare presentations include recognition of an atrial tumor due to thrombosis, arterial and cerebral emboli, syncope, and recurrent wheeze [1]. Cardiac murmurs characteristic of mitral stenosis or regurgitation, and signs of pulmonary hypertension may be present. CTS is most commonly misdiagnosed as primary pulmonary hypertension or mitral stenosis on the basis of similar clinical, radiologic, and electrocardiographic findings [1]. CTD is characterized by the persistence of the right sinus venosus valve, resulting in complete septation of the right atrium, and is frequently associated with severe cardiac malformations, particularly of the right heart, including pulmonary artery stenosis or atresia, tricuspid valve abnormality, atrial septal defect, and Ebstein's anomaly. The presentation of CTD is highly variable, with some remaining asymptomatic and diagnosed incidentally, and others presenting with right-sided heart failure, right ventricular outflow obstruction, or supraventricular arrhythmias [3].

## Prevalence

The prevalence of CT is unknown but it is thought to account for 0.1–0.4% of all congenital heart diseases. The male to female ratio is 1.5 to 1. No racial predilection, risk factors, or genetic abnormalities are known to be associated with CT [1,3].

## Molecular and Systemic Pathophysiology

CTS results from the failure of pulmonary veins to insert into the posterior left atrial wall. The resulting fibromuscular membrane divides the left atrium into two segments: a postero-superior chamber (false left atrium), which incorporates the pulmonary veins, and an antero-inferior chamber (true left atrium), which communicates with the mitral orifice. The fibromuscular membrane obstructs pulmonary venous blood flow, eventually resulting in a rise in pulmonary venous and arterial pressures. The embryologic basis remains uncertain but three theories exist: malincorporation, malseptation, and entrapment [1,3]. Malseptation results from abnormal growth of the septum primum. The entrapment and malincorporation theories refer to the left horn of the sinus venosus entrapping the common pulmonary veins, and preventing its incorporation into the left atrium. CTD results from the failure of the right sinus venosus valve to regress during embryogenesis, eventually forming a membrane dividing the right atrium into two chambers. Normally,

the right sinus venosus valve regresses by the 12th week of gestation.

### Diagnostic Principles

Diagnosis is usually made within the first year of life, but often difficult given the varied presentation. Electrocardiogram may show right-axis deviation, left atrial enlargement, and right ventricular hypertrophy. Chest radiographs may demonstrate cardiomegaly and increased pulmonary vascularity [4]. Two-dimensional or transesophageal echocardiography is considered the diagnostic modality of choice. Recently, three-dimensional echocardiography and magnetic resonance imaging have been described as sensitive and non-invasive diagnostic tools [1]. Cardiac catheterization can suggest the presence of CTS if the measured pulmonary arterial wedge pressure is greater than the left atrial pressure. Most exhibit elevated right ventricular, pulmonary artery, and pulmonary artery wedge pressures [4].

### Therapeutic Principles

Although rare, cor triatriatum is an important diagnosis to recognize as it is amenable to surgical correction. Of those recognized in infancy, there is a reported 75% mortality among untreated patients. A right or left atrial transseptal approach to the excision of the membrane is the treatment of choice. The mortality associated with surgery is 15–20% at 30 days postoperatively, with a long-term mortality of less than 10% and a near-normal life expectancy [5]. Reports of balloon catheter dilation have been described, but long-term outcomes remain to be determined [1]. No recommendations for infective endocarditis prophylaxis exist.

## Cori-Forbes Disease

►Glycogenosis Type III

## Cornea Farinata and other Variants

►Corneal Dystrophy, Pre-Descemet

C

## Corneal Dystrophy, Endothelial Fuchs

Walter Lisch[1], Berthold Seitz[2], Andreas Janecke[3]
[1]Department of Ophthalmology, Klinikum Hanau, Hanau, Germany
[2]Department of Ophthalmology, University of Saarland, Homburg/Saar, Germany
[3]Division of Clinical Genetics, Innsbruck Medical University, Innsbruck, Austria

### Synonyms

Endo-epithelial corneal dystrophy; FECD

### Definition and Characteristics

FECD is a bilateral, often asymmetric disorder that usually manifests after the fourth decade of life. However, several families have been described with disease onset consistently before 30 years of age (early-onset FECD). The earliest sign, cornea guttata (microscopic refractile, hyaline excrescences on Descemet's membrane), can progress to stromal edema, epithelial bullae, and subepithelial fibrosis (or scarring). From onset, it often takes two decades for FECD to impair the function of the corneal endothelium and lead to impaired vision. Autosomal dominant transmission has been described in a number of pedigrees, and this mode of inheritance might also apply in a number of apparently sporadic cases. Autosomal dominant transmission has been particularly described in early-onset FECD. Some classical FECD pedigrees are also compatible with X-chromosomal inheritance of the disease [1].

### Prevalence

FECD was first described by Fuchs in 1917 [1]. Krachmer and associates examined 228 relatives of individuals with confluent corneal guttata and found 38% of those over age 40 affected [1]. The female to male ratio has been reported to be as high as 4 to 1. FECD has been described in many populations. There is some racial variation, since it is extremely rare in Japanese.

### Genes

A locus for early-onset FECD was mapped to chromosome 1p34.3-p32 by linkage analysis in a

three-generation family, and a Gln455Lys mutation in the COL8A2 gene was identified in affected patients [2]. The same mutation was identified in two further early-onset FECD families, and in a family with posterior polymorphous dystrophy (PPCD). Three COL8A2 mutations, Arg155Gln, Arg304Gln, and Arg434His, were identified in further familial and sporadic FECD cases [2]. Two mutations, Gly357Arg and Pro575Leu, were detected in two additional familial cases, were absent among controls, but did not segregate with the disease in these families leaving their significance unclear. A total of nine putative heterozygous missense mutations were found among 116 unrelated FECD patients. Most mutations were associated with early-onset FECD [2]. The Arg434His mutation, however, was later shown not to segregate with the disease in a classical FECD family [3]. Moreover, the complete sequencing of COL8A2, and the functional candidate gene COL8A1, did not identify any further mutation in 15 familial cases of classical FECD [3]. A COL8A2 Leu450Trp mutation was subsequently identified in another large early-onset FECD family, whereas no COL8A2 mutations were found in 62 unrelated classical FECD cases. COL8A2 encodes the α2 chain of type VIII collagen, which is a major component of Descemet's membrane.

Homozygous or compound heterozygous mutations in SLC4A11 encoding a sodium-borate cotransporter, have been recently identified in a distinct, autosomal recessively inherited dystrophy, congenital hereditary endothelial dystrophy (CHED2). Vithana and associates [4] considered SLC4A11 a candidate gene for FECD, and identified four heterozygous mutations, T754M, G709E, E399K, and the truncating c.99_100delTC deletion, in four of 89 patients with FECD. These mutations were distinct from those identified in CHED2 patients, and absent among controls. However, family studies were not conducted to show segregation or de-novo occurrence of these mutations. Functional studies implicated loss-of-function as the underlying mechanism concerning both FECD and CHED2 mutations [4]. Consequently, heterozygous carriers of CHED2 mutations would be expected to present with FECD, but this has not reported to-date.

Characteristics related to PPCD can be seen in relatives of patients with FECD, and vice versa. Analysis of the PPCD gene, TCF8, in 72 classical FECD cases revealed only one sporadic patient with an Asn696Ser mutation. In summary, no mutations have been unequivocally associated with classical FECD to date. Two loci for classical FECD have been mapped to chromosomes 13ptel-q12.13, and 18q21.2-q21.32, in large autosomal dominant pedigrees [5].

## Molecular and Systemic Pathophysiology

FECD is characterized by a slow, continuous loss of morphologically and physiologically altered endothelial cells, eventually leading to corneal edema. The endothelial cells synthesize a thickened Descemet's membrane, a collagen-rich basal lamina, with focal excrescences of altered basement membrane material. It has been suggested that mutant COL8A2 improperly interacts with other molecules in the extracellular matrix, resulting in sites of structural weakness in Descemet's membrane that allow the extrusion of material that forms the guttae. The irregular basal lamina topography appears to indent physically and stretch the endothelial cells, which may compromise their ability to transport electrolytes and maintain corneal clarity. Alternatively, abnormal collagen VIII may interfere with the differentiation of the endothelium, e.g. by interfering with cell adhesion [5], representing a defect of neural crest terminal differentiation. See the chapter on ►Congenital Hereditary Endothelial Dystrophy for a discussion on the loss of SLC4A11 function.

## Diagnostic Principles

The clinical diagnosis of FECD is based on slit lamp examination in direct and indirect illumination in early stages. The landmark of FECD represents fine or coarse, and patchy or distinct excrescences (cornea guttata) of the corneal endothelium. A beaten-metal appearance of the endothelium can be found after coalescence of guttae. Cornea guttata is often combined with fine endothelial pigmentations or with patches of pigmentation. In a later stage, the patient develops stromal and epithelial edema showing as corneal clouding, with symptoms of glare and hazy vision, and reduced visual acuity. This stage of the disorder is very much influenced by environmental conditions, so that vision may fluctuate at different times of day. Epithelial edema and visual symptoms are often worse on waking, after an overnight period of eye closure. Epithelial edema disappears as the day progresses and vision improves. With time, the corneal edema spreads peripherally, and microcystic epithelial edema with epithelial bullae ensues, Descemet's membrane develops folds, and vision falls. Eventually, painful bullous keratopathy can result and bullae can rupture. In end-stage FECD, subepithelial fibrous scarring appears centrally with further loss of central vision. This clinically dense gray sheet of scar tissue consists histologically of active fibroblasts between the epithelium and Bowman's layer. Light microscopy shows polymegathism and pleomorphism of endothelial cells. Ultrastructurally, there is generalized cellular thinning over the aces of the excrescences, with an overall reduction in the endothelial cell count. Descemet's membrane is thickened with normal anterior banded zone and a thickened posterior layer. Differential diagnosis includes PPCD, and x-linked endothelial corneal dystrophy (XECD).

## Therapeutic Principles

Visually significant corneal edema is treated with topical hyperosmotic agents such as 5% NaCl drops 4–8 times per day. Penetrating keratoplasty (PKP) or alternatively, replacement of the posterior cornea, called Descemet's stripping endothelial keratoplasty, is the treatment of choice for patients with reduction in vision sufficient to impair activities of daily living, and has a good prognosis. A potential therapeutical option could be corneal collagen crosslinking with riboflavin to reduce stromal and epithelial edema.

## Synonyms

François-Neetens speckled corneal dystrophy; FCD

## Definition and Characteristics

FCD is an autosomal dominant disorder characterized by small oval, stellate, comma-shaped, or doughnut-shaped white flecks scattered in all layers of the corneal stroma. Typically, the stroma in between the flecks is clear, and the epithelium, Bowman's layer, Descemet's membrane, and the endothelium are normal. Vision is generally not affected, and there is no or only little progression of the disease. Corneal sensation may be reduced.

## Prevalence

FEC is a rare corneal disorder first described by François and Neetens in 1957 [1]. Fifty-one family members in three generations were included in their study and 31 persons were found to be affected from FCD. One African-American family including 11 FCD members in three generations has been described [2]. Li and associates presented ten unrelated families of European origin that contain 69 individuals, including 32 affected individuals [3].

## Genes

The FCD locus has been mapped to a 24-cM region of chromosome 2q35 flanked by D2S289 and D2S516 [4]. Li and associates identified the phosphatidylinositol-4-phosphate 5-kinase type III sequence (PIP5K3) gene as the cause of FCD [3]. To date, eight independent mutations have been reported: Asn701Thr; Leu706Val; Val1207Ala; Arg851X; Gln988X; Gln1030X; Arg1038X; Lys1103Arg.

## Molecular and Systemic Pathophysiology

The PIP5K3 gene is a member of the phosphoinositide 3-kinase family, which comprises dual-specifity enzymes possessing an intrinsic protein kinase activity inseparable from a lipid kinase activity. It has been suggested that PIP5K3 selectively regulates the shorting and traffic of peripheral endosomes containing lysosomally directed fluid phase cargo by controlling the morphogenesis and function of multivesicular bodies. PIP5K3 is important for post-Golgi vesicle processing.

## Diagnostic Principles

The clinical diagnosis of FCD is based on slit lamp examination in direct and indirect illumination, best seen with dilated pupil. The tiny lesions, with discrete or scalloped borders, may be best appreciated in indirect illumination and may appear refractile. It has been suggested that, because of its subtle presentation, FCD might be much more common than has been appreciated in the literature [5]. Ultrastructurally, the abnormal keratocytes contain both excess glycosaminoglycan in membrane-bound vacuoles with fibrogranular substance and lipids in smaller membrane vacuoles with

electron-dense lamellar bodies [2]. In contrast to Macular corneal dystrophy (MCD) no underlying mechanism or mucopolysaccharide abnormality has been discovered in FCD.

## Therapeutic Principles

No therapy is required.

## Synonyms

Subepithelial amyloidosis; Primary familial amyloidosis of the cornea; GDLD

## Definition and Characteristics

GDLD is an autosomal-recessive disorder characterized by the deposition of amyloid material in the subepithelial space of the cornea. Clinical manifestations appear in the first decade of life. In the early stage of the disease, whitish-yellow, subepithelial, and nodular lesions are seen in the central cornea. Later, these coalesce to form an extended mulberry-like, whitish-yellow corneal opacity. Subepithelial and superficial stromal neovascularization has also been reported in advanced cases. In practice, the spectrum of GDLD symptoms is broad, and to date we can distinguish four distinct types: (i) typical mulberry type, (ii) band keratopathy type, (iii) stromal opacity type, and (iv) Kumquat-like type. The band keratopathy phenotype seems to be the most prevalent. Until today, it is unclear if the four different phenotypes might shift from one to another with time. GDLD is a progressive disorder combined with photophobia, tearing, redness, and painful attacks due to recurrent epithelial erosions. Vision is severely impaired in most of the cases.

## Prevalence

GDLD is a rare corneal disorder first described by Nakaizumi in 1914 [1]. The incidence of this disease is estimated to be 1 in 300,000 in Japan, whereas only a few cases have been reported in European and American patients. It occurs also in Vietnamese, Indian, Tunisian, and Turkish families. Ide and associates presented the four various clinical manifestations of this dystrophy [2].

## Genes

A chromosomal locus for GDLD has been mapped to 1p32 by linkage analysis [3]. The membrane component, chromosome 1, surface marker 1 (M1S1) gene (now referred to as tumor-associated calcium signal transducer 2, TACSTD2 gene) was identified as responsible for GDLD. TACSTD2 is a single exon gene, spanning about 1.8 kb of genomic DNA, and coding for a protein of 323 amino acids. Homozygous or compound heterozygous mutations in the M1S1 gene were identified in a number of GDLD patients: Q118X mutation (82.5%), 632delA (7.5%), Q207X (5.0%), S170X (5.0%), and others including 520insC, Y184C, L258-liter 261del, K84X, C108R, L186P, M1R, 8bpins, Q118E, V194E, C119S, 870delC, 1117delA, E227K, C66X, F114C. The Q118X mutation has a very high frequency among Japanese patients and is considered a GDLD founder mutation for the Japanese population.

## Molecular and Systemic Pathophysiology

The TACSTD2 protein has been identified initially as a tumor-associated antigen. The gene is expressed in a variety of human epithelial cells and carcinomas, and its product is a type I transmembrane protein with several predicted glycosylation sites. The role of TACSTD2 is not well understood, although it has been suggested to function as a cell–cell adhesion receptor in cancer cells.

The gene structure is indicative of a function in cell signal transduction, which is corroborated by the observation that GDLD-associated mutations in TACSTD2 result in several orders of magnitude higher epithelial permeability and pronounced cell function defects as compared to control samples [4]. Immunofluorescence analysis revealed that neither ZO-1 nor occludin was expressed in the tight junction areas of surface epithelial cells; there was no expression of claudin-1 or desmoplakin in the epithelial surface layer of GDLD corneas [5]. Integrin α6, β4, α3, and β1 were expressed along the serrated surface of the basement membrane (BM). Laminin-5 and collagens IV and VII were widely expressed throughout the BM, and lactoferrin was expressed in the amyloid deposits and thickened BM. In corneas with the Q118X mutation, there is a disturbance in cell-to-cell and cell-to-substrate junctions [5].

## Diagnostic Principles

The clinical diagnosis of GDLD is based on slit lamp examination in direct and indirect illumination, fluorescein staining, best seen with dilated pupil. The lesions of the classical mulberry type of GDLD are opaque in direct and translucent in retroillumination.

These characteristic lesions present multiple subepithelial gelatinous excrescences that appear early in life. It is important to know that subepithelial band keratopathy may appear in the early stage of GDLD. The consequence is to perform a genetical molecular analysis in every case of subepithelial band keratopathy with unknown origin to include or exclude a mutation in the TACSTD2 gene. The primary subepithelial band keratopathy of GDLD without endothelial changes is to distinguish from the secondary band keratopathy of the three endothelial corneal dystrophies, XECD, CHED, PPCD, due to primary endothelial alterations visible in retroillumination and by dilated pupil (see also chapter Corneal dystrophy, X-linked endothelial). In GDLD, there was amyloid accumulation, primarily beneath the epithelium, of Congo red-positive deposits with birefringence under polarized light.

## Therapeutic Principles

The GDLD epithelial erosions may be treated at first with topical antibiotics and artificial tears. In a case of band keratopathy an option of therapy could be phototherapeutic keratectomy (PTK) to smoothen the corneal surface after removal of the band keratopathy with EDTA chelating. Treatment of advanced disease includes superficial keratectomy, lamellar keratoplasty, and penetrating keratoplasty. Because recurrence of GDLD approaches 50% of eyes after penetrating keratoplasty limbal allografting is being performed in the attempt to diminish the likelihood of recurrence.

## Synonyms

Groenouw corneal dystrophy type I; GCDI

## Definition and Characteristics

GCDI is an autosomal dominantly inherited disorder characterized by small crumb-like granules, 0.1–0.3 mm in diameter, separated from one another in the center of the anterior corneal stroma. The peripheral 2 mm or so of the stroma remain clear. The dystrophy manifests in the first decade of life. GCDI runs through three stages. First opacities occur in children resembling radiating lines. Subsequently, the opacities increase in number and size. In the third stage, a ground-glass haze appears between the opacities in the superficial stroma. Recurrent painful attacks due to epithelial erosion occur in GCDI in about 60% of patients most frequently between 20 and 50 years of age. GCDI is slowly progressive, leading to significant visual loss after the

age of 40 years. The homozygous form of GCDI causes dense, confluent placoid opacities in the anterior stroma and poor visual acuity already in childhood. These corneal changes are reminiscent of the opacity of Reis-Bücklers CD (RBCD).

## Prevalence

GCDI is rare, and was first described by Groenouw in 1890 [1]. In 1938, Bücklers proposed a systematic classification of the corneal dystrophies in three groups: Granular CD (GCD), Macular CD (MCD), and Lattice CD (LCD) (classical CDs), [1]. Reports of GCDI are from (alphabetically): Argentina, Austria, Belgium, China, Denmark, England, France, Germany, Greece, Hungary, Italy, Japan, Jugoslavia, New Zealand, Norway, Poland, Romania, Russia, Spain, Sweden, Switzerland, Turkey, and USA [2]. The order by frequency of the three classical CDs in Germany is: (i) Granular CD, (ii) Macular CD, and (iii) Lattice CD.

## Genes

A chromosomal locus for GCDI had been mapped to 5q31 by linkage analysis. The clinically distinct CDs, Granular CD II (GCDII), Lattice CD (LCD), Reis-Bücklers CD (RBCD), and Thiel-Behnke CD (TBCD) had been mapped to the same region of 5q31 [3]. All these corneal dystrophies are due to mutations in the transforming growth factor beta-induced (TGFBI) gene (kerato-epithelin gene) [4]. To date, five mutations have been reported as causing GCDI: Arg555Trp; Arg124-Ser; Arg124Leu; Arg123His; Thr125_Glu126 del. Okada and associates described a patient homozygous for the Arg555Trp mutation [5].

## Molecular and Systemic Pathophysiology

More than 30 TGFBI mutations have been identified in six clinically different corneal dystrophies. Most of these mutations likely lead to defective protein folding, thus altering the cell-matrix interactions and resulting in a corneal stromal accumulation of mutated gene product into deposits [4]. It is proposed that the specific location and type of mutation lead to the differences in deposition observed in these various corneal dystrophies. The TGFBI mutations that involve the arginine-124 residue in exon 4 eliminate a phosphorylation site, and mutations concerning arginine-555 in exon 12 affect a coiled-coil domain [4]. GCDI appears to be the first eye disease in which homozygosity for a dominant allele has been genetically identified with the consequence of increased severity of the disease compared with the heterozygote [5]. The true function of the kerato-epithelin protein is still unclear. Mutations involving codons 124 and 555 account for more than half of TGFBI-associated diseases. Distinct mutations of codon 555 can result in GCDI or Thiel-Behnke CD (TBCD), and distinct mutations of codon 124 can result in GCDI, GCDII, RBCD and LCDI. The mechanisms by which the mutations at the same codon lead to clinically different diseases are unknown. Moreover, an Arg124Leu mutation can result in either GCDI or in RBCD.

## Diagnostic Principles

The clinical diagnosis of GCDI is based on slitlamp examination in direct and indirect illumination, best seen with dilated pupil, and fluorescein staining. The landmark of GCDI are multiple, central, subepithelial crumb-like, discoid opacities. The corneal stroma between these lesions is clear. In GCDII there are only few stars and rings, located also in the center of the cornea. GCDI patients suffer more from pain attacks due to epithelial erosions than GCDII patients. In an early stage of the disease it can be difficult to distinguish clinically between a singular case of GCDI, macular CD (MCD) and lattice CD (LCD). The appearance of only one lattice line excludes GCDI and MCD. The pattern of transmission helps to distinguish GCDI from the autosomal recessive inherited MCD at this stage. Ultrastructurally, the lesions of GCDI consist of electron-dense rod-shaped and rhomboidal structures.

## Therapeutic Principles

GCDI induced epithelial erosions may be treated at first with topical antibiotics and artificial tears. The use of contact lenses can be useful and helpful. In the fifth decade lamellar or penetrating keratoplasty may be required for patients with GCDI. However, recurrences may be observed in more than 90% of penetrating GCDI keratoplasties after six years postop. Therefore, phototherapeutic keratektomie (PTK) is the treatment option of first choice, today.

## Synonyms

"Avellino" corneal dystrophy; GCDII

## Definition and Characteristics

Large rings with punched-out centers, powdery disks or stellate elements in the center of the cornea dominate the picture in this autosomal-dominantly inherited CD. The rings and disks are located in the superficial stroma, whereas the stars extend to the deeper stroma. These opacities are usually so few in number that they can be counted. The peripheral cornea is free of opacifications. The dystrophy manifests in the second decade of life, progression is delayed about 20–30 years and is characterized more by individual growth than by increase in number of opacities. In a subsequent stage, some units enlarge, creating a "sword-like" or "christmas-tree" appearance. Rarely, coalescing rings and disks create ground-glass haziness in a third stage of the disease. Recurrent painful attacks due to epithelial erosions occur less frequently in GCDII than in GCDI. The homozygous form of GCDII presents already in childhood with reduced visual acuity due to two distinct types of opacities in the anterior stroma: (i) Gray-white spot-like and confluent opacities and (ii) Reticular gray-white diffuse opacities with several round translucent spaces.

## Prevalence

GCDII is a rare superficial corneal disorder presented first by Bücklers in 1938 [1]. He described the corneal appearance in form of ring-shaped opacities in a finger-shaped arrangement. Weidle distinguished GCDI and GCDII clinically [2]. The name "Avellino" leads back to the trace of three GCDII families in the Italian Province of Avellino [3]. We examined three GCDII families from Eastern Europe without relationship to the region of Avellino. GCDII is more frequent than GCDI in Japan and Korea. We propose that the term "Avellino" CD should not be used anymore. Most patients with the homozygous form of GCDII were found in Japan.

## Genes

A chromosomal locus for GCDII had been mapped to 5q31 by linkage analysis. This dystrophy represents one of the five transforming growth factor beta-induced gene (TGFBI) CDs (Granular CDI, Lattice CD, Reis-Bücklers CD, Thiel-Behnke CD). GCDII was associated with an Arg124His mutation in all patients reported to-date [4].

However, GCDII shows considerable intra- and interfamilial phenotypic variation. Homozygosity for the Arg124His mutation was first reported by Watanabe and associates [5]. Japanese patients with type I opacities do not share a common birthplace. However, patients with type II opacities traced their origin to the Tottori prefecture in western Japan.

## Molecular and Systemic Pathophysiology

Amyloid was demonstrated within some of the granular corneal deposits by light and electron microscopy. Different mutations at the same TGFBI residue lead to different phenotypes, supposedly depending on how the specific mutation altered protein folding and subsequently aggregation into characteristic lesions. Indeed different missense replacements of the Arg-124 residue produce GCDI and II, Reis-Bücklers CD (RBCD) and lattice CD type I (LCDI). However, additional confounding factors, are likely involved in determining the severity of the phenotype.

## Diagnostic Principles

The clinical diagnosis of GCDII is based on slit-lamp examination in direct and indirect illumination, fluorescein staining, best seen with dilated pupil. The landmark of GCDII are few, superficial star- and ring-like opacities in a central discoid form and often in a finger-shaped arrangement. GCDII patients suffer rarely from dystrophy induced pain attacks due to epithelial erosions than GCDI patients. The visual acuity of age-related individuals with GCDII is better on the average than with GCDI and does not drop below 0.3. Histologically, the lesions of GCDII show both amyloid and hyaline properties [3].

## Therapeutic Principles

The rare GCDII induced epithelial erosions may be treated at first with topical antibiotics and artificial tears. The use of contact lenses can be helpful. Phototherapeutic keratectomy (PTK) is the treatment option of first choice in an advanced stage of the disease, widely avoiding lamellar or penetrating keratoplasty. Obligatory recurrences postop are to observe. The intraoperative use of topical 0.02% mitomycin C in conjunction with PTK may prevent or delay the recurrences of GCDII. However, LASIK can exacerbate GCDII and should be avoided in patients with this condition.

## Synonyms

Band-shaped and whorled microcystic corneal dystrophy; LECD

## Definition and Characteristics

LECD is an X-chromosomal dominant epithelial disorder characterized by bilateral or unilateral grey, band or feathery-like stripes with a whorled or wheel-spotted pattern partly extending from the limbus into the pupillary zone in direct illumination. In indirect illumination these opacities consist of multiple densely crowded clear microcysts. The cornea between affected areas is clear. First symptoms are often small spoke-like epithelial lesions in childhood. The cysts tend to increase in number with age and can involve the visual axis with the consequence of reduced vision and mild photophobia. Until now, no LECD-induced epithelial defects have been reported. Both sexes are equally affected.

## Prevalence

LECD is rare. Lisch and associates [1] first described the distinctive clinical symptoms in one familiy in Hessen, Germany, recognizing LECD as a new entity in 1992. Further examinations of this family disclosed a total of 19 patients in 6 generations [2]. Other reports of sporadic and familial LECD cases are from USA, Germany, Spain and Denmark [3,4].

## Genes

Absence of father-to-son transmission of the disease in a six-generation family suggested X-linked inheritance of LECD. Linkage studies with six and four markers flanking the keratin K3 and K12 loci excluded linkage to either of these autosomal genes. A scan of the X-chromosome produced significant evidence for linkage to the short arm of the X-chromosome within or near the pseudoautosomal region (Xp 22.3) [2]. The LCED gene itself has yet to be identified.

## Molecular and Systemic Pathophysiology

The fact that both male and female patients show a similar phenotype is well compatible with a localization of the LECD gene within the pseudo-autosomal region Xp (PAR1) [1]. Genes residing within PAR1 exhibit "autosomal" rather than sex-specific manifestations. These genes escape X inactivation and are present on both sex chromosomes. On the other hand the radial disposition of some of the observed epithelial opacities in LECD recall the vortex arrangement of the epithelium encountered in Fabry disease caused by mutations in the alpha-galactosidase A gene on Xq22 in form of cornea verticillata and in some drug-induced epithelial keratopathies [5]. Lyonisation refers to the random inactivation of one X chromosome in each cell of normal XX females, and it might be assumed, that in a female carrier of an X-linked disorder such as LECD or Fabry disease, half of the limbal stem cells would produce a progeny of opaque epithelial cells and half would produce a progeny of clear cells. Consequently it might be expected that carrier females showed a lesser degree of corneal epithelial opacity than affected males [4]. However, such a dosage effect with regard to the degree of corneal opacity has neither been reported in Fabry disease nor in LECD.

## Diagnostic Principles

The clinical diagnosis of LECD is based on the slit-lamp examination in direct and indirect illumination, best seen with dilated pupil. The different greyish epithelial opacity patterns observed in direct illumination typically disclose multiple, crowded clear microcysts in

retroillumination. In contrast, Meesmann corneal dystrophy (MECD) is characterized by multiple, solitary clear microcysts in indirect illumination. The greyish cornea verticillata of Fabry disease represents multiple fine lines consisting of crowded punctiform changes.

Histology of debridment specimes showed extensive epithelial vacuolisation of all affected cells, with a sharp demarcation between affected and unaffected regions.

## Therapeutic Principles

LECD may be an entirely asymptomatic disorder that is discovered by chance and requires no treatment. Where the enlarged opacities ocur in the visual axis they may disturb vision [1,3]. The dystrophy recurred after multiple debridment. The use of hard and soft contact lenses over some weeks can decrease the epithelial opacification and improve visual acuity [1]. However, without continual wear of contact lenses a recurrence of LECD can be observed. Another option of therapy would be the phototherapeutic keratectomy (PTK).

## Synonyms

Groenouw corneal dystrophy type II; Fehr spotted dystrophy; MCD

## Definition and Characteristics

MCD is an autosomal-recessive disorder characterized by multiple, irregular, gray-white opacities extending to the limbus and diffuse opacification of the stroma. The symmetric changes of MCD are usually first noted between 3 and 8 years of age, characterized by subepithelial multiple central flecks and superficial clouding in central stroma. This opacification consisting of flecks and diffuse clouding extends to the periphery and usually involves the entire thickness of the cornea by the second decade of life. MCD is often associated with reduced corneal thickness. In addition, MCD patients may present with recurrent corneal erosions and attacks of irritation and photophobia that occasionally are quite severe. Vision is usually severely affected by the time the patient reaches the 20s or 30s.

## Prevalence

MCD is a rare corneal disorder first described by Groenouw in 1890 [1]. MCD is the least common of the three classical stromal dystrophies (GCD, LCD, MCD). MCD is very common in Iceland, despite the small population of this country. Other reports are from Japan, USA, Europe, Saudi-Arabia, and Vietnam. In 1964, Klintworth and associates disclosed that MCD represents an inherited acid mucopolysaccharide storage disease of the corneal fibroblast [2].

## Genes

MCD maps to chromosome 16q23.1-23.2 and is due to mutations in a carbohydrate sulfotransferase gene (CHST6) which leads to under sulfation of the glycosaminoglycan keratan sulfate [3]. Immuno-detectable keratansulfate (KS) was deficient in the serum and corneas of some but not all patients with MCD giving rise to three immunophenotypes, MCDI, IA and II. In MCDI, the commonest variety, there is almost not detectable sulfated KS in serum or cornea. In MCDIA, disclosed in Saudi-arabian and German patients, sulfated KS is absent from the serum but is detectable in the cornea within keratocyte accumulations. In MCDII there are normal amounts of sulfated KS in both the serum and corneal intracytoplasmic and stromal deposits. Following linkage analysis, mutations were identified in the CHST6 gene. Numerous missense, nonsense, and frameshift mutations in MCDI and IA patients have been reported. Deletions and/or rearrangements in the upstream region as well as missense mutations have been reported in MCDII.

## Molecular and Systemic Pathophysiology

An other important observation was the low level of keratan sulfate synthesis by organ cultured MCD corneas and of lumican, the major keratan sulfate-containing proteoglycan [4].

C-GlcNAc6ST, encoded by CHST6, tranfers sulfate to position 6 of GlcNAc residues during biosynthesis of KS glycosaminoglycans in the cornea. KS is the major glycosaminoglycan of corneal stroma. KS glycosaminoglycan chains are N-linked to asparagine residues on distinct core proteins forming the KS proteoglycans (KSPGs) lumican, keratocan or mimecan. The highly anionic nature of the sulfate moiety of KS confers a water-holding ability that contributes to maintaining corneal transparency (Funderburgh 1986). Many of the mutations for MCDI were reported to be located in the binding sites for the high-energy sulfate donor, 3-phosphoadenosine 5′- phosphosulfate, or the binding pocket for the acceptor, GlcNAc, associated with decreased or lost enzyme activities. The decreased level of C-GlcNAc6ST activity in corneas from MCD patients likely results in the formation of the low-sulfated KS accumulating within the keratocyte, the surrounding stroma, the subepithelial area, Bowman's layer, Descemet's membrane, and the endothelium of MCD-affected corneas. Low-sulfated KS is also believed to disturb the role of KSPGs in influencing collagen fibril organization and tissue hydration [5]. CHST6-induced loss of function does not cause symptoms outside the cornea suggesting that other keratan GlcNAc 6-O-sulfotransferases are expressed in other tissues.

## Diagnostic Principles

The clinical diagnosis of MCD is based on slit lamp examination in direct and indirect illumination. The MCD landmark is characterized by fleck-like opacities out to the limbus and down to the endothelium combined with diffuse stromal clouding. MCD must be distinguished from other causes of corneal clouding in childhood, which include congenital glaucoma, CHED, PPCD, and some forms of systemic mucopolysaccharidoses. In an early stage of disease it can be difficult to distinguish clinically between a singular case of GCDI, MCD and LCD (see also chapter ►Corneal Dystrophy, Granular Type I). The three types of MCD are clinically and histologically identical. Ultrastructurally, MCD is characterized by the accumulation of glycosaminogylcans between the stromal lamellae, underneath the epithelium, and within the keratocytes and the endothelial cells. The glycosaminoglycans stain with Alcian blue, colloidal iron, metachromatic dyes, and PAS.

## Therapeutic Principles

MCD induced epithelial erosions may be treated at first with topical antibiotics and artificial tears. The use of contact lenses can be useful and helpful. Penetrating keratoplasty (PKP) or deep anterior lamellar keratoplasty may be required for MCD patients. Recurrences are seen late in both lamellar and penetrating grafts. Phototherapeutic keratectomy (PTK) for the treatment of MCD has a poor long-term outcome.

## Synonyms

Juvenile epithelial dystrophy of the cornea; MECD

## Definition and Characteristics

MECD is an autosomal dominantly inherited epithelial disorder characterized in direct illumination by diffuse grey opacities in different patterns: random, whirled, sectorial, interpalpebral or unilateral and sparing the perilimbal region. These opacities, in indirect illumination, consist of multiple solitary, round, and transparent cysts producing rarely refractile lines due to a coalescence of several cysts. The intervening cornea

remains clear. The cysts tend to increase in number with age. The alterations are usually asymptomatic but in a minority of patients rupture of the epithelial microcysts may cause recurrent punctate erosions with pain attacks, blepharospasm, lacrimation, and photophobia over several days. These symptoms occur mostly in childhood and decrease in adolescence but can occur at any age. Vision is often unaffected throughout life. However there may be attacks of discomfort and visual disturbance in the fourth or fifth decade. The so-called Stocker-Holt type is interpreted as a variant of MECD with more severe signs and symptoms.

## Prevalence

MECD is a rare epithelial disorder. Meesmann and Wilke presented three families from Schleswig-Holstein, Northern Germany, as a new epithelial dystrophy in 1939 [1]. Behnke and Thiel showed that all hitherto known cases of MECD in Schleswig-Holstein could be traced back to a common ancestor in 1620 [2]. 763 family members in 12 generations were included and MECD could be established in 120 cases. Further family reports of MECD are from the USA, Germany, The Netherlands, Japan, Northern Ireland, Switzerland, Taiwan and Saudi-Arabia. Stocker and Holt described MECD in 20 members of a large family living in North Carolina, USA [3]. The family was of Moravian descent and had emigrated from Saxony in 1741.

## Genes

MECD is caused by mutations in the keratin K3 gene at chromosome 12q13 and the keratin K12 gene at chromosome 17q12 encoding two cornea-specific cytokeratins, CK3 and CK12 respectively [4]. Mutation Arg135Thr in K12 was found in the descendants of the original family studied by Meesmann. To date, 18 independent mutations have been reported:

K3: Arg503Pro; Glu509Lys.
K12: Met129Thr; Gln130Pro; Leu132Val; Asn133Lys; Arg135Gly; Arg135Ile; Arg135Thr; Arg135Ser; Ala137-Pro; Leu140Arg; Val143Leu; Lle391_Leu399dup; Jle426Val; Jle426Ser; Thr429Asp; Thr429Cys.

Intrafamiliar variation in the severity of the disease among affected individuals is well described, and no genotype-phenotype correlation is apparent.

## Molecular and Systemic Pathophysiology

Epithelial cells contain three types of cytoskeletal systems: 6-nm actin microfilaments, 23-nm microtubules, and 10-nm keratin intermediate filaments [5]. The intermediate filament cytoskeleton has been shown to be responsible for resisting traumatic damage to the cell. In the cornea, the limbal cells primarily express keratins K5 and K14, and keratins K3 and K12 are predominantly expressed by epithelial cells. Targeted ablation of K12 in transgenic mice has been shown to produce a phenotype of corneal epithelial fragility, reminiscent of the epithelial corneal dystrophy in humans [5]. All reported K3 and K12 mutations cluster in the helix boundary motifs which are critical in filament assembly. The K3 and K12 mutations of MECD are predicted to cause major disruption of the intermediate filament architecture in corneal epithelial cells, leading to lysis of these cells. The fragility of cells expressing K3 and K12 presumably manifests itself as microcysts, which are small blisters in the anterior epithelium. Electron microscopy of intracytoplasmic "peculiar substance" represents a focal collection of fibrillogranular material surrounded by tangles of cytoplasmic filaments. These cytoplasmic inclusions are identified as keratin aggregates, similar to those found in epidermolysis bullosa simplex when mutations occur in the helix boundary motifs of K5 or K14 [5].

## Diagnostic Principles

The clinical diagnosis of MECD is based on the slit lamp examination in direct and indirect illumination, fluorescein staining, best seen with dilated pupil. The different greyish epithelial opacity patterns observed in direct illumination typically disclose multiple, solitary, perlucide microcysts in retroillumination. In contrast, Lisch epithelial corneal dystrophy (LECD) is characterized by multiple, crowded perlucide microcysts in indirect illumination. The bleb pattern of EBMD can be seen only indirectly. In each case of unilateral keratitis with epithelial erosions the contralateral eye should be examined with regard to dystrophic microcystic epithelial changes indicating a dystrophy. In such a situation the punctiform epithelial erosions can masquerade the cystic dystrophic changes. The correct diagnosis is then not a keratitis but an epithelial dystrophy induced keratopathy.

## Therapeutic Principles

MECD may be an entirely asymptomatic disorder that is discovered by chance and requires no treatment. MECD induced punctiform epithelial erosions may be treated at first with topical antibiotics and mydriatics in the acute phase and topical lubricants at night in the chronic phase. The use of soft contact lenses can decrease epithelial microcysts in MECD. The dystrophy recurred after simple debridment. In elderly patients with severe complaints of MECD lamellar or penetrating keratoplasty was performed but with a possible epithelial recurrence after some years.

Today the phototherapeutic keratectomy (PTK) is recommended before an intended lamellar or penetrating keratoplasty. Both procedures have the problem of recurrence. It is important to postpone grafting as long as possible as these patients tend to be regrafted because of recurrences.

## Synonyms

Posterior amorphous stromal dystrophy; PACD

## Definition and Characteristics

PACD is an autosomal dominant disorder characterized by a sheet-like opacification of the posterior stroma. The lesions can be centroperipheral, extending to the limbus, or peripheral, the latter with less pronounced findings and symptoms. There are often transparent stromal breaks in the opacification. Visual acuity is often only mildly affected as the stroma thins from a normal of 0.5 mm centrally to as low as 0.3 mm.

## Prevalence

PACD is a very rare disorder. Carpel and associates presented a pedigree in three generations [1]. This pattern was confirmed in a study spanning five generations of a single pedigree [2]. The condition may be congenital in some cases. Until today, four families with PACD were reported from USA and one from UK [3].

## Genes

Not reported.

## Molecular and Systemic Pathophysiology

Ultrastructurally, there are abnormally oriented collagen fibers and abnormal keratocytes with disorganization of the posterior lamellae. A fibrillar layer resembling stromal collagen fibers interrupts Descemet membrane [4]. These findings are not pathognomonic of this dystrophy and may be found in other abnormalities.

## Diagnostic Principles

The clinical diagnosis is based on slit lamp examination in direct and indirect illumination, best seen with dilated pupil. The landmark of PACD is characterized by patches of gray sheets in the deep storma from limbus to limbus, often combined with clear stromal ring or breaks. Reported associations with PACD include corectopia, pseudopolycoria, iridocorneal adhesions, and other iris abnormalities. The possible congenital onset, lack of progression and association with iris abnormalities has raised the question whether this may in fact be a mesodermal dysgenesis rather than a corneal dystrophy.

## Therapeutic Principles

No therapy is required.

## Synonyms

Schlichting corneal dystrophy; PPCD

## Definition and Characteristics

PPCD is an autosomal dominantly inherited disorder characterized by changes at the level of Descemet's membrane and endothelium. The corneal abnormalities can be divided into three patterns: (i) Vesicle-like lesions, (ii) Band lesions, and (iii) Diffuse opacities. The landmark of PPCD represent the vescicular- and band-like lesion. Unilateral band lesions can be observed relatively often in solitary cases. When the changes are of minor degree, the condition is stationary and there is little effect on vision. In these cases the disorder may only be detected coincidentally at routine examination. Rarely, corneal edema occurs and ranges from minimal stromal thickening to bullons keratopathy with severe visual impairment. Approximately 25% of PPCD patients have peripheral anterior synechiae. Elevated intraocular pressure occurs in about 15% of patients. This association can occur either with anatomically open angles or with angle closure. The mechanism for angle closure can be easily understood, as it is due to the epithelial-like endothelium migration across the trabecular meshwork, resulting in peripheral anterior synechial closure. The age of PPCD onset is variable, from the early teens to late adulthood. Great variation in disease severity within and between families has been reported. In very rare instances PPCD may manifest as a cloudy cornea in the first decade of life.

## Prevalence

First description of PPCD are published by Koeppe in 1916, Theodore in 1939, and Schlichting in 1941 [1]. Cibis and associates examined 61 affected members of eight families with an inherited endothelial corneal dystrophy. They concluded that it is not possible on clinical grounds to separate congenital hereditary endothelial dystrophy (CHED) as an entity distinct from PPCD [1]. Krachmer's publication represented the largest series of PPCD cases reported, including eight families with 120 individuals [2]. Risk factors for severe disease included the presence of iridocorneal adhesions and increased intraocular pressure. Only 27% of patients had iridocorneal adhesions.

## Genes

Following linkage analysis, heterozygous mutations in three genes, VSX1, TCF8 (ZEB1), and COL8A2, were identified in PPCD. TCF8 mutations might account for up to 45% of PPCD cases, and are associated with abdominal hernias in a subset of patients. TCF8 mutations show high but incomplete penetrance. De novo mutations occur frequently. To date, 18 TCF8 nonsense and frame-shifting mutations have been reported suggesting loss of function as the underlying pathomechanism [3]. TCF8 and VSX1 encode transcription factors. VSX1 mutations Gly160Asp and Asp144Glu were thought to cause PPCD in a small number of patients [4]. These mutations were later also observed in controls, and associated with a distinct condition, keratokonus, suggesting either incomplete penetrance or manifestation of symptoms dependent on the genetic background. VSX1 mutations His244Arg and Ala256Ser were found to segregate with PPCD plus macular degeneration and PPCD with retinal and craniofacial anomalies in larger families. These findings support the significance of VSX1 mutations in PPCD, and highlight possible pleiomorphic effects of such mutations. Screening for mutations in the gene encoding collagen type VII α2 (COL8A2), implicated in Fuchs endothelial corneal dystrophy (FECD), revealed a Gln455Lys mutation in the two patients from one family. The symptoms of PPCD are infrequently found in Alport syndrome (hereditary nephritis with hearing loss) caused by mutations in collagen IV genes. A further locus for PPCD has been mapped in large autosomal dominant pedigrees to a 2.7-cM region on chromosome 20p11.2. This locus excludes VSX1 and overlaps with a locus for autosomal dominant congenital hereditary endothelial dystrophy (CHED1) [5].

## Molecular and Systemic Pathophysiology

Several histological studies have demonstrated that the "endothelial cells" in affected regions show epithelial features, including the presence of cytokeratins, intercellular desmosomes and numerous microvilli. Fibroblasts may also be present. On the basis of this it has been postulated that neural crest cells destined to form the corneal endothelium, fail to differentiate, or undergo an abnormal transformation in gestation, causing them to retain a degree of pluripotentiality and behave like epithelial cells. This results also, in an abnormal Descemet's membrane in affected regions. In PPCD, the anterior banded zone is normal, but the posterior, non-banded zone is abnormal, in keeping

with a dysplastic process affecting the formation of basal lamina by the endothelial cells postnatally. Collagen type VIII is a major component of Descemet's membrane and it has been suggested that the mutated collagen interferes with endothelial cell differentiation. It is not clear what gives rise to the patchy endothelial involvement in PPCD. TCF8 has been implicated in repression of epithelial cell adhesion genes such E-cadherin and desmoglein, and a role in the regulation of type I collagen expression, important for the maintenance of an endothelial phenotype.

## Diagnostic Principles

The clinical diagnosis of PPCD is based on slit lamp examination in direct and indirect illumination. The changes may be best seen by retroillumination with dilated pupil. Three types of anomalies can be seen at the level of Descemet's membrane. The different forms may occur together in the same cornea: (i) Vesicular Form: Vesicles are small, round, discrete structures which are found in clusters of 2–20 and may occur anywhere on the cornea without effect on vision. Vesicles may increase in number, remain stationary or regress. Larger, confluent, geographic lesions are also seen, surrounded by a denser gray halo. When these lesions are extensive, there may be an overlying stromal edema. (ii) Linear Form: These are glistening, band-shaped figures about 1 mm wide and few millimeters in length with roughly parallel, irregular borders, giving them a "snail track" appearance. Their orientation varies. Thickening of Descemet's membrane may produce excrescences which project slightly into the anterior chamber. They are gray in direct illumination and refractile on retroillumination. (iii) Diffuse Form: The diffuse form is characterized by an irregular thickening of Descemet's membrane, sometimes associated with a diffuse stromal haze and with a characteristic, beaten metal appearance on specular microscopy. Specular microscopy may be particularly helpful in the diagnosis of PPCD, when the vesicles appear as dark rings with scalloped edges, surrounding a mottled center containing large, irregular cells. On transmission electron microscopy an extreme thinning or absence of the posterior non-banded layer of Descemet's membrane form layers up to 25 nm thick. Multi-layered epithelial-like cells with microvilli and desmosomes can be seen that may stain positive with anti-CK7 antibodies on immunhistochemsitry. PPCD must be differentiated from ICE syndrome which is characterized in the most cases by sporadic occurrence and unilateral presentation. The corneal clouding type of PPCD at birth should be included in the differential diagnosis of congenital glaucoma, congenital infections, CHED, X-linked endothelial corneal dystrophy (XECD) in males, and metabolic diseases.

## Therapeutic Principles

Most patients with PPCD never require treatment, but penetrating keratoplasty or posterior lamellar keratoplasty may be required for those with severe corneal edema. Krachmer found, that 57% of his patients, with iridocorneal adhesions required corneal transplantation [2]. Similarly, only 14% of patient in Krachmer's series had increased intraocular pressure, yet 62% of patients with increased intraocular pressure required corneal transplantation. PPCD can recur after transplantation [2]. In the 22 corneal transplants, four corneas developed retrocorneal membranes, three of which led to opacified grafts.

## Synonyms

Cornea farinata and other variants; PDCD

## Definition and Characteristics

In PDCD multiple fine gray dots are seen in the posterior stroma in the form of punctate, linear, circular, comma, boomerang, wormlike, dendritic shapes, and punctiform crystalline opacities. These lesions are most often bilateral and symmetric and occur after age 30. They may be diffuse, central, or form a ring, sparing the peripheral and central cornea. Visual acuity is usually not affected. PDCD is not a well-defined entity. Although there is no definite pattern of inheritance, it has been described in families over 2–4 generations. The subtype punctiform and crystalline PDCD reported to be autosomal dominant in one pedigree may represent a specific dystrophy.

## Prevalence

PDCD is very rare. 1967 Grayson and Wilbrandt described 22 cases of PDCD and classified the different opacities in six patterns [1]. They reported this dystrophy in siblings, and it has been described in three pedigrees over two generations. Fernandez-Sasso and associates described punctiform crystalline PDCD in four generations of a single pedigree in 46 family members with a probable autosomal dominant inheritance [2]. Hints of confirmation do exist [3].

## Genes

Not reported.

## Molecular and Systemic Pathophysiology

Ultrastructurally, enlarged keratocytes near Descemet's membrane contain PAS-pative material and vacuolation [4]. Membrane bound intracellular vacuoles containing electron dense material suggestive of secondary lysosomes consistent of lipofuscin-like lipoprotein.

## Diagnostic Principles

The clinical diagnosis is based on slit lamp examination in direct and indirect illumination, best seen with dilated pupil. The filiform and linear PDCD patterns have to be differentiated against the diffuse opacities and band lesions in posterior polymorphous corneal dystrophy (PPCD).

## Therapeutic Principles

No therapy is required.

## Synonyms

Granular corneal dystrophy type III; GCDIII; RBCD

## Definition and Characteristics

RBCD is an autosomal dominantly inherited disorder characterized by subepithelial and superficial stromal alterations extending almost to the limbus. It presents painful erosions in infancy and is associated with fine, granular opacities that spread and become geographic-like with time. The geographic-like opacities are to be regarded as a landmark of RBCD. The full stage of RBCD can be observed in the first decade combined with blurred vision.

## Prevalence

RBCD is a rare superficial corneal disorder presented first by Bücklers in 1949 [1]. Weidle described a Caucasian RBCD family with a total of 30 patients in 7 generations [2]. Other reports of true RBCD cases are from France, The Netherlands, USA, Germany, and Japan. RBCD has been frequently confused in the literature with Thiel-Behnke corneal dystrophy (TBCD), which is characterized by honeycomb corneal appearance [2].

## Genes

A locus of RBCD has been mapped to chromosome 5q31 by linkage analysis. Clinically distinct corneal dystrophies, the granular corneal dystrophies I, II (GCDI, II), and lattice corneal dystrophy I (LCDI) were mapped to the same locus [3]. Munier and associates constructed a yeast artificial chromosome contiguous map covering the region to which these four autosomal dominant corneal dystrophies were mapped

and identified heterozygous mutations in the TGFBI gene in all these dystrophies, although the patients given a diagnosis of RBCD were diagnosed with TBCD in retrospect [4]. Okada and associates demonstrated in Japanese patients for the first time that RBCD is associated with a TGFBI Arg124Leu mutation, and is also genetically to be distinguished from TBCD, which is caused by an Arg555Gln mutation [5]. We were able to analyze the complete coding region of the TGFBI gene in four individuals from the Caucasian RBCD family of Weidle (unpublished data). All four affected members were heterozygous for the Arg124Leu mutation, further highlighting a genotype–phenotype correlation in RBCD.

## Molecular and Systemic Pathophysiology

A feature of RBCD is the rapid progression of its corneal opacities and severe impairment of vision in the teens. This relatively more severe clinical course of RBCD compared with LCD I and GCD II may well be the result of the structure of the particular amino acid that replaces arginine in codon 124, a hot spot for keratoepithelin mutations [4]. Arginine is charged polar, as is histidine found in GCD II, whereas cysteine (LCDI) is uncharged polar, and leucine (RBCD) is nonpolar. Consequently, arginine and histidine are chemically hydrophilic and cysteine has an intermediate nature, whereas leucine is hydrophobic. Therefore, the three-dimensional structure of Arg124Leu-mutated TGFBI would be expected to differ most from that of wild type when it is compared with the other two mutations in codon 124. However, the opacities are identical to those in GCDI and stain red with Masson's trichrome and appearing as rod-shaped bodies by transmission electron microscopy.

## Diagnostic Principles

The clinical diagnosis of RBCD is based on slit lamp examination in direct and indirect illumination, fluorescein staining, best seen with dilated pupil. In an early stage of the disease it can be difficult to distinguish clinically between RBCD and TBCD. In a later stage, the RBCD landmark is characterized by geographic-like and those of TBCD by honeycomb-like appearance. RBCD patients suffer from dystrophy-induced pain attacks due to epithelial erosions in the first and second decades of life. RBCD is characterized ultrastructurally by the presence of "rod-shaped" deposits in the corneal epithelium and stroma. That is why we can find terms for RBCD as "Superficial variant of granular dystrophy" or "Atypical granular dystrophy" or "Granular corneal dystrophy III (GCD III)" in the past literature. These terms are not justified because of the completely different clinical features of RBCD, GCD I and GCD II. The TBCD has a distinctly different appearance by electron microscopy, being characterized by the presence of electron-dense "curly filaments."

## Therapeutic Principles

RBCD-induced epithelial erosions may be treated at first with topical antibiotics and artificial tears. The severe pain that attacks in the first decade disappears slowly in the second decade and completely after lamellar or penetrating keratoplasty. In all cases of RBCD, a surgical intervention is indicated in the first or second decade. The dystrophy recurred quickly after simple debridement. Lamellar and penetrating keratoplasties resulted in recurrences after 1 until 4 years post-operation with severe reduction of visual acuity, necessitating recurrent grafting of the same eye.

Phototherapeutic keratectomy (PTK) could be an option to keratoplasty which can be repeated.

[2]Division of Clinical Genetics, Innsbruck Medical University, Innsbruck, Austria
[3]Department of Ophthalmology, University of Saarland, Homburg/Saar, Germany

## Synonyms

Schnyder crystalline corneal dystrophy; SCCD; Central crystalline corneal dystrophy of Schnyder; SCD

## Definition and Characteristics

Schnyder CD is an autosomal dominantly inherited disorder characterized by subepithelial central disc- or ring-like opacities consisting of crowded, multicolored, needle-shaped crystals. The surrounding cornea of the crystalline opacity may demonstrate diffuse white changes of different extension. Symptoms are usually present in the first decade of life. There are trait carriers of Schnyder corneal dystrophy (SCD) who only present diffuse disc- or ring-like opacities with few or without crystals. Its possible that additional crystals can be observed in- or outside of the diffuse opacity in a later stage. SCD is often associated with an arcus lipoides. There is an unexplained association with hypercholesterolemia. However, there are SCD patients without arcus lipoides and hypercholesterolemia. Rarely, SCD can lead to painful epithelial erosion. Follow-up of SCD patients has shown a progression of the diffuse opacities to the corneal periphery and throughout the stroma, but in contrast less progression of crystal formation. The progression of SCD opacities leads to decreasing visual acuity by the third to fourth decade. SCD is often associated with decreased corneal sensation.

## Prevalence

SCD is a rare corneal disorder first described by van Went and Wibaut in 1924 [1], and subsequently, in 1929, by Schnyder [2]. There are less than 150 articles in the published literature with less than 100 cases. Weiss identified in a retrospective study 115 affected individuals from 34 SCD families from USA, Germany, UK, Taiwan, Japan, Turkey and Czech Republic [3]. Further SCD family reports are from the following countries: The Netherlands, Switzerland, Argentina, Denmark, France, Canada and Italy.

## Genes

A chromosomal locus for SCD had been mapped to 1p34-36 by linkage analysis. After redefining the candidate region, Weiss and associates [4] and, independently and simultaneously, Orr and associates [5] both identified mutations in the UbiA prenyltransferase domain containing 1 (UBIAD1) gene as the cause of SCD. UBIAD1 contains a putative prenyltransferase domain for which the archetype is the bacterial protein UbiA (ubiA 4-hydroxybenzoate octaprenyltransferase).

To date, eleven independent putative mutations have been reported: Asn102Ser, Asp112Gly, Arg119Gly, Thr175Ile, Asn232Ser, Gly177Arg, Leu121Phe, Asp118Gly, Ser171Pro, Gly186Arg and Asp236Glu. The occurrence of the Asn102Ser mutation in five unrelated SCD families with different ethnicities suggests that this may be a mutation hot spot [4,5].

## Molecular and Systemic Pathophysiology

UBIAD1 encodes a protein that is predicted to contain several transmembrane helices and a putative prenyltransferase domain that could play a role in cholesterol metabolism [4]. UBIAD1 interacts with the C-terminal portion of apolipoprotein E that is known to mediate cholesterol solubilization and removal from cells. Prenyl-binding proteins such as UBIAD1 might play a role in sensing and regulating metabolite levels intracellularly and/or systemically [5]. UBIAD1 also has a proposed role in cancer. The gene was detected in gene expression studies in transient bladder carcinoma cells. It is upregulated in particular cancer types.

## Diagnostic Principles

The clinical diagnosis of SCD is based on slit lamp examination in direct and indirect illumination, best seen with dilated pupil. The SCD landmark is characterized either by nest-like or disc- or ring-like opacities consisting of crowded comma-shaped multicolored crystals in the subepithelial center of the cornea often associated with an arcus lipoides. In contrast, cystinosis is characterized by multiple, solitary punctiform crystals in the whole superficial corneal layer without an arcus lipoides. The noncrystalline type of SCD in form of ring- or disc-like diffuse opacities with or without arcus lipoides is to distinguish from the fish-eye disease and LCAT deficiency. These two systemic disorders are characterized by a complete diffuse opacity in the superficial corneal layer combined with a peripheral ring, which is not compatible with a true arcus lipoides. SCD is characterized ultrastructurally by abnormal accumulation of lipid and dissolved cholesterol in the epithelium, Bowman's layer, and throughout the stroma.

## Therapeutic Principles

Significant visual impairment due to crystalline and/or diffuse subepithelial and stromal opacifications needs surgical interventions such as lamellar or penetrating keratoplasties in patients of 50 years and above [3]. SCD recurrences occur in form of crystals at the transplant border and of diffuse subepithelial changes at the center 4–5 years after keratoplasty. Phototherapeutic keratectomy (PTK) is the treatment option of first choice, today.

## Synonyms

Witschel corneal dystrophy; CSCD

## Definition and Characteristics

CSCD is an autosomal dominantly inherited disorder characterized by a rather diffuse flaky or feathery clouding, slightly more prominent in the central cornea than in the periphery. Corneal erosions are not present. Some trait carriers have severe photophobia and others have a searching nystagmus and alternating esotropia. The full stage of CSCD can be observed either congenitally or in the first decade combined with blurred vision.

## Prevalence

CSCD is a rare stromal disorder of the cornea first presented by Turpin and associates in 1939 [1]. Witschel et al. examined a branch of a French family and an additional unrelated pedigree [2]. Further reports are from Norway and Belgium.

## Genes

A locus of CSCD has been mapped to chromosome 12q22 by linkage analysis [3]. Subsequent sequencing of candidate genes revealed a frameshift mutation in the DCN gene that encodes for decorin, predicting a C-terminal truncation of the decorin protein. A distinct frameshift mutation with the same consequence on the protein level was identified in another CSCD family [4].

## Molecular and Systemic Pathophysiology

Decorin, a dermatan sulfate proteoglycan, is known to be involved in several important biological processes such as collagen fibrillogenesis, the ability to modulate growth factor activity, tyrosine kinase receptor activity, angiogenesis, and tissue remodeling [5]. Decorin binds to multiple collagen types, including types I, II, III, and VI. Homozygous decorin knockout mice present with marked skin fragility but do not show corneal anomalies. Bredrup and associates hypothesize that the truncated decorin causes corneal opacities by disturbing the regularity of corneal collagen, thus exerting its effect in a dominant negative fashion [3].

## Diagnostic Principles

The clinical diagnosis of CSCD is based on slit lamp examination in direct and indirect illumination, best seen with dilated pupil. In an individual case, it can be difficult to distinguish clinically between CSCD and congenital hereditary endothelial dystrophy I, or II (CHED I, II) and posterior polymorphous corneal dystrophy (PPCD). However, in CHED I, II and rarely in PPCD the corneas typically show a ground-glass opacification, whereas in CSCD the corneal changes consist of a flaky or feathery clouding of the stroma. Progression of the disease has been described [2]. Most trait carriers suffer from severe visual impairment. Histologically, in the corneal stroma of CSCD, lamellae of normal collagen fibrils are separated by abnormal layers that consist of thin filaments. The endothelium has a normal appearance, in contrast to the endothelial corneal dystrophies.

## Therapeutic Principles

Penetrating keratoplasties (PKP) were generally performed in the first or second decade and rarely later in CSCD [2,3]. Bredrup and associates reported 11 trait carriers who had undergone unilateral or bilateral PKP [3]. The mean follow-up time was 19.5 years. Ten transplanted corneas were without sign of opacities, whereas six showed minor signs of recurrence. In one patient the graft was described to have significant changes comparable to the remaining host cornea 3 years after surgery.

## Synonyms

SMCD

## Definition and Characteristics

We know of only one report of SMCD by Feder et al. [1] in 1993. The onset of this disorder in the first decade is characterized by frequent, recurrent epithelial erosions. These subside during adolescence and are followed by progressive decreasing vision due to bilateral subepithelial opacities and haze, involving the entire cornea, but most severe centrally. Irregularly shaped, dense, gray-white, subepithelial patches can also be observed in the central and paracentral parts of the cornea.

## Prevalence

Feder et al. [1] reported about one family of Slowakian descent including seven affected family members in two generations. Six of them had a history of corneal erosions in childhood.

## Genes

The molecular basis is not known. Feder et al. [1] postulated autosomal dominant inheritance in their presented pedigree, but an X-chromosomal inheritance is not to be excluded due to the absence of a father-to-son transmission.

## Molecular and Systemic Pathophysiology

Histopathology reveals a subepithelial band of eosinophilic, periodic, acid-Schiff-positive, alcian blue-positive, hyaluronidase-sensitive material anterior to Bowman's layer. Electron microscopy demonstrates subepithelial deposition of fine fibrillar material consistent with glycosaminoglycans. Immunohistochemical analysis indicates that the accumulated material contained a combination of chondroitin-4-sulfate and dermatan sulfate. Whether this storage results from a localized deficiency of dermatan degradation analogous to a generalized defect in type VI mucopolysaccharidosis is unknown [2].

## Diagnostic Principles

The clinical diagnosis of SMCD is based on slit lamp examination in direct and indirect illumination. This dystrophy can resemble Reis-Bücklers corneal dystrophy (RBCD) with irregularly shaped mounds, dots, and plaques that extend anteriorly from the level of Bowman's layer, and Thiel-Behnke corneal dystrophy (TBCD), all of which feature erosions in the first decade. The clinical appearance of RBCD is characterized by geographic-like and those of TBCD by honeycomb subepithelial opacities often combined with episodes of corneal erosion [3]. Electron microscopy discloses rod-shaped bodies in RBCD and electron-dense curly fibrils in TBCD [3]. These findings are quite distinct from the proteoglycan material observed in SMCD [1]. RBCD and TBCD are caused by mutations in the transforming growth factor beta-induced (TGFBI) gene on chromosome 5q31.

## Therapeutic Principles

Penetrating keratoplasty and superficial keratectomy have been performed on two patients [1]. Another option of therapy would be phototherapeutic keratectomy (PTK) due to the superficial changes of SMCD.

## Synonyms

Honeycomb corneal dystrophy; TBCD

## Definition and Characteristics

Thiel-Behnke corneal dystrophy (TBCD) is an autosomal dominantly inherited disorder characterized by subepithelial alterations, affecting all but a peripheral 1–2 mm of the cornea. It presents in infancy with infrequent recurrent erosions and is associated with diffuse-cloudy opacities, which spread and become honeycomb-like with time. The honeycomb-like subepithelial opacities appear between the ages of 10–20 years and are to be regarded as a landmark of TBCD.

## Prevalence

TBCD is a rare superficial corneal disorder described first in a family from Schleswig-Holstein, Northern Germany by Thiel and Behnke in 1967 [1]. Fifty-five family members in 11 generations were included in their study and 26 persons were found to be affected from TBCD. Weidle demonstrated that TBCD and Reis-Bücklers corneal dystrophy (RBCD) have been frequently confused in the literature [2]. A number of patients from USA, Italy, Switzerland, France, and Japan are to be classified as TBCD, according to a review by Weidle [2] and Küchle and associates [3].

## Genes

Two chromosomal loci for TBCD have been mapped to 5q31 and to 10q23–24 by linkage analyses. Okada and associates demonstrated in Japanese patients for the first time that TBCD was associated with a transforming growth factor beta-induced (TGFBI) Arg555Gln mutation at the chromosome 5q31 locus [4]. A number of patients with TBCD were subsequently reported to carry this mutation, establishing a genotype–phenotype correlation, and distinguishing it both clinically and genetically from RBCD, which is caused by an Arg124Leu mutation of TGFBI. Distinct mutations in TGFBI cause a number of corneal dystrophies. Yee and associates presented a family of 47 members with the clinical and histological features of TBCD [5]. A gene mutation has not been reported yet at the disease locus on chromosome 10q23–24 (LOD score of 4.0).

## Molecular and Systemic Pathophysiology

Mutations of Arg555 are predicted to alter solubility or stability of the protein rather than structure. In contrast to the opacities resulting from distinct TGFBI mutations, the Arg555Gln mutation causes a subepithelial layer of fibrous tissue accumulating in a wave-like configuration, but amyloid and Massons trichrome stain are not found. Whether the TBCD gene on chromosome 10q23–24 encodes a protein that interacts with TGFBI remains speculative.

## Diagnostic Principles

The clinical diagnosis of TBCD is based on slit-lamp examination in direct and indirect illumination, fluorescein staining, best seen with dilated pupil. In an early stage of the disease it can be difficult to distinguish clinically TBCD and RBCD [2]. In a later stage, the TBCD landmark is characterized by honeycomb-like appearance of the corneal opacities. Rarely TBCD patients suffer from dystrophy-induced pain attacks due to epithelial erosions during infancy. A slowly progressive deterioration in vision can be observed. TBCD is characterized ultrastructurally by the presence of electron-dense “curly filaments” [2].

## Therapeutic Principles

TBCD-induced epithelial erosions may be treated at first with topical antibiotics and artificial tears. The dystrophy recurs after simple debridement. In elderly patients lamellar or penetrating keratoplasty may be required. However, recurrences may be observed after 1 year postop. Phototherapeutic keratectomy (PTK) is the treatment option of first choice, today. It may be repeated. Thus corneal transplantation can be postponed or even avoided.

### Synonyms

XECD

### Definition and Characteristics

Schmid and associates presented the first fully documented report on an X-linked endothelial corneal dystrophy in a large family in 2006 [1]. The phenotype can be highly variable.

Tiny, irregular endothelial alterations resembling moon craters are the common, characteristic feature in males and females, and appear to have developed in all mutation carriers at least by the third decade of life. This symptom is not associated with subjective visual complaints, although mean best-corrected visual acuity can be reduced in some instances. In addition, male patients can present with congenital corneal clouding in form of ground glass, milky appearance with or without nystagmus, and severely reduced vision. Subepithelial band keratopathy develops in some male patients after the age of 40 years and results in blurred vision.

No instance of male-to-male transmission of the disease was encountered in this large family suggesting X-linked inheritance [1].

### Prevalence

One large family including 35 affected family members in four generations from Western Austria has been described [1,2].

### Genes

Significant evidence was found for linkage between the disease and two markers in the region q25 of the X chromosome, thus defining a new endothelial corneal dystrophy locus. Fifty family members were included in the study. Two markers mapping to Xq25, DXS8057, and DXS1047, yielded LOD scores of 4.58 (at $\theta = 0.091$) and 8.27 (at $\theta = 0$), respectively. By multipoint analysis, a maximum LOD score of 10.90 was obtained between markers DXS8057 and DXS1047. The XECD critical interval contained 72 genes, and a mutation has not been reported to date.

### Molecular and Systemic Pathophysiology

As candidate gene appeared XPNPEP2 from the critical interval encoding a hydrolase specific for N-terminal imido bonds that are common to several collagen degradation products as mutations in the extracellular matrix component COL8A2 were associated with endothelial dystrophies [3]. Another candidate of interest was the hypothetical protein LOC392549, which is similar to glyceraldehyde 3-phosphate dehydrogenase (GAPD) since serial analysis of gene expression in the corneal endothelium of Fuchs endothelial corneal dystrophy (FECD) found GAPD as one of 36 genes that were under-expressed compared with normal endothelium [4]; 43 of 72 genes from the candidate region are ubiquitously expressed including expression in the eye as revealed by database searches.

### Diagnostic Principles

The clinical diagnosis of XECD is based on slit lamp examination in direct and indirect illumination. Congenital corneal clouding in form of milky ground glass appearance, present in some XECD patients, is a landmark of congenital hereditary endothelial dystrophy (CHED) and rarely in posterior polymorphous corneal dystrophy (PPCD) [5]. We emphasize the importance to examine the mother of such patients for moon crater-like endothelial changes of the cornea in retro-illumination and with dilated pupil to search or rule out XECD. In a case of congenital corneal opacification, all causes of a congenital and secondary glaucoma have to be considered. In contrast to CHED

and PPCD, elevated IOP and iridocorneal adhesions do not appear to be features in XECD. The occurrence of a subepithelial band keratopathy in endothelial corneal dystrophies has been interpreted as a secondary and late feature, and has rarely been reported in CHED and PPCD, but appears to be common in males with XECD. Moon crater-like endothelial changes can be observed above and below the band of opacification in retro-illumination and with dilated pupil. Another hereditary band keratopathy without endothelial changes can be observed in gelatinous drop-like corneal dystrophy (GDLD). Irregularities of the posterior corneal layer resembling moon craters, described as having a peau d'orange texture in PPCD and CHED, were common to all individuals with XECD being the sole manifestation in females and in some males. The endothelial alterations in XECD are irregularly in contrast to the regular cornea guttata, a landmark of Fuchs endothelial corneal dystrophy (FECD). Histopathology of a diseased corneal button of XECD revealed an abnormal anterior banded zone indicating endothelial dysfunction already present before birth since the structure of Descemet's membrane can be seen as a record of development and senescence.

## Therapeutic Principles

Ten eyes of six patients with subepithelial band keratopathy underwent a penetrating keratoplasty [1]. In one patient a penetrating keratoplasty was performed in 1973 [2]. The last examination of this patient in 2003 demonstrated no recurrences on the transplant. Another option of therapy could be phototherapeutic keratectomy (PTK) to smoothen the corneal surface after removal of the band keratopathy with EDTA chelating. Congenital corneal clouding did not need surgical intervention in two patients from this large family (unpublished observation) [1].

## Synonyms

Maumenee corneal dystrophy; CHED

## Definition and Characteristics

CHED is a bilateral symmetric disorder characterized by corneal opacification that ranges from a diffuse haze to a ground-glass milky appearance. The corneal opacification extends to the limbus without clear zones. It is associated with marked corneal thickening, often 2–3 times normal. There are two types of CHED: (i). the autosomal dominant type or CHED1 and (ii). the autosomal recessive type or CHED2. In CHED1 the cornea is often clear at birth, corneal opacification is slowly progressive, and nystagmus is generally absent. Asymptomatic relatives of patients with CHED1 can manifest endothelial opacifications in the form of moon-crater-like appearance, peau d'orange texture or PPCD like changes. In CHED1 a slow progressive visual impairment is possible. In CHED2 corneal clouding is present at birth or in the neonatal period often combined with possible nystagmus. The visual acuity is markedly disturbed. But most authors hold the view that CHED1 and CHED2 are not distinguishable by their clinical manifestations. The rare occurrence of a subepithelial band keratopathy in CHED has been interpreted as a secondary and late feature (see also ▶Corneal Dystrophy, X-linked Endothelial). CHED may coexist with congenital glaucoma.

## Prevalence

Cases consistent with CHED were described sporadically in the European literature under many different names. 1960 Maumenee suggested that this disease arose from an abnormality in the endothelial cells [1]. These findings were confirmed by Pearce and associates who gave the disease its current name [2]. There exist only few descriptions of CHED1. CHED2 is rare in most countries, but it is the second most frequent corneal dystrophy in Saudi Arabia and South India, likely the result of consanguineous marriages.

## Genes

A locus for CHED1 was mapped to chromosome 20p11.2-q11.2 by linkage analysis [3]. The candidate region of 2.7-cM was flanked by microsatellite markers D20S48 and D20S471. This candidate region of CHED1 nearly completely overlaps with a locus of another endothelial corneal dystrophy, posterior polymorphous corneal dystrophy (PPCD). Mutations at these loci have not been reported for either condition, and it remains unknown whether these two clinically distinct conditions may be caused by allelic mutations. In CHED2 the positional candidate approach led to the identification of bi-allelic mutations in the Sodium-borate cotransporter SLC4A11 gene [4] suggesting genetic homogeneity in CHED2. Many mutations in SLC4A11 have been identified: Tyr47Ser; Arg82Arg; Arg112X; Arg158Tro; Arg158Glu; Val208Ala; Arg209Trp; Ser213Tro; Ser213Leu; Ser232Asn; Arg233Cys; Glu287Tro; Glu293_Glu296del; Gly103Val; Lys118Thr; Arg329X; Thr401Lys; Gly418Asp; Leu440Val; Tyr460_Ala461deliusThr; Gly464Asp; Leu473Arg; Arg488Lys; Ser489Lys; Ser569Arg; Thr584Lys; Arg605X; Glu632X; Thr747Thr; Arg755Trp; Arg755-Glu; Tro773Leu; Asp797del; Glu803X; Arg804His; Leu807Arg; Leu808Arg; Val824Met; Thr833Met; Leu843Tro; Met856Val; Arg869His; Arg869Cys; Arg875X.

## Molecular and Systemic Pathophysiology

SLC4A11 encodes a sodium-borate cotransporter of the cell membrane. In-vitro analysis of missence mutations showed failure to reach the mature size and reduced levels of accumulated protein suggesting that mutants were not processed through the endoplasmic reticulum [4]. CHED2 is thus caused by loss of SLC4A11 function. As a borate transporter, SLC4A11 may have a key role in the growth and terminal differentiation of neural crest cells during the formation of the endothelium. Its functional loss causes endothelial cell death leading to secondary corneal edema. Borate leads to phosphorylation of both MAP-Kinase and extracellular signal-related kinases, molecules involved in regulation of cell cycle and growth. It was speculated that some of the morphological features observed in CHED2 are achieved through a deregulated cascade [4].

## Diagnostic Principles

The clinical diagnosis of CHED is based on slit lamp examination in direct and indirect illumination. The landmark of CHED represents a diffuse corneal clouding in form of ground-glass milky appearance. Other causes of congenital corneal clouding must be ruled out first: congenital glaucoma, congenital infections, early-onset posterior polymorphous corneal dystrophy (PPCD), X-linked endothelial corneal dystrophy (XECD) in males, and metabolic diseases. It is very important to examine the parents and other family members of patients with congenital corneal cloudings at the slit lamp to disclose moon-crater like endothelial alteration. Ultrastructurally, the lesions of CHED consist of abnormal endothelial morphology, with irregular and multinucleated cells containing abnormal cells organelles. Descemet's membrane is thickened with normal anterior fetal banded zone and a thickened posterior banded zone. The distribution of collagen types I, III, and V within the posterior collagenous layer of Descemet's membrane supports morphologic observations of fibroblast-like changes in the endothelium in CHED [5].

## Therapeutic Principles

In CHED1 and 2 with complete corneal clouding penetrating keratoplasty (PKP) or posterior lamellar keratoplasty (PLKP) are the options of treatment.

# Cornelia de Lange Syndrome

Jolanta Wierzba, Angelo Selicorni
Department of Pediatrics, Hematology, Oncology and Endocrinology, Medical University of Gdansk, Gdansk, Poland

## Synonyms

Brachmann-de Lange syndrome; CdLS

## Definition and Characteristics

Cornelia de Lange syndrome (CdLS; OMIM 122470) is a rare, multisystem malformation and developmental disorder characterized by prenatal and postnatal growth delay, mental retardation, distinct facial dysmorphisms, hirsutism, upper limb anomalies, small hands and feet. Gastrointestinal, ocular, genitourinary, heart malformations and hearing impairment coincide commonly [1].

## Prevalence

Estimated incidence of CdLS is between 1:10,000 and 20,000 live births. The M/F ratio is close to one.

## Genes

So far, heterozygous mutations of genes: NIPBL, SMC1A, SMC3 have been identified to cause CdLS phenotype [2–4]. The NIPBL gene, human homolog of the drosophila nipped-B gene and Saccharomyces cerevisiae sister chromatid cohesion gene, Scc2 located on band 5p13.1, consists of 47 exons. The point NIPBL mutations, small insertion and deletions in coding regions, regulatory regions and at splice junction have been identified in about 50% CdLS patients. A large (5.2 kb) NIPBL rearrangement detected using MLPA analysis was described also. Mutations in the genes SMC1A and SMC3, homologs to Scc1 and Scc3 in yeast, located on band Xp11 and 10q25, respectively, which encode different subunits of the cohesin complex are responsible for a few cases of CdLS (about 5%). All described mutations are predicted to retain an open reading frame, and no truncating mutations were identified. Previous data implies that locus heterogenity is involved in CdLS. Chromosomal rearrangements, including regions of different chromosomes except 6, 15, 16, 19, 20 and 22 have been identified in a large number of patients with a CdLS phenotype.

## Molecular and Systemic Pathophysiology

CdLS syndrome is undoubtedly a result of early developmental disorder. The detailed mechanisms and the sequela of the developmental events are still undisclosed and in general far from being understood. The specific, but variable clinical features suggest disarray of developmental sequence of protein expression.

Sister-chromatid cohesion in humans depends on the cohesin complex encoded by genes homologous to Scc1, Scc2 and Scc3 in yeast. In the last years alterations of some cohesion regulators (ESCO2, NIPBL, SMC1 and SMC3) have been implied in Roberts syndrome, SC focomelia and CdLS syndrome, respectively. Based on those observation a link between mutation of some genes coding the cohesin complex and CdLS phenotype has been revealed. The NIPBL gene product, a protein named delangin, consisting of 2,804 aminoacids, is the human homologue of the fungal Scc2, and drosophila nipped-B protein which belong to the family of chromosomal adherins. Although its function in mammalian systems has not yet been elucidated, NIPBL may play a similar role in humans as it has been reported for its homologs in yeast and Drosophila being engaged in sister chromatid cohesion. The precocious sister chromatid separation was identified in CdLS only in one large report [5]. The drosophila nipped-B gene is involved in enhancer–promoter communication and regulates Notch-signaling and other development pathways. The NIPBL may play a similar role. Its wide expression in the embryonic limb bud, branchial arch and craniofacial mesenchymes is consistent with anomalies observed in CdLS. Mutations of the SMC1A and SMC3 genes, which encode different subunits of the cohesion complex, have been identified in some patients with a CdLS phenotype. Both genes, although necessary in the cohesion process, are thought to be involved in genome stability, DNA repair and recombination, as well as a gene expression.

The most recent analysis of the NIPBL gene has revealed a caldesmon domain, a calponin domain, and two calmodulin binding motifs. It is possible that NIPBL, like caldesmon/calponin, is modulated by calmodulin. Decreased levels of caldesmon and calponin are associated with smooth muscle contractility. Hence, a decrease in NIPBL may be associated with increased smooth muscle contractility, what could explain gastrointestinal hyperactivity, which occurs commonly in almost all CdLS mutation-positive patients.

## Diagnostic Principles

Diagnosis mainly depends on the recognition of the variable association between prenatal and postnatal growth deficiency, hirsutism, microcephaly and distinctive facial features. These dysmorphisms are easily recognizable at birth in a large portion of patients and change little throughout life. Facial features include: low frontal hairline, well-defined and arched eyebrows, long lashes, synophrys, depressed nasal bridge with anteverted nostrils, long flat philtrum, thin lips, down turned corners of mouth, high arched palate, micrognathia. Upper limbs

involvement varies from small hands and/or feet with proximally placed thumbs and fifth fingers clinodactyly to severe limb reduction defects with peculiar ulnar side rays involvement. Abnormal elbow movements are frequently observed due to hypoplasia of proximal radial bone. Congenital heart defects, genitourinary, ocular abnormalities, and cleft palate can be occasionally observed. The CdLS phenotype is characterized by great variability. Since 1993 a distinction between mild and classical phenotypes has been proposed, but it is sometimes difficult to discriminate sharply the patients into two rigid classes [1]. The psychomotor retardation varies from mild to profound and is combined with a lack of speech or speech impairment. The hyperactivity, aggression, self injuries and the autistic–like behavior is observed in the majority of mostly the classic phenotype. Common medical problems are gastro-esophageal reflux evident in up to 70% patients, hearing loss, teeth problems and seizures. Gene mutations have already been identified in more than 50% cases with the CdLS phenotype. Some reports suggested a genotype–phenotype correlation for NIPBL mutations. In particular truncating mutations seem to be associated with more severe neurologic and auxologic phenotypes; missense mutations show milder phenotypes. The phenotype of patients with SMC1A and SMC3 mutations seems less pronounced, but the number of described patients is too small to allow general conclusions. Several phenotypes with apparently nonsyndromic mental retardation have been reported.

## Therapeutic Principles

In the absence of a causal therapy the CdLS individuals are currently managed using a multidisciplinary approach of symptomatic care. Patients with symptoms of GER require intensive medical therapy, sometimes with operative procedures, including the Nissen fundoplication and the gastrostomy tube (G-tube). Surgical repair may also be recommended in patients with cardiac defects or severe limb anomalies. Application of appropriate hearing aids is recommended in children with hearing loss. In the majority of the CdLS individuals, who exhibit profound psychomotor delay, a thorough assistance is necessary. Problems with the verbal communication need professional aid with employment of specific verbal and non verbal strategies. Educational approaches and eventually drug therapy is required to face behavioural problems.

# Coronary Artery Anomalies, Congenital

Yskert Von Kodolitsch, Wulf Ito
Heartcenter, Cardiology, University Hospital Hamburg-Eppendorf, Hamburg, Germany

## Synonyms

ACAOS, APOC, ALCAPA, Bland-White-Garland syndrome

## Definition and Characteristics

An anatomical variant of the coronary arteries that occurs with a frequency of less than 1% in the general population is considered anomalous (see [1]).

## Prevalence

According to the literature, coronary anomalies affect ≥1% of the general population; this percentage is derived from cineangiograms performed for suspected obstructive disease [2]. With the use of above mentioned criteria, however, a recent angiographic study yielded an overall incidence of 5.64% (Table 1).

## Genes

In affected individuals, a distinct trait of inheritance or underlying gene defects remain to be determined.

## Molecular and Systemic Pathophysiology

Coronary anomalies may be associated with ventricular arrhythmia, heart failure, and sudden death, which most frequently occur during vigorous exercise. Myocardial ischemia is likely the major mechanism of disease but complications are still difficult to predict in a given patient. However, most anomalies are likely not to cause ischemia and thus, remain asymptomatic (Table 2). Embryonal development of the coronary arteries takes place by vasculogenesis, that is the in situ self-organization of a vascular plexus from mesenchymal precursor cells that invade the myocardium (Fig. 1).

**Coronary Artery Anomalies, Congenital. Table 1** Incidence of coronary anomalies, as observed in a consecutive series of 1,950 angiograms [3]

| Coronary anomaly | Number | Percent |
|---|---|---|
| Coronary anomalies (total) | 110 | 5.64 |
| Split RCA | 24 | 1.23 |
| Ectopic RCA (right cusp) | 22 | 1.13 |
| Ectopic RCA (left cusp) | 18 | 0.92 |
| Fistulas | 17 | 0.87 |
| Absent left main coronary artery | 13 | 0.67 |
| CFX arising from right cusp | 13 | 0.67 |
| LCA arising from right cusp | 3 | 0.15 |
| Low origination of RCA | 2 | 0.1 |
| Other anomalies | 3 | 0.15 |

CFX, circumflex coronary artery; LCA, left coronary artery; RCA, right coronary artery

**Coronary Artery Anomalies, Congenital. Table 2** Ischemia occurring in coronary anomalies [1,4]

| Type of ischemia | Coronary anomaly |
|---|---|
| No ischemia | Majority of anomalies (e.g., split RCA, ectopic RCA from right cusp, ectopic LCA from left cusp) |
| Episodic ischemia | ACAOS, coronary fistulas, myocardial bridges |
| Obligatory ischemia (resting ischemia) | APOC (e.g., ALCAPA, also known as Bland-White-Garland syndrome), coronary ostial atresia or severe stenosis |

Currently, the role of different growth factors such as angiopoietins (Ang-1, Ang-2), fibroblast growth factor-2 (FGF-2), platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), tyrosinkinase receptors TIE1 and TIE2, and genes such as the zinc finger protein friend of GATA-2 (FOG-2), the epicardium and vascular cell adhesion molecule 1 (VCAM-1), and the cell adhesion molecule blood vessel epicardial substance (Bves) get elucidated for their basic role in coronary vasculogenesis, angiogenesis, and embryonic arteriogenesis [3]. Experiments with disruption of some of these factors have been shown to cause specific phenotypes of coronary anomaly [3,4]. Moreover, cardiac neural crest cells contribute to the tunica media of the aorta, the aorticopulmonary septum, parasympathetic ganglia of the cardiac plexus and are necessary for development of the coronary orifices. In chicken embryos, surgical ablation of cardiac neural crest cells was shown to result in coronary artery anomalies [5].

## Diagnostic Principles

Particularly male athletes with dyspnoea or chest pain, syncope, and a history of aborted sudden death should undergo heart catheterization even if echocardiography and a treadmill tests yield negative results. Conventional nuclear stress tests usually fail to demonstrate ischemia even with presence of severe symptoms and thus, alternative techniques should be used including intravascular ultrasound, intracoronary Doppler ultrasound, intracoronary pressure devices, and new stress-testing protocols [1,4].

## Therapeutic Principles

Therapeutic intervention usually requires demonstration of a functional relevance of the coronary anomaly. Therapy aims at restoring proper blood flow and prevention of ischemia. Thus, APOC including ALCAPA usually require surgical intervention either by reimplanting the anomalous artery into the aorta or by ligation and bypass of the anomalous artery, whereas ACAOS may be treated by placing a stent into the segment of the coronary artery, which suffers systolic compression by running within the aortic wall.

# Coronary Artery Disease

Nilanjana Maulik
Molecular Cardiology and Angiogenesis Laboratory, Department of Surgery, University of Connecticut Health Center, Farmington, CT, USA

## Synonyms

Coronary atherosclerosis; Ischemic heart disease; Myocardial ischemia; Myocardial infarction; Angina pectoris; Angina; Heart attack

## Definition and Characteristics

Coronary artery disease causes narrowing of the coronary arteries [1] that leads to reversible or irreversible myocardial injury when the blood flow to the myocardium is decreased or stopped by stenosis or blockade.

## Prevalence

In the Western world ischemic coronary disease is the leading cause of morbidity and mortality which remains a major public health problem with 15 million affected patients world wide, a 5-year mortality of 50%, and a healthcare expenditure of 1–2% of the total health care budget in developed countries.

## Genes

Several risk factors for coronary artery disease have been identified predominantly via epidemiologic and association studies [2]. These risk factors, including hypertension, diabetes mellitus, and hypercholesterolemia, are each influenced by several genetic traits. Thus, coronary artery disease is likely polygenic in nature.

### Molecular and Systemic Pathophysiology

Coronary artery disease predominantly involves the epicardial coronary arteries, the left main, left anterior descending, left circumflex, and right coronary arteries. A significant stenosis (obliteration of >70% of arterial lumen) causes myocardial ischemia, or lack of blood supply proportionate to the metabolic demand, in the region of distribution of the epicardial coronary artery [3]. At a cellular/molecular level, coronary artery disease starts as a "fatty streak" in the arterial wall and progresses to develop the atheromatous plaque, which consists of lipid, fibrous tissue, macrophages, and smooth muscle cells with variable contribution from each [1].

### Diagnostic Principles

Cardiac catheterization, which involves injection of radioopaque dye into coronary arteries via catheters, remains the gold standard for the diagnosis of coronary artery disease [3]. However, several forms (exercise or pharmacological) of "stress testing" are frequently used to diagnose the presence of significant coronary artery disease. Specific changes in electrocardiogram, heart wall motion (by echocardiography or cardiac ultrasound), and myocardial blood supply (by nuclear imaging with radioactive compounds) during stress identify the presence of significant coronary artery disease [4].

### Therapeutic Principles

Depending on the severity of disease and other therapeutic considerations, patients with coronary artery disease are treated with medications with or without interventions directed at reopening the luminal narrowing by balloon angioplasty. By reducing the force of heart contraction and heart rate, these medicines primarily reduce myocardial oxygen demand, thereby minimizing the adverse effects of the lack of blood supply. Although angioplasty can restore blood supply, it may be associated with reappearance of the blockage, and should be performed in carefully selected patients. A significant proportion of patients may not be candidates for revascularization with either percutaneous coronary intervention (PCI) or coronary artery bypass surgery (CABG) [5].

## Coronary Atherosclerosis

►Coronary Artery Disease

## Coronary Restenosis

Rainer Voisard
Department of Internal Medicine II – Cardiology, University of Ulm, Ulm, Germany

### Definition and Characteristics

The literal meaning of restenosis is the reoccurrence of stenosis. Coronary restenosis occurs in coronary arteries that had been treated with various percutaneous coronary interventions (PCIs), aiming at a free arterial blood flow (TIMI III-flow).

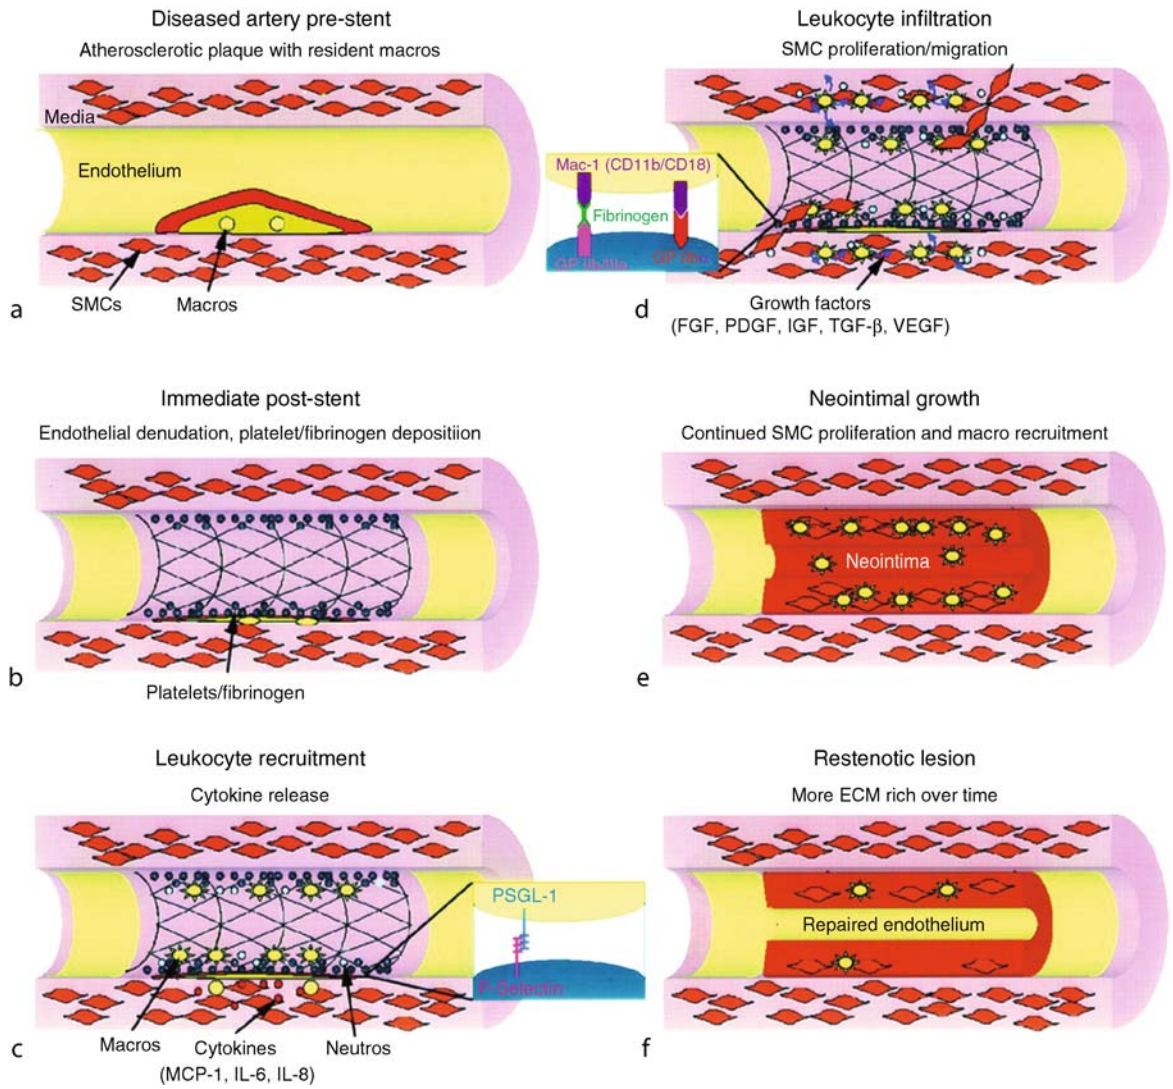
### Prevalence

In 1997, over one million PCIs have been performed worldwide, in 2001, the number rose to over two million. During the first three decades, after the first PCI in an awake human in 1977 (Dr. Andreas Gruentzig, Zürich, Switzerland), restenosis occurred in 20–40% of the patients within 3–6 months after the intervention, almost independently of the technique applied. The combination of balloon/stents, balloon/irradiation, and balloon/drug eluting stents (DES) has modified the characteristics of restenosis. After balloon/DES, the percentage of patients suffering from restenosis was reduced below 10% [1].

## Molecular and Systemic Pathophysiology

The pathophysiology of restenosis is very complex, an integrated view of the molecular and cellular events has been proposed by Welt and Rogers ([2]; Fig. 1).

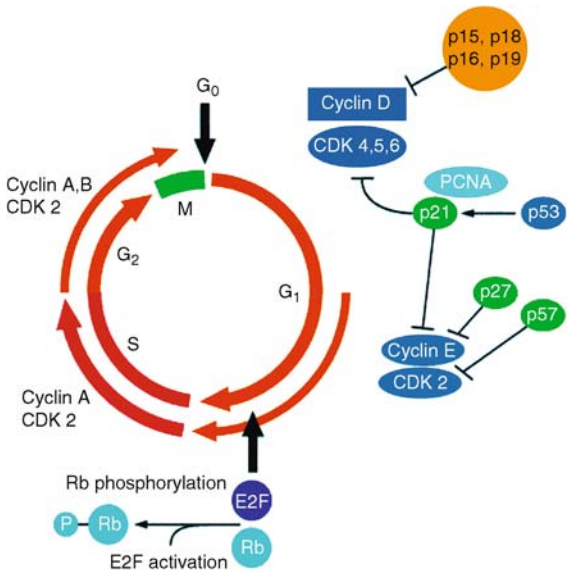
Immediately after ballooning or stenting deendothelialization, crush of the plaque and stretch of the entire artery occur. Activated platelets on the surface attach to circulating leukocytes (LC). LC then bind to the surface via direct attachment to platelet receptors such as glycoprotein (GP)Ib-α and through cross-linking with fibrinogen to the GPIIb/IIIa receptor. Migration of LC across the platelet–fibrin layer and diapedesis into the tissue is caused by chemical gradients of chemokines released from smooth muscle cells (SMC) and resident macrophages. Firm attachment of LC is mediated by members of the β2 integrin family, LFA-1 (αLβ2, CD11c/CD18), which bind to endothelial counterligands (e.g., intercellular adhesion molecule-1 (ICAM-1)), to endothelial-associated ECM proteins (e.g., fibrinogen), or to glycosaminoglycans. The initial tethering and rolling of LC on platelet P-selectin are followed by their firm adhesion and transplatelet migration, processes that are dependent on leukocyte-Mac-1 and platelet GPIb-α [3].



**Coronary Restenosis. Figure 1** The cascade of restenosis. (a) Atherosclerotic lesion before intervention. (b) Endothelial denudation and platelet–fibrinogen deposition immediately after stent placement. (c, d) Reactive leukocyte recruitment, infiltration, and SMC migration and proliferation in the days after injury. (e) Neointimal thickening in the weeks after injury, with continued SMC proliferation and monocyte recruitment. (f) Long-term (weeks to months) change from a predominantly cellular to a more ECM-rich plaque (Reprinted with permission from Welt FG, Rogers C (2002) Arterioscler Thromb Vasc Biol).

During the proliferation, phase growth factors are released from platelets, LC and SMCs, which stimulate migration of SMCs from the media into the neointimal space. The resultant neointima consists of SMCs, extracellular matrix (ECM), and macrophages. Mechanical injury or growth factors trigger the SMC progress through the G1/S transition of the cell cycle, as summarized by Boehm and Nabel ([4]; Fig. 2).

The different phases of the cell cycle of eukaryotic cells are regulated by a series of protein complexes composed of cyclins (D, E, A, B), cyclin-dependent kinases (CDKs; CDK4, CDK2, $p34^{cdc2}$) and their cyclin-dependent inhibitors (CKIs; $p27^{Kip1}$, p70, $p16^{INK4}$). The function of CKIs is regulated by changesin their concentration as well as in their localization in the cell. The concentration of $p27^{Kip1}$ is controlled predominantly by ubiquitin–proteasome pathway. The CKIs have distinct temporal and spatial patterns of expression in normal, injured, and diseased arteries. $P27^{Kip1}$ is downregulated after arterial injury when cell proliferation increases. $P21^{Cip1}$ is not observed in normal arteries but is upregulated along with $p27^{Kip1}$ in later phases of arterial healing response and is associated with a significant decline in cell proliferation and an increase in procollagen and transforming growth factor-β synthesis. These findings suggest that $p27^{Kip1}$ and $p21^{Cip1}$ are endogenous regulators of G1 transit in vascular SMCs and inhibit cell proliferation after arterial injury. $P27^{Kip1}$ and $p21^{Cip1}$ bind and alter the activities of cyclin D-, cyclin E-, and cyclin A-dependent kinases (CDK2) in quiescent cells, leading to the failure of G1/S transition and cell cycle arrest. Overexpression of $p27^{Kip1}$ or $p21^{Cip1}$ into balloon-injured arteries produces a significant reduction in SMC proliferation and neointimal thickening [3]. Apart from the proliferative response, apoptosis was detected in hypercellular restenotic tissue. Four major groups of molecules are involved: (i) caspases, (ii) the adaptor proteins that control the activation of initiator caspases, (iii) members of the TNF group and their associated receptors (TNF-R), and (iv) members of the Bcl-2 family of proteins [1].



**Coronary Restenosis. Figure 2** Regulation of the cell cycle. Progression through the G1 phase of the cell cycle occurs by the assembly and phosphorylation of cyclin and CDKs. The CKIs act as brakes to halt the cyclin and arrest cycles. PCNA indicates proliferating cell nuclear antigen; Rb, retinoblastoma; P, phosphorylated (Reprinted with permission from [4]).

Over a longer period of time, the artery enters a phase of remodeling involving ECM protein degradation and resynthesis. Accompanying this phase is a shift to fewer cellular elements and greater production of ECM. The level of $p27^{Kip1}$ is also regulated by constituents of the ECM. Mature collagen (polymerized type 1 collagen) suppresses $p70^{S6K}$ and has been shown to increase the levels of $p27^{Kip1}$, whereas monomeric collagen, which is present during degradation of ECM in the synthesis phase of restenosis, downregulates $p27^{Kip1}$. In both balloon-treated and stented arteries, reendothelialization of at least a part of the injured vessel surface may occur [3].

## Diagnostic Principles

Noninvasive techniques are carried out in rest and after physical activity and describe the ischemic consequences of the renarrowing process in the heart muscle, as ST-depression in the electrocardiogram (ECG), postponed appearance of radioactive tracer substances in the heart muscle (SPECT, PET), and reduced contractility of the ventricular wall (ultrasound; radionuclide angiography (RNA); cardiovascular magnetic resonance (CMR); computer tomography (CT)). Both invasive and noninvasive techniques describe directly the lumen of the coronary artery. Coronary angiography is still the gold standard for the diagnosis of restenosis. Quantitative intravascular ultrasound (IVUS) and angioscopic controls may be used for several purposes during PCI. Noninvasive techniques as CMR and coronary CT are currently under investigation [5].

## Therapeutic Principles

The use of DES has substantially decreased the incidence of restenosis. Restenosis may require repeated percutaneous coronary intervention.

# Coronary Spasm

Hiroki Teragawa, Kazuaki Chayama
Department of Medicine and Molecular Science, Graduate School of Biomedical Sciences, Hiroshima University, Hiroshima, Japan

## Synonyms

Coronary spastic angina; Variant angina; Vasospastic angina; Prinzmetal angina

## Definition and Characteristics

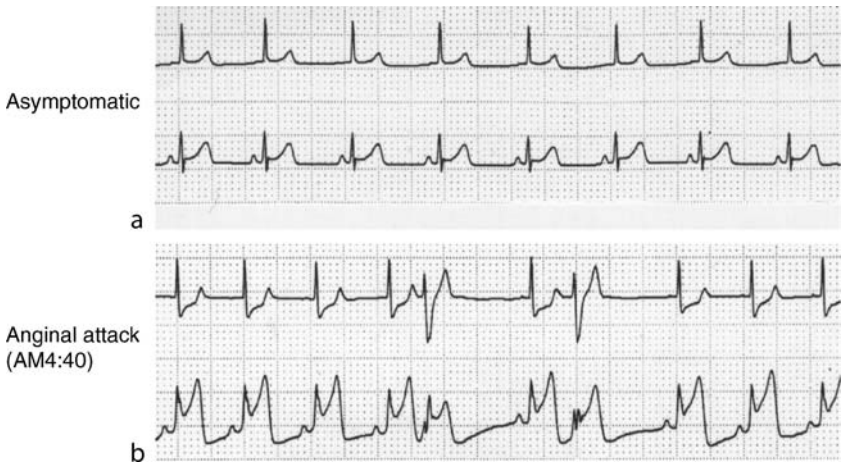
Coronary spasm is defined as a dynamic and transient reduction in the luminal diameter of epicardial coronary arteries due to increased vasomotor tone, leading to myocardial ischemia. It was first reported as variant angina by Prinzmetal et al. [1], who demonstrated reversible myocardial ischemia accompanied by ST segment elevation on the electrocardiogram (ECG). At present, it is believed that coronary spasm plays an important role in the pathogenesis of not only variant angina but ischemic heart disease as well, including other forms of angina, acute myocardial infarction, and ischemic sudden death. In general, patients with coronary spasm are younger than those with organic coronary stenosis and cigarette smoking is considered to be a major risk factor for coronary spasm. Typically, there is a circadian variation with an increased prevalence of anginal attacks from midnight to the early morning. During coronary spasm, ST segment elevation on the ECG is frequently observed (Fig. 1) although ST segment depression is sometimes seen when the coronary artery is not completely occluded due to coronary spasm. Therefore, clinical syndromes caused by coronary spasm, including variant angina, are collectively known as coronary spastic angina (CSA). In addition, life-threatening arrhythmias such as atrioventricular block, ventricular tachycardia, and ventricular fibrillation, are also frequently observed during coronary spasm.

## Prevalence

No overall value for the prevalence of coronary spasm can be given. However, there seems to be a racial heterogeneity in coronary spasm [2] with coronary spasm observed more frequently in Eastern populations.

## Genes

Because endothelial dysfunction is one of the causes of coronary spasm, endothelial nitric oxide synthase



**Coronary Spasm. Figure 1** Ambulatory monitoring in a patient with coronary spasm. (a) In the asymptomatic state, there were no significant ST changes on the ECG. (b) When the patient had chest pain at 4:40 in the early morning, the ECG demonstrated marked ST elevation in the precordial leads, accompanied by premature ventricular contractions.

(eNOS) gene variants (T-786→C mutation and a missense Glu298 Asp variant) have been associated with coronary spasm.

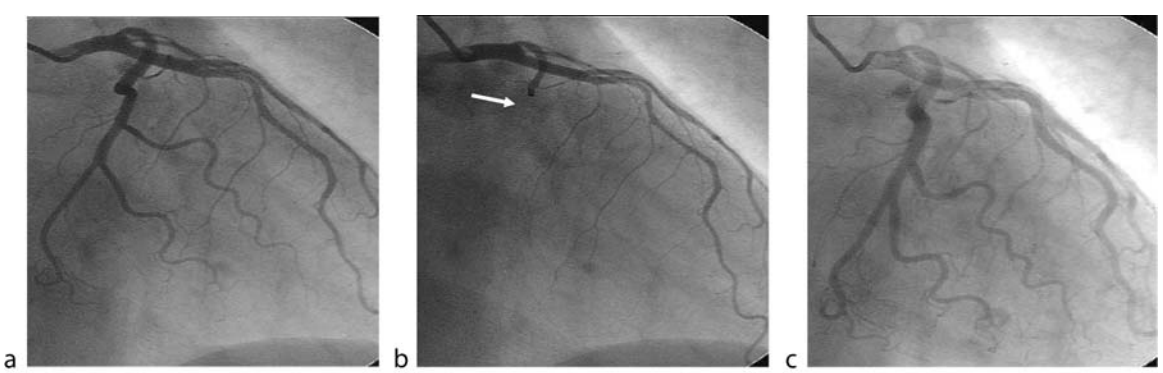
## Molecular and Systemic Pathophysiology

The precise mechanisms underlying coronary spasm remain to be elucidated, but several factors have been implicated in the pathogenesis of coronary spasm. First, the provocation of coronary spasm by acetylcholine (ACh) and its prevention by atropine and alpha-adrenergic receptor blockers may suggest an important role for the parasympathetic nervous system and for the activation of alpha-adrenergic receptors. Second, endothelial dysfunction, due to eNOS gene mutation, an increased concentration of reactive oxygen species induced by cigarette smoking, vitamin C deficiency, insulin resistance, and vascular inflammation, may be responsible for the pathogenesis of coronary spasm. Third, hyperreactivity of coronary smooth muscle cells due to an increase in the calcium-sensitivity of the vascular myosin chain has been proposed as one of the mechanisms of coronary spasm.

## Diagnostic Principles

There have been no established criteria for diagnosing coronary spasm. In fact, treatment with vasodilators may sometimes be initiated when ST segment elevation is documented during an ambulatory monitoring in patients who have chest symptoms at rest, especially from midnight to the early morning. In addition, treatment with vasodilators may be continued when such drugs, prescribed as a test drug, are effective in relieving anginal attacks in such patients. Hyperventilation testing may cause coronary spasm, especially in the early morning although this test is thought to be less sensitive but highly specific in diagnosing coronary spasm. Coronary angiography is useful in patients with suspected coronary spasm, not only to establish a final diagnosis of coronary spasm using spasm-provocative medications but also to exclude the presence of organic coronary stenosis (Fig. 2).

With respect to spasm-provocative medications, there are mainly two agents: ergonovine maleate (EM) and ACh. Intravenous administration of EM was used previously but has not been widely adopted because there is a risk of causing multivessel coronary spasm including right and left coronary arteries, simultaneously. Therefore, instead of intravenous administration, intracoronary infusion of EM has often been used. ACh also is infused intracoronarily as a spasm-provocative drug. The spasm-provocation tests using intracoronary infusion of these drugs are effective in producing coronary spasm with fewer major complications [3]. However, the duration of coronary spasm seems to be shorter using ACh than using EM and thus ACh may be safer in performing spasm-provocation tests on both the left and right coronary arteries. On the other hand, ACh itself causes sinus bradycardia and atrioventricular block and thus a temporary pacemaker is needed to prevent such arrhythmias induced during ACh infusion. A positive provocative test is defined as the presence of subtotal or total occlusion of a coronary artery due to coronary spasm on the angiogram accompanied by chest pain and/or ST segment changes on the ECG. Nitroglycerin is infused intracoronarily to relieve coronary spasm when the diagnosis of coronary spasm is made.



**Coronary Spasm. Figure 2** Coronary angiography and spasm-provocative testing in a patient with coronary spasm. (a) There was no organic coronary stenosis on the angiogram. (b) After intracoronary infusion of ergonovine maleate (EM, 30 μg), coronary angiography demonstrated a total occlusion in the proximal segment of the left circumflex coronary artery. (c) After intracoronary administration of nitroglycerin, coronary spasm completely resolved and the coronary artery dilated.

### Therapeutic Principles

Prohibiting cigarette smoking is important and may reduce the activity of coronary spasm. Long-acting calcium channel blockers are the first line therapy, and additional long-acting nitrates and/or nicorandil also are effective. However, these medications do not always prevent coronary spasm and patients should be advised to use sublingual nitrates without hesitation when they experience symptoms. Furthermore, it has been shown that the potential for causing coronary spasm does not disappear and patients should be advised not to stop taking vasodilators by themselves even if they have symptoms for a long time. It is known that abrupt cessation of vasodilators therapy sometimes causes severe rebound anginal attacks. Monotherapy with beta blockers should be avoided because it can worsen coronary spasm due to a relative increase in alpha-adrenergic activity. When coronary spasm is refractory to conventional therapy, medications such as vitamin C, anti-depressive drugs, and denopamine are occasionally effective. Treatment with coronary stenting has been shown to be effective in such patients while the long-term prognosis, including restenosis, remains unclear.

[2]Neurogenetics Laboratory, IRCCS Stella Maris Foundation, Calambrone, Pisa, Italy

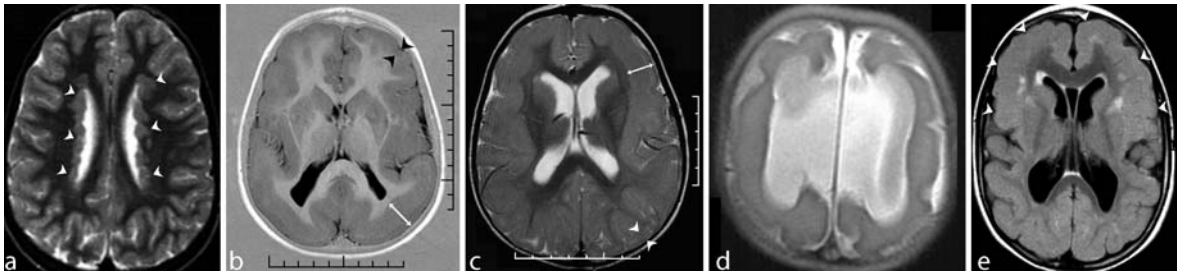
### Definition and Characteristics

Malformations of the cerebral cortex represent a major cause of developmental disabilities, severe epilepsy and reproductive disadvantage [1]. Several malformation syndromes caused by abnormal cortical development have been recognized and specific causative gene defects have been identified. Disorders affecting neuronal migration are characterized by abnormal neuronal positioning during development of the cerebral cortex. Epilepsy is often present and tends to be severe, although its incidence and type vary in different malformations. The physiopathological mechanisms relating cortical malformations to epilepsy remain elusive.

Periventricular nodular heterotopia (PNH) is a malformation of neuronal migration in which a subset of neurons fails to migrate into the developing cerebral cortex (Fig. 1a).

There is a wide spectrum of clinical presentations with some correlation between the size of PNH and the likelihood of concomitant cortical impairment and clinical severity [2]. X-linked PNH is mainly seen in females presenting with normal to borderline intelligence and epilepsy ranging in severity from mild to intractable. FLNA mutations have been reported in all familial cases and in about 25% of sporadic patients. A few living male patients with bilateral PNH due to FLNA mutations are on record [3]. Mild missense mutations or mosaic mutations account for survival of affected males who may in turn transmit their genetic defect to their daughters. A rare recessive form of PNH due to ARGEF2 gene mutations has also been reported in children with microcephaly, severe delay and early seizures.

Classical lissencephaly (LIS) and subcortical band heterotopia (SBH) are related cortical malformations secondary to abnormal migration of neurons during early brain development. Lissencephaly is characterized by absent (agyria) or decreased (pachygyria) cortical convolutions, producing a smooth cerebral surface [1] (Fig. 1b). Subcortical band heterotopia (SBH) is a related disorder in which there are



**Cortical Malformations and Migration Disorders. Figure 1** MRI of patients with cortical malformations. (a) Typical classic bilateral PNH in a woman with a missense mutation of the FLNA gene. Bilateral nodules of subependymal heterotopia are contiguous and rather symmetric, extensively lining the ventricular walls (white arrows). (b) Classical lissencephaly in a boy with LIS1 gene mutation: typical posterior > anterior malformative pattern with relative preservation of the gyral pattern and cortical thickness in the anterior brain. Cortical thickness is around 6 mm in the frontal lobes (black arrows; normal cortical thickness = 4 mm) and around 3 cm in the posterior brain (white arrow). (c) Lissencephaly in a girl with DCX mutation: typical anterior > posterior malformative gradient. Cortical thickness is around 2 cm in the frontal lobes (single white arrow) and around 4 mm in the posterior brain (double white arrows). (d) X-linked lissencephaly with corpus callosum agenesis and ambiguous genitalia due to mutation of the ARX gene. Note absence of the corpus callosum with ventriculomegaly and lissencephaly. (e) Bilateral frontoparietal polymicrogyria (black arrows) in a girl with the GPR56 gene mutation and Lennox-Gastaut Syndrome.

bilateral bands of grey matter interposed in the white matter between the cortex and the lateral ventricles [1] (Fig. 1c). The overlying cortex is usually normal with the exception of shallow sulci. Lissencephaly-pachygyria and SBH result from mutations of either LIS1 or DCX genes [4]. LIS1 mutations cause a more severe malformation in the posterior brain regions. Most children have severe developmental delay and infantile spasms, but milder phenotypes are on record, including posterior SBH owing to mosaic mutations of LIS1. The LIS1 gene is also responsible for all cases of Miller-Dieker lissencephaly, which is caused by large deletions of LIS1 and contiguous genes. DCX mutations usually cause anteriorly predominant lissencephaly in males and SBH in females. Mutations of DCX have also been found in males with anterior SBH and in their female relatives with normal brain appearance on magnetic resonance imaging.

Autosomal recessive lissencephaly with cerebellar hypoplasia, accompanied by severe delay, hypotonia, and seizures, has been associated with mutations of the reelin (RELN) gene. X-linked lissencephaly with corpus callosum agenesis and ambiguous genitalia in males is associated with mutations of the ARX gene (Fig. 1d). Affected boys have severe delay and seizures with suppression-burst EEG.

Polymicrogyria is characterized by an excessive number of small and prominent convolutions spaced out by shallow and enlarged sulci, giving the cortical surface a lumpy aspect [1]. Among several syndromes featuring polymicrogyria, bilateral perisylvian polymicrogyria shows genetic heterogeneity, including linkage to chromosome Xq28 in some pedigrees, autosomal dominant or recessive inheritance in others and an association with chromosome 22q11.2 deletion in some patients. The latter is frequently asymmetric, with a striking predisposition for the right hemisphere. About 65% of patients have severe epilepsy. Recessive bilateral frontoparietal polymicrogyria (Fig. 1e) has been associated with mutations of the GPR56 gene [5].

## Prevalence

Classic lissencephaly has a prevalence of 11.7 per million births but the prevalence of the other phenotypes is unknown.

## Genes

*PNH*: Filamin A (FLNA) on chromosome Xq28, coding for the filamin A protein; ARFGEF2 located on 20q13.13 coding for the brefeldin A-inhibited GEF2 (BIG2) protein.

*Isolated lissencephaly and SBH*: LIS1 or PAFAH1B1 on 17p13.3, coding for the LIS1 (platelet-activation factor acetylhydrolase E, isoform 1B, α subunit) protein; DCX or XLIS on Xq22.3, coding for the doublecortin protein.

*Lissencephaly with cerebellar hypoplasia*: RELN on 7q22, coding for the reelin protein.

*Lissencephaly with abnormal genitalia*: ARX on Xp22.13, coding for the aristaless-related protein.

*Bilateral frontoparietal polymicrogyria*: GPR56 in 16q12.2–21, coding for the G-protein-coupled receptor 56.

## Molecular and Systemic Pathophysiology

Filamin A is an F-actin-binding cytoplasmic cross-linking phosphoprotein composed of three major

functional domains. FLNA dimers bind membrane-associated proteins such as integrins, tissue factor and glycoprotein Iba. FLNA also promotes orthogonal branching of actin filaments and is important for coagulation and vascular development.

LIS1 functions as a regulatory subunit of platelet-activating factor acetylhydrolase (PAF-AH), an enzyme that degrades the bioactive lipid PAF. The LIS1 protein co-localizes with microtubules and promotes their stabilization. It might exert its effects on migration through microtubules.

ARX is expressed at high levels in both dorsal and ventral telencephalon, including the neocortical ventricular zone and the germinal zone of the ganglionic eminence. Arx deficient mice show deficient tangential migration and abnormal differentiation of GABAergic interneurons in the ganglionic eminence and in the neocortex.

GPR56 belongs to the G-protein-coupled receptor family. The pattern of expression of mouse Gpr56 as well as the topography of the cortical abnormality in patients harboring homozygous mutations strongly suggests that Gpr56 regulates cortical patterning.

### Diagnostic Principles

Magnetic resonance imaging techniques are required to identify cortical malformation phenotypes, genetic analysis to identify associated genes and family ascertainment to identify mutation carriers.

### Therapeutic Principles

Pharmacological therapy for epilepsy and rehabilitation for motor impairment are required.

## Cortical Tremor

►Epilepsies, Familial Benign Myoclonic

## Corticobasal Degeneration

Alexander Storch[1], Johannes Schwarz[2]
[1]Department of Neurology, Technical University of Dresden, Dresden, Germany
[2]Department of Neurology, University of Leipzig, Leipzig, Germany

### Synonyms

Corticobasal ganglionic degeneration; CBGD; CBD

### Definition and Characteristics

Corticobasal degeneration (CBD) is a chronic progressive sporadic neurodegenerative disease involving cortical and basal ganglia neurons, which was first described in 1968. CBD is classified as a tauopathy (together with progressive supranuclear palsy (PSP), frontotemporal dementia (FTD) and others) according to the neuropathological hallmarks of this disease. In most patients clinical and neuropathological changes remain asymmetric for many years. Clinical symptoms include a hypokinetic-rigid parkinsonian syndrome, dystonia, cortical reflex myoclonus, apraxia, dysphasia, cortical sensory deficits, dementia and the characteristic "alien limb" sign.

The CBD phenotype is rarely observed in other neurological conditions, such as Whipple disease, spinocerebellar ataxia type 8 (SCA8) or "frontotemporal dementia and parkinsonism linked to chromosome 17 (FTDP-17)." It is still under discussion whether CBD is a single entity or whether CBD is a subtype of PSP.

### Prevalence

CBD is a very rare disorder. The prevalence seems to be lower than related disorders such as progressive supranuclear palsy (PSP) or fronto-temporal dementias. One study in a Japanese population reported a prevalence of 1.7 per 100,000 inhabitants [1].

### Genes

Thus far, no locus or gene could be identified to be associated with a monogenetic form of CBD. However,

CBD is significantly associated with a haplotype of the Tau gene (H1) [2]. Molecular analyses revealed no mutations in this gene in sporadic cases or familial tauopathy with a CBD phenotype.

### Molecular and Systemic Pathophysiology

Neuropathological features include an asymmetric degeneration predominantly of frontal cortex, anterior parietal cortex and basal ganglia. This degeneration is associated with swollen and excentric nuclei in the remaining neurons. Neurofibrillary tangles consisting of the tau protein are present in substantia nigra, similar to those reported in PSP. Other changes include Pick cells, Pick bodies, senile plaques and Lewy bodies [3].

The pathophysiology of CBD is largely unknown. The finding of a genetic association of CBD with a haplotype of the Tau gene (H1) and a further association with over-production of the four-repeat isoform of the tau protein, led to the hypothesis of altered tau protein homeostasis and subsequent assembly of the tau protein with four repeats in nerve cells and glial cells. Indeed, neuropathological analysis of CBD revealed a characteristic neuronal and glial pathology with tau filaments comprising predominantly four-repeat tau [4].

### Diagnostic Principles

Diagnosis relies on characteristic clinical symptoms including cortical and basal ganglia dysfunctions described above. Clinical criteria consisting of features of cortical impairment combined with basal ganglia dysfunctions have been proposed but have not been validated [5]. Imaging studies such as magnetic resonance imaging or positron emission tomography confirm the asymmetry of neuronal loss or metabolism, with particular atrophy of parietal structures.

### Therapeutic Principles

At present, no pharmacological treatment for CBD is available. Levodopa is not effective. Treatment relies on physical therapy and other supportive strategies.

### Synonyms

Cowden disease; Multiple hamartoma syndrome; OMIM 158350

### Definition and Characteristics

Autosomal dominant tumor suppressor gene defect leading to multiple benign hamartomas of the breast (breast fibroadenomas), thyroid (thyroid adenomas), and skin including trichilemmomas around the mouth, eyes, and chin (99% of the patients), acral keratosis (acrokeratosis verruciformis), sclerotic fibromas, cobblestone-like papillomas of the gingival and buccal mucosa. In addition, multinodular goiter, gastrointestinal polyps as well as breast cancer (25–50% in female patients), thyreoid cancer (3–10% of patients), and endometrial cancer may develop. Other associated symptoms are macrocephaly, genitourinary abnormalities, and dysplastic gangliocytoma of the cerebellum ("Lhermitte-Duclos disease," LDD) [1,2].

### Prevalence

1:200,000 to 250,000 (Dutch population).

### Genes

Germline mutation in PTEN (also known as MMAC1 or TEP1) gene, localized on chromosome 10q22-q23.3, loss of heterozygosity.

### Molecular and Systemic Pathophysiology

PTEN ("phosphatase and tensin homolog deleted on chromosome ten") is a tumor suppressor gene in the germline, which plays a role in organizing the relationship of different cell types within an organ during development. PTEN has nine exons encoding a 403 amino acid protein, a dual-specificity phosphatase that dephosphorylates both lipid and protein substrates. As a protein phosphatase, PTEN has been shown to dephosphorylate, e.g., focal adhesion kinase. As a lipid phosphatase, PTEN dephosphorylates the D3 position of phosphatidylinositiol 3,4,5-triphosphate (Ptd-Ins(3,4,5)P3) resulting in decreased activation of the PI3-kinase/AKT pathway. Ptd-Ins(3,4,5)P3 is a critical second messenger in the regulation of cell growth functioning to mediate growth factor induced activation of cell growth signaling, in particular through the serine-threonine kinase AKT, a known cell survival-promoting antiapoptotic factor. Mutation in the PTEN gene leads to the accumulation of Ptd-Ins(3,4,5)P3 and thereby to disturbed cell growth during development.

PTEN germline mutations have been identified scattered largely over the entire gene. Since the expression of Cowden disease-associated symptoms shows great interindividual variations, it is possible that some of the different phenotypes may be a result of different PTEN mutants functioning via different signaling pathways [2]. For example, it was speculated that the larger N-terminal truncation may be responsible for the more severe LDD phenotype [3].

### Diagnostic Principles

The International Cowden Consortium defined pathognomic criteria (facial trichilemmomas, acral keratoses, papillomatous lesions, and mucosal lesions), major criteria (breast cancer, thyroid cancer, macrocephaly, LDD, endometrial carcinoma), and minor criteria (thyroid lesions, goiter, mental retardation, gastrointestinal hamartomas, fibrocystic disease of breast, lipomas, fibromas, genitourinary tumors, or malformations) [4].

### Therapeutic Principles

Single but not all cutaneous lesions can be treated by surgical removal, physically by laser ablation or chemically by topical 5-fluorouracil. The patients have a high risk for developing malignancies and should be carefully controlled including regular mammographies, gynecologic examinations, thyroid scanning, and blood examinations [1]. No gene, dietary or pharmacological therapy is available as of yet.

## Craniopharyngioma

Alexander K. C. Leung[1], Kam-Lun Ellis Hon[2], Chiu-Wing Winnie Chu[3]
[1]Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada
[2]Department of Pediatrics, Prince of Wales Hospital, Hong Kong Special Administrative Region, People's Republic of China
[3]Department of Diagnostic Radiology and Organ Imaging, Prince of Wales Hospital, Hong Kong Special Administrative Region, People's Republic of China

### Definition and Characteristics

Craniopharyngiomas are benign, epithelial neoplasms of the sella and parasellar region [1]. The craniopharyngioma is located in the suprasellar region in 20–41%

of cases and in both intrasellar and suprasellar region in 53–75% of cases [2]. Purely intrasellar craniopharyngiomas are rare in childhood. Although benign and slowly growing, the tumor is locally invasive and can be clinically aggressive because of its location and adhesion to surrounding structures. The tumor can extend forward to compress the optic chiasm, downward to compress the pituitary gland, upward to encroach onto the third ventricle, and backward to encroach onto the posterior fossa [3]. Most craniopharyngiomas become symptomatic in the first decade of life. The presenting features are those of increased intracranial pressure, visual field defects, hypopituitarism, and hypothalamic dysfunction. These include headache, nausea/vomiting, decreased visual acuity, visual defects usually in the form of bitemporal hemianopia, papilloedema, optic atrophy, tiredness, growth failure, delayed puberty, impotence (in adult males), galactorrhea–amenorrhea syndrome (in adult female), diabetes insipidus, inappropriate antidiuretic hormone secretion syndrome, precocious puberty, poor or excessive weight gain, cranial nerve palsy, ataxia, somnolence, cognitive dysfunction, emotional lability, hallucinations, and paranoic delusions [2].

## Prevalence

The incidence is ~1.3 cases per 100,000 children per year [2]. The sex ratio is equal [1]. The tumor has a bimodal age distribution with a peak between 5 and 14 years of age and a second peak between 50 and 74 years of age [2]. Craniopharyngiomas are the most common nonglial tumors and comprise 5–15% of intracranial tumors in childhood [2].

## Genes

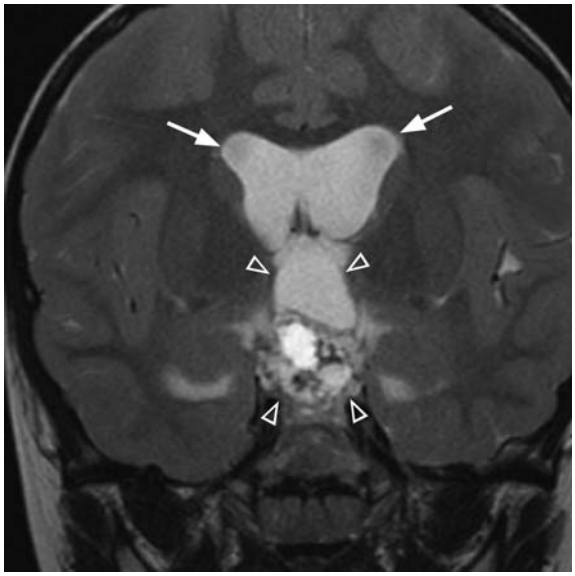
β-catenin gene mutations have been found in the adamantinomatous type, affecting exon 3 [2,3]. Though rarely, a number of chromosomal aberrations such as translocation and deletion have been described [2,3].

## Molecular and Systemic Pathophysiology

Craniopharyngiomas arise either from neoplastic transformation of embryonic squamous cell rests of the involuted craniopharyngeal duct, connecting the stomodeal ectoderm with the evaginated Rathke's pouch or from metaplasia of adenohypophyseal cells in the pituitary stalk or gland [1,2]. Remnant cells may remain dormant for years before forming a tumor [4]. Craniopharyngiomas are subdivided into adamantinomatous and papillary types. The adamantinomatous type predominates in childhood, typically has cystic and solid components with calcifications, and is minimally invasive [2]. The cyst may contain a turbid, yellow-brown, cholesterol-rich fluid (machine-oil fluid), which is characteristic of this kind of tumor. Histologically, the solid portion of the tumor consists of clusters of pallisading columnar epithelial cells that form sheets, nodular whorls, and irregular shapes around stellate epithelial cells [1,2]. There are also areas of "wet" keratin consisting of desquamated epithelial cells [5]. The papillary type is seen almost exclusively in adults, is predominantly solid without calcifications, and is less infiltrative. Histologically, the tumor is composed of mature squamous epithelium forming pseudopapillae growing around a fibrovascular core [1,2]. All craniopharyngiomas stain positive for cytokeratin and epithelial membrane antigen [5]. Compared with nonrecurrent craniopharyngiomas, recurrent craniopharyngiomas have higher microvessel density values, lower levels of galectin-3 and macrophage migration inhibiting factor, lower levels of retinoic acid receptor β, and higher levels of retinoic acid receptor γ.

## Diagnostic Principles

The differential diagnosis includes other space-occupying lesions in the sellar and suprasellar areas, such as optic glioma, chordoma, suprasellar arachnoid cyst, and pinealoma. Clinically, a craniopharyngioma is characterized by increased intracranial pressure, visual disturbances, and endocrine dysfunction. Plain radiographs of the skull may show curvilinear areas of suprasellar calcifications and enlarged sellar with sellar destruction. CT scan usually reveals the cystic component and intratumoral calcifications [3]. MRI helps to



**Craniopharyngioma. Figure 1** An 8-year-old boy with craniopharyngioma. Coronal T2-weighted image shows a heterogeneously hyperintense tumor mass (arrowheads) in the suprasellar region abutting the third ventricle causing obstructive hydrocephalus and dilatation of bilateral lateral ventricles (arrows).

delineate the extent of the tumor and its relationship to surrounding vessels and ventricles (Fig. 1) [3].

### Therapeutic Principles

Complete microsurgical resection of the tumor, if feasible, is the most effective treatment for the symptomatic patient. This can be achieved by the transcranial or transsphenoidal approach. Endocrine and ophthalmological evaluation is crucial pre and posttreatment. Other treatment options include subtotal resection with postoperative radiotherapy, intracystic irradiation, intracystic bleomycin, stereotactic radiosurgery, stereotactic radiotherapy, and systemic chemotherapy [2].

Biochemical Genetics and National Neonatal Screening Laboratories, Department of General Pediatrics, University Children's Hospital Vienna, Vienna, Austria

### Synonyms

Creatine deficiency syndrome due to X-linked creatine transporter gene defect; CT1 defect; CRTR defect; CRTR

### Definition and Characteristics

X-linked recessive deficiency of secondarily active creatine transport across cell membranes. Characteristic clinical manifestations include variable degrees of mental retardation, and epilepsy. Female carriers may have learning disabilities [1–3].

### Prevalence

The true prevalence is unknown. Since its first description in 2001, 13 male patients and 13 female carriers with CRTR deficiency from seven families have been reported. It has been speculated that CRTR deficiency is the most prevalent cause of X-linked mental retardation in males [1–3].

### Genes

The creatine transporter gene SLC6A8 (OMIM #300036) has been mapped to Xq28. SLC6A8 consists of 13 exons varying in size from 100 to 250 base pairs and spans a total of approximately 8.4 kb (GenBank accession no. Z66539) [1,4]. It is expressed at higher levels in skeletal muscle and kidneys and at lower levels in brain, testis, colon and heart. A second creatine transporter gene SLC6A10 (OMIM # 601294) has been mapped to chromosome 16 p11. The coding sequence of SLC6A10 is 97.1% identical to the sequence of SLC6A8

with an overall similarity of 94.6%. SLC6A10 is solely expressed in testis and most likely represents a pseudogene.

## Molecular and Systemic Pathophysiology

Creatine is synthesized mainly in liver, kidney and pancreas by two enzymatic reactions catalyzed by arginine:glycine amidinotransferase (AGAT) and by guanidinoacetate methyltransferase (GAMT). Creatine is transported via the blood stream to tissues including skeletal muscle and brain and taken up intracellularly against a large concentration gradient via a sodium and chloride dependent creatine transport system. In these tissues, creatine and creatine phosphate serve as important intracellular energy stores that are available for ATP synthesis. The creatine transporter belongs to a superfamily of proteins that include different transport systems for the transport of neurotransmitter (dopamine, GABA, serotonin and noradrenalin) as well as for amino acids (taurine, glycine and proline). Most molecular studies of intra-cerebral creatine metabolism have been performed in rat brain tissue and extrapolated to the situation in humans. Although in these animals the enzymes of creatine synthesis are expressed almost ubiquitously in all neuronal tissues, in humans, deficiency of the (cerebral) creatine transporter leads to a severe reduction of intracerebral creatine concentrations [5]. If creatine synthesis also occurs in human neuronal tissues, the intracerebral synthesis may not compensate for lack of creatine transport. Animal models for CRTR deficiency do not exist so far, but as soon as available, they will provide a tool for the improved understanding of pathophysiology and treatment of human CRTR deficiency.

## Diagnostic Principles

Creatine concentrations in plasma and urine are found to be increased while guanidinoacetate levels are within normal limits in patients with creatine transporter deficiency. Urinary creatine/creatinine ratio typically exceeds a value of 2.0 (normal <1.5) and serves as a diagnostic marker. As in other disorders of creatine synthesis (GAMT and AGAT deficiencies) cerebral creatine stores are depleted as demonstrated by in vivo proton magnetic resonance spectroscopy. Confirmatory testing includes analysis of creatine uptake in fibroblasts and lymphoblasts and mutation analysis of the SLC6A8 gene [1–3].

## Therapeutic Principles

Creatine supplementation has been used without obvious clinical benefit for the patients. Even at high doses no increase of cerebral creatine concentrations has been observed.

## Synonyms

Cat cry syndrome; 5p deletion syndrome; 5p syndrome; 5p monosomy

## Definition and Characteristics

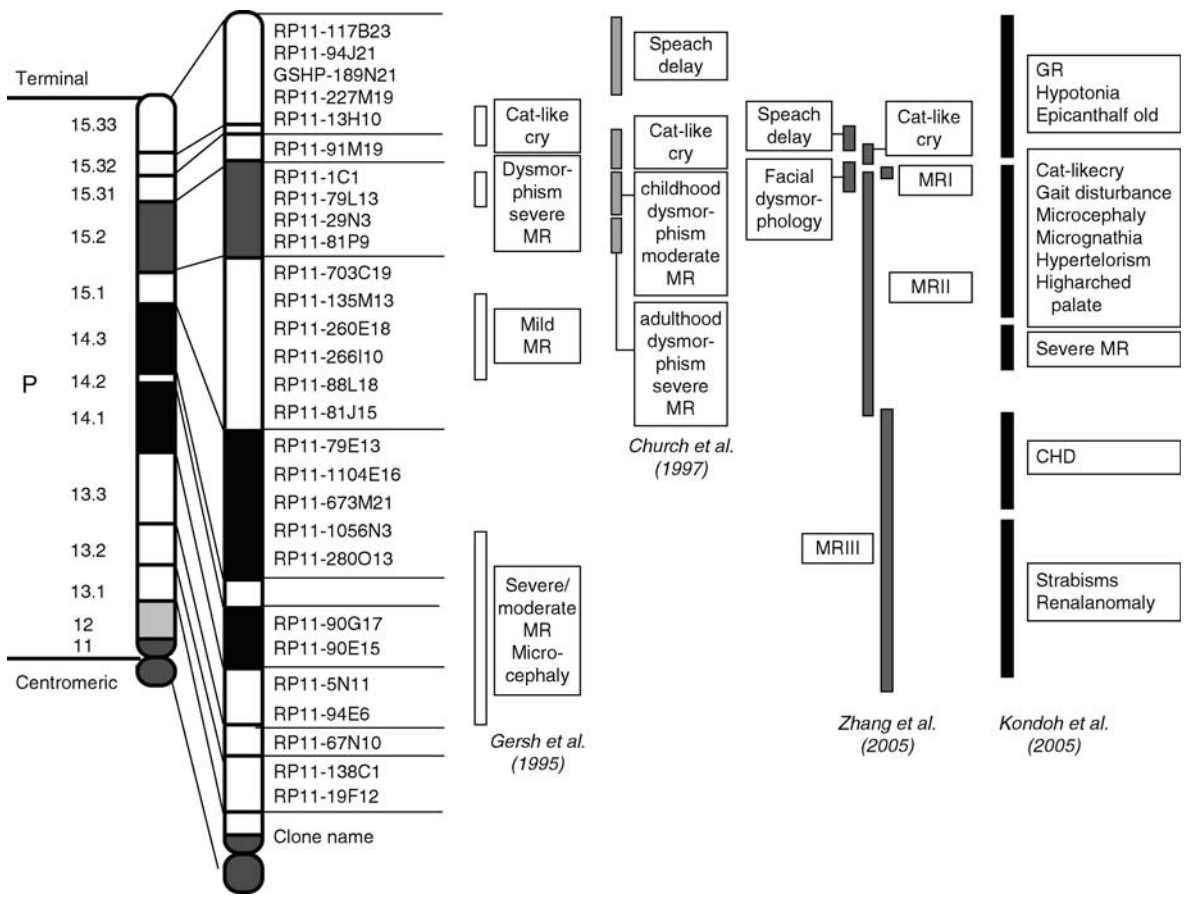
Cri-du-chat syndrome is a chromosomal aberration syndrome of partial deletions on the short arm of chromosome 5, and was first reported by Lejune et al in 1963. The deleted size can vary among patients: it can be so small as to be detected only by fluorescent in situ hybridization (FISH) analysis using the probes located on 5p15.2 or p15.3, or beyond the entire short arm. The critical chromosomal region is suggested to be 5p15.2–5p15.3, and major clinical features are high-pitched cat-like cry, mental retardation, microcephaly, hypertelorism and epicanthal folds [1].

## Prevalence

Cri-du-chat syndrome is one of the most common human chromosomal deletion syndromes [1]. The incidence is between 1:15,000 and 1:50,000. The prevalence may be as high as 1% among the population of profound mental retardation. Sex ratio (male/female) is 0.72.

## Molecular and Systemic Pathophysiology

The basic defect of this syndrome is due to a partial deletion, either terminal or interstitial, of the short arm of chromosome 5, 5p15.2–p15.3 [2]. This may result from either a de novo deletion of the short arm (about 85%) or unbalanced translocation inherited from a carrier parent (about 15%). The frequency of mosaicism in cri-du-chat syndrome is reported to be 3.7%. There are many reports about the correlations between



**Cri-du-Chat Syndrome (Chromosome 5 Short Arm Deletion). Figure 1** Scheme of phenotype–genotype correlation of the short arm of chromosome 5.

genotypes and phenotypes in cri-du-chat syndrome [2–5] (Fig. 1).

Apparently, the severity and spectrum of clinical features depend on the size and location of the deletion. Previous studies on a large series of deletions of varying size mapped 5p15.3 to be responsible for the high-pitched cry. Our case presented below suggests that the region responsible for cat-like cry may be located on the proximal part to RP11-91M19 located on 5p15.31. On the other hand, most of other phenotypes were mapped to 5p15.2. Because our patient lacks cat-like cry and mental retardation, the region distal from RP11-91M19 does not appear to be critical for mental retardation [4]. The delta-catenin gene was reported to be important in the developmental abnormalities and expressed early in neuronal development. Since the corresponding region (Rp11-79L17) was conserved in our case, this gene might be essential for mental conditions. Zhang et al. (2003) reported that the deletion of hTERT gene, located on 5p15.33, in cri-du-chat syndrome might impair normal fetal development. However, although we have carefully analyzed our cri-du-chat syndrome patients with and without intrauterine growth retardation (IUGR), there was no correlation between IUGR and hTERT deletion [4]. Those results are against the proposed role of the hTERT gene in normal fetal development. Most recently, array comparative genomic hybridization analysis of 94 patients with cri-du-chat syndrome have localized the region associated with the cry to 1.5 Mb in distal 5p15.31 between D5S2054 and D5S676; speech delay to 3.2 Mb in 5p15.32–15.31 between D5S417 and D5S635; and the region associated with facial dysmorphology to 2.4 Mb in 5p15.2–15.31 between D5S208 and D5S2887 [5].

## Diagnostic Principles

Clinical features are shown in Table 1. Cardinal findings of cri-du-chat syndrome are low birth weight, profound mental retardation, growth retardation, severe feeding problem in infancy, high-pitched cat-like cry in infancy, microcephaly, large frontal sinus in adults, micrognathia, hypertelorism, strabismus, downslant, epicanthus, broad nasal base, high-arched narrow/broad and flat palate, malocclusion, low-set/poorly formed ears, small iliac wings or increased iliac angle, pes planus and simian crease. One of the most characteristic features during the newborn period is a high-pitched cat-like cry that is usually considered diagnostic for the syndrome; however, chromosomal analysis is required as a reliable diagnostic method. Although conventional Gimsa (G) banding method is sufficient for most cases of the syndrome, some patients can be diagnosed only by FISH analysis [4] (Fig. 2).

Cri-du-chat syndrome cannot be ruled out even though conventional chromosomal analysis shows normal karyotype. FISH analysis with the probe(s) located on

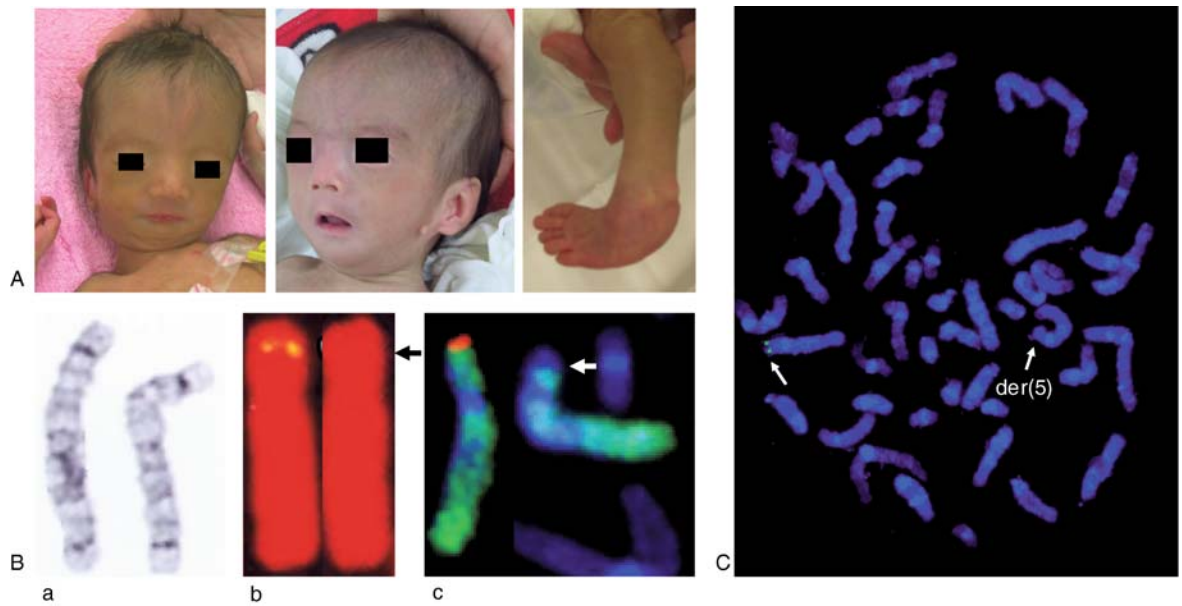
| **Hair** | premature graying hair |
| **Skin** | *simian crease, high positioned axial triradius, supernumerary flexion crease |

*Cardinal findings.



**Cri-du-Chat Syndrome (Chromosome 5 Short Arm Deletion). Figure 2** A 1-year-old girl with clinical features typical of cri-du-chat syndrome, presenting with IUGR, hypotonia, cat-like crying, severe bilateral talipes valgus and peculiar facies (Fig. 2A). Although her karyotype was reported to be normal by ordinary G-banding method (Fig. 2B), FISH analysis using a probe, D5S23, targeting 5p15.2 demonstrated chromosomal micro-deletion of 5p15.2 (Fig. 2B). Furthermore, whole FISH painting of chromosome 5 of this patient suggest that his chromosome 5 was derivative, resulting from unbalanced translocation from 5p14.3 (Fig. 2B). However, her derivative chromosome 5 could not be distinguished from normal chromosome 5 by the length and the Gimsa staining pattern. C. Prenatal diagnosis by FISH analysis using a probe, D5S23. Arrows indicate chromosome 5s.

5p15.2–p15.3 should be considered when cri-du-chat syndrome is suggested from clinical findings.

## Therapeutic Principles

Symptomatic relief should be given. Surgical intervention for strabismus, congenital cardiac defects, laryngeal malacia, and other malformations is sometimes needed. Anti-convulsant(s) are administered if epilepsy occurs. Special education is also considered.

# Crigler-Najjar Disease

►Crigler-Najjar Syndrome

# Crigler-Najjar Syndrome

Peter L. M. Jansen
Academic Medical Center, Amsterdam,
The Netherlands

## Synonyms

Crigler-Najjar syndrome type 1; Crigler-Najjar syndrome type 2 (Arias syndrome); Hereditary nonhemolytic unconjugated hyperbilirubinemia; Crigler-Najjar disease

## Definition and Characteristics

Autosomal recessive disease characterized by severe nonhemolytic unconjugated hyperbilirubinemia

since birth. Crigler-Najjar syndrome type 1, no phenobarbital response; Crigler-Najjar syndrome type 2, decrease of serum bilirubin upon phenobarbital administration.

## Prevalence

Very rare, approximately 1 per million.

## Genes

UGT1A1 on chromosome 2q37, gene encoding bilirubin uridinediphosphoglucuronate glucuronosyltransferase (bilirubin UDPglucuronosyltransferase).

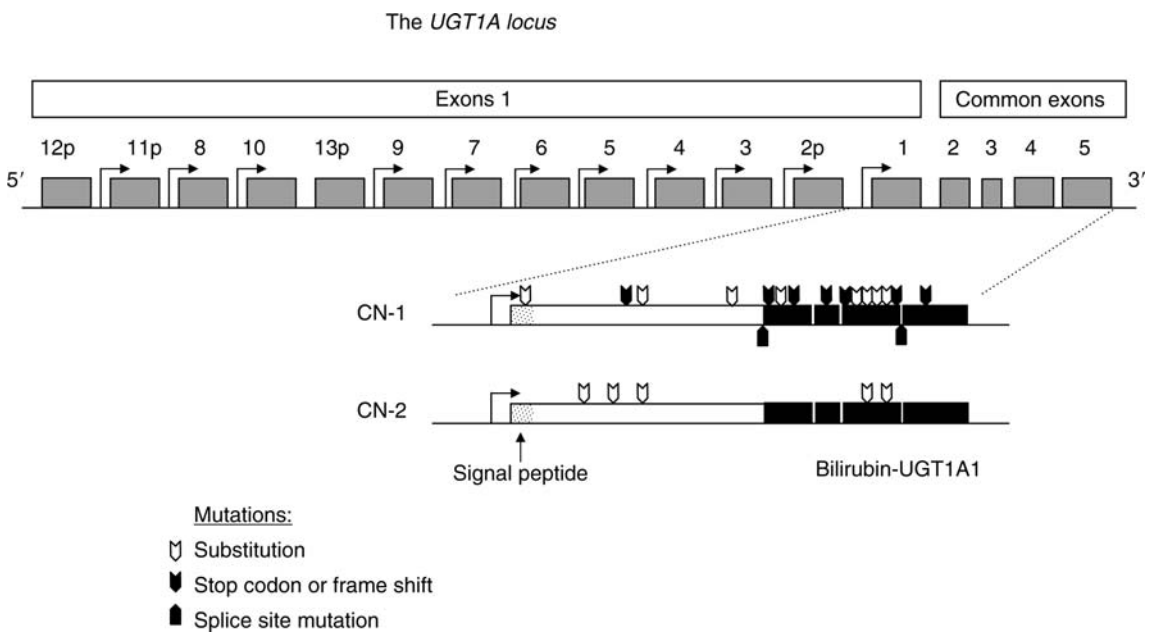
## Molecular and Systemic Pathophysiology

Bilirubin is conjugated to bilirubin mono- and diglucuronide in the endoplasmic reticulum of the hepatocytes in the liver. This is mediated by the enzyme bilirubin UDPglucuronosyltransferase UGT1A1. UGT1A1 is encoded by the UGT1 gene. This gene encodes a number of UGT's catalyzing the glucuronidation of bilirubin, quinols, and phenols. Two members of the UGT1A family accept bilirubin as substrate UGT1A1 and UGT1A4 but only UGT1A1 contributes significantly to bilirubin glucuronidation [1].

Without glucuronidation, bilirubin cannot be secreted into the bile. In patients with Crigler-Najjar syndrome type 1 (CNS-1), bilirubin glucuronidation is completely absent and in patients with CNS-2, bilirubin glucuronidation is partially deficient [2]. Likewise serum levels of unconjugated bilirubin in these patients are elevated to above ~340 μmol/l (CNS-1) or between 150–340 μmol/l (CNS-2). Bile of patients with CNS-1 contains only trace amounts of bilirubin while in CNS-2 patients bile contains bilirubin mono- and diglucuronide in low concentrations, with an increased proportion of monoglucuronide. Another difference between CNS-1 and CNS-2 is that CNS-1 patients do not respond to phenobarbital treatment while in CNS-2 serum bilirubin levels can be lowered by phenobarbital by more than 30% [3].

The bilirubin glucuronidation deficiency in CNS is due to mutations in the UGT1A1 gene (Figure 1).

Many of these mutations cause single amino acid substitutions that completely (CNS-1) or partially (CNS-2) inactivate the enzyme, other produce stop codons or are frame shift mutations resulting in a truncated protein (CNS-1). Genetic lesions in both CNS-1 and CNS-2 occur in any of the five exons of the UGT1A1 gene. CNS-1 and CNS-2 are autosomal recessive diseases.



**Crigler-Najjar Syndrome. Figure 1** The organization of *UGT1*. Four exons [exons 2–5] at the 3′ end encode the common carboxyterminal domain of all UGT isoforms encoded by this gene. This domain contains the membrane spanning region and the UDP-glucuronic acid binding site. Upstream of these four exons are a number of exon's that encode the substrate binding site that confers the substrate specificity to the enzyme. For example, UGT 1A6 and UGT1A7 are phenol glucuronidating enzymes and UGT 1A1 is the bilirubin glucuronidating enzyme. Each of the exon 1's is preceded by a different promotor allowing differential regulation of the various UGT1 enzymes. Each unique exon 1 is spliced to exon 2 and the intervening mRNA segment is spliced out. A number of mutations is indicated.

## Diagnostic Principles

The serum unconjugated bilirubin concentration, the response to phenobarbital, bile analysis, and possibly an enzyme-activity test on a liver biopsy (rarely done), will lead to the diagnosis. However, as in any other genetic disease, mutation analysis will provide the final proof.

Prenatal diagnosis can be performed. This should preferably be done when the mutation has already been established in an older child with the disease.

## Therapeutic Principles

Treatment consists of liver transplantation in patients with CNS-1 or life-long phenobarbital treatment in patients with CNS-2. With intensive phototherapy liver transplantation can be postponed to adolescence in patients with CNS-1. At this age phototherapy becomes less effecive. Neonates with CNS-1 are at risk to die of kernicterus unless treated by exchange transfusion immediately after birth and phototherapy [4]. In these patients phototherapy has to be continued for many years until transplantation. Also adult patients with CNS-1 can develop kernicterus; for CNS-2 this is rare but has been reported.

Treatment goals should be to maintain the molar ratio of bilirubin to albumin <0.5 in neonates and <0.7 in older children and adults [5]. Drugs should be administered with care since many drugs can displace bilirubin from albumin and thus enhance the risk for kernicterus. For this reason drugs have been classified in different safety classes (for list see [5]).

Experimental modes of treatment include hepatocyte transplantation (only temporary treatment as bridge to transplantation) or auxilliary partial liver transplantation. Gene therapy has been done in animal models but not yet in humans.

# Crohn's Disease

Jürgen Schölmerich
Department of Internal Medicine I, University Medical Center Regensburg, Regensburg, Germany

## Definition and Characteristics

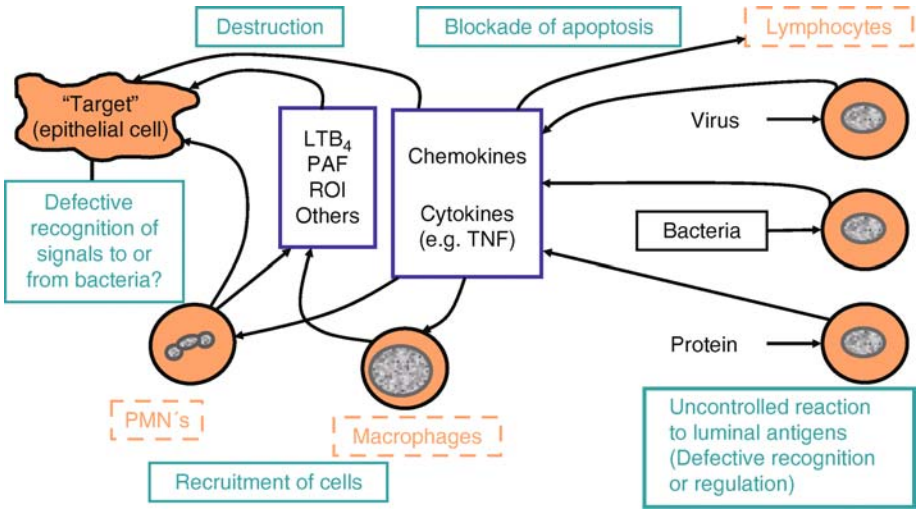
Chronic panintestinal transmural inflammation with additional manifestations on skin, eyes, joints, liver, and several other organs. Dominant symptoms are abdominal pain, weight loss, diarrhea, and growth retardation in children. Special features are perianal lesions and fistulae.

## Prevalence

Incidence and prevalence are very variable regionally and ethnically. In Central Europe, prevalence is reported as around 100–200/100,000 inhabitants and incidence as 4–10/100,000 per year. The peak manifestation age is between 15 and 35 years. The disease is more frequent in countries with "westernized life style," while 20–30% have a positive family history and monozygotic twins have a much higher concordance than heterozygotes.

## Genes

Epidemiological data show clearly that genetic factors define susceptibility for Crohn's disease. This seems to be a group of complex genetic diseases, which manifest after exposition toward one or several thus far unknown triggers in susceptible individuals. Numerous genome wide linkage studies have defined at least nine susceptibility loci (IBD1–IBD9). In 2001, several groups have reported the first gene contributing to susceptibility of Crohn's disease, namely CARD15/NOD2 on chromosome 16. In Caucasian patients 27–38% have one of the three main risk alleles and 8–17% carry two copies as compared with 1% of controls [1]. Meanwhile, several other susceptibility genes have been described. These require mostly confirmation and clarification of the disturbed functions. This is true for the organic cation transporters OCTN1 and 2 on chromosome 5q31, for the Drosophila disc large homologue 5 (DLG5) on chromosome 10 and



**Crohn's Disease. Figure 1** Principles of pathophysiology of Crohn's disease.

the receptor for interleukin-23 (IL23R) on chromosome 1p31 among others [2]. A defective production and/or secretion of local antibiotic peptides such as defensins seems to be another genetic defect. Most of the thus far suggested genes play a role in the innate immune system [3]. In addition, the intestinal barrier seems to be defunct [4].

## Molecular and Systemic Pathophysiology

Numerous environmental factors are obviously involved in manifestation of the disease, which only appeared with the advent of the "European or North American life style" and now increases in frequency in the developing and recently developed countries of the former Third World. Association studies point in particular to early childhood hygiene, increased use of antibiotics and non-steroidal antiphlogistics (NSAID), contraceptives, and nutrition components. An inflammation of the mucosa and the whole bowel wall including the fat on the serosal side develops obviously due to a lack of tolerance against the autochthonous bacterial flora, which is individual in every human. In the chronic phase of inflammation, a persistent activation of the intestinal immune system is present whereby different cell populations have a role (Fig. 1).

An activation of the immune system is also present in the whole organism leading to the extraintestinal manifestations on numerous organs, in particular skin, eyes, and joints.

## Diagnostic Principles

History and physical examination can suggest Crohn's disease to some extent. However, only a combination of endoscopic findings, histology, and imaging by MRT, video capsule, or double ballon endoscopy is able to exactly define localization and extent of the disease. Laboratory studies such as CRP or ESR can indicate inflammation, the findings are unspecific, however. Negative microbiological findings are of importance to differentiate a flare from (super) infection [5].

## Therapeutic Principles

There is no cure for Crohn's disease. For an acute flare glucocorticosteroids are still very effective and the basis of treatment. In order to reduce side effects, non-systemic steroids such as budesonide are used to act on the mucosa in the ileum and proximal colon. For remission maintenance and for steroid-refractory or -dependent courses long-term immunosuppression with azathioprine, methotrexate, and TNF-antibodies can be used. Less severe flares are treated with the topically acting 5-aminosalicylic acid (5-ASA), which is also used for remission maintenance in those patients. Antibiotics are given for infectious complications such as fistulae. Nutritional therapy is used in children with growth retardation. Surgery is needed for abscesses, fistulae, and stenosing complications [5].

# Cronkhite-Canada Syndrome

Karsten Schulmann, Christian Pox, Wolff Schmiegel
Medical Department, Ruhr-University Bochum, Bochum, Germany

## Synonyms

CCS

## Definition and Characteristics

Cronkhite-Canada syndrome (CCS) is a very rare sporadic, non-familial polyposis syndrome. It was first described in 1955 by Cronkhite and Canada [1]. CCS is characterized by the presence of non-adenomatous juvenile type or hamartomatous polyps that occur throughout the gastrointestinal tract excluding the esophagus [2]. Polyposis is associated with malabsorption and protein losing enteropathy. The vast majority of affected individuals present with weight loss, chronic diarrhea, edema, anemia, alopecia, skin pigmentation and onychodystrophia. The risk of developing gastrointestinal cancer seems to be increased, especially for colorectal and gastric cancer [3,4]. CCS associated with colorectal cancer frequently includes serrated adenomatous lesions.

## Prevalence

CCS is a very rare disease. So far less than 250 publications on CCS are available in the medical literature. The majority of reports are from Japan, suggesting a higher incidence in Japan. CCS seems to affect both genders equally. The average age of onset is 55 years with a range from 31 to 85 years. However, a few juvenile cases have been described.

## Genes

The genes involved in CCS are not studied systematically. A few case reports with P53 overexpression and microsatellite instability have been published.

## Molecular and Systemic Pathophysiology

Comprehensive studies evaluating the pathogenesis of CCS are not available yet. There is no evidence for a genetic, environmental or specific infectious origin.

## Diagnostic Principles

The diagnosis is based on the detection of polyposis with associated features of malabsorption. There is significant phenotypic overlap between the features of CCS, juvenile polyposis (JPS) and Peutz-Jeghers syndrome (PJS), and in particular in the morphology of intestinal hamartomatous polyps [2].Genetic testing may be useful in selected cases to rule out PJS and FJP.

## Therapeutic Principles

Nutritional support, antibiotics, corticosteroids, anabolic steroids, histamine-receptor antagonists and surgical treatment have all been used with variable rates of success [5]. The effectiveness of corticosteroid therapy in many cases of CCS seems to support an involvement of the immune system in the pathogenesis of CCS. Cases of spontaneous remission after nutritional support have also been reported. Symptomatic treatment including correction of electrolyte disturbances is mandatory. Severe malabsoprtion may require colectomy. Cancer surveillance using upper and lower endoscopy may be benefitial.

# Croup

James E. Crowe, Jr.
Program in Vaccine Sciences, Vanderbilt University, Nashville, TN, USA

## Synonyms

Laryngotracheobronchitis; Croup syndrome; Whooping cough (as a variant)

## Definition and Characteristics

Croup is a clinical syndrome of respiratory disease that affects infants and young children, most often between the ages of 3 months and 5 years. Boys are affected more often than girls. The disease is most common in the fall season in temperate areas. Croup is characterized by a harsh "barking" cough, stridor (a high-pitched sound heard during labored inhalation), often accompanied by hoarseness of speech. Most cases are associated with only mild distress, but some individuals suffer severe respiratory illness leading to respiratory failure. About half of subjects have fever, but otherwise systemic elements of disease are lacking. Symptoms are caused by inflammation of the airway, most prominently in the larynx but also involving the upper airway above the vocal cords and the large airways below the cords, especially the trachea and bronchi.

The differential diagnosis in children with stridor and respiratory distress also includes bacterial tracheitis, bacterial epiglottitis, and foreign body aspiration. These conditions can constitute medical emergencies and require different therapeutic approaches. A condition known as spasmodic croup also occurs, due to laryngeal spasms, which is more easily reversible than infectious croup, using conservative measures like mist inhalation or cool air.

## Prevalence

Croup has a peak annual incidence in the second year of life of nearly 5%. In North America, in odd-numbered years, the number of children presenting during the peak season is approximately 50% more than during even-numbered years.

## Molecular and Systemic Pathophysiology

Croup is most often caused by one of the parainfluenza viruses, primarily type 3 but also types 1, 2, and 4. Other common pediatric respiratory viral pathogens have been associated frequently with croup syndrome, including respiratory syncytial virus, human metapneumovirus, and influenza virus type A or B. Less classical causes include the viruses measles, adenovirus, enteroviruses, and the bacterium Mycoplasma pneumoniae.

The respiratory distress of croup results principally from mucosal edema of the airways, which is associated with the inflammatory response of the host. Direct effects of viral infection on airway epithelial cells also may contribute to disease, especially if epithelial necrosis and shedding occurs. The disease is primarily one of altered airway physiology, as the extent of signs and symptoms depends on the diameter and architecture of the larynx and trachea. Narrowing of the subglottic region affects inspiration, during which airflow is impeded, and during coughing when intrathoracic pressure compresses the inflamed and narrowed airway. Airflow in the large airway becomes less efficient due to turbulence. Infants are most susceptible because of their narrow airways; premature infants may be at increased risk for this reason. Some infants may be at increased risk due to airway abnormalities, such as tracheomalacia, a weakness and floppiness of the walls of the trachea that is congenital or due to damage from prolonged intubation or a vascular compression. Synchronous chest wall and abdominal movements are used in normal breathing, but in severe croup asynchronous chest and abdominal movement can occur. Such movements can lead to fatigue, poor air exchange marked by $CO_2$ retention and hypoxia, and eventually failure to achieve adequate respiration ("respiratory failure").

## Diagnostic Principles

The presence of a barky cough and inspiratory stridor during the fall in temperate areas is nearly sufficient to diagnose the condition. Radiographs also can be used to support the diagnosis. Frontal (anteroposterior) radiographs of the cervical spine reveal the steeple sign, a sign that appears when the normal lateral convexities of the subglottic trachea are lost. Narrowing of the subglottic lumen produces an inverted V appearance of the tracheal air column, which resembles a church steeple. Blood tests, for the most part, are unrevealing. The complete blood count typically shows a predominance of white blood cells that are lymphocytes, instead of the elevated neutrophil count seen in bacterial diseases. A pulse oximeter, a trancutaneous sensor, is often used to determine the oxygen saturation of the blood; saturations below 90–92% suggest impending respiratory failure. Oxygen and $CO_2$ content of the blood also can be measured using arterial blood gas sampling.

## Therapeutic Principles

The treatment of croup depends on the severity of symptoms. The most conservative treatment of croup involves administration of inhaled mist. Croup occurs in cooler months of the year, and sometimes exposure to cool night air can reduce stridor.

Mild croup can be treated with observation, but children with mild stridor can benefit from the anti-inflammatory effect of steroid treatment delivered by nebulization for a rapid topical delivery to the airway and/or oral treatment. Widespread use of corticosteroids for viral croup has had a major impact on morbidity of this disease.

Moderate to severe croup with acute respiratory distress is treated in the emergency department with oxygen and nebulized epinephrine in addition to steroids. Epinephrine mediates rapid constrictive effects that facilitate opening of the airway. Generally, children requiring oxygen therapy and epinephrine are hospitalized. Hospitalization

of children with croup is uncommon, with fewer than 5% admitted. Children with respiratory failure are treated in the ICU setting with intubation and mechanical ventilation.

Croup is typically a disease that resolves in time without specific antiviral therapy. Most cases are mild, and moderate severity cases often respond well to therapy. The course of illness ranges from a few days to 2 weeks. Rarely complete respiratory failure can occur; if untreated, croup can result in death but mortality in the U.S. is extremely rare.

## Synonyms

Crouzon's disease; Crouzon craniofacial dysostosis

## Definition and Characteristics

Crouzon syndrome is a craniofacial abnormality syndrome involving aberrant bone mineralization or excess calcification of normally non-mineralized tissues. Common clinical signs of Crouzon syndrome include the premature synostosis of (coronal, sagittal and lamdoid) cranial sutures (craniosynostosis). This results in an abnormal head shape and increased intracranial pressure. Patients commonly also exhibit significant maxillary hypoplasia with relative mandibular prognathism, class III dental malocclusion, a beak-shaped nose, hypertelorism, exopthalmus and strabismus. Radiographic exam may reveal evidence of cranial digital markings, calcification of the stylohyoid ligament, vertebral fusions, mild foot anomalies and atresia of cranial foramina including the choanae and external auditory canals. Up to 50% of patients have mild to moderate hearing loss. A small percentage of patients have a bifid uvula or full cleft palate. Others may exhibit elbow joint stiffness. Mental retardation is rare.

## Prevalence

Crouzon syndrome: 16.5/1,000,000.

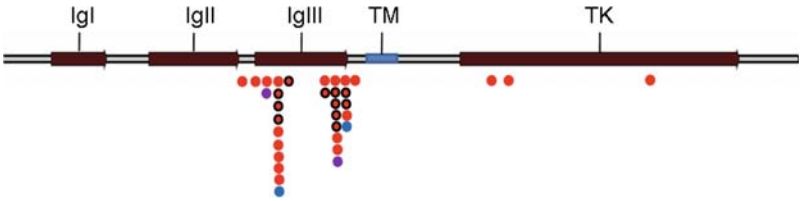
## Genes

In Crouzon syndrome missense mutations (or occasionally small insertions or deletions) in fibroblast growth factor receptor 2 (FGFR2, 10q26) have ben identified. Mutations are commonly found within the extracellular IgIII domain, and less commonly within the extracellular IgI domain and intracellular tyrosine kinase domains (Fig. 1).

Crouzon syndrome mutations in FGFR2 show an autosomal dominant expression pattern, with variable penetrance. The high somatic occurrence of Crouzon syndrome FGFR2 mutations associated with increased paternal age is related to the enhanced expansion of spermatogonial cells that carry these mutations [1].

## Molecular and Systemic Pathophysiology

Fibroblast growth factor receptors comprise a family of evolutionarily conserved transmembrane proteins known to be critical for the normal development of multiple organ systems/tissue types. FGFR's are receptor tyrosine kinases and elicit signaling via ligand binding, receptor dimerization, auto-phosphorylation, and subsequent recruitment and activation of docking and adaptor proteins at the plasma membrane. Upon ligand binding, FGFR2 directly activates PLCγ and indirectly, via docking and adapter proteins, activates MAPK and PI3K. FGF/FGFR signaling could control bone mineralization and/or calcification of normally non-mineralized tissues (such as the cranial suture) via several distinct mechanisms. FGF/FGFR signaling may control pre-osteoblast/osteoblast recruitment, proliferation, apoptosis, differentiation, ability to produce osteoid or ability to mineralize osteoid. Unfortunately, studies linking expression of craniosynostosis mutant FGFR's with changes in cellular phenotype have revealed conflicting and inconsistent results. It is a commonly held belief that the Crouzon syndrome associated FGFR2 mutations act as gain of function mutations in terms of inducing FGFR



**Crouzon Syndrome. Figure 1** Location of Crouzon syndrome associated mutations in FGFR2. Mutations in the FGFR2 gene associated with Crouzon syndrome are mapped onto the protein structure. Extracellular immunoglobulin-like domains I, II and III are denoted IgI, IgII, IgIII. Transmembrane and tyrosine kinase domains are labeled TM and TK, respectively. Red symbols denote missense mutations. Missense mutations creating or eliminating a cysteinyl residue are indicated as red symbols with black outline. Blue symbols denote small deletions. Purple symbols denote small insertions.

signaling. Crouzon syndrome associated mutations commonly result in the elimination or creation of a cysteine. This type of mutation yields the potential for ligand independent, intramolecular disulfide bonding. Crouzon syndrome associated mutations in FGFR2 do result in ligand independent activation in terms of autophosphorylation, dimerization and tyrosine kinase activity [2]. Yet, attempts to elicit MAPK signaling in cells transfected with the Crouzon mutant $FGFR2^{C342Y}$ shows significantly diminished activation of MAPK upon ligand stimulation of these cells [3]. Additionally, the Crouzon syndrome associated $FGFR2^{C278F}$ mutation results in increased receptor degradation and reduced cell surface expression [4]. These results suggest that Crouzon syndrome associated mutations in FGFR2 may not result in increased FGF signaling in the conventional sense. It is possible that, dependent upon cell type, Crouzon syndrome associated mutations in FGFR2 might influence cell phenotype by causing enhanced FGFR2 signaling, by causing FGFR2 signaling from an inappropriate subcellular compartment (ER and Golgi versus cell surface and endosomal membranes), or by enhancing FGFR2 degradation to such an extent that total FGFR2 signaling is diminished. This potentially contentious latter possibility is supported by the observation that FGFR2IIIc knockout and knockdown mouse models exhibit a phenotype that includes craniosynostosis [5]. Determination of which of these mechanisms pertains to craniosynostosis will require development of methods to address the extent of FGFR2 signaling induced by the mutant receptors in vivo.

## Diagnostic Principles

The diagnosis of Crouzon syndrome is based upon the clinical finding of craniosynostosis in combination with characteristic facial features and a lack of severe hand or foot anomalies. A diagnosis of Crouzon syndrome can be confirmed by genetic testing for mutations within FGFR2.

## Therapeutic Principles

Treatment for patients presenting with Crouzon syndrome commonly includes pediatrics, multiple surgeries to normalize craniofacial shape and diminish intracranial pressure, dental and orthodontic care to treat the class III malocclusion, social work for aid in understanding diagnosis and treatment options and enhancing the family's ability to deal with the social implications of having a child with a craniofacial abnormality, genetic testing and genetic counseling to provide recurrence risk information.

## Cryptorchidism

Alexander K. C. Leung
Department of Pediatrics, Alberta Children's Hospital, The University of Calgary, Calgary, AB, Canada

### Synonyms

Undescended testis (testes)

### Definition and Characteristics

Cryptorchidism is a development defect characterized by failure of the testis to descend into the scrotum. Unilateral cryptorchidism is twice as common as bilateral cryptorchidism [1]. In those infants with unilateral cryptorchidism, the right side is affected twice as often as the left side [2]. Nonpalpable testes comprise approximately 20% of all cases of cryptorchidism [1]. Of the nonpalpable testes, approximately 50% are intra-abdominal, 45% are atrophic or absent, and 5% are located in the inguinal canal but missed by palpation [1]. The scrotum on the affected side appears flat and empty (Fig. 1) [2].

### Prevalence

Cryptorchidism affects 3 to 5% of term male infants at birth [1]. The prevalence is estimated to be 100% in infants who weigh less than 900 g, 60% in those 900–1800 g, and 25% in those 1800–2000 g [2]. The rate of spontaneous descent after birth is high, especially in preterm infants, such that the overall prevalence is 1.8% by 1 month of age and 0.8% by 1 year of age [1].

### Genes

Primordial germ cells from the yolk sac migrate along the dorsal mesentery of the hindgut and reach the

**Cryptorchidism. Figure 1** A 6-month-old boy with bilateral cryptorchidism.

genital ridge by the sixth week of gestation. Under the influence of the sex-determining region Y (SRY)-linked gene, the testis-determining gene on the short arm of the Y chromosome, the indifferent gonad differentiates into the fetal testis.

## Molecular and Systemic Pathophysiology

At eight weeks' gestation, fetal Sertoli cells, stimulated by follicular-stimulating hormone (FSH), secrete müllerian inhibiting factor (MIF), which causes regression of the müllerian ducts. By 10 to 11 weeks' gestation, fetal Leydig cells, stimulated by placental chorionic gonadotropin (hCG) and pituitary luteinizing hormone (LH), secrete testosterone, which induces the formation of the vas deferens, epididymis, and seminal vesicle from the Wolffian ducts. Transabdominal migration of the testis occurs between the 7th and 12th weeks of gestation. Testicular descent is a complex event, which requires the interaction of both hormonal and mechanical factors. A normal hypothalamic-pituitary-gonadal axis is necessary for testicular descent. Androgens, calcitonin gene-related peptide, descendin, and gubernaculum play an important role in testicular descent. The coordinated activity of the smooth and striated muscles in the gubernaculum helps to propel the testis into the scrotum. The progressive rise in intra-abdominal pressure with growth of the abdominal viscera has been proposed as a force that participates in the descent of the testis down the inguinal canal. Cryptorchidism might result if there is a disturbance of any of these factors.

## Diagnostic Principles

An undescended testis has to be differentiated from a retractile testis. A retractile testis can be brought into the scrotum without any tension on the spermatic vessels and will remain in the scrotum unless the cremasteric reflex is stimulated. The ipsilateral hemiscrotum is usually well developed. Other differential diagnosis includes ectopic testis, ascending testis, and absent testis. Ultrasonography might be considered in obese children for the detection of an inguinal testis, in neonates with bilateral nonpalpable testes for localization of the testes and the exclusion of a uterus, and in those with an absent testis for the presence of ipsilateral renal agenesis [3]. Laparoscopy should be performed for the location of a nonpalpable testis.

## Therapeutic Principles

Cryptorchidism may be treated with a surgical procedure, hormonal therapy (hcG or GnRH), or a combination of these two options. The reported success rates of hormonal therapy are widely variable: 14–50% for hCG therapy, and 6–70% for GnRH therapy [4]. Orchidopexy is the most reliable method to treat undescended testis and remains the treatment of choice in most patients. Orchidopexy should be performed between 6 and 12 months of age, provided that a surgeon with pediatric training and experience performs the procedure [5].

## Synonyms

Hypercortisolism; Hypercorticism

## Definition and Characteristics

Cushing's syndrome (CS) is the clinical picture that develops in patients with chronic hypercortisolemia. Because of the metabolic effects of glucocorticoids and/or adrenal androgens, a wide range of typical symptoms develops during long-term overexposure to these hormones. Extrinsic CS depicts glucocorticoid excesses that are due to chronic administration with agents binding to the glucocorticoid receptor to treat other diseases. Intrinsic CS summarizes all cases with overproduction of glucocorticoids, which originates within the patients affected. ACTH-dependent CS is due to ACTH excess either by pituitary tumors (also termed Cushing's disease (CD)) or when illegitimately secreted by other tumors, such as in paraneoplastic syndromes. ACTH-independent hypercortisolism is of adrenal origin. The so-called pseudo-CS can be found in patients with intrinsic hypercortisolism due to physiological upregulation of the hypothalamic–pituitary–adrenal (HPA) axis, which can be found for instance in pregnancy, alcoholism, and prolonged stress, such as in critically ill patients or in major depression.

## Prevalence

The incidence of endogenous CS is about 2 to 4 new cases per million of population per year. In patients suffering from type 2 diabetes with poor blood glucose control and hypertension and in women with polycystic ovary syndrome, the prevalence of CS ranges is about 2%.

In the majority of cases, CS is the result of glucocorticoid therapy, followed by endogenous ACTH-dependent forms and adrenal hypersecretion of glucocortcoids. In children, ACTH-independent forms of endogenous CS are very rare.

## Genes

The disorder may be due to activating R201 mutations in the GNAS1 (Gsα) gene with activation of the cAMP pathway and oversecretion of ACTH, which have been identified in basophilic adenomas. Several other genetic defects may result in Cushing's syndrome associated with other disorders (see Table 1).

## Molecular and Systemic Pathophysiology

Harvey Cushing found in 1932 that basophilic adenomas of the pituitary gland are the cause for this clinical syndrome. These tumors can occur in multiple endocrine neoplasia (MEN) type 1 or spontaneously. They may carry activating GNAS1 (Gsα) mutations. Pituitary carcinomas have a distinct clonal composition compared with benign adenomas.

ACTH binds to its G-protein-coupled receptor in adrenal steroidogenic cells and stimulates production of glucocorticoids, adrenal androgens, and mineralocorticoids. Therefore, hypokalemia is more pronounced in patients with ACTH-dependent CS. ACTH can also be expressed illegitimately by other solid tumors that are derived from neuroendocrine cells, such as lung cancer, thymomas, small carcinoids, pheochromocytomas, and others. Genetic defects leading to a corticotroph-like differentiation of these tumor cells are not known. Adrenal ACTH secretion can also originate from pituitary–adrenal hybrid tumors. It is suspected that oversecretion of and drive by the POMC-derived peptides, including ACTH, can provoke development of adrenal nodules, which is also the case in congenital adrenal hyperplasia (CAH). On the other

**Cushing's Syndrome. Table 1** Causes of Cushing's Syndrome due to tumor syndromes

| Origin | Syndrome | Disorder |

| Other tumors | Ectopic ACTH syndrome | Ectopic POMC peptide expression, ectopic V2-receptor expression |

hand, adrenal tumorigenesis can result from several hereditary mutations, such as in Li-Fraumeni syndrome. These patients may also develop other tumors, including breast cancer, leukemias, soft tissue sarcomas, and gliomas. In the Beckwith-Wiedemann syndrome, there is also a susceptibility to develop other tumors besides adrenocortical carcinomas. It is associated with embryonal cancers (Wilms tumors, rhabdomyosarcoma, and hepatoblastomas), macroglossia, macrosomia, ear pits or ear creases, and midline abdominal-wall defects. In Carney complex, occasionally also termed as MEN type 3, CS may present atypically without centripedal obesity but shows typical stigmata, e.g., spotty skin pigmentation. In addition to a primary pigmented nodular adrenal disease, this syndrome affects other organs also, e.g., heart, skin, and breast through multiple myxomas or schwannomas, and may also cause tumors of the pituitary gland and the testes. Abnormalities of hormone receptors that interfere with the G-protein receptor-coupled protein kinase A pathway have also been implicated in adrenal tumorigenesis. Hypercortisolism due to aberrant (over)expression of G-protein-coupled and other receptors has been described. Next to IL-1, other interleukins also have been associated with hypercortisolism, such as interleukin-6, which can be ectopically expressed by pheochromocytomas. Primary oversecretion of glucocorticoids by adrenocortical cells produces a negative feedback to the hypothalamus and the pituitary gland, which leads to suppression of ACTH and also other pituitary hormones.

## Diagnostic Principles

Characteristic clinical signs include weight gain, truncal obesity with "moon face," facial plethora, "buffalo hump," but a loss of subcutaneous fat. The skin is vulnerable to bruises and may also exhibit hyperpigmentation and purple skin striae of 1-cm width. Hypercortisolism leads to central suppression of other hormone axes (e.g., growth retardation in children, gonadal insufficiency with menstrual irregularities, and even hypothyroidism). Excess of adrenal androgens may cause precocious puberty or virilization in children or hirsutism and acne in adults. Oversecretion of adrenal estrogens may lead to feminization of male patients. Other typical symptoms are muscle wasting and fatigue/weakness. Complications of chronic hypercortisolism include carbohydrate intolerance or diabetes mellitus, hypertension, and osteoporosis. In addition, polyglobulia with thrombocytosis and leukocytosis but lymphocytopenia may point to the diagnosis of Cushing's syndrome and is often followed by hypokalemia, hypernatremia, and hypoproteinemia.

In a first screening step, cortisol should not be higher than 1.8 μg/dl at 8 a.m. following 1 mg of dexamethasone the night before to rule out the diagnosis. Urinary free cortisol is normal when less than 80 μg/24 h. In a second confirmation step, various tests can be employed. CS is most likely when cortisol levels at midnight are higher than 7.5 μg/dl; cortisol levels are higher than 5.0 μg/dl in the dexamethasone suppression test; there is elevation of cortisol and ACTH after administration of CRH or DDAVP, or there is no elevation of ACTH and cortisol during an insulin-induced hypoglycemia. Suppressed ACTH levels are found when the adrenals are the source of hypercortisolism. Computed tomography or MRI imaging is helpful to identify adrenal tumors or enlargement and contributes to differentiate between benign and malign lesions. Normal or even elevated ACTH

levels are an argument for ACTH-dependent CS. In ACTH-dependent CS, the source of ACTH secretion has to be identified. If it is of pituitary origin, usually there is a rise of ACTH following CRH and a suppression of ACTH and cortisol below 50% of basal values after 8 mg of dexamethasone. Inconclusive results have to be checked employing the more sensitive CRH test during bilateral inferior petrosal sinus blood sampling. Central CS is characterized by a gradient of central to peripheral ACTH of more than 3. If central CS is most likely, an MRI of the pituitary should be performed. If ectopic ACTH syndrome is suspected, other laboratory results can contribute to clarify this diagnosis and include chromogranin A, plasma metanephrines, neuron-specific enolase, calcitonin, and cyfra. Imaging techniques include computed tomography of thorax and abdomen and sometimes even an octreotide scan and an MRI of the thorax.

### Therapeutic Principles

When CS is nonhereditary and is of adrenal origin, laparoscopic adrenalectomy or an adrenal-sparing operation is the treatment of choice in case of a single nonmalignant tumor. In most cases with bilateral macronodular adrenal disease, it is sufficient to remove the largest adrenal to prevent adrenal insufficiency. Exploration of the sella region by an experienced neurosurgeon with transsphenoidal removal of the basophilic adenoma is the treatment of choice in CD. If there is recurrent CD that is incurable by neurosurgery, bilateral adrenalectomy or even stereotactic irradiation of the pituitary can be performed to prevent development of a Nelson's tumor. Bilateral adrenalectomy should also be considered when the source of ACTH secretion can not be identified and pharmacotherapy is insufficient. Aggressive surgery should be performed in malign diseases such as adrenocortical and neuroendorcrine cancers.

Extrinsic CS can be reversed when lower dosages of glucocorticoids are administered. This is especially important in patients with chronic rheumatic diseases. Temporary pharmacotherapy is used to control hypercortisolism prior to definite treatment or to gain time during the diagnostic procedure. The following drugs proved to be successful: ketoconazole up to 1.4 g per day, metyrapone up to 3 g per day, aminogluthemide up to 1 g per day, or trilostane. In serious hypercortisolism, etomidate is an alternative to control cortisol excess. Long-term pharmacotherapy in adrenocortical cancer should include mitotane (lysodren) because of its steroidotoxic adrenolytic effect.

In cases with aberrant (over)expression of G-protein-coupled receptors, blockade of this receptor is sometimes an adequate approach. Somatostatine treatment, however, has been shown insufficient in long-term protocols and can only delay operation.

### Definition and Characteristics

Cutis laxa is characterized by prematurely redundant and inelastic skin. The skin involvement is most frequently generalized and congenital. ADCL and ARCL1 are usually progressive, whereas ARCL2 shows regression of skin laxity. Individual subtypes of cutis laxa are distinguished based on inheritance patterns and associated clinical findings. ADCL is generally a mild connective tissue disease that can be associated with adult-onset emphysema and aortic aneurysms. In contrast, developmental emphysema, often coupled with obstructive or aneurysmal disease of the great vessels in ARCL1 can result in high rates of infantile mortality. ARCL2 is associated with a combined glycosylation defect, delayed closure of the fontanel, growth and developmental delay, polymicrogyria and seizures. De Barsy syndrome is characterized by dwarfism, mental retardation and corneal opacity. XCL is allelic with

►Menkes Disease. The two diseases form a phenotypic continuum with XCL at the mild end.

## Prevalence

No prevalence data have been published yet.

## Genes

*ADCL*: –1 frameshift mutations and a partial tandem duplication in ELN (7q11.2) encoding elastin (reviewed in [1]).
*ARCL-I*: point mutations in FBLN5 (14q32.1) encoding fibulin-5 [2] or in FBLN4 (11q13) encoding fibulin-4 [3], also known as EGF-containing fibulin-like extracellular matrix protein 2 (EFEMP2).
*ARCL2*: point mutations and partial deletions in ATP6V0A2 (12q24) encoding the A2 subunit of the vesicular H+-ATPase [4].
*De Barsy syndrome*: gene unknown.
*XCL*: hypomorphic mutations in ATP7A, encoding a $Cu^{2+}$ -transporting ATPase, alpha polypeptide [5].

## Molecular and Systemic Pathophysiology

A common feature of all cutis laxa syndromes is a dysfunction of elastic fibers, extracellular structures made of fibrillin microfibrils embedded in and surrounding elastin. In ADCL, frameshift mutations in one of the last five exons of ELN lead to the synthesis of a mutant elastin precursor, tropoelastin, that lacks a functional C-terminus (Fig. 1).
